The primary goal of treatment is the prevention of corneal scarring and vision loss. Management is often co-managed by other specialists, such as a gastroenterologist, dentist, dermatologist, etc., when extraocular involvement is present.

Medical

Medical management includes ocular surface lubrication and antibiotic ointments to prevent infectious keratitis. Long-term management typically requires systemic immunosuppressive therapy for active disease. Blepharitis and dry eye syndrome are also treated with vigorous warm compresses, punctual occlusion, and doxycycline as needed (Krachmer et al. 2005).

Systemic

Various systemic immunosuppressive medications have been used to treat OCP. Immunomodulatory therapy is typically maintained for at least 1 year with a goal of complete resolution of all conjunctival inflammation. Systemic steroids may be used for 8–12 weeks with a taper once immunomodulatory therapy becomes effective (Krachmer et al. 2005).

Dapsone 2 mg/kg/day × 12 weeks has been shown to be 70% successful in stage III OCP patients and is used for less active cases of OCP (Krachmer et al. 2005; Foster et al. 2013). Important side effects to monitor for include G6PD deficiency and hemolytic anemia.

Cyclophosphamide 2 mg/kg/day is the treatment of choice for severe OCP. Weekly CBCs are used to monitor for leukopenia for 3 months upon starting cyclophosphamide.

Azathioprine 2 mg/kg/day has been used in patients who fail dapsone (or other agents) with resolution in roughly half of cases (Krachmer et al. 2005; Foster et al. 2013). CBCs are used to monitor for bone marrow suppression.

Methotrexate and mycophenolate mofetil have been used for alternative or step-down therapies with some success when other treatments are unresponsive.

Surgical

Many patients with OCP will develop cicatricial entropion, which contributes to ocular surface disease. Epilation and/or quickert everting sutures can be performed for temporary relief of trichiasis/entropion prior to more long-term surgical options for entropion repair such as Weis procedure, tarsal fracturing, transmarginal rotation procedure, and anterior lamellar recession. Amniotic membrane transplantation or mucous membrane transplants can be used for forniceal reconstruction in stage II or worse OCP. Limbal stem cell transplant and/or penetrating keratoplasty may be needed for severe cases. Surgical procedures are best performed when the active inflammatory condition has been quiescent for a period of time to best achieve success and avoid excessive scarring/failure (Krachmer et al. 2005).

Prognosis

Prolonged periods of remission of active OCP occur in approximately 33% of patients. Remission periods last on average 34 months (Foster et al. 2013) Ongoing follow-up, even after remission, is recommended given the chronic, relapsing nature of OCP.

Epidemiology

Incidence is estimated to be between 1:8,000 and 1:46,000 ophthalmic patients (Krachmer et al. 2005). The average age of diagnosis is between the ages of 60 and 70 (Krachmer et al. 2005). Insidious onset and smoldering of symptoms can delay diagnosis of actual disease onset. Like other autoimmune disorders, OCP has a higher predisposition to affect women more than men with a 2:1 ratio (Weisenthal 2013). Occurrences of OCP in patients younger than 30 are rare. OCP can affect all races.

Penetrating Eyelid Injuries

Gary Joseph Lelli[1], Benjamin Levine[1], Christopher Zoumalan[2] and Kira L. Segal[1]

[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

[2]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA

Synonyms

Avulsion; Laceration

Definition

Partial or full thickness penetration of the eyelid and ocular adnexal structures.

Etiology

Penetrating eyelid injury may result from causes such as a motor vehicle accident, assault with a sharp object, or a fall (Nerad 2001). Lacerating trauma to the eyelid may also be seen in the context of a bite injury (see Fig. 1a, b).

Clinical Presentation

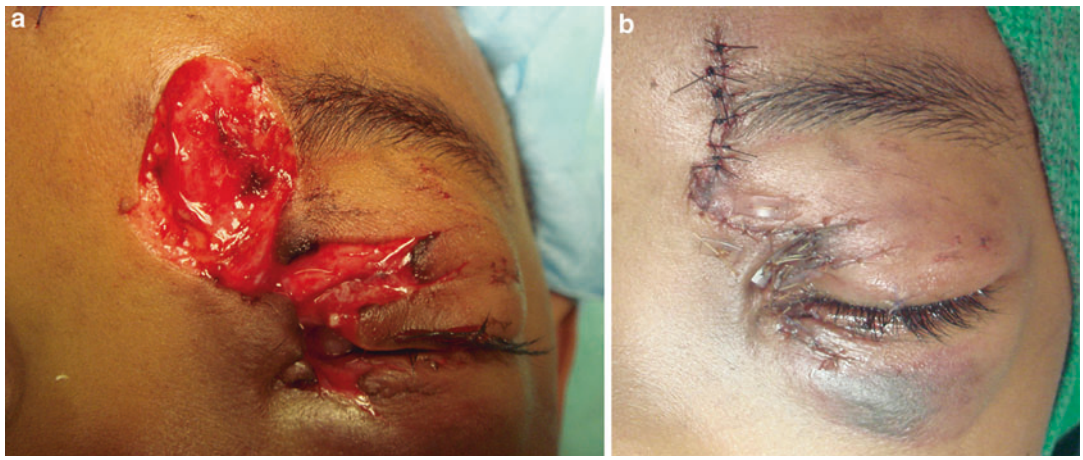
Penetration of the eyelid can be an isolated incident but most often occurs in the setting of multisystem trauma. The physician's primary role is to rule out life-threatening injury and to stabilize the patient. Sight-threatening injuries should then be addressed. The eyelid wound is explored to identify injured anatomic structures and the extent of damage. Fat present in the wound implies violation of the orbital septum and consequently, damage to the levator palpebrae superioris muscle is suspected. Full thickness eyelid trauma increases initial suspicion of globe injury. Tissue loss in the context of eyelid laceration is unusual, whereas shrinkage of tissue is more common (Weiner and Bedrossian 2002). Full thickness laceration can cause canthal avulsion, although this is more commonly seen following blunt trauma. With any penetrating injury to the medial aspect of the upper or lower eyelid, the ophthalmic examination should inspect for canalicular involvement. Additionally, penetrating injuries may leave foreign bodies in the eyelid or orbit.

Diagnostics

Examination of the patient's eye precedes examination of the eyelid. Following the eye exam, a thorough clinical examination via direct inspection of the wound is the physician's most important tool to determine the location, extent, and severity of the penetrating injury. A suspicion of a foreign body in the wound warrants imaging of the region. CT scanning of the orbit is the first line imaging protocol. If the medial aspect of the eyelid is involved, the canalicular system is inspected by careful probing. Damage to the levator is suspected when orbital fat is present within the wound and can be evaluated by measuring the levator excursion of the upper eyelid.

Differential Diagnosis

Trauma to the orbit, periocular trauma, ruptured globe.



Penetrating Eyelid Injuries, Fig. 1 (**a**) Preoperative photograph of patient status post dog bite injury with lacerations to the brow, upper eyelid, lower eyelid, and canalicular system. (**b**) Immediate postoperative photograph of penetrating dog bite injury

Prophylaxis

Penetrating injury to the eyelid can be prevented by the use of protective eyewear and polycarbonate eye glasses.

Therapy

The goal of treatment is to return normal function and cosmesis to the eyelid. Trauma to the eyelid should be repaired within 48–72 h following injury. The well-vascularized eyelid allows for somewhat delayed closure as it is at lower risk for infection. Some clinicians utilize broad spectrum oral antibiotics until wound treatment is initiated. This is particularly important in animal and human bite wounds. A general medical history should include inquiry regarding recent tetanus injections. Repair of the wound involves reapproximating tissues to their appropriate anatomic locations. If the levator muscle is found to be damaged, it is sutured back to its original location along the anterior border of the tarsus. If canalicular trauma is involved, repair can be accomplished at the same time as tissue repair. Medial or lateral canthal tendon avulsions are repaired by reinserting the appropriate limb of the canthal tendon to its bony insertion.

Prognosis

Given the highly vascular nature of the eyelid, wounds heal with minimal scarring and eyelid asymmetry. Full thickness eyelid injuries that affect the eyelid retractors may result in blepharoptosis. If the penetrating injury occurs along the lid margin, notching or asymmetry can manifest. Penetrating injuries may also cause retraction of the upper or lower eyelid secondary to fibrotic changes.

Epidemiology

Eyelid injury predominantly occurs in males aged 20–30 (Savar et al. 2008).

Penetrating Injuries

Marcelo Cerullo
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Perforating ocular laceration

Definition

Penetrating eye injuries refer to a full-thickness wound, with or without an exit wound. It may be associated with a retained foreign body intraocularly.

Etiology

Penetrating injuries are usually caused by sharp objects that enter the globe.

Clinical Presentation

Penetrating ocular lacerations can be divided into three categories: (1) injuries in which the offending object was immediately removed prior to presentation and in which there is no retained foreign body, (2) injuries caused by objects that pass completely through the globe that are then withdrawn (such as from a needle) without a retained foreign body, and (3) injuries in which a foreign body is retained completely or partially inside the globe.

Diagnosis

Initial diagnosis is often made on the basis of the history, which must be taken carefully and completely even if the patient does not report on suspect a penetrating ocular trauma. Many case reports have indicated that in circumstances in which there was metal work performed, penetrating ocular injuries (from filings or small fragments) must be suspected. Patients should be asked about changes in vision, foreign body sensation, or any sensation that suggests surface abnormalities of the globe or corneal abrasion. Clinical signs include conjunctival hyperemia or an obvious foreign object, though hemorrhage of the conjunctiva or subconjunctiva might obfuscate any direct visualization. Corneal abrasion may be visible on ophthalmic exam; signs include vertical abrasions that are specific for retained foreign bodies on the superior tarsal conjunctiva under the upper lid. A complete examination of *both* eyes is warranted, as injury to one should indicate the possibility of injury to the other. The lid should be everted and a dilated fundoscopic exam performed, as well as evaluations with a slit lamp exam, anterior chambers, and lens clarity. Plain radiography may be employed when a foreign body is suspected to have been retained and often will require surgical removal, though CT scan is preferred to determine the degree of ocular damage. After imaging, exploration under anesthesia should be undertaken urgently, by opening the conjunctiva and detaching of the rectus muscles. The wound, once identified, should be exposed, and displaced or damaged tissue should be noted (Kanski et al. 1999).

Differential Diagnosis

Penetrating injuries can be divided into several classes based on the depth and extent of the trauma. Corneal wounds with an intact anterior chamber may not require any surgical intervention as they will self-seal with or without a bandage contact lens. If corneal damage is suspected, a stromal infiltrate usually appears if a foreign body has been present for more than 24 hours. If the foreign body is organic (such as wood), microbial keratitis must be suspected, and in the case of metal (especially iron), foreign bodies are seen as rust-colored circular opacities on slit lamp examination. In instances in which the anterior chamber appears compromised, a dense cellular reaction is indicative of microbial ulceration of the cornea and secondary endophthalmitis. The degree of lens damage (if any), anterior/posterior scleral laceration, and retinal damage or detachment should be ascertained. For foreign bodies that are deep, the Seidel test should be performed. In the Seidel test cobalt-blue filter on the slit lamp is used to observe the area of suspected injury. A local anesthetic is placed on the eye and on a fluorescein strip which is applied to the area of injury. Since the pH of the anterior chamber is different from the surface, leaking aqueous fluid dilutes the dye on the strip (Gersenblith and Rabinowitz 2012).

Prophylaxis

Prevention of penetrating ocular trauma requires protective eye- or face wear during high-risk activities. As soon as a laceration is ascertained, the injured eye should be protected and the risk of comorbid symptoms reduced (i.e., pain, swelling, and possible associated vomiting mitigated with analgesics and/or anti-emetics). Tetanus immunization status should be elicited in the initial history taking. Corneal wounds that are left to heal spontaneously require topical antibiotics (such as

polymyxin B/bacitracin twice or thrice daily for up to 1 week). Broad spectrum antibiotics should be administered perioperatively intravenously and intravitreally to prevent endophthalmitis. A topical steroid and a mydriatic may be needed in the case of traumatic iritis. In the case of extensive damage to the globe, enucleation is advised to prevent sympathetic ophthalmia. If the damaged eye demonstrates no perception of light after suture repair within 10 days, then enucleation should be considered to prevent sympathetic ophthalmia, as well (Kuhn 2008).

Therapy

For small lacerations without a foreign body, self-healing with topical antibiotics (as indicated above) is sufficient. However, for larger and deeper lacerations (greater than 1 cm across), sutures are required to close. For corneal lacerations, the depth and number of the penetration(s) should be noted, as undue exploration for deep foreign material may exacerbate scarring. These lacerations are usually closed using nylon sutures with buried knots, and the repair should make the wound watertight. Corneal rust rings may be removed with an ophthalmic burr. For penetrating injuries that have resulted in scleral laceration, uveal or vitreous prolapse can occur through the wound. In this case, they are fully exposed with the aim of repositioning them within the globe. In many cases of corneal or scleral injury, the lens capsule is damaged, leading to hydration of the lens that ultimately causes marked intraocular inflammation. Usually, a second operation is needed to aspirate the lens or to determine whether further surgery is required on the retina (as there will be better visualization of the anterior chamber) (Probst et al. 2012).

Prognosis

Prognosis is highly dependent on the (1) severity of the injury and (2) the immediacy and completeness of evaluation and treatment. Frequent follow-up diminishes the risk of postoperative infections and complications, as well as allowing for reexamination to determine if further repair is needed. If the lens is completely damaged by the time of a second operation, the insertion of an intraocular lens (IOL) depends upon whether enough of the posterior capsule has been retained and how much iris has been retained (Kuhn 2008).

Epidemiology

Penetrating injuries are three times as common in males than in females, and over half of the injuries occur in adolescents and young adults. This is likely due to the fact that three main causes are assault, occupational accidents (e.g., working underneath a car or in a machine shop, doing woodwork, and fishing), and injuries occurring in sports. In the case of high-velocity impact injuries or injuries involving larger objects, there are often associated eyelid lacerations, which indicate the possibility of injury to the globe (Gerstenblith and Rabinowitz 2012).

Synonyms

Perfluorocarbon liquid (PFCL); Perfluorodecalin (C10F18); Perfluoro-n-octane; Perfluoron; Perfluorophenanthrene; Vitreon; Vitreous substitute

Definition

PFCL is a synthetic fluorinated hydrocarbon containing carbon–fluorine bonds. Some also contain other elements such as hydrogen, bromide, and nitrogen. It is commonly used as an intraoperative tool to assist the manipulation of the retina, particularly in complicated retinal detachments. In general, all PFCLs are odorless and colorless, have low viscosity, and have higher specific gravity and density than water.

A few low-density PFCLs have been investigated for potential use in ophthalmology. Of these perfluorodecalin (C10F18) was found to possess higher efficacy and was approved by the United States Food and Drug Administration for intraocular use. In the United States, perfluoro-n-octane is available as Perfluoron and perfluorophenanthrene is available as Vitreon. In Europe there are many brands of perfluorodecalin as well as perfluoro-n-octane marketed for intraocular surgery.

Indication

The main clinical indications for the intraocular use of perfluorocarbon liquids are detachments with giant retinal tears, detachments with complicated proliferative vitreoretinopathy (PVR), traumatic retinal detachments, removal of posterior lens fragments and posteriorly dislocated intraocular lenses, drainage of suprachoroidal blood, and macular rotation with a 360° retinotomy.

PFCL has also been reported to be useful in the retinal detachment associated with diabetic retinopathy, detachment associated with disk coloboma, detachment from retinopathy of prematurity, vitrectomy for endophthalmitis, displacement of submacular hemorrhage during surgical drainage, and excision of subretinal membranes. Surgical principles are the same. It helps stabilize the retina, displaces subretinal blood, reveals preretinal membranes, and assists drainage of subretinal fluid (SRF).

Contraindication

If a large posterior hole is present, perfluorocarbon liquid should not be used because there is a high probability of it going into the subretinal space.

Techniques and Principles

PFCL is a popular surgical tool due to several advantages: (1) its optical clarity allows manipulations under PFCL; (2) its high density and specific gravity allow flattening of the retina and unrolling of folds and also avoid the need for a posterior retinotomy to drain subretinal fluid (SRF); (3) it has different refractive indexes from saline enabling a visible PFCL-fluid interface, which aids intraocular maneuvers and its final removal; (4) it has a higher boiling point than water and no interference to laser wavelengths allowing endophotocoagulation under PFCL; (5) it has low surface tension and high interfacial tension which tend to hold it as a continuous bubble and reduce the risk of PFCL migration into subretinal space through the break; (6) its low viscosity allows easy injection and aspiration even with small gauge vitrectomies; (7) its immiscibility with water resists infiltration by saline and blood and allows a clear operating field despite intraoperative bleeding; (8) its immiscibility with silicone oil (SO) allows PFCL–SO exchange, which is helpful when treating giant retinal tears by reducing risk of slippage.

The majority of researchers at this time recommend the use of PFCL only as an intraoperative tool. Nevertheless some researchers have reported its safe use for short-term postoperative internal tamponade. In all cases, after PFCL has served its function, it should be removed completely from the vitreous cavity. Depending on the indication of PFCL use, PFCL–fluid, PFCL–air, or PFCL–SO exchange could be performed.

The general technique for the use of PFCL is as follows. Complete peripheral vitrectomy and at least initial removal of posterior retinal membranes are performed. The PFCL is injected with a blunt needle over the optic nerve head, flattening the posterior retina. The fluid is slowly injected, being careful to keep the tip of the injection cannula within the initial PFCL bubble to prevent fish-egging at the time of injection. The fluid is injected up to the level of the most posterior break. Membrane dissection and relief of traction are performed to assist in displacing posterior subretinal fluid or blood anteriorly. If traction has not been completely cleared and injection was too forceful, PFCL may go through breaks into the subretinal space. Fluid–air exchange is performed to allow residual subretinal fluid trapped anteriorly to drain through the break. As the air–fluid exchange continues, the blunt needle is allowed to passively PFCL until a thin layer remains on the retina. From 0.5 to 1 mL of BSS is then injected into the eye. The PFCL develops small droplets in the saline phase and can be identified and removed easily. BSS is then removed, leaving the retina flattened under air. Laser or cryopexy may then be administered. Final vitreous substitution is performed with air, gas, or SO injection. Direct PFCL–SO exchange may also be performed. As SO is lighter than PFCL, it floats on top of PFCL and fills the eye from anterior to posterior in parallel to PFCL passive aspiration.

The use of PFCL has allowed a rational method of reattaching giant retinal tears in the supine position. The high specific gravity of the PFCL creates a tamponade at the posterior edge of the break, allowing laser treatment before fluid–air exchange or fluid–SO exchange. This substantially reduces the rate of posterior slippage.

The use of PFCL has also changed the management of PVR. Before the introduction of PFCL, PVR would be dealt with from anterior to posterior. After PFCL was introduced, dissection of membranes starting from the posterior pole was made possible. This is a safer approach as it reduces the risk of iatrogenic tears and the trauma to the retina.

PFCL offers several advantages for addressing the challenges of surgical management of traumatic retinal detachment: (1) it helps stabilize the retina during vitrectomy; (2) it assists in separating the posterior hyaloid and retina; (3) it displaces preretinal, subretinal, or suprachoroidal blood; (4) it assists in the removal of incarcerated vitreous or the retina; (5) it assists in the removal of dislocated lens, intraocular lens implant (IOL), or intraocular foreign bodies (IOFB); (6) it maintains a clear media for visualization.

PFCL facilitates removal of dislocated lens, as it can be used to float the lens fragment away from the surface of the retina. This allows easier manipulation of the lens fragment during phacofragmentation and reduces the risk of injuring the retina. It is particularly useful when the dropped lens is associated with retinal detachment, where subretinal migration of fragments is prevented.

Macular rotation with a 360° retinotomy depends on PFCL, followed by liquid–SO exchange to attach the retina. Macular rotation is a surgical procedure to treat macular degeneration with subfoveolar involvement by detaching the entire retina so as to move the fovea to a position with underlying retinal pigmented epithelium that is not involved by exudative or atrophic macular degeneration. If the macular rotation is successful, counterrotation of the globe with muscle surgery is required to avoid diplopia and cyclotropia.

Outcome

The advent of PFCL technique in the surgical repair of giant retinal tears hugely improved the anatomical success rate to over 88%, even without the use of a scleral buckle.

The success rate for severe PVR has been reported to range from 84% to 96%. PFCL use also shortens operative time and allows more thorough removal of membranes.

In one series of 14 patients with detachment arising from penetrating ocular trauma, all retinas flattened intraoperatively with the use of PFCL without retinotomy. Factors associated with a lower long-term success rate were patients younger than 20 years of age, patients with previous vitrectomy, patients with a posterior retinal injury site, and patients with subretinal hemorrhage for more than 2 weeks.

Complications

Toxicity from extended intraocular use has been reported in animal as well as human reports. Toxicity to ocular tissues may be chemical or mechanical. Most toxicities are related to incomplete removal of PFCL at the end of surgery.

During surgery, predisposing factors for PFCL going under the retina include: (1) PFCL breaking into droplets, (2) giant retinal tears, and (3) incomplete relief of tractional membranes on the retina. If PFCL has accidentally penetrated under the retina, it should be removed, as it may over time migrate under the fovea, may reduce retinal function, and may cause central scotomas. Retinal hole formation has also been reported in long-standing subretinal PFCL. Even in case that subretinal PFCL is noticed postoperatively, it should be drained, as retinal sensitivity is regained after PFCL drainage.

If PFCL enters the anterior chamber, it may cause visual disturbance, corneal endothelial loss, as well as rise in intraocular pressure (IOP). Pupil block glaucoma has also been reported following the use of PFCL. PFCL removal is indicated under these circumstances and can be done at the slit lamp.

Peribulbar Anesthesia

Armin Wolf
Department of Ophthalmology, Ludwig-Maximilians Universität München, München, Germany

Synonyms

Extraconal anesthesia; Parabulbar anesthesia

Definition

Percutaneous application of anesthetics into the extraconal space of the orbit.

Epidemiology

Peribulbar anesthesia (PBA) is used by a large number of surgeons as it combines low incidence of complications during anesthesia with a relatively good motor block (Alhassan et al. 2008). It is especially used in cataract surgery.

History

Development and acceptance of peribulbar anesthesia is closely related to development of cataract surgery. While in earlier times of cataract surgery, large incisions at the sclerolimbal region were necessary, full anesthesia or retrobulbar anesthesia was anesthetic mode of choice. With development of phacoemulsification, clear cornea incision, and small incision cataract surgery, the trauma and discomfort during cataract surgery became less severe; thus other techniques of anesthesia became more accepted.

Clinical Features

As PBA presents a needle block, all needles may be used; however, in order to avoid injury of the

globe, blunt needles are preferred. The reasons for this technique are a reduced risk of causing injury to the intraconal structures. The volume of anesthetic applied in PBA is higher than in retrobulbar anesthesia (RBA) (up to 12 ml) (Nouvellon et al. 2010). However, the onset of motor block after PBA may take longer than after (RBA). For cataract surgery, a sufficient motor block with anesthesia is achieved within 5 min in 85%. There are several techniques and various entry sites for PBA. A single injection technique with the least risk of injury has to be distinguished from a several injection technique at several sites. However, the nasal superior peribulbar space should be avoided as the extraconal space is narrow at this location (Nouvellon et al. 2010). The injection depth should be limited as in deeper orbit, the space between extraocular muscles and orbit wall becomes virtual.

Tests

Several test have shown that risk of injury to globe and other structures is lesser in PBA than in RBA; however, onset of motor block has been shown to take longer in BPA.

Differential Diagnosis

Retrobulbar anesthesia (RBA), intraconal anesthesia

Etiology

The term "peribulbar anesthesia" is self-explaining.

Treatment

See also "Clinical Features." Injection sites for PBA may be medial canthus, lacrimal caruncle, seminularis fold of the conjunctiva and temporal inferior.

Periocular Injection of Ocular Drugs

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Indication

Periocular injections are used for regional anesthesia and akinesia (lidocaine), blepharospasm and hemifacial spasm (botulinum toxin), and chemoreduction of tumor (topotecan and carboplatin), to induce ptosis in cases of corneal exposure, for the treatment of strabismus (botulinum toxin), and for the treatment of cystoid macular edema and unresponsive uveitis (triamcinolone acetonide).

Adverse Effects

Injections in the retrobulbar space carry a risk of hemorrhage especially in patients using anticoagulation therapy. Retrobulbar hemorrhages can lead to permanent visual loss due to ischemia. Increased intraorbital pressure compresses the ciliary arteries supplying the optic nerve.

Periocular injections of botulinum toxin can lead to transient blepharoptosis, ectropion, lagophthalmos, and strabismus.

Triamcinolone can increase intraocular pressure when injected in the subtenon space. Intralesional triamcinolone used in darkly pigmented patients can cause depigmentation of the overlying skin.

Peripheral Corneal Guttata (Hassall-Henle Bodies/Warts)

Rasha Ali
Department of Ophthalmology, Wohl Eye Center, University of Minnesota, Bloomingdale, IL, USA

Synonyms

Hassall-Henle bodies; Hassall-Henle warts

Definition

Peripheral corneal guttata are hyaline-filled excrescences of Descemet's membrane that occur in the peripheral cornea. These guttata are associated with normal aging. Corneal guttata that occur in the central cornea are pathologic, such as seen with Fuch's dystrophy, fleck dystrophy, corneal degenerations, or long-standing inflammatory disorders.

Corneal guttata may be associated with impaired endothelial function and may consequently disrupt the deturgescent activity of the endothelium, resulting in corneal edema.

On examination with specular microscopy, guttata appear as dark small spots on the endothelium. Histologically, they resemble mushroom caps sitting on the endothelium.

Etiology

The dysfunctional overproduction of hyaline basement membrane by endothelial cells results in the formation of corneal guttata.

Occurrence

Hassall-Henle bodies normally occur in the peripheral cornea in adults older than 25 and become more common with age.

Classification

Non-pathologic anatomic finding

Peripheral Keratitis

Alan Fremder Utria
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Definition

Peripheral keratitis is inflammation of the outermost part of the cornea. The cornea can be divided topographically into central and peripheral portions. In the outermost portion, the peripheral cornea, the tissue begins to transition to conjunctival, episcleral, and scleral tissue. Due to the proximity of the peripheral cornea to these tissues, it is more susceptible to some disorders that do not typically affect the central portion.

Persistent Hyperplastic Primary Vitreous

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Persistent fetal vasculature (PFV); Persistent posterior fetal fibrovascular sheath of the lens; Persistent tunica vasculosa lentis

Definition

Persistent hyperplastic primary vitreous (PHPV) is a congenital anomaly of the eye in which there is failure of regression of the fetal primary vitreous and hyaloid vasculature. The etiology of this abnormal persistence is unknown. Most cases are seen in normal, full-term infants without other systemic findings and are unilateral.

PHPV can be further classified into three different subtypes depending on location of the persistent fetal vasculature:

1. Anterior PHPV – Retrolental fibrovascular opacities, elongated ciliary processes, cataract, and microphthalmia.
2. Posterior PHPV – Vitreous membrane or stalk from optic nerve head, retinal folds or

dysplasia, tractional retinal detachment, and optic nerve hypoplasia.
3. Combination of anterior and posterior PHPV – Most common. Findings of both anterior and posterior PHPV are present.

Etiology

In normal embryological development of the eye, the primary vitreous forms around the seventh week and begins to regress around the twentieth week of fetal development. By birth, normally all remnants of the primary vitreous and hyaloid vasculature have regressed. In PHPV, there is failure of this regression. The etiology leading to this persistence of fetal primary vitreous and hyaloid vasculature is not known. Although some reports exist describing associations with systemic or neurological diseases, most patients with PHPV are healthy, full-term infants with no other systemic problems.

Clinical Presentation

Findings of PHPV are present at birth and may be identified at the newborn exam. Patients with more posterior PHPV may not be identified until later in childhood when other visual symptoms are noted. Patients may be found to have glaucoma, strabismus, or leukocoria. Possible findings associated with PHPV include microphthalmia, cataract, retrolental plaques, shallow anterior chamber, elongated ciliary processes, persistent hyaloid artery, retinal or optic nerve dysplasia, macular abnormalities, vitreoretinal adhesions, and retinal detachment.

Diagnosis

Diagnosis is based on clinical exam findings, exams done under anesthesia, and augmented by other imaging modalities. PHPV can be visualized by ultrasound (A-scan and B-scan), computer tomography (CT), and magnetic resonance imaging (MRI). Additionally, visual evoked potentials (VEP) may be helpful to assess vision potential.

Differential Diagnosis

PHPV must be differentiated from other causes of leukocoria such as congenital cataract, retinoblastoma, Coat's disease, toxocariasis, retinopathy of prematurity (ROP), retinal astrocytomas, Norrie's disease, familial exudative vitreoretinopathy (FEVR), and other causes of retinal detachments.

Prophylaxis

None. PHPV occurs most commonly in otherwise healthy, normal infants

Therapy

Treatment of PHPV varies with the extent of findings associated with PHPV. The treatment spectrum spans from conservative observation to surgical management. Surgical intervention is aimed at improvement in visual acuity and should be performed early to increase likelihood of useful vision. Many surgical strategies are described in the literature and continue to evolve with advances in surgical technique and instrumentation. Most include a vitrectomy with or without a combined lensectomy. Aggressive amblyopia treatment is necessary postoperatively.

Prognosis

Prognosis is very dependent on the type and extent of PHPV and on the timing of diagnosis. Patients with purely anterior PHPV have a better prognosis than those with combined or posterior PHPV.

Epidemiology

PHPV is isolated and sporadic. Epidemiologic data is poor.

Persistent Pupillary Membrane

Michael Rabinowitz and Tara Uhler
Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Synonyms

Hyperplastic persistent pupillary membrane. (Some authors consider these to be different than persistent pupillary membranes. See Clinical Relevance below.)

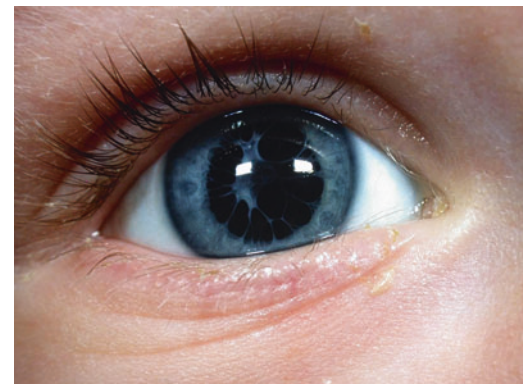
Definition

The presentation of incomplete involution of the in utero pupillary membrane with or without accompanying blood vessels from the underlying tunica vasculosa lentis.

Structure

In utero, the neural crest-derived iris stroma extends across the fetal pupil with strands arising from the iris collarette. There may be communications with the underlying tunica vasculosa lentis, a network of vessels formed by the anterior extension of the hyaloid artery, on the anterior lens surface especially in the peripheral regions. In the third trimester, these strands that cross the pupil resorb. Regression is aided by macrophage phagocytosis, the dysfunction of which may predispose to pupillary membranes. If there is failure of resorption, a pupillary membrane (Fig. 1) may be seen postnatally.

Persistent pupillary membranes (PPM) are usually spontaneous, random occurrences. There are rare reports of autosomal dominant inheritance and documented correlation with TORCH infections. Although most often isolated, these membranes may be seen in association with other anterior segment defects such as microcornea, microphthalmos, coloboma, and megalocornea.



Persistent Pupillary Membrane, Fig. 1 Photograph of a persistent pupillary membrane (Courtesy of Dr. Alex V. Levin, Wills Eye Institute)

Function

None

Clinical Relevance

Presentation

PPM are present in 95% of newborns and 20% of adults; the decrease in incidence with advancing age is felt to be due to natural dissolution perhaps induced by the daily movements of the pupil. Persistent pupillary membranes have variable presentations. Most often they are fine gray, filamentary projections extending from the iris collarette; the ends may be free floating in the anterior chamber or attached to another area of the iris collarette. Origination from the collarette distinguishes persistent pupillary membranes from inflammatory membranes that arise from the borders of the pupil. Pupillary membranes may appear pigmented. Rarely, they may be thick and hyperplastic, obstruct the visual axis, or be associated with attachment to the anterior lens capsule and predispose to localized anterior polar cataract.

Differential Diagnosis

- Inflammatory membrane/posterior synechiae
- Microcoria
- Axenfeld-Rieger syndrome

Significance

Even when substantial in size, PPM are rarely clinically significant. Associated anterior lens opacities are usually not in the visual axis, and cataracts seldom progress. Rarely, membranes may bleed if traumatized. In premature infants, cases have been reported in which a vascular connection between the pupillary membrane and the tunica vasculosa lentis acted as a conduit for the spread of organisms (e.g., *candida*) causing lens abscess in a septic child. Finally, if particularly large, PPM may obstruct the visual axis and cause amblyopia. Some authors classify these as separate entities called hyperplastic persistent pupillary membranes.

Treatment

Most PPM are small and either resolve or become asymptomatic by 1 year of age. If visually significant, medical therapy with pupillary dilation, without paralysis of accommodation (e.g., phenylephrine 2.5%), is usually effective. Rarely, laser therapy to the strands or surgical management, including iridectomy or pupilloplasty, have been performed to improve visual prognosis. After surgery, careful monitoring for the development of cataract, amblyopia, and glaucoma is necessary.

Synonyms

Manual phacofragmentation

Definition

Phacofragmentation is a surgical technique for lens removal and is used in refractive and cataract surgery. This technique means the manual deterioration of the crystalline lens nucleus and the removal of lens pieces through a 4–5 mm wound.

Epidemiology

Cataract surgery is the most common surgery worldwide. Detailed data about the incidence of cataract surgery do not exist, but there are approximately ten million operations per year worldwide. The frequency and the operation technique varied among developed and undeveloped countries. In the USA nearly 80% of all cataract surgeries are accomplished by phacoemulsification. Phacofragmentation is an operation method that is accomplished in special cases when the nucleus of the crystalline lens is probably very hard and phacoemulsification might be problematic.

History

Extracapsular cataract extraction was performed since the middle of the eighteenth century. In former times the extraction of the nucleus happened as a mass without fragmentation through a wide incision.

Large incisions have several disadvantages such as problems with wound healing, vitreous loss, or infections. In 1988 Kansas et al. published in addition to the small incision technique of phacoemulsification another small incision cataract extraction technique using manual phacofragmentation. Since that time the operation method of phacofragmentation underwent several changes and amendments.

Clinical Features

The utilization of phacofragmentation is reserved for difficult cases in cataract surgery. In cases of advanced cataract, the preferred operation method of phacoemulsification is not suitable because of the callous nucleus of the lens. In these cases phacoemulsification can affect higher complications because of the higher ultrasound energy for deterioration of the hardened nucleus such as endothelial decompensation. Another reason for practicing phacofragmentation is a luxated lens in the vitreous body because of ocular trauma or connective tissue diseases such as Marfan's syndrome, homocystinuria, or Marcheani's syndrome. Lens removal is then advocated because it may induce uveitis and glaucoma. In these cases

phacofragmentation is often combined with pars plana vitrectomy.

Test

To examine best postoperative results thorough slit-lamp examination with dilated pupil, Scheimpflug imaging and measurement of uncorrected and best spectacle-corrected visual acuity are essential.

Etiology

See "Clinical Features" section above.

Treatment

Several different methods of phacofragmentation have been employed such as quarters extraction technique or prechop manual phacofragmentation.

The prechop manual phacofragmentation is described here. The nucleus in this technique is manually split into two fragments by prechopper forceps and the fragments removed through a 5.5–6.5 mm temporal clear corneal incision. After capsulorhexis, hydrodissection, hydrodelineation, and surface cortex aspiration, a prechopper forceps is gently passed into the center of the nucleus core and the nucleus is fragmented into two pieces. Each piece is prolapsed into the anterior chamber and extracted with corneal forceps and hooks via small incision.

Phacotrabeculectomy

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Combined trabeculectomy; Phacoemulsification and posterior chamber intraocular lens (IOL) implantation

Definition

A surgical technique that is used in patients with a coexisting affection of glaucoma and cataract. The technique includes a combination of phacoemulsification, intraocular lens

implantation, and trabeculectomy. Phacoemulsification and intraocular lens implantation are surgical treatments for cataract, and trabeculectomy is a penetrating filtering surgical procedure for various types of open-angle and normal-tension glaucoma. The technique of phacotrabeculectomy can include either both operations performed through the same incision (a one-site procedure) or through separate incisions (two-site procedure).

Epidemiology

Combined glaucoma and cataract surgeries are increasing in popularity because both cataract and glaucoma are age-related diseases, and the recent technical improvements in small-incision phacoemulsification have reduced the risk of postoperative or tissue trauma.

History

Lyle et al. first introduced the term phacotrabeculectomy in the literature in 1991. The combined procedure of phacoemulsification, posterior chamber intraocular lens (IOL) implantation, and trabeculectomy has been advocated for treating coexisting glaucoma and cataract. In several studies since the early 1990s, a positive effect of phacotrabeculectomy on the reduction of eye pressure was shown. Negative side effects were also seen as there are bleb leaks, hypotony, flat anterior chamber, choroidal detachment, and endophthalmitis. That was a reason for the development of other combined surgical techniques for the reduction of the eye pressure at the end of the 1990s as there was phacoviscoanalostomy.

Clinical Features

According to the World Health Organization, cataract is the first and glaucoma is the third most common cause of blindness worldwide. A major risk factor for both of these diseases is aging, and therefore the coexistence of cataract and glaucoma is not uncommon.

A combined cataract and glaucoma surgery is an appealing therapeutic approach because of the increased risk of cataract development in some glaucoma patients, the increased risk of cataract development after glaucoma surgery, and the need to minimize trauma and cost induced by two surgical procedures.

Test

For checking the postoperative outcome, it is necessary to control the intraocular pressure in close meshed gaps. Furthermore uncorrected and best-corrected vision acuity and thorough slit-lamp examination are essential constituent parts of postoperative control.

Another surgical procedure for combined treatment of cataract and glaucoma is:

- Phacoviscoanalostomy

Phacoviscocanalostomy

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Combined viscocanalostomy; Phacoemulsification and posterior chamber intraocular lens (IOL) implantation

Definition

A surgical technique that is used in patients with a coexisting affection of glaucoma and cataract. The technique includes a combination of phacoemulsification, intraocular lens implantation, and viscocanalostomy. Phacoemulsification and intraocular lens implantation are surgical treatments for cataract, and viscocanalostomy is a non-penetrating filtering surgical procedure for various types of open-angle and normal-tension glaucoma.

History

Viscocanalostomy is a relatively new, surgical procedure that was first described and developed by Stegmann et al. in 1999. Then phacotrabeculectomy and trabeculectomy were common surgical procedures for reducing the eye pressure in patients with glaucoma. These techniques are known to be connected with several potentially serious complications as there are bleb leaks, hypotony, flat anterior chamber, choroidal detachment, and endophthalmitis. In contradiction viscocanalostomy in combination with phacoemulsification is reported to efficiently and safely reduce intraocular pressure (IOP) while improving visual acuity.

Epidemiology

Combined glaucoma and cataract surgeries are increasing in popularity because both cataract and glaucoma are age-related diseases, and the recent technical improvements in small-incision phacoemulsification have reduced the risk of postoperative or tissue trauma.

Clinical Feature

According to the World Health Organization, cataract is the first and glaucoma is the third most common cause of blindness worldwide. A major risk factor for both of these diseases is aging, and therefore the coexistence of cataract and glaucoma is not uncommon.

A combined cataract and glaucoma surgery is an appealing therapeutic approach because of the increased risk of cataract development in some glaucoma patients, the increased risk of cataract development after glaucoma surgery, and the need to minimize trauma and cost induced by two surgical procedures.

Test

For checking the postoperative outcome, it is necessary to control the intraocular pressure in close meshed gaps. Furthermore uncorrected and best-corrected vision acuity and thorough slit-lamp examination are essential constituent parts of postoperative control.

Differential Diagnosis

Another surgical procedure for combined treatment of cataract and glaucoma is:

– Phacotrabeculectomy

Description

Viscocanalostomy can be both first and second step of the procedure. The original idea of

phacoviscocanalastomy was an aqueous humor passage from the anterior chamber through an intact window in Descemet's membrane above Schwalbe's line into a subscleral lake and ultimately through surgically made openings into Schlemm's canal.

Phakic Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Phakic IOL; PIOL

Definition

An additional artificial intraocular lens to correct a refractive error that is placed in an eye in which the existing crystalline lens has not been removed (Kohnen and Koch 2006).

Epidemiology

Phakic IOLs are implanted throughout the world with rising numbers. Due to its spectrum of indications, phakic IOL surgery accounts for less than 1–2% of all refractive surgical procedures.

History

The first experience with phakic IOLs was by Barraquer and Strampelli in the middle of the last century using an anterior chamber design. Due to the high complication rate that often demanded explantation of the IOL, this novel method was abandoned and no phakic IOL was manufactured or implanted for the following 20 years. In the 1970s, J. Worst developed an iris-fixated anterior chamber IOL, which was first implanted into aphakic eyes by P. Fechner (Fechner and Alpor 1986). Several modifications of this IOL have been performed since then in order to gain more space between the phakic IOL and the cornea in order to increase safety for the corneal endothelium. In the 1980s and the 1990s, great technological progress in both IOL manufacturing and surgical techniques was attempted, and several polymethyl methacrylate (PMMA) angle-supported anterior chamber phakic IOLs were developed (Hardten et al. 2003). However, all of them were subsequently phased out of the market due to unacceptable rates of complications, including corneal endothelial cells loss, pupil ovalization, glare and halos, and chronic anterior uveitis. Current studies with the newly developed foldable anterior chamber angle AcrySof show that these problems can be reduced and that safety of the corneal endothelium is ensured.

Clinical Features

Implantation of phakic IOLs has been demonstrated as an effective, safe, predictable, and stable procedure to correct moderate and high refractive errors. Complications are rare and are mostly related to the site of implantation. However, longer follow-up studies are needed to establish long-term safety of these lenses. Development of new anterior segment imaging devices is changing preoperative and postoperative management of phakic IOLs, increasing safety profiles and allowing for a more accurate follow-up. Moreover, exact measurements of anterior chamber diameter, anterior chamber depth, and ciliary sulcus diameter are improving the phakic IOL selection and thus decreasing the risk of unwanted complications. The potential clinical applications and the range of information they may yield are being continuously explored and further developed.

Tests

In order to ensure safety of phakic IOLs, several inclusion criteria must be considered:

- Age over 21 years
- Stable refraction of at least 1 year
- Absolute contraindication for corneal surgery
- Iridocorneal anterior chamber angle of at least 30°
- Corneal endothelial cell count over 2,300/mm^2 (2,500 >21 years, 2,000 >40 years)
- Anterior chamber depth of at least 2.7 mm for Acrysof and Artisan-Verisyse
  For implantable collamer lens (ICL), at least 2.8 mm for myopic and at least 3 mm for hyperopic lenses
  For phakic refractive lens (PRL), at least 2.5 mm
- Regular pupillary function
- Mesopic pupillary diameter below 5–6 mm

Differential Diagnosis

An aphakic IOL is an IOL that is implanted in an aphakic eye and is usually placed in the capsular bag. A supplementary pseudophakic IOL is an IOL that is implanted in an eye with an artificial IOL (see also piggyback or Add-On IOL).

Etiology

Phakic IOLs are divided into anterior chamber phakic IOLs, iris-fixated phakic IOLs, and posterior chamber phakic IOLs.

Treatment

Implantation of a phakic IOL is usually a treatment option for eyes that cannot undergo excimer laser correction, e.g., due to higher ametropia (over minus 8 D or over plus 4 D) or underlying corneal keratectatic disease.

Pharmacologic Anisocoria

Danielle L. DeBacker[1], Andrew R. Davis[1], Sumayya J. Almarzouqi[2] and Andrew G. Lee[2,3,4,5,6]

[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Definition

Pharmacologic anisocoria refers to anisocoria as caused by a pharmacological agent. Anisocoria further defines a state of unequal pupillary size between the two eyes (typically greater than 0.4 mm in diameter).

Etiology

Pharmacologic anisocoria specifically refers to anisocoria due to the iris sphincter or dilator muscle by a pharmacological agent.

Mydriatic agents include sympathomimetic and parasympatholytic medications. The sympathomimetics include α1-adrenergic agonists (e.g., epinephrine or neosynephrine containing eye or nasal drops or sprays, the topical glaucoma agent, apraclonidine, and various cardiac medications). These medications act to directly stimulate the iris dilator muscle by increasing norepinephrine activity on α1 receptors. Other mydriatic agents include recreational, psychoactive drugs such as cocaine (inhibits reuptake of norepinephrine) and amphetamine (stimulates release of norepinephrine). These same indirect sympathomimetic agents can be used topically to pharmacologically test the integrity of the ocular sympathetic pathway.

Mydriatic agents whose mechanism involves blocking the iris sphincter muscle in order to decrease parasympathetic tone (i.e., parasympatholytics) include anticholinergic medication. Common anticholinergic medication involved in pharmacologic anisocoria includes diagnostic eye drops used for dilated fundus exams (e.g., tropicamide) and therapeutic eye drops (e.g., atropine, cyclopentolate) including some over the counter parasympatholytic topical preparations. Ipratropium inhalers, scopolamine transdermal patches, and rarely chronic use of sinus decongestants like diphenhydramine are additional anticholinergic agents responsible for anisocoria. Further, exposure to jimsonweed and other belladonna alkaloids from the *Datura* genus may induce unilateral mydriasis.

Pharmacologic anisocoria may also be a result of miotic agents which cause constriction of the pupil in comparison with the other pupil. Chronic use of topical pilocarpine and other muscarinic agonists in glaucoma therapy permanently affects the pupil's ability to dilate through direct stimulation of M3 receptors on the iris sphincter muscle. Exposure to acetylcholinesterase inhibitors used in insecticides and flea collars can also produce pharmacologic miosis or anisocoria.

Clinical Presentation

Pharmacologic anisocoria in contrast to physiologic anisocoria is typically greater than 0.4 mm. The anisocoria may be greater in the dark (failure

to dilate) or in the light (failure to constrict). Conjunctival blanching and eyelid retraction may occur in cases caused by sympathomimetic drugs. Assessment of accompanied symptoms is critical in order to further establish the etiology of anisocoria and rule out more serious pathologies.

Diagnostics

Performing a thorough patient history relating to medication history, recreational drug use, and environmental exposure is key in diagnosing pharmacologic anisocoria. Physical examination of the pupils should be performed in dark and bright light to first determine which pupil is abnormal. When conducting the pupillary light reflex examination in bright light, if the larger pupil constricts poorly, the anisocoria will typically involve a mydriatic pupil. If the smaller pupil does not effectively dilate in dim light, then the abnormal pupil is miotic. Pharmacologic mydriasis due to a parasympatholytic agent produces anisocoria that is worse in the light.

Further diagnostic methods for pharmacologic anisocoria caused by mydriatic agents include pilocarpine testing. The direct-acting parasympathetic agent pilocarpine 1% can be used to determine if there is pharmacologic blockade. Note that pilocarpine testing is not as useful for sympathomimetic-related mydriasis and topical pilocarpine is usually a stronger stimulus for the sphincter to constrict than the adrenergic stimulation of the iris dilator muscle.

Finally, appropriate laboratory testing via serum or urine testing for verification of suspected systemic organophosphate exposure and drug overdose.

Differential Diagnosis

Physiologic anisocoria, Horner's syndrome, Adie's tonic pupil, oculomotor nerve palsy, eye trauma resulting in mechanical damage of the iris, uveitis, neovascularization of the iris in diabetic eye, or ocular ischemic syndrome.

Prophylaxis

Avoid use of offending pharmacological agents.

Therapy

Discontinuation of responsible pharmacological agent if possible.

Prognosis

Pharmacologic anisocoria should resolve over days or weeks depending upon the pharmacokinetics of the responsible agent.

Epidemiology

Pharmacologic anisocoria from inadvertent exposure typically occurs in health care workers with access to topical agents but may occur in any age, either gender, and any ethnic group. Patients with blue irides may have more noticeable effects of pharmacologic anisocoria due to differential drug absorption after exposure.

Phlycten; Phlyctenular keratoconjunctivitis; Phlyctenulosis

Definition

A phlyctenule is an inflammatory nodule of the ocular surface, found in the cornea or the conjunctiva. It is often located near the limbus but can occur anywhere in the cornea or conjunctiva. Clinically, the lesions are nodular, are yellow or pink white in color, and are associated with surrounding neovascularization in the cornea or adjacent hyperemia of the bulbar conjunctiva. They can become ulcerated. The word "phlyctenule" originates from the Greek word "phlyktaina," meaning "blister." Phlyctenulosis is believed to be a type IV hypersensitivity to bacterial antigens, most notably *Staphylococcus* species, *Propionibacterium acnes*, and other bacterial antigens. In addition to its association with systemic *Mycobacterium tuberculosis* infection, phlyctenulosis has also been associated with systemic worms and parasites. The meibum of patients with phlyctenular keratoconjunctivitis has been reported to contain bacteria such as *Staphylococcus epidermidis* and *Corynebacterium* species. Phlyctenulosis affects mostly children and young adults and has been associated with eyelid margin disease. Histologically, monocytes and monocyte-derived cells predominate. Polymorphonuclear leukocytes, T lymphocytes, and – to a lesser extent – B lymphocytes and plasma cells can be found as well. The mainstays of treatment are eyelid hygiene and oral antibiotics, particularly when the phlyctenule is associated with blepharitis related to *Staphylococcus* or rosacea. Topical steroids are also used to reduce inflammation and neovascularization. Sometimes, the lesion can be refractory to topical steroids. In such cases, topical cyclosporin A or tacrolimus can be offered as treatment.

Photochromic Foldable Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The term "photochrome" means capable of darkening or changing color when exposed to light. Photochromism can be defined as the ability of a material to reversibly change its visible absorption spectrum on exposure to activating radiation and to revert to its original absorption spectrum on removal of the activating radiation or on substituting radiation of a different wavelength (Werner et al. 2006).

Epidemiology

One of the most famous reversible photochromic applications is color changing lenses for sunglasses, as found in eyeglasses.

History

Organic photochromic compounds have been known for over a hundred years and date back to the era of Alexander the Great. However, they excited little commercial interest until the 1950s. Inspired by the work of E. Fischer and Y. Hirshberg who first reported photochromism in spiropyran analogues in 1952, intense studies on photochromic compounds have continued up to the present. In ophthalmology, yellow IOLs were introduced on the market in the 1990s with the idea that light with a short wavelength may damage the retinal pigment epithelium and the neurosensory retina (Kohnen and Koch 2009). Medennium Inc. recently developed an IOL with photochromic properties. According to the manufacturer, this IOL has an ultraviolet (UV) near-blue absorption curve similar when exposed to UV light, while it behaves as a standard UV-absorbing IOL in an indoor environment.

Clinical Features

The clinical benefit of photochromic IOLs is currently under investigation.

Tests

The clinical benefit of photochromic IOLs is currently under investigation.

Differential Diagnosis

Blue-filter IOLs might inhibit the phototoxic effect of blue light on the macula and therefore reduce the risk of developing age-related macular degeneration. Yellow IOLs might decrease contrast sensitivity and color vision under mesopic conditions (Wenzl et al. 2009). Photochromic IOLs are clear under mesopic and scotopic conditions and turn yellow under photopic conditions.

Etiology

The term photochromic refers to greek "phos" = light and "chroma" = color.

- ▶ Laser Focal Treatment

Photodisruption

Rahul Yadav
Department of Ophthalmology, Center for Visual Sciences, University of Rochester, Rochester, NY, USA

Introduction

Photodisruption is the disruption of tissues due to the rapid ionization of molecules caused by exposure to laser light. It is a commonly used technique for performing minimally invasive intraocular surgery. The first clinical use of photodisruption was demonstrated in 1972, when photodisruption with a pulsed ruby laser was used to treat open-angle glaucoma. However, it was not until the development of Q-switched Nd:YAG lasers in the early 1980s that photodisruption became truly clinically useful.

Mechanism of Action

Biological tissue is not a very strong absorber of visible light; however, a tightly focused pulsed laser can produce very high intensity of light in the focal volume and result in the nonlinear absorption of the light. This absorption of energy causes the temperature in the focal volume to rise to ~10,000 K, resulting in the formation of plasma (via thermionic emission of electrons) which then expands through avalanche or cascade ionization. The rapid temperature increase in the plasma is accompanied by a pressure increase in the focal region. This increased pressure and plasma expansion cause the generation of a shockwave and the formation of a cavitation bubble, which eventually collapses.

The plasma formation is the main mechanism that mediates the surgical effect of photodisruption, as it essentially causes evaporation of material from the focal volume of the laser beam, allowing the high-precision cutting of tissue. Since the entire process is mediated by nonlinear effects, only a very small focal volume is affected. No thermal side effects from the laser light are observed and very little damage of the surrounding tissue is expected. However, the generation of the shock wave and cavitation bubble can cause disruption of peripheral tissue around the focal volume. This additional disruption may sometimes be desirable, but at other times contributes toward unwanted side effects of the surgical procedure.

Applications

The high-precision cutting and relatively low peripheral damage of the photodisruption technique make it ideally suited for micromachining applications and minimally invasive surgery. Of the two, the clinical application of disruption is

more widespread. In fact, photodisruption is now a well-established technique for performing intraocular surgery: iridotomy for acute angle-closure glaucoma and capsulotomy for secondary cataract are routinely performed using this technique, and other procedures such as pupillary membranectomy, synechialysis, and division of the vitreous membranes have also been performed successfully. Typically used systems for clinical photodisruption involve Nd:YAG lasers with pulse widths of a few nanoseconds and energies in the range of low millijoules.

The major advantage of photodisruption is that it is a minimally invasive technique, requiring no surgical entry into the eye and can be easily performed as an outpatient procedure. The major disadvantage is the potential damage to the tissue surrounding the laser focus. One way to circumvent the damage to peripheral tissue is to use laser pulses with lower energy. Picosecond or femtosecond laser pulses, which have a lower energy threshold for plasma formation than nanosecond pulses, have been shown to improve the precision and minimize unwanted disruption in Nd:YAG ocular surgery. In fact, it is possible to photodisrupt tissues with subcellular precision using femtosecond pulses. Thus it may be possible to extend the use of photodisruption to applications requiring single-micron-level precision.

Photokeratoscopy

Chris M. Pruet
Ruiz Department of Ophthalmology and Visual Science, University of Texas Health Science Center at Houston, Houston, TX, USA

Synonyms

Corneal topography; Placido disk; Placido ring

Definition

Calculation of the corneal power based upon the manner in which light is reflected from the anterior surface of the cornea.

Purpose

Determination of corneal power.

Principle

Rings of light are reflected from the anterior surface of the cornea producing an image which is captured by a computerized keratometer. The pattern of the reflection is analyzed to determine the anterior corneal curvature. This curvature is then converted into corneal power.

The main assumption in this mode of keratometry is that the posterior corneal curvature is assumed to be normal. The anterior surface of the cornea is converging (positive), whereas the posterior surface is diverging (negative). These keratometers combine a measured anterior corneal curvature and an assumed posterior curvature

to provide an estimated total corneal power based upon Snell's law of refraction. To compensate for the assumed posterior curvature, a decreased index of refraction is used for corneal power calculations: the cornea has an actual index of refraction of 1.376, whereas most photokeratoscopes use an index of refraction of 1.3375 (Budak et al. 1999).

Photokeratometers provide information on axial power (the power relative to the visual axis) and instantaneous power (the power relative to the points immediately around a corneal location). Axial power maps offer a more global description of shape, while instantaneous radius of curvature maps provides the details of local curvature (Gobbi et al. 1998). Astigmatism is calculated based upon the steepest (highest power) and flattest (lowest power) meridians at various distances from the optical axis. The symmetry or irregularity of this astigmatism along with the location of maximum corneal power is useful for the diagnosis of corneal ectatic diseases (Piñero et al. 2010).

Indication

Need for determination of corneal power/astigmatism.

Clinical concern for corneal topography irregularity (i.e., keratoconus, keratoglobus, pellucid marginal degeneration, irregular astigmatism, etc.).

Advantage/Disadvantage

This exam is noninvasive and rapid and yields valuable information related to corneal power, astigmatism, and corneal abnormalities related to changes in corneal shape such as keratoconus, pellucid marginal degeneration, and keratoglobus. (See figures for examples of keratoconus and regular astigmatism.)

The main limitation for this exam is its assumption of normal posterior corneal topography. It is known that the posterior curvature of the cornea can help in the early diagnosis of keratoconus and contributes to corneal astigmatism. Devices that map the posterior cornea may be of use in providing a more complete and accurate power of the cornea and assist in the diagnosis of ectatic disease (Tang et al. 2005).

There are two main types of imaging for the posterior cornea. The first method uses placido technology to determine the anterior corneal curvature and reconstructs the posterior corneal curvature using pachymetry determined by either scanning slit technology (used by the Orbscan II) or by Scheimflug imaging (used by the Pentacam, Sirius, and Galilei). The second method involves directly imaging the anterior and posterior cornea using an anterior segment optical coherence tomography (ASOCT) unit and reconstructing pachymetry from this data. More information on this can be found in the "Computerized Corneal Topography" section.

Synonyms

Corneal endothelium image; Specular photomicroscopy

Definition

Specular microscopy (contact and noncontact techniques), a camera-mounted, slit-lamp-like instrument, allows visualization and photography of the corneal endothelial mosaic. Wide-field microscopy encompasses 200 cells per frame and can be done at multiple corneal sites, usually centrally. At birth the endothelial density is about 6,000 cells, and in adult the normal endothelial density averages 2,400 cells per mm^2 (1,500–3,500 range) and decreases with age. The normal endothelial cell is shaped as a regular hexagon.

There are several specular microscopy instruments commercially available, both contact and noncontact. All the instruments have computer integration and semi- or fully automated analyses. Some instruments allow manual analysis and/or adjustments to the automated system. Perhaps, the most widely used clinical instrument in the United States is the *Konan NonCon Robo* series. In addition, HAL offers a contact specular microscope. Although it is less comfortable for the patient, it provides sharp, wide-field images regardless of corneal thickness or disease.

Purpose

Specular microscopy is the study of the changes in different layers of the cornea under very high magnification (100 times greater than slit-lamp biomicroscopy), which is mainly being used to assess the endothelial layer. The image is analyzed with respect to the cellular size, shape, density, and distribution.

Principle

When a light beam of the specular photomicroscope passes through the cornea, it encounters a series of interfaces between optically distinct regions. Small amount of light is reflected specularly (i.e., like a mirror) back toward the photomicroscope when the angle of reflection is the same angle of incidence. This specular light is captured by the photomicroscope and forms an image which can be photographed and analyzed. The following parameters can be calculated from specular images:

- Cell density: the normal endothelial cell density decreases with age. Endothelial cell normally exceeds 3,500 cells/mm^2 in children and gradually declines with age to approximately reach 2,000 cells/mm^2 in older people. An average cell density's value for adults is 2,400 cells/mm^2 (1,500–3,500), with cell size's mean of 150–350 μm^2.
- Coefficient of variation: the standard deviation of the mean of cell area divided by the mean cell area gives the coefficient of variation. It is a unit-less number, normally less than 0.30. Polymegathism is an increased variation in individual cell area. It is typically increases with wearing contact lens. Corneas with significant polymegathism (more than 0.40) might not tolerate intraocular surgery.
- Percentage of hexagonal cell: the percentage of cells with six apices should ideally approach about 100% and decrease with age; however, lower percentage of cells indicates a diminishing state of health of the endothelium. Pleomorphism is increased variability in cell

shape. A cornea with high pleomorphism (more than 50% non-hexagonal) might not tolerate intraocular surgery.

Indication

- Prior to surgery, evaluating the functional reserve of the corneal endothelium prior to intraocular surgery is the most important indication. A clear cornea with normal pachymetry (i.e., thickness) is not necessarily associated with normal endothelial morphology or cell density.
- Donor cornea: evaluation regarding suitability for penetrating keratoplasty.
- To demonstrate pathology: particularly cornea guttae irregularities and posterior polymorphous dystrophy.

Contraindication

While specular microscopy is desirable for evaluation of wide assortment of corneal diseases, direct applanation of the objective (contact) may be contraindication in patients with irregular corneal epithelium and/or epithelial dystrophy or patients wearing therapeutic or continuous-wear hydrogel lenses that should not be removed.

In general optimal photographs are obtained when the cornea is relatively thin and clear with minimal scarring or edema.

Advantage/Disadvantage

The advantages of the microscopy are that it can detect pleomorphism (cells deviating from normal shape), cell dropout as in Fuchs dystrophy, and polymegethism (abnormal cell size variation). Which all contribute to endothelial dysfunction and corneal edema.

The microscopy has several disadvantages. The corneal epithelial cells do not normally present a flat surface suitable for specular microscopy. Also, most specular microscopic studies of the corneal endothelium determine mainly the endothelial cell density of the central endothelium in order to attempt to consistently examine the same endothelial cell area over time. In addition, changes in the central corneal endothelium in both density and morphology may take some time (months or years) to be reflected. The specular microscopy does not reflect the impact of a surgical procedure that primarily damages the peripheral cornea. Moreover, the paracentral and the peripheral endothelium, in particular superiorly, have higher cell density and may assist in maintaining central endothelial density and function.

Photoreceptor Cells

Joseph J. Carroll
Department of Ophthalmology, Eye Institute-Medical College of WI, Milwaukee, WI, USA

Definition

Light-sensitive cells residing in the posterior layer of the neural retina.

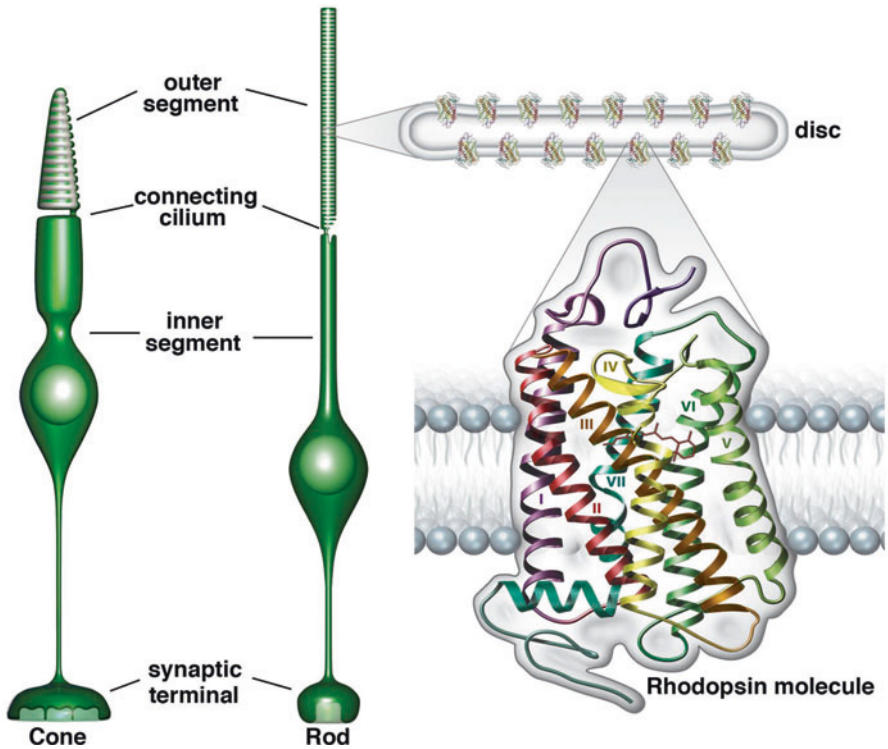
Basic Characteristics

Structural Specialization

The two basic types of photoreceptor in the human retina are rods and cones. Rods outnumber cones by nearly 20:1. In general, photoreceptors consist of an outer segment, an inner segment, and a synaptic terminal (see Fig. 1). The inner segment is the metabolic center of the photoreceptor, housing the nucleus, mitochondria, and other cellular machinery. The outer segment contains the proteins involved in phototransduction. Connecting the inner and outer segments is the connecting cilium, a microtubule-based structure, through which all newly synthesized proteins are transported to the outer segment. The outer segment of both rods and cones consists of stacks of membranous disks – in cones the disks are continuous with the plasma membrane of the cell, whereas in rods they are free-floating. The photopigments are integral membrane proteins located within the lipid membrane of these outer segment disks (see Fig. 1). Photopigment is very abundant with some 100 million photopigment molecules being embedded throughout the outer segment of each rod and cone cell. It is estimated that photopigments represent about 90% of the protein molecules in the outer segment.

Functional Specialization

While both are involved in the detection of light, rods and cones provide distinct functional utility for the human visual system. This enables the visual system to function over a wide range of light intensities. Rods are much more sensitive than cones and thus function well at low light levels (rods can detect a single photon of light!). Cones function at higher light levels and are less sensitive. Paradoxically, the majority of our vision is cone based, despite the fact that cones are outnumbered by rods in the human retina. Another important difference between rods and cones is that cones do not saturate, whereas rods do. Saturation means that as the light level is



Photoreceptor Cells, Fig. 1 Basic structure of rod and cone photoreceptors (Reprinted with permission from Elsevier)

gradually increased, there reaches a point where rods will no longer increase their response in proportion to the stimulus intensity. A final difference between rods and cones is their spectral response properties. This feature is determined by the photopigment present in the outer segment – rods contain a photopigment with maximum sensitivity at 500 nm. A given cone photoreceptor will contain one of the three spectral subtypes of cone photopigment, short-, middle-, or long-wavelength sensitive (S, M, and L), which have peak sensitivity at 415, 530, and 560 nm, respectively.

Topographical Arrangement of Rods and Cones

The rods and cones are distributed unevenly across the human retina. The central fovea contains exclusively cones, the first rods don't appear until about 175 μm from the foveola. Rod density peaks around 12° eccentricity to a value of 180,000 rods/mm^2. Despite changes in density, rods remain nearly constant in diameter across the retinal surface (about 2 μm). Peak cone density occurs in the fovea, and there is significant intersubject variation in peak cone density, from 80,000 to 300,000 cones/mm^2. Cone density falls off precipitously moving away from the fovea in all directions, dropping to about 30,000 cones/mm^2 at 1.5° eccentricity. As cone density falls, the average cone diameter increases. After about 10°, the density of cones reaches a near constant value of 7,000 cones/mm^2, until the extreme edge of the neural retina, where there is an increase in the density of cones to about 15,000 cones/mm^2.

As stated earlier, there are three spectral subtypes of cone – S, M, and L. S cones comprise less than 10% of the total cone number and can be distinguished from L and M cones based on their more cylindrical shape and that they connect to distinct neural circuitry. Like the rod and cone mosaics as a whole, the S-cone distribution varies topographically. The density of S cones is lowest in the central fovea, with an S-cone-free zone of about 125 μm. Peak S-cone density occurs at about 1° eccentricity. There is a high degree of similarity between the L and M cones (perhaps the *only* difference between an L and an M cone is the respective photopigment). The L and M cone submosaics appear to be randomly interleaved, and L cones generally outnumber M cones in the human retina by a factor of 2, though there is inter- and intra-retina variation. For example, the relative ratio of L/M cones increases moving into the peripheral retina, and the central ratio can vary over a 40-fold range across individuals with normal color vision.

Photorefractive Keratectomy (PRK)

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonym

PRK

Definition

Photorefractive keratectomy (PRK) is a ▶ corneal refractive surgical treatment using the ▶ excimer laser for surface tissue ablation. It is known as the

first surgical technique to treat myopia with ► corneal excimer ablation. The first treatments were performed independently in the mid-1980s by Theo Seiler in Berlin and Marguerite McDonald in New Orleans. The surgical technique is rather simple: After scraping off the corneal epithelium, the excimer laser ablation is performed. Besides the advantages of simplicity and leaving a higher portion of corneal tissue unaltered than lamellar techniques, several disadvantages such as pain in the early postoperative period and a prolonged ► wound healing reaction including the formation of corneal haze and regression are described. These shortcomings led to the development of lamellar techniques such as LASIK on the one hand and to modifications such as LASEK (laser subepithelial keratomileusis) and epi-LASIK on the other hand. However, PRK and its modifications are still in use.

Cross-References

► Excimer Lasers
► Refractive Surgery

Phototherapeutic Keratectomy

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Excimer laser phototherapeutic keratectomy; PRK

Definition

Excimer laser procedure for treatment of superficial corneal diseases and surface irregularities by ablating superficial corneal tissue without damaging adjacent untreated tissue.

Epidemiology

As the number of corneal refractive surgery procedures is increasing, so will the number of PTK for treatment of complications.

History

After its introduction in 1983 to perform surface ablations of the cornea, the excimer laser was approved for PTK in 1988 by the Food and Drug Administration.

Clinical Features

The excimer laser emits high-energy ultraviolet radiation at a wavelength of 193 nm and enables the user to treat corneas at a very high precision rate.

Tests

Thorough slit-lamp examination of the eyes and keratometric, keratographic, and pachymetric readings are required for preoperative planning to assure the best possible results.

Differential Diagnosis

Other corneal treatment methods are:

- LASIK
- LASEK

Etiology

See History section above.

Treatment

After topical anesthesia, the epithelium is removed either with the laser or manually with a

blade. After the surface has been removed and Bowman's layer is exposed, the excimer laser is focused on the surface to remove the proper tissue. Finally the ablated surface is covered with a bandage contact lens and postoperative medication is given.

Phototransduction Cone/Rod

Joseph J. Carroll
Department of Ophthalmology, Eye Institute-Medical College of WI, Milwaukee, WI, USA

Definition

Biochemical cascade by which light energy is converted into electrical signals.

Basic Characteristics

Phototransduction occurs in the photosensitive cells of the human retina: photoreceptor cells (rods and cones) and the melanopsin-containing ganglion cells. As the photosensitive ganglion cells appear to employ phototransduction processes similar to invertebrates, we focus here on the phototransduction cascade of rods and cones.

Photopigment Structure

Human photopigments consist of a chromophore (11-*cis*-retinal) and a protein portion (opsin). The chromophore is covalently bound via a protonated Schiff base linkage with a lysine residue in the opsin molecule. The opsins are a member of the protein superfamily of G protein-coupled receptors (GPCRs). All GPCRs (including opsins) have seven transmembrane s domains, in addition to C-terminal, N-terminal, and short loops that reside outside the membrane (intra- or extracellular). It is the 11-*cis*-retinal that is light absorbing, though in solution its peak absorbance is at 380 nm. The linkage to opsin shifts the absorption spectrum into the visible region of the spectrum.

Phototransduction Cascade

Upon absorption of a photon, 11-*cis*-retinal undergoes an isomerization to all-*trans*-retinal. This occurs on the order of about 200 fs. This isomerization induces a conformational change in the opsin portion of the photopigment, which in turn leads to the activation of transducin. Transducin, in its inactive state, is bound to GDP. Upon activation, transducin releases GDP and binds GTP. The a-subunit of transducin (still bound to GTP) then dissociates from the band g-subunits. The a-subunit/GTP complex then activates phosphodiesterase, which catalyzes the breakdown of cGMP to 5′GMP. cGMP is needed to hold open the cGMP-gated (CNG) sodium channels, so the decreased concentration of cGMP causes the sodium channels to close. As a result, the photoreceptor cell hyperpolarizes and decreases its release of the neurotransmitter glutamate. The decrease in glutamate release causes a graded hyperpolarization of the OFF bipolar cells and a graded depolarization of the ON bipolar cells. The hyperpolarization of the

photoreceptor results in a closure of voltage-gated calcium channels, and the reduction in calcium concentration plays an important role in deactivation of the cascade (see below).

Deactivation of the Phototransduction Cascade

The reduction of calcium concentration enables guanylyl cyclase-activating protein (GCAP) to bind to guanylyl cyclase (GC), thus increasing its activity and converting GTP to cGMP. The decrease in calcium concentration also results in an increased affinity of the CNG channels for cGMP, due to the dissociation of calmodulin from the CNG channels. cGMP concentration rises, causing the reopening of the cGMP-gated sodium channels. In addition, the reduction in calcium causes recoverin (normally bound to calcium) to dissociate from rhodopsin kinase. The rhodopsin kinase phosphorylates the activated opsin molecule, which decreases its affinity for transducin. The final step of deactivation of opsin is the binding of arrestin to the phosphorylated opsin. GTPase-activating protein induces the a-subunit of transducin to hydrolyze its GTP to GDP. This inactivates phosphodiesterase, which in turn halts the conversion of cGMP to GMP.

All-*trans* retinal undergoes reduction to all-*trans*-retinol by retinol dehydrogenase. It is then transported to the retinal pigment epithelium (RPE). All-trans retinol is converted back to 11-*cis*-retinol by the isomerase RPE65 and then to 11-*cis*-retinal by 11-cis retinol dehydrogenase transported back to the photoreceptor outer segment.

Phototransduction Cone/Rod, Table 1 Involvement of phototransduction proteins in retinal disease

Affected protein (rod *or* cone)	Disease
Rhodopsin (rod)	ADRP, ARRP, CSNB
S-cone opsin (cone)	Tritan color vision defect
L-cone opsin (cone)	Protan color vision defect or BCM if both L and M opsins
M-cone opsin (cone)	Deutan color vision defect or BCM if both L and M opsins
Phosphodiesterase (rod)	ARRP, CSNB
Transducin (rod)	CSNB (Nougaret disease)
Transducin (cone)	Rod monochromacy (achromatopsia)
CNG channel (rod)	ARRP
CNG channel (cone)	Rod monochromacy (achromatopsia)
Rhodopsin kinase (rod)	CSNB (Oguchi disease), ARRP
Arrestin (rod)	CSNB (Oguchi disease), ARRP
Guanylate cyclase (both)	CRD, LCA
Guanylate cyclase-activating protein (both)	Cone dystrophy

Retinal Diseases Associated with the Phototransduction Cascade

Nearly every protein involved in the phototransduction cascade (including recovery and deactivation) has been associated with some form of retinal disease. A comprehensive list can be found at http://www.retina-international.org/sci-news/, though a subset is listed below in Table 1.

Definition

Phthirus pubis, also known as pubic lice or crab louse, is a parasitic arthropod that infects, most commonly, human pubic hair. Infestation of the pubic hair is called pediculosis pubis or phthiriasis pubis. Transmission occurs through direct contact with an infected person or through shared use of linens. Via one of these mechanisms, phthirus pubis can also infect the eyelashes, which is called pediculosis ciliaris or phthiriasis palpebrarum. Ocular infection is usually bilateral and causes pruritis, burning, and irritation. Secondary conjunctivitis and preauricular adenopathy can also result.

Synonyms

Benign anisocoria; Central anisocoria; Congenital anisocoria; Essential anisocoria; Simple anisocoria

Definition

Physiological anisocoria is a non-pathologic difference in the size of the two pupils with normal light and near reflex reactions. The difference in size is typically less than 0.4 mm and almost never greater than 1 mm (Colby 2014). The disparity remains constant during constriction and dilation (Baloh and Jen 2012).

Basic Characteristics

Physiological anisocoria is the most common cause of anisocoria and occurs in about 20% of the population. Physiological anisocoria may be intermittent. It can vary from week to week and occasionally from hour to hour. It is considered to be a genetic or developmental phenomenon (Rucker 2012). Physiologic anisocoria tends to be equal in light and dark lighting conditions, the pupils are round, and the light and near responses are normal (Kanski 2011).

Diagnostics

Although generally not needed, some patients with physiologic anisocoria may require topical testing to exclude Horner syndrome.

Add-on intraocular lens; Piggyback; Supplementary pseudophakic IOL

Definition

Implantation of two or more intraocular lenses (IOLs) into the posterior chamber of the same eye.

Epidemiology

Due to its spectrum of indications for piggyback IOL implantation, this type of refractive surgery is performed infrequently.

History

Piggyback IOL implantation was first reported by J. Gayton in 1993. He implanted a pair of plano/convex PMMA IOLs with the plano surfaces opposed in a capsular bag/sulcus configuration in an eye with microphthalmos (Gayton and Sanders 1993). J. P. Gills was the next surgeon to perform piggyback implantation, reporting a series of eyes in which he implanted multiple PMMA IOLs in the capsular bag. In 1995, J. P. Gills showed surgical videos in which he implanted up to four IOLs into the same capsular bag in an effort to enhance depth of field. Application of foldable IOLs to piggyback implantation finally led to a marked increase of applications. Primary piggyback implantation was now also performed for additional indications, such as extending the power range for toric and multifocal IOLs (Gayton et al. 1999). The first case of piggybacking a multifocal IOL was presented in 1999. Today, secondary piggyback implantation evolves as a major modality for correction of pseudophakic refractive error in special situations such as extremely myopic, keratoconic, pediatric, and post-penetrating keratoplasty eyes (Mejía 1999).

Tests

In patients with small pupil diameter, diagnostic evaluation of the posterior chamber can be difficult with biomicroscopic examination. Anterior chamber imaging techniques like optical coherence tomography (OCT) or ultrasound biomicroscopy (UBM) are helpful to confirm status post piggyback IOL implantation (Baumeister and Kohnen 2006).

Differential Diagnosis

Interlenticular opacification may suggest a clinical aspect similar to IOL opacification.

Etiology

"Piggyback IOL" and "add-on IOL" are nowadays often used as synonyms. In the strict sense, the term "piggyback" means a primary implantation of at least two IOLs into the capsular bag of an aphakic eye, and the term "add-on" IOL stands for a secondary implantation of an IOL into the ciliary sulcus of a pseudophakic eye.

Treatment

According to the indications, there are three types of piggyback IOLs:

- Monofocal
- Multifocal
- Toric

The main concern of this type of surgery is the unique complication of the development of postoperative interlenticular opacification (ILO). The anterior surface of the anterior IOL adheres to the anterior capsule, and the posterior surface of the posterior IOL adheres to the posterior capsule preventing cell migration from the equatorial bow to the posterior capsule. This migration is directed to the interlenticular space. To avoid this complication, one should take care to remove lens epithelial cells completely during surgery to make the capsulorhexis larger than the IOL optic and prefer implantation of the posterior lens into the capsule and the anterior lens into the ciliary sulcus in order to avoid an interlenticular space that may support cellular ingrowth.

Pigment Epitheliopathy

Shiri Shulman
Ophthalmology Division, Tel-Aviv Medical Centre, Tel-Aviv, Israel

Synonyms

Acute multifocal placoid pigment epitheliopathy; Acute posterior multifocal placoid pigment epitheliopathy; Placoid pigment epitheliopathy

Definition

An acute disease of the choroid and pigment epithelium associated with placoid lesions, occurring in young otherwise healthy individuals.

Etiology

Unknown.

Acute posterior multifocal placoid pigment epitheliopathy is a rare eye disease presenting in otherwise healthy young individuals and may affect both genders equally. In most cases a flu-like illness precedes the onset of ocular symptoms and therefore a viral association was suggested.

A genetic predisposition may also be present with an association to HLA-B7 and HLA-DR2.

Numerous infections were described with association to APMPPE including mumps, streptococcus group A, tuberculosis, Lyme disease, and adenovirus type 5 infections.

An association with hepatitis B vaccination was also described.

A number of noninfectious systemic conditions have been reported in connection with APMPPE, including erythema nodosum, Wegener granulomatosis, polyarteritis nodosa, scleritis and episcleritis, sarcoidosis, and ulcerative colitis.

Several authors described central nervous system involvement ranging from headache in 50% of patients to rarely occurring cerebral vasculitis and even ischemic stroke.

These diverse associations may lead to the conclusion that APMPPE is associated with immune response.

Clinical Presentation

The typical clinical presentation of APMPPE is a sudden onset of painless visual loss, often bilateral with the fellow eye becoming involved within days to weeks. Some patients present with scotomas or metamorphopsia. In some patients, photopsias precede the visual loss.

On clinical examination, there are minimal signs of ocular inflammation with mild to moderate vitritis apparent in less then half of the patients.

Funduscopic findings include multiple, flat, creamy white placoid lesions at the level of the RPE and deep neurosensory retina, varying in size from 1 to 2 disc areas scattered throughout the posterior pole and the equator.

New peripheral lesions may appear in a linear or radial manner over the next few weeks with older lesions resolving within 2–6 weeks turning into permanent retinal pigmentary alterations.

Optic nerve head swelling may be present.

Atypical findings include retinal vasculitis, retinal vascular occlusions, macular edema, retinal neovascularization, and exudative retinal detachment.

A rare variant of APMPPE named relentless placoid chorioretinitis or ampigenous choroiditis has features of both APMPPE and serpigenus choroidopathy. The acute retinal lesions are similar to those seen in APMPPE but take a chronic relapsing course with appearance of new lesions and growth of subacute lesions up to 2 years after the initial presentation. Immunosuppressive therapy may be warranted in these cases.

Diagnosis

The diagnosis of APMPPE is based on the characteristic clinical presentation as well as imaging. Fluorescein angiography (FA) and indocyanine green angiography (ICG-A) were the mainstay of imaging modalities in APMPPE, but recently newer technologies such as higher resolution spectral domain optical coherence tomography (Sd-OCT) and fundus autofluorescence (FAF) are emerging giving additional insight regarding the pathophysiology of the disease.

FA findings during the acute phase of the disease include early hypofluorescence (blockage) of lesions corresponding to but typically more numerous than those seen on fundus examination. On late phases hyperfluorescence of the lesions due to staining is noted.

With resolution, various degrees of hyper- or hypofluorescence may be evident due to hyper- or hypopigmentation of the lesions (Fig. A).

ICG-A reveals choroidal hypofluorescence with hypervisualization of the underlying choroidal vessels in early and late stages of the imaging (Fig. B).

These findings may be seen during both acute and inactive stages of the disease with the lesions becoming smaller or resolving in the inactive stages.

Fundus autofluorescence (FAF) imaging show hypoautofluorescence in the area of the APMPPE lesions early in the disease, which then become hyperautofluorescent.

Sd-OCT of patients with AMPPE reveals a variety of abnormalities. The earliest phase seems to involve variable amounts of subretinal fluid with subretinal hyper-reflective material and rapid resolution of these subretinal lesions. Later in the disease course, lesions reveal either partial or complete restoration of the outer retinal architecture or may progress to thinning of the outer nuclear layer, disruption of the RPE layer, and atrophy.

There is still a controversy whether the lesions of APMPPE represent a primary involvement of the RPE or a choroidal perfusion abnormality with secondary involvement of the RPE and photoreceptors.

Nevertheless, taking the FA, ICG, and FAF imaging findings suggest a primary choroidal pathology with a secondary RPE and photoreceptors.

The choroidal perfusion abnormalities seen early on FA and ICG angiography are more numerous than the overlying placoid lesions seen on clinical examination; abnormalities noted on FAF imaging appear later and are fewer in number. All of these implicate a primary choroidal process.

Differential Diagnosis

Differential diagnosis includes:

Serpigenous choroidopathy
Multiple evanescent white dot syndrome (MEWDS)
Vogt-Koyanagi-Harada (VKH)
Persistent placoid maculopathy (PPM)

Prophylaxis

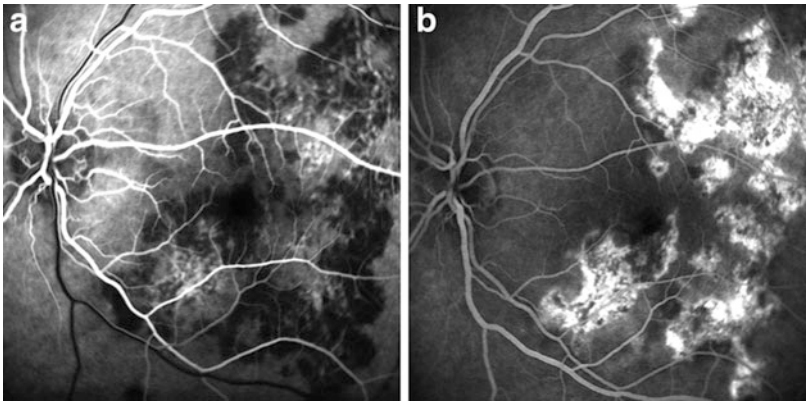
Unclear

Therapy

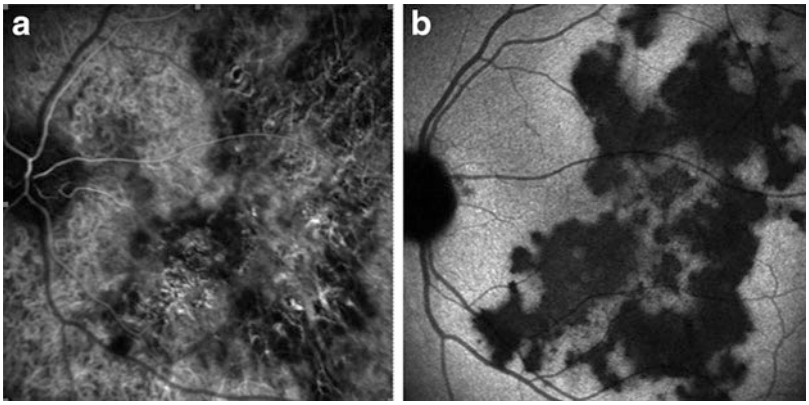
There are no prospective clinical trials regarding the value of treatment in patients with APMPPE. Nevertheless, reduced visual acuity, macular lesions, or CNS involvement are usually indications for systemic steroid treatment.

Prognosis

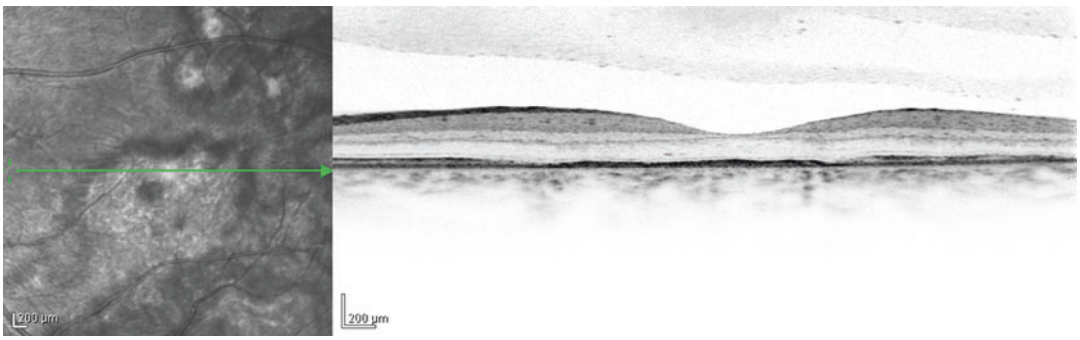
APMPPE is considered a relatively benign syndrome. Nevertheless, most patients have some reduction in visual function with 42% of eyes achieving a visual acuity of 20/40 or less.



Pigment Epitheliopathy, Fig. 1 (**a**, **b**) Early and late FA of a left eye in an 18-year-old patient with APMPPE demonstrate early hopofluorescence of the lesions with late hyperfluorescence



Pigment Epitheliopathy, Fig. 2 (**a**, **b**) Early and late ICG-A demonstrate hypofluorescence of the lesions in early and late frames



Pigment Epitheliopathy, Fig. 3 Sd-OCT demonstrates photoreceptor and RPE irregularities

Epidemiology

A single epidemiologic study reports an annual incidence of 0.15/100,000 Figs. 1, 2, and 3.

Detachment of the retina pigment epithelium

Definition

Retinal pigment epithelium detachment (PED) is a localized elevation of the retinal pigment epithelium (RPE) that loses its adherence from the underlining, inner collagenous layer of the Bruch's membrane. A PED can be found in a certain number of choroidal diseases as well as in some systemic conditions. Accordingly to the content, PEDs can be of various nature such as drusenoid, serous, vascularized, fibrovascular, and cellular. A drusenoid PED is occurring in a dry age-related macular degeneration (ARMD) and is secondary to the coalescence of drusen material in large agglomerates under the RPE. A serous PED is produced by the accumulation of fluid between RPE and Bruch's membrane; serous PEDs develop in several diseases like exudative ARMD, polypoidal choroidal vasculopathy (PCV), central serous chorioretiniopathy (CSC), choroidal inflammations, and various systemic and drug-related conditions. A third type of PED is the vascularized (hemorrhagic) PED that is generally associated with the ingrowth of neovascular choroidal vessels under the RPE (type 1 choroidal neovascularization) in exudative ARMD. A fibrovascular PED is an evolution of the vascular PED when the fibrous component predominates. A PED can also be cellular, due to the infiltration of the sub-RPE space by inflammatory or neoplastic proliferation. Finally, mixed types of PEDs can be found.

Etiology

The two main causes of PED are ARMD – and its variants polypoidal choroidal vasculopathy (PCV) and retinal angiomatous proliferation (RAP) – and central serous chorioretinopathy (CSC). However, even if less frequently, PEDs can be found in several systemic disorders of inflammatory, infectious, neoplastic, and iatrogenic nature (Table 1).

Inflammatory conditions include tubulointerstitial nephritis and uveitis syndrome and type II membranoproliferative glomerulonephritis. Other inflammatory conditions are inflammatory bowel disease, systemic lupus erythematosus, and sarcoidosis in which PEDs are often seen associated with neurosensory serous retinal detachments and subretinal fluids.

Infectious and immunologic causes comprehend pseudohistoplasmosis syndrome, choroiditis by *Blastocystis hominis*, poststreptococcal syndrome, and neurosyphilis.

Neoplastic conditions include Waldenström macroglobulinemia and multiple myeloma, where immunoglobulins accumulate under the RPE, and acute myeloid leukemia and large cell non-Hodgkin lymphoma, where neoplastic cells infiltrate the sub-RPE space causing the detachment. Even if rarely, choroidal nevi and

Pigment Epithelium Detachment, Table 1 Ocular and systemic conditions associated with PEDs

Ocular		Systemic			
Degenerative	Idiopathic	Inflammatory	Infectious	Neoplastic	Iatrogenic
AMD	CSC	Tubulointerstitial nephritis and uveitis syndrome	Pseudohistoplasmosis syndrome	Waldenström macroglobulinemia	Pamidronate
PCV	Small multifocal idiopathic PEDs	Type II membranoproliferative glomerulonephritis	Blastocystis hominis	Multiple myeloma	Corticosteroids
RAP		Inflammatory bowel disease	Poststreprococcal syndrome	Large cell non-Hodgkin lymphoma	Hemodialysis
		Systemic lupus erythematosus	Neurosyphilis	Acute myeloid leukemia	Organ transplantation
		Sarcoidosis		Choroidal nevi	
				Melanoma	

melanoma can be complicated by the development of a neovascular PED.

Among the drugs that promote the development of a PED are the pamidronate, a drug used to treat osteoporosis, and corticosteroids. Steroids are probably responsible of the PEDs seen in pregnancy and in organ transplantation with a mechanism similar to that seen in CSC.

Lastly, a condition characterized by the development of idiopathic, small, multifocal, and bilateral PEDs has been described.

Pathogenesis

The pathogenesis can be different depending on the type of PED. Drusenoid PEDs arise from the confluence of soft drusen, while the origin of serous and vascularized PEDs associated with the ARMD is not completely understood. A theory suggests that serous PED in ARMD is originated either from serous exudation from a hyperpermeable choroidal system through an intact Bruch's membrane or is secondary to fluid leakage from new vessels coming from the inner layers of Bruch's membrane into the subretinal pigment epithelium space (Gass 1984). According to another theory, aging promotes an increased deposition of lipids in Bruch's membrane that becomes hydrophobic and impermeable (Bird 1991). Thus, fluids would be unable to cross the diseased Bruch's membrane and accumulate into the sub-RPE space. A choroidal neovascularization (CNV) can be or not associated with PED.

Two peculiar forms of ARMD, namely, RAP and PCV, are associated with PEDs. RAP is a particular form of neovascularization involving both retinal and choroidal compartments that are anastomosed. RAPs are associated with vascularized PED that have a particular poor prognosis. The other form is the so-called PCV characterized by the development of extensive choroidal neovascular membranes growing between RPE and Bruch's membrane and ending with bulbar vascular dilations termed polyps. In PCV, wide and multiple vascularized PEDs that are frequently complicated by hemorrhages were developed.

PEDs in CSC are probably secondary to an abnormal choroidal circulation with hyperpermeable vessels. This is followed by increased hydrostatic pressure that forces the RPE to detach. The dysfunction of RPE leads fluids to cross into the subretinal space with development of an associated retinal detachment.

Clinical Presentation

PEDs associated with ARMD, both serous and vascularized, can cause reduction of visual acuity and distorted vision if they involve the macula. A hemorrhage within a vascularized macular PED

invariably causes an abrupt loss of vision. Serous PEDs associated with CSC have no influence on visual function if they are located outside the macular area. PEDs in the fovea can reduce or not visual acuity depending from the damage of the photoreceptor layer. Generally metamorphopsias and loss of vision in CSC depend on the associated serous retinal detachment.

Various types of PED have different ophthalmoscopic features. Drusenoid PED has the aspect of a pale yellow dome-shaped lesion under the RPE and is often surrounded by soft drusen. This lesion can be irregular and tend to be rather flat in some cases; pigment can be found on the top of the drusenoid detachment. Serous PED appears as a circular, yellow-orange elevation of RPE with well-defined borders. A vascularized PED can be indistinguishable from a serous PED only using ophthalmoscopy. Suspicious signs of a neovascular component are an irregular form and elevation of the serous PED and, more importantly, a notched border; the presence of subretinal exudates or hemorrhages, especially near the border of the PED, is pathognomonic of vascularization. When a large hemorrhage occurs in the vascularized PED, it acquires a dark brown color.

Diagnostics

The diagnosis of PED is greatly aided by techniques like fluorescein angiography, indocyanine green angiography (ICGA), fundus autofluorescence (FAF), and optical coherence tomography (OCT) (Mrejen et al. 2013).

Fluorescein angiography (FA). Drusenoid PEDs show a tenuous hyperfluorescence during the early phase of FA that slightly increases in the late phase. The serous PED displays typical features on FA examination. It shows early hyperfluorescence that increases due to the pooling into the detachment; the hyperfluorescence persists in later stages and can be attributed to staining of the fluid within the PED. FA is not always able to differentiate nonvascularized (serous) from vascularized PED; a choroidal neovascular membrane can sometimes be recognized as a hyperfluorescent lesion generally located near the borders of the PED. Generally, a vascularized PED shows a stippled hyperfluorescence that increases in later phases due to staining.

Indocyanine green angiography (ICGA). With ICGA examination the drusenoid PED is hypofluorescent and no hyperfluorescent areas are seen throughout the examination. ICGA shows the serous PED in ARMD as a hypofluorescent area both in the early and in the late phase (dark disk), secondary to a masking effect on the choroid from the fluid in the PED. However, ICGA frequently allows to distinguish serous PEDs from neovascular PEDs: the neovascular choroidal membrane appears as a hyperfluorescent circumscribed area generally seen as a notch in the border of the PED (hot spot) or a hyperfluorescent wide lesion standing out against the surrounding hypofluorescence (plaque). The first finding is a sign of active lesion, while the second is typical of quiescent neovascularization. In any case a hyperfluorescence of the PED in the late phase of ICGA is a sign of neovascular choroidal membrane. The ICGA findings in serous PED due to CSC are slightly different, since the PED in the mid-phase of ICGA acquires a hyperfluorescence due to choroidal hyperpermeability, and then, in later stages, it appears hypofluorescent with a characteristic hyperfluorescent ring.

Fundus autofluorescence (FAF). FAF is useful to demonstrate a PED, but has a very limited value in differentiating among the various types of PED. Drusenoid PEDs display various grades of hyperautofluorescence that can be irregular. Also serous and vascularized PEDs are hyperautofluorescent, with a hypoautofluorescent halo. The choroidal neovascular membrane is not recognizable with FAF.

Optical coherence tomography (OCT). OCT shows the PED as a prominence of the RPE detached from the underlying Bruch's membrane. In drusenoid PED this prominence can be irregular and the content hyperreflective, even if some areas can exhibit a less dense material; the pigment over the detachment is highly hyperreflective. In serous and vascularized PEDs, the borders of the lesion are neatly demarcated while the material inside the PED cannot be well appreciated in all the cases due to the limited ability of

OCT to penetrate the PED. A better resolution of the content of the PED is obtained with such OCT instruments or modalities that better explore deeper structures like the spectral-domain OCTs with the enhanced depth imaging (EDI) modality or the swept-source OCTs. A pure serous PED has a hyporeflective content, while the presence of hyperreflective material, especially adherent to the outer side of RPE, is suggestive of CNV. The evolution of a serous or vascular PED toward a fibrovascular PED is heralded by hyperreflective stratifications in the subretinal pigment epithelium space that represent the fibrous component of the detachment.

Differential Diagnosis

With ARMD being the first cause of PED, patient clinical history is fundamental for the diagnosis. The differential diagnosis among the various types of PED in ARMD is largely based on imaging techniques. In rare cases a brown elevation of RPE in the macular region could be suggestive of choroidal melanoma or subretinal pigment epithelium hemorrhage from various causes. FA, ICGA, OCT, and ultrasonography represent fundamental diagnostic tools.

Therapy

The therapy of PED in exudative ARMD is mainly based on the use of intravitreal injection of anti-VEGF drugs. These injections are performed as frequently as monthly even if many protocols are proposed, changing with experience. One of the most applied treatment consists in a loading phase of a drug, followed by further injections if any fluid is found with OCT examination; eyes treated in this manner show only a minimal reduction of visual acuity after 2 years and substantial reduction of the PED (Battaglia Parodi et al. 2013). However, despite the success of anti-VEGF drug treatments in drying the subretinal and intraretinal fluids associated with CNV, PEDs are often resistant to therapy, and in the long-term many eyes continue to show the PEDs as well as some extrafoveal subretinal fluid. Frequent injections of anti-VEGF drugs are associated with increased development and extension of geographic atrophy, so that the frequency of injections must be held at the minimum necessary to control the neovascular process.

Photodynamic therapy (PDT) with verteporfin was a standard treatment for exudative ARMD before the anti-VEGF era. It's still used today for patients with PEDs associated with PCV as well as in selected cases of exudative ARMD with extrafoveal lesions or choroidal vessels that can be localized by ICGA.

PDT combined with intravitreal injection of triamcinolone acetonide has been demonstrated to stabilize visual acuity and to decrease relapses of the PED. However, the use of intravitreal triamcinolone has been reduced for the high rate of complications like cataract and glaucoma that occurs with this treatment.

Prognosis

Drusenoid PEDs can persist more or less unchanged for years, but often evolve toward atrophy: the drusen-like material inside the PED reabsorbs, the detachment flattens, and atrophy of external retina follows. After a mean of 4.6 years, 28% of drusenoid PEDs persist, 49% evolve in geographic atrophy, and 13% develop choroidal neovascularization.

The evolution of serous PEDs in ARMD is various and, after 3 years, they can persist, flatten, or be associated with choroidal neovascularization with about a similar chance. A different evolution is seen in PEDs associated with CSC: they tend to flatten in most cases, leaving a slight pigmentary change, and persist in about one-third of cases.

Vascularized PEDs (i.e., a PED with sub-RPE neovascularization) have a relatively more benign prognosis than ARMD with subretinal neovascularization. However, a vascularized PED can evolve toward a hemorrhagic PED due to the bleeding from the choroidal neovascular membrane. Negative prognostic factors are the size of the vascularized PED, the turbidity of the

sub-RPE fluid, and the erosion of the RPE from the choroidal neovascular membrane that invades the subretinal space (type 2 neovascularization). Most of neovascularized PEDs complicated by hemorrhages develop disciform scars in a few months with resulting visual acuity below 20/200. The therapy with the injection of anti-VEGF drugs can halt the evolution of the vascularized PED. Especially after numerous intravitreal anti-VEGF drug injections, many PEDs evolve toward fibrovascular PEDs: the PED tends to flatten, the surface becomes corrugated, and the content becomes more dense with prevalence of fibrous component. A possible complication of PED, occurring in about 15% of cases, either spontaneously or following an injective therapy, is the tear of the retinal pigment epithelium.

RPE tears can be the cause of abrupt visual acuity drop in patients with exudative ARMD. Even if the pathogenesis of RPE tears is not completely understood, it is thought that an underlying choroidal neovascular membrane contracts, and the tangential shear forces cause dehiscence and separation of the epithelial basement membrane. Typical clinical features of this condition are RPE mounding and adjacent RPE atrophy. Potential risk factors for an RPE tear are a large-sized PED, central PED height, PED volume, presence of subretinal fluid, and long duration of treatment. In particular the severity of visual loss is correlated with the size and location of the tear: tears larger than 1 disk in diameter and those involving the fovea have bad prognoses. They are more likely to evolve with a severe vision loss and are least likely to respond to anti-VEGF therapy. On the other hand, small RPE tears located away from the fovea have better prognoses. If they are associated with subretinal fluid, vision may improve due to the positive response to following anti-VEGF therapy.

Epidemiology

PEDs are a frequent manifestation of ARMD and they are seen in up to 62% of eyes with advanced ARMD (Coscas et al. 2007).

Summary

The Pigment epithelium detachment (PED) is the separation of the retinal pigment epithelium from the Bruch's membrane, with the space between these layers filled with serous, vascular, fibrovascular or cellular material. The leading causes of PED are age-related macular degeneration and central serous chorioretinopathy. PED appears as a yellow, dome-shaped retinal elevation, better seen with the aid of fluorescein angiography and optical coherence tomography. The evolution of PED is variable and depends from its nature; the therapy is mainly based on the use of intravitreal injecton of anti-VEGF drugs.

Pigment Epithelium, Ciliary Body, and Iris

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Definition

The pigment epithelium of the ciliary body is part of the double epithelial layer covering the ciliary processes and is contiguous anteriorly with the iris pigment epithelium and posteriorly with the retinal pigment epithelium.

The iris pigment epithelium is the posterior layer of the iris and is derived embryologically from neural ectoderm.

Structure

Each ciliary process is covered by a double epithelial layer which consists of an outer pigmented layer and an inner nonpigmented layer. The base of the pigmented epithelial cells faces the stroma of the ciliary process. The stroma contains vessels which provide water and ions for aqueous production. These molecules pass between pigmented epithelial cells and accumulate behind the tight junctions present between the nonpigmented cells.

The iris pigment epithelium consists of two layers (anterior cuboidal layer and posterior columnar layer) that are densely packed with melanin. The posterior layer is covered with a basement membrane that is continuous with the retina and ciliary body.

Function

The ciliary body pigment epithelium may have a minimal role in the blood aqueous barrier because of the presence of gap junctions between these cells and between the pigmented and nonpigmented epithelial cells of the ciliary body.

Clinical Relevance

The ciliary body pigment epithelium may be involved in reduction of intraocular pressure after transscleral cyclophotocoagulation for the treatment of glaucoma.

A ciliary body melanocytoma is a benign tumor that can directly invade angle structures and cause elevated intraocular pressure.

A ciliary body melanoma can be associated with high or low intraocular pressure, pigment dispersion, invasion of the angle by tumor, angle closure induced mechanically by the tumor, rubeosis irides, or neovascular glaucoma.

In pigment dispersion syndrome, contact of the posterior iris with the lens zonules causes atrophy of the iris pigment epithelium and the classic spoke-like mid-peripheral transillumination defects.

Pigmentary Glaucoma

Ursula Schlötzer-Schrehardt
Universität Erlangen-Nürnberg, Augenklinik mit Poliklinik, Erlangen, Germany

Synonyms

Glaucoma associated with pigment dispersion syndrome (PDS)

Definition

Secondary open-angle glaucoma associated with PDS, an autosomal dominant disorder, in which irido-zonular friction disrupts the iris pigment

epithelium dispersing pigment granules throughout the anterior chamber.

Etiology

The underlying condition, PDS, can be explained by the anatomical phenomenon of posterior iris concavity, caused by reverse pupillary block due to increased irido-lenticular contact and physiological events such as blinking and exercise. Increased aqueous pressure in the anterior chamber promotes a backward bowing of the iris and mechanical rubbing against the zonular fibers of the lens leading to liberation of iris pigment. PDS is believed to be strongly influenced by genetic background with linkage to chromosomal locations 7q35-36 and 18q22.

Clinical Presentation

PDS is a bilateral disorder. Key features are the dispersion and accumulation of pigment on anterior segment structures such as the iris, lens, zonules, trabecular meshwork, and corneal endothelium, where it forms a characteristic vertical spindle-shaped pattern termed "Krukenberg's spindle." Gonioscopic examination of the chamber angle shows a dense, homogenous band of pigment in the full circumference of the trabecular meshwork. Radial, midperipheral, slit-like transillumination defects are typically present in the iris. The key signs of pigmentary glaucoma (PG) match those for PDS, but additionally involve elevated intraocular pressure, optic nerve head cupping, and visual field changes. Exercise may increase pigment dispersion and intraocular pressure in some patients.

Diagnosis

Classical diagnostic signs include the presence of a Krukenberg's spindle, wide-open chamber angle with dense trabecular pigmentation, and radial, slit-like, midperipheral iris transillumination defects on slit-lamp examination. Posterior iris concavity may be detectable by gonioscopy, ultrasound biomicroscopy, or anterior segment optical coherence tomography. Diagnosis of PG involves signs of glaucoma (elevated intraocular pressure, optic neuropathy, visual field loss) in the presence of PDS (Figs. 1 and 2).

Differential Diagnosis

Differential diagnosis of PDS and PG includes conditions associated with excessive pigment dispersion, such as pseudoexfoliation syndrome and pseudoexfoliative glaucoma, primary open-angle glaucoma, uveitis, ocular melanoma and melanocytoma, diabetic iridopathy, trauma, complications of ocular surgery, and age-related changes.

Prophylaxis

Laser iridotomy might be considered a prophylactic measure, but whether it can prevent the development of PG remains to be proven.

Therapy

Treatment of PG follows the same regimen as primary open-angle glaucoma, but with some special considerations. Miotics not only lower intraocular pressure but also decrease irido-zonular contact and pigment liberation and may prevent further progression. Peripheral Nd:YAG laser iridotomy may be effective in eliminating reverse pupillary block, relieving the posterior iris bowing, and preventing pigment release in patients with marked iris concavity.

Prognosis

Prognosis is usually good and the majority of PDS cases do not progress to PG. PDS and PG tend to decrease in severity or become quiescent with advancing age due to exhausted liberation of pigment.

Pigmentary Glaucoma, Fig. 2 Typical iris configuration and increased irido-lenticular contact in a patient with pigment dispersion syndrome using anterior segment optical coherence tomography (Courtesy: R. Laemmer, Erlangen)

Epidemiology

PDS typically affects Caucasian individuals (about 2% of general populations). PDS is most commonly observed in female and male myopic patients 30–50 years old and PG is more prevalent in young myopic males. Approximately 20% of PDS cases have PG at initial diagnosis. The glaucoma conversion rate has been reported to be 10% at 5 years and 15% at 15 years.

Synonyms

Complexion-associated melanosis; Conjunctival melanoma; Conjunctival nevus; Primary acquired melanosis

Definition

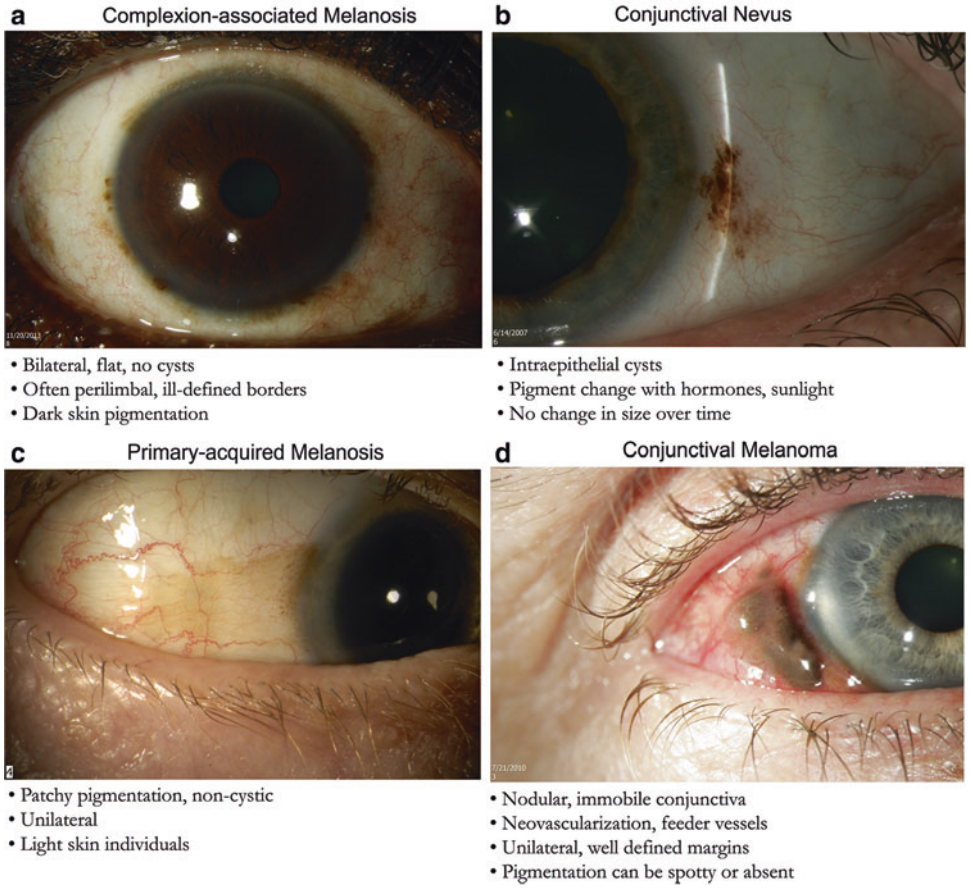
Pigmented tumors of the conjunctiva are comprised of four melanocytic lesions: complexion-associated melanosis, conjunctival nevus, primary acquired melanosis (PAM), and malignant melanoma (Harooni et al. 2011). Other lesions that can result in pigmentary changes visible on or through the conjunctiva include ocular melanocytosis and pigmented squamous cell carcinomas of the conjunctiva.

Etiology

- Complexion-associated melanosis is a result of hyperpigmentation of the conjunctival epithelium without any melanocytic proliferation. These lesions are usually seen in individuals with darker skin pigmentation. Historically, complexion-associated melanosis has often been referred to as "racial melanosis."
- Conjunctival nevi are derived from melanocytic proliferation and can be acquired or congenital. Pathologically they can be junctional, with melanocytes located at the junction of the epidermis and the dermis, and compound, in which melanocytes remain in the epithelium and have also infiltrated into the intradermal layers, or subepithelial, in which melanocytes are located only in the intradermal layers. Nevi are often characterized by cysts that can be seen clinically and pathologically. The cysts may grow, causing the nevus to appear to grow.
- Primary acquired melanosis (PAM) is a collection of melanocytes enclosed within the epithelium of the conjunctiva (Oellers and Karp 2012). Pathologic examination can reveal atypical cells within the lesion. The distinction between PAM with atypia and PAM without atypia is histologic and cannot be made clinically.
- Conjunctival melanoma is composed of malignant melanocytic cells. These lesions can arise from conjunctival nevi, from PAM with atypia, or de novo.

Occurrence

- Complexion-associated melanosis is common in individuals with dark skin pigmentation. There has been no reported incidence of this entity progressing to conjunctival melanoma.
- Conjunctival nevus is the most common pigmented conjunctival tumor, representing up to 52% of all conjunctival melanocytic tumors. It is most common in Caucasians (89%), but can occur in all races. The mean age at presentation is typically between the first and second decades of life. The rate of progression to melanoma is very low, up to 0.7% over 7 years.
- Primary acquired melanosis (PAM) is most commonly found in Caucasian adults but is seen in all races. The average age at presentation is between 50 and 60 years old. PAM without atypia has no malignant potential. Studies have shown that PAM with atypia can progress to malignant melanoma in 13–50% of cases (Oellers and Karp 2012; Shields and Shields 2004). In patients with severe atypia, rates of progression may be even larger.
- Conjunctival melanoma is uncommon, with a rate of 0.5 cases per one million in the United States. This represents only 5% of the melanomas of the ocular region. The average patient is middle aged (most in the fourth to seventh decade of life) and Caucasian (94% of all cases). However, conjunctival melanoma is seen in all ages (ranging from 10 to 91 years) and all races. Conjunctival melanoma is



Pigmented Lesions of the Conjunctiva, Fig. 1 Distinctive characteristics of the four major pigmented lesions of the conjunctiva

derived from PAM in 74% of cases, as a de novo malignancy in 21% of cases, and from nevus in 4% of cases. Metastatic disease occurs via lymphatic dissemination in up to 25% of patients with conjunctival melanoma after 15 years.

Classification

Given the malignant and metastatic risk of the pigmented conjunctival tumors, proper diagnosis is imperative. Some characteristics can help distinguish the lesions apart. Figure 1 outlines clinical characteristics suggestive of each entity.

Calcified epithelioma of Malherbe

Definition

A rare, benign tumor originating from the matrix of the hair root.

Etiology

The exact etiology is uncertain; however, mutation in the gene encoding betacatenin (CTNNB1) has been described as a cause of tumor growth in the hair follicle. It can occur almost anywhere on the body but has a propensity to occur in the head and neck region, often involving the eyelid or eyebrow. It is most commonly seen in children and adolescents and with a female predominance (Albert and Jakobiec 2008; Levy and Ilsar 2008; Shields and Shields 2008).

Clinical Presentation

Typically presents as a solitary, firm, nontender, dermal or subcutaneous nodule, freely movable covered by normal, pink, or bluish skin. Usually slow growing over months or years but can occasionally exhibit rapid growth. Multiple pilomatrixomas have been observed, mainly in association with myotonic dystrophy (Albert and Jakobiec 2008; Shields and Shields 2008).

Diagnostics

Pilomatrixoma is often misdiagnosed clinically and the correct diagnosis only established after excision and histological examination. Histopathologically, this tumor is composed of ghost cells (shadow cells), basaloid cells, and calcium deposits (Albert and Jakobiec 2008; Levy and Ilsar 2008).

Differential Diagnosis

Differential diagnosis includes ▶ epidermal cyst, ▶ dermoid cyst, ▶ pyogenic granuloma, ▶ chalazion, ▶ sebaceous adenoma, ▶ basal cell carcinoma, ▶ keratoacanthoma, and ▶ hemangioma.

Prophylaxis

Unknown

Therapy

Surgical excision

Prognosis

Usually, this tumor has a benign course, although malignant transformations have been described (Shields and Shields 2008).

Epidemiology

Reported incidence varies widely in the literature; between 1:316 and 1:10,500 (Albert and Jakobiec 2008; Levy and Ilsar 2008; Shields and Shields 2008).

Pinguecula

Kathleen Jee
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

A pinguecula is a common, elevated, nonmalignant growth of elastic tissue on the bulbar conjunctiva extending toward the limbus but sparing the cornea.

Etiology

It is believed that a pinguecula is a conjunctival degenerative change caused by actinic damage, particularly from ultraviolet (UV) radiation. The development of pingueculae is associated with aging, UV light exposure, and environmental traumas such as dust, wind, and sand. It is postulated that the nasal prevalence of pingueculae is from the reflection of UV light off the nose. The deposition of advanced glycation end products may be involved. These end reaction products of sugars and proteins can occur with UV radiation and the aging process, inducing oxidative stress

and molecular damage. Histologically, pingueculae are characterized as elastotic degeneration of subepithelial collagen with hyalinized connective tissue. In elastotic degeneration, tissue stains positively for elastin but is not degraded by elastase (Krachmer et al. 2011).

Clinical Presentation

A pinguecula presents as a yellow-white, elevated, avascular thickening of the bulbar conjunctiva adjacent to the limbus in the interpalpebral zone. The most common location is on the nasal side but may be seen temporally and is usually a bilateral phenomenon. The triangular-shaped thickening tapers in the direction of the angle of the eye. Calcification may be present. Patients are generally asymptomatic but may complain of irritation if the pinguecula is inflamed.

Diagnosis

Slit-lamp or external examination is the best way to diagnose pingueculae.

Differential Diagnosis

It is important to distinguish a pterygium from a pinguecula. A pterygium, while histologically similar to a pinguecula, is distinguished by fibrovascular tissue that grows onto the cornea. Pingueculae do not have vascularized tissue and do not cross the limbus. Dyskeratosis and epithelial tumors can be differentiated by their epithelial location compared to the subepithelial location of pingueculae.

Prophylaxis

Avoid UV light exposure and environmental traumas (sand, wind, and dust).

Therapy

Because pingueculae are slow growing, treatment is not usually necessary. Topical lubrication can be used to mitigate ocular irritation. Excision is rare but may be considered if cosmetically displeasing, chronically inflamed, exceedingly bothersome, or disruptive of contact lens wear. Inflammation of the pinguecula (pingueculitis) can occur and is treated with lubricants, topical corticosteroids, or topical nonsteroidal anti-inflammatory drugs.

Prognosis

Most pingueculae are asymptomatic and slow growing with little clinical significance. Uncommonly, there may be recurrent inflammation or irritation requiring further management.

Epidemiology

Pingueculae are the most frequent conjunctival change observed clinically. Prevalence increases with age. Pingueculae are seen very commonly in the eighth decade.

Synonyms

Plate-haptic IOL

Definition

A plate-haptic posterior chamber intraocular lens is an IOL which has plate haptics that are positioned in the capsular bag or in the ciliary sulcus.

Epidemiology

Most IOLs available in the market are made of "loop" or "C" haptics.

History

The Staar plate-haptic IOL became the first FDA-approved toric IOL in 1998 (Hardten et al. 2003).

Clinical Features

Tests

Biomicroscopy in pharmacological mydriasis should reveal type of haptic.

Differential Diagnosis

A plate-haptic posterior IOL may be either an aphakic IOL (fixated in the capsular bag or the ciliary sulcus) or a phakic IOL (fixated in the ciliary sulcus or floating on the crystalline lens) and can be either toric or non-toric.

Etiology

IOLs with its optic and haptic made of the same material are termed "single-piece IOL," and IOLs with its optic and haptic made of different material are called "three-piece IOL" (Kohnen and Koch 2009).

Polypoidal Choroidal Vasculopathy

Adrian Koh
Eye and Retina Surgeons, Singapore, Singapore

Synonyms

Idiopathic polypoidal choroidal vasculopathy (PCV); Multiple recurrent serosanguineous retinal pigment epithelial detachments in Black

women; Posterior uveal bleeding syndrome (PUBS)

Definition

Polypoidal choroidal vasculopathy (PCV) is a macular disorder characterized by recurrent hemorrhage within the retina and retinal pigment epithelium (RPE). It is characterized by the presence of choroidal vascular channels (also known as the branching vascular network, BVN) ending in polyp-like dilations in the peripapillary and macular area.

Etiology

The etiology is still unknown. There are similarities between the genetic predisposition to PCV and to wet AMD. For example, a functional SNP at the promoter of serine protease HTRA1 was associated with a tenfold increased risk of developing PCV and choroidal neovascularization in Asians. Common causative genes include complement factor H on chromosome 1q23–32, albeit with different SNPs: Y402H (for neovascular AMD); rs3753394, rs800292 (for PCV); and HTRA2/ARMS2 on chromosome 10q26.

Clinical Presentation

The most common manifestations are submacular hemorrhage, hemorrhagic pigment epithelial detachment, serous pigment epithelial detachment, subretinal lipid exudates, neurosensory detachment, chronic central serous chorioretinopathy, and orange-red subretinal nodules (Fig. 1).

Diagnosis

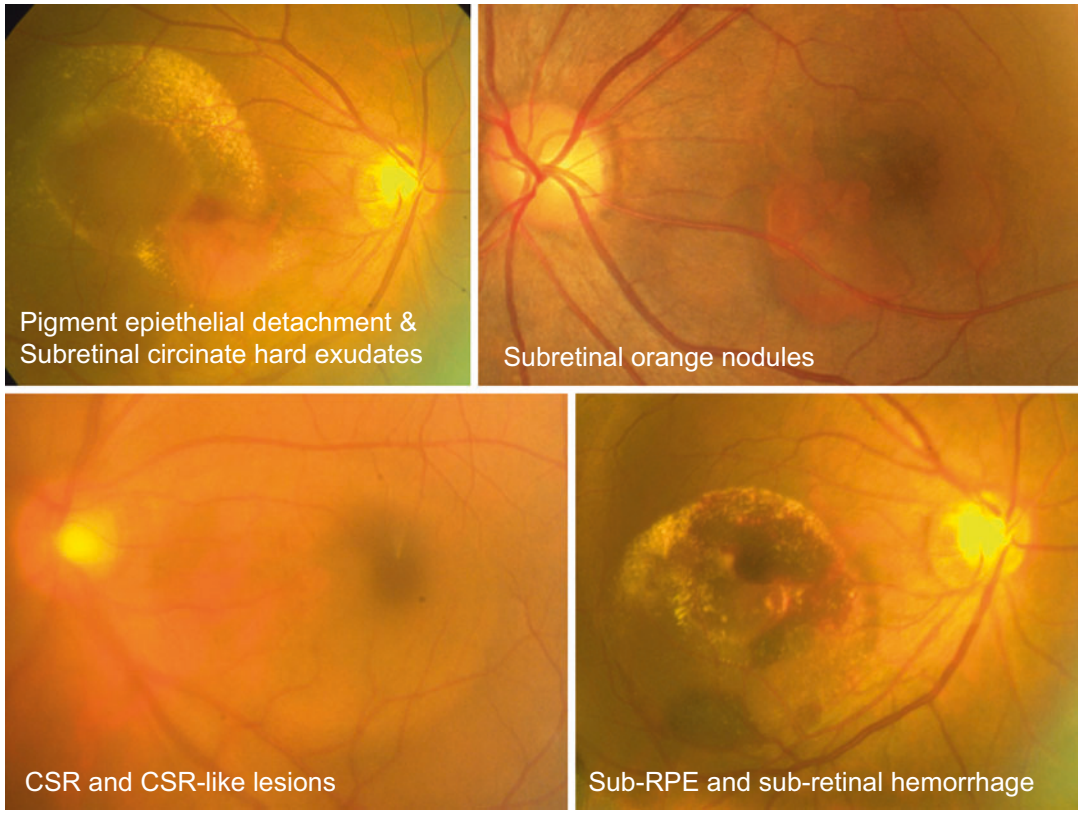
The most important diagnostic features are clinically visible orange sub-RPE polypoidal nodules and early nodular hyperfluorescence on stereo-ICG angiography. Spectral domain optical coherence tomography (OCT) is helpful in identifying these polypoidal nodules, which typically appear as sharply angulated inverted V-shaped elevation of RPE, lying between RPE and Bruch's membrane. The BVN appears as irregular undulation of RPE, with overlying and adjacent neurosensory detachment. Serous pigment epithelial detachments are frequently seen. Enhanced depth imaging is useful to differentiate PCV from CNV in AMD, because the choroidal thickness is typically increased in PCV due to choroidal congestion, especially where there is leakage on ICGA.

Fluorescein angiography is not diagnostic of PCV. The most common patterns are occult CNV, notched pigment epithelial detachment, hemorrhagic pigment epithelial detachment, and chronic central serous chorioretinopathy.

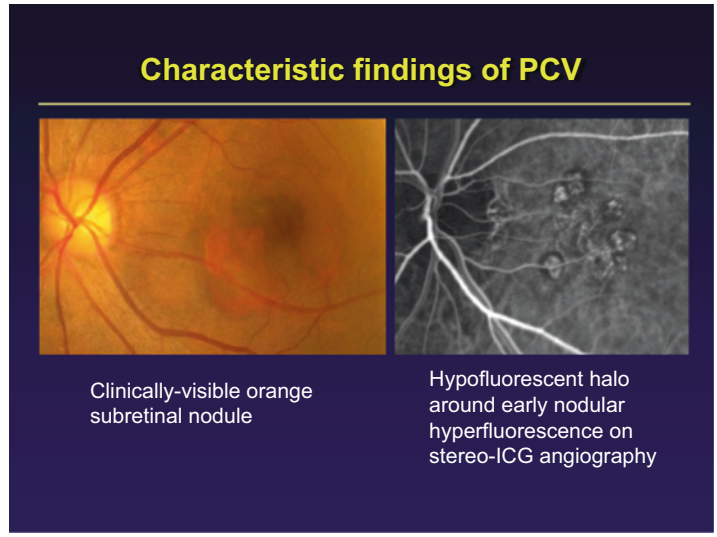
The gold standard of diagnosis of PCV is indocyanine green stereo-angiography (ICGA) (Koh et al. 686–716). The key features on ICGA are early focal nodular hyperfluorescence appearing within the first 5–6 min of the early phase of the angiogram. The plane of hyperfluorescence lies internal to large choroidal vessels, and these nodular structures protrude toward the observer and elevate the RPE layer. Other supporting features include a penumbra or halo of hypofluorescence surrounding the nodule in the early phase, followed by reversal of dye pattern in the late phase (20–30 min) due to staining of the walls of the structure, with the core having the dye emptied out, leaving an outer ring of hyperfluorescence surrounding central hypofluorescence (Fig. 2). In rare cases, pulsatility of the nodule can be observed on videoangiography, which is a pathognomonic feature of PCV that definitely differentiates it from CNV or RAP (Fig. 3).

Differential Diagnosis

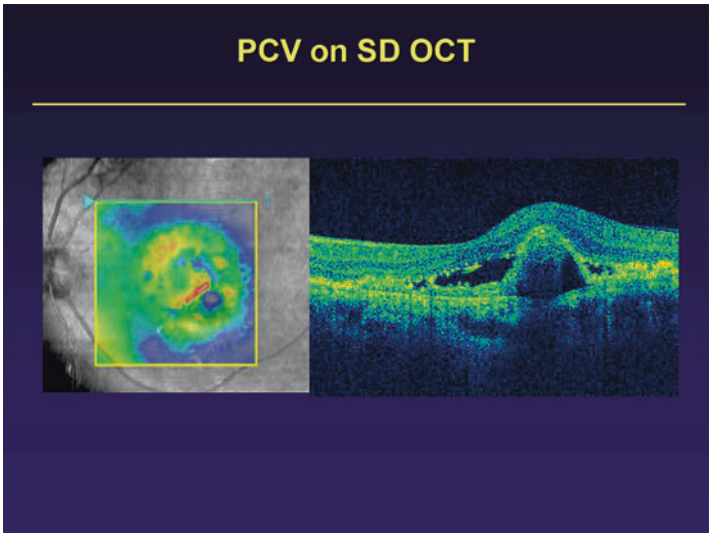
The most important differential diagnoses are occult choroidal neovascularization (CNV) and retinal angiomatous proliferation (RAP). Other entities to consider are central serous chorioretinopathy, retinal micro- or macroaneurysms, choroidal vascular knuckle, or RPE atrophy (Figs. 4 and 5).



Polypoidal Choroidal Vasculopathy, Fig. 1 Common clinical manifestations of PCV. The most common presentations of PCV are hemorrhagic pigment epithelial detachment, submacular hemorrhage, orange subretinal nodules, and neurosensory detachment

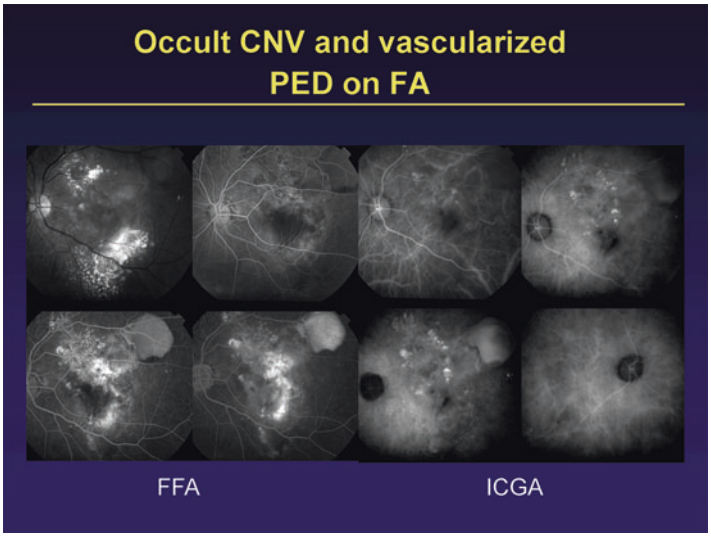


Polypoidal Choroidal Vasculopathy, Fig. 2 Characteristic findings of PCV. Orange subretinal nodules are seen in about 50% of cases on clinical examination but are almost pathognomonic of the condition. Indocyanine green angiography is the gold standard of diagnosis: a hypofluorescent halo surrounding early nodular hyperfluorescence within the first 5–6 min of the ICG is diagnostic



Polypoidal Choroidal Vasculopathy, Fig. 3 Spectral domain OCT findings in PCV. While ICGA is required for diagnosis of PCV, spectral domain OCT may be complementary by revealing sharp angular inverted V-shaped protrusions of the RPE, with surrounding pigment epithelial detachment and/or neurosensory detachment. Intraretinal edema is uncommon, unlike in retinal angiomatous proliferation (RAP), an important differential diagnosis. The polypoidal lesions lie between the RPE and Bruch's membrane. The branching vascular network may also be visible as irregular undulation or elevation of the RPE above the Bruch's membrane

Polypoidal Choroidal Vasculopathy, Fig. 4 Fundus fluorescein angiography is not diagnostic of PCV. Most PCV show occult patterns of leakage on the fluorescein angiogram. Another common finding is notched and hemorrhagic pigment epithelial detachments

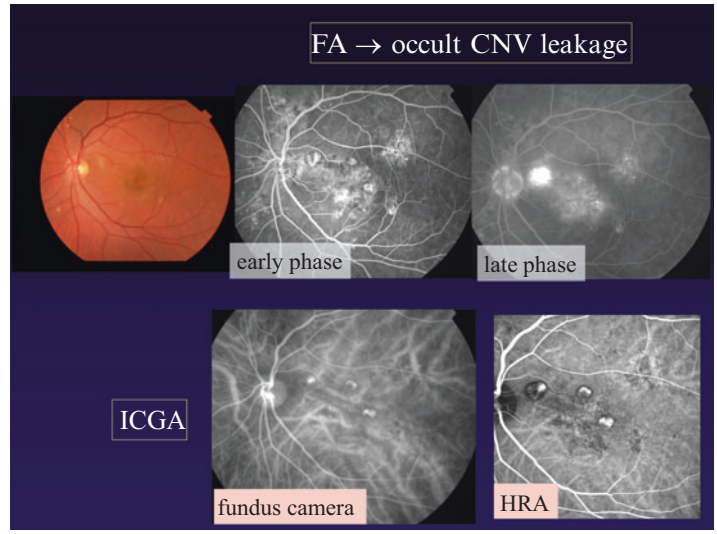


Prophylaxis

While there are no specific prophylactic treatments for PCV, AREDS-type supplementation may be given since PCV is considered a subtype of wet AMD.

Therapy

The primary goal of treatment in PCV, as in other subtypes of exudative AMD, is improvement or maintenance of vision. This can be achieved through the reduction and resolution of exudation



Polypoidal Choroidal Vasculopathy,
Fig. 5 ICGA features of PCV. The characteristic early nodule hyperfluorescence with a surrounding halo (penumbra) of hypofluorescence is diagnostic. In the later phases of the ICG angiogram, there is often a reversal of this pattern of fluorescence – central hypofluorescence with surrounding hyperfluorescence as the ICG dye leaches into the wall of the polypoidal lesion, and is washed out of its core

from the two components of PCV: the polyps themselves and/or the branching vascular network (BVN). Complete closure of polyps, confirmed on indocyanine green angiography, is a desirable secondary objective, especially in cases with persistent fluid at the macula despite multiple repeated ant-VEGF treatments due to active polyps. Furthermore, persistent polyps are associated with subsequent submacular hemorrhage, which may be massive and accompanied by severe visual loss, due to associated fibrosis and RPE atrophy (Figs. 6 and 7).

Options for therapy include the following:

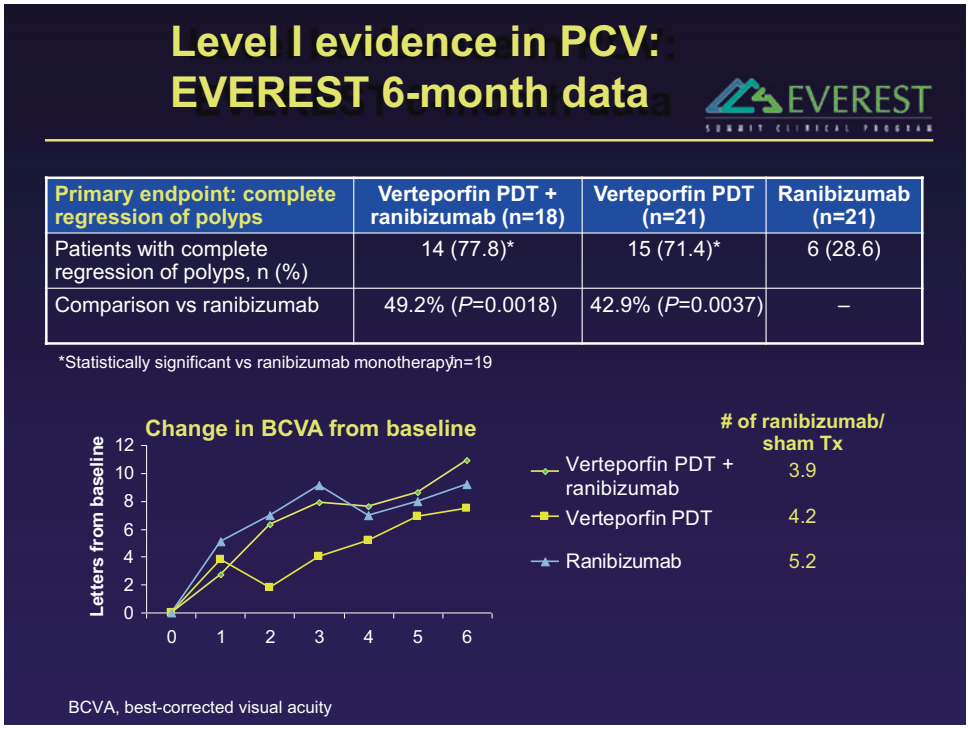
For extrafoveal PCV, focal ICG-guided laser photocoagulation may be used to occlude polypoidal lesions with moderate burn intensity. Chalky-white burns required to ablate choroidal neovascularization are not necessary. Recurrence rates are as high as 50%, and the subsequent lesions may be more extensive and hemorrhagic than the original. When lesions are subfoveal or juxtafoveal, the treatment options are verteporfin PDT (monotherapy), anti-vascular endothelial growth factor (VEGF) monotherapy, or verteporfin PDT-anti-VEGF combination therapy.

Laser Photocoagulation

Laser photocoagulation only has a role in ablating extrafoveal (preferably extramacular) polyps. Rarely, it may be effective in treating the entire complex of polyps with BVN which are extrafoveal. Limitations of laser photocoagulation include high rates of recurrences, formation of new lesions, enlargement of photocoagulation scars, tear or rip of the RPE, and iatrogenic choroidal neovascularization. Hence rates of visual loss as high as 45% have been reported following laser photocoagulation alone (Yuzawa et al. 2003).

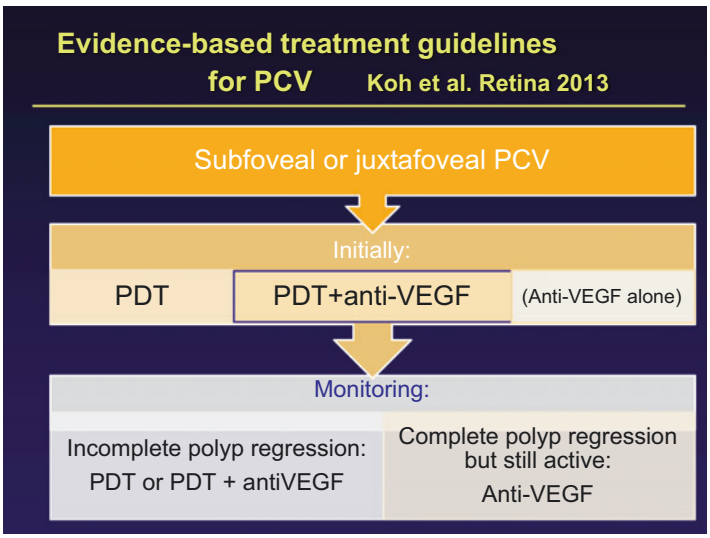
Verteporfin (Visudyne TM) Photodynamic Therapy

Verteporfin PDT has been shown to be effective in closure of polyps in PCV, but relatively ineffective in resolving activity arising from the BVN. Unlike CNV, treatment of PCV with verteporfin PDT results in mean improvement in visual acuity of eight letters at 12 months, with 25% of patients experiencing significant gains in vision of at least three Snellen lines; only 8% of patients in this prospective interventional study lost vision. 86% patients had cessation of fluorescein leakage at 1 year. Similarly, in the EVEREST trial, the mean change of visual acuity in the PDT-treated group was +7.5 letters at 6 months. The rate of complete closure of polyps was 71%, and that of partial but incomplete closure was 85.8% (Koh et al. 2012). Interestingly, the BVN seems more resistant to PDT treatment, with the majority of cases remaining unchanged despite repeated PDT. Another advantage of PDT is that the treatment-



Polypoidal Choroidal Vasculopathy, Fig. 6 The EVEREST study was part of the SUMMIT trials designed to evaluate the efficacy and safety of combination therapy of verteporfin PDT and ranibizumab in AMD and PCV. This is the first randomized controlled clinical trial to show that PDT, either alone or in combination with ranibizumab, was more effective than ranibizumab alone in complete regression of polyps at 6 months, with good visual acuity and OCT outcomes. The number of ranibizumab injections was the lowest in the combination group

P



Polypoidal Choroidal Vasculopathy, Fig. 7 Flowchart of clinical logarithm for treatment of PCV as proposed by the International Panel of PCV Experts

free period was significantly longer than was the case for CNV in AMD patients.

Studies comparing the visual outcome of PDT to anti-VEGF show that anti-VEGF therapy gives better visual results compared to PDT alone. This is because PDT is associated with complications such as acute vision decrease, increased subretinal hemorrhage, RPE tears, and, later, progressive RPE atrophy (Hirami et al. 2007). The major limitations of PDT monotherapy are reduction of vision in the long term, recurrence of polyps, persistence of BVN activity, secondary choroidal neovascularization (CNV), and progressive RPE atrophy. In 20–40% of cases, secondary CNV occurs within 2 years. Repeated full-fluence PDT gives rise to persistent choroidal ischemia, upregulation of VEGF, and RPE atrophy, all of which contribute to unsatisfactory long-term visual outcomes.

Anti-VEGF Monotherapy

The relative role of VEGF in the pathogenesis of PCV is variable: authors have shown no VEGF expression in the vascular endothelial cells of PCV, while one case report found strong expression of VEGF positivity in the vascular endothelial cells of PCV associated membrane. There were higher levels of aqueous VEGF in the eyes with PCV when compared to normal controls, albeit at lower levels than neovascular AMD.

Anti-VEGF therapy such as ranibizumab (Lucentis) and aflibercept (Eylea TM) is currently the gold-standard treatment for neovascular AMD, with significant rates of avoidance of moderate visual loss (over 95%) and doubling of visual angle (31%). This effect is maintained over three years. Ranibizumab monotherapy is also effective in achieving similar visual outcomes in PCV (Koh et al. 2012). Another indication for anti-VEGF therapy is for patients with good presenting visual acuity (e.g., 20/40 or better). Aflibercept has also been used to treat ranibizumab-tachyphylaxis in PCV cases. However, the polyp closure rate with bevacizumab and ranibizumab alone remains low. In the EVEREST trial, complete closure of polyps with ranibizumab therapy alone at 6 months was 28% compared to over 70% with verteporfin photodynamic therapy. In a retrospective study of three initial monthly injections of bevacizumab, only 1 out of 11 cases showed closure of polyps on the ICGA. Anecdotal evidence from VIEW 2 for probable PCV cases suggests a higher rate of polyp closure with aflibercept, but this remains unconfirmed. In addition, while anti-VEGF is effective in controlling exudation, the size of the BVN remained unchanged. What is undisputed, however, is the role of anti-VEGF therapy in treating activity of the BVN.

Combination Therapy: PDT with Anti-VEGF Agents

0There are good biologic and scientific rationales for combining verteporfin PDT with anti-VEGF therapy, in that both therapies employ different mechanisms of action which may be synergistic. While PDT is best for polyp regression, anti-VEGF is excellent at improving vision by reducing exudation from polyps and BVN activity. Anti-VEGF also mitigates post-PDT upregulation of VEGF through choroidal ischemia, thereby reducing the risk of acute vision decrease sometimes observed in PDT monotherapy, and might minimize the risk of post-PDT subretinal hemorrhage. EVEREST provided level 1 evidence in favor of PDT-ranibizumab combination in terms of polyp closure rate, number of ranibizumab treatments required, and equivalent short-term (6 months) visual outcome with ranibizumab alone (Koh et al. 2012). Similar results were observed in patients treated with PDT-bevacizumab combinations. The efficacy and safety of PDT with aflibercept have yet to be reported. Used together, the number of anti-VEGF injections can also be reduced. What is unestablished is the long-term visual results of combination therapy. Some studies suggest that while visual outcomes are good in the first 6–12 months, there is a significant drop-off into the second and third years.

Several authors have utilized modified PDT protocols such as reduced fluence PDT, in combination with anti-VEGF agents, with the aim of reducing the potential complications associated with PDT. These protocols have yet to be tested against conventional full-fluence PDT-anti-VEGF combination regimens. In recurrent cases, an important strategy might be to minimize the

laser treatment size by targeting only ICG-guided polyp lesions, rather than the entire lesion complex.

Optimal Treatment Regimens

There are several questions regarding optimal treatment regimens which remain unanswered. PCV may not respond to standard anti-VEGF monotherapy. While combination therapy may be an effective strategy, it is not clear if treatment should be concurrent or sequential. The use of initial anti-VEGF monotherapy might preclude the need for PDT and hence prevent related complications (Japanese guidelines recommend anti-VEGF monotherapy for patients with good VA [0.6–1.0]). Administration of anti-VEGF prior to PDT may allow more efficient delivery of the PDT laser to the consolidated target lesion; however, too long between anti-VEGFs and PDT might obviate the potential benefit that resolution of the exudation allows more efficient delivery of PDF laser to the consolidated target lesion. Efficacy appears better with anti-VEGF administered 2 days prior to PDT than 7 days prior to PDT. Concurrent (same day) administration of anti-VEGF agent and PDT means that PDT is applied when the anti-VEGF concentration peaks; this may counteract VEGF upregulation resulting from PDT-induced tissue hypoxia.

Other unresolved issues pertain to the need for three loading doses when combining therapies, which may be less important than for anti-VEGF monotherapy. There are also reported case series utilizing "triple therapy" comprising PDT, anti-VEGF with corticosteroids such as subtenon, or intravitreal triamcinolone. The author's own standard of care is to use reduced fluence ICG-guided PDT in combination with intravitreal anti-VEGF and dexamethasone. Controlled clinical trials will be needed to ascertain their true effectiveness.

Re-treatment criteria should be based on disease activity: reduced visual acuity, macular thickening from fluid, leakage from polyps, and/or BVN. Treatment modality will then depend on which is the predominant cause: persistent polyps should be selectively treated with PDT in combination with anti-VEGF, while activity from BVN alone should be managed using anti-VEGF monotherapy, since PDT has little effect on the activity or size of the BVN and might accelerate RPE atrophy and photoreceptor cell loss. The objective in re-treatment is to minimize complications from PDT, by reducing the frequency, spot size, and possible fluence.

Prognosis

The disease generally follows a remitting and relapsing course, with spontaneous remissions in between episodes of serosanguineous maculopathy. About half (50%) of patients are expected to suffer moderate or severe visual loss over 5 years. The main causes of poor vision in PCV are fibrosis and disciform scarring, RPE and neuroretinal atrophy, cystic degeneration, breakthrough vitreous hemorrhage, and, rarely, massive suprachoroidal hemorrhage and phthisis bulbi.

Epidemiology

There is a clear predilection for patients of Oriental Asian and Afro-Caribbean origin. The prevalence of PCV in Oriental Asian races such as Chinese, Japanese, and Korean ranges from 20% to 50% of all cases presenting as exudative maculopathy, compared to 8–10% in Caucasian White people. There is no significant gender predilection. Age of presentation is almost a decade younger than typical AMD. In addition, bilateral disease is found in only about 20% of cases, compared to about 50% of neovascular AMD over 5 years.

Port-Wine Stain (Nevus Flammeus)

Mithaq Vahedi
Department of Ophthalmology, William Beaumont Hospital, Royal Oak, MI, USA

Synonyms

Hemangioma; Nevus flammeus; Strawberry mark; Vascular nevus

Definition

A port-wine stain refers to a congenital angioma and is named as such due to the deep red hue rising from its vascularity. Found most commonly on the face, these grow proportionately with the body and darken over time from a pink to red-purple tone. Distribution is typically unilateral and respects the vertical midline. Facial lesions are typically distributed along the pattern of a branch of the trigeminal nerve, but frequent the forehead and upper eyelid, and hemihypertrophy of the face may develop. Oral lesions are present in 25% of patients. Port-wine stains represent a classic feature of Sturge-Weber Syndrome, a phakomatosis with cutaneous, central nervous system and ocular abnormalities, in which ocular findings include glaucoma, abnormal plexus of episcleral vessels, iris or optic nerve coloboma, tortuous retinal vessels, and choroidal angioma.

Definition

A port-wine stain (PWS), or nevus flammeus, is a type of birthmark caused by a capillary

malformation in the skin. It is present at birth and typically grows in proportion with the child. Commonly occurring on the face, it can be a sign of a phakomatosis, Sturge-Weber syndrome (SWS), a congenital neurological and skin disorder that also includes abnormal blood vessels on the surface of the brain (ipsilateral cerebral leptomeningeal vascular malformations), and subsequent neurologic complications.

Differential Diagnosis

The presence of a PWS is not sufficient for the diagnosis of Sturge-Weber syndrome, and many cases of PWS are sporadic and isolated. In addition to SWS, however, other potential differential diagnoses include nevus simplex, infantile hemangioma, arteriovenous malformation, and linear scleroderma.

Diagnosis

The diagnosis of a PWS is made clinically. In order to diagnose SWS, leptomeningeal capillary-venous malformations should also be present. A cranial magnetic resonance imaging (MRI) with contrast is typically used to detect the presence of these malformations in the brain.

Pathogenesis

The pathogenesis of capillary malformations is unknown. Several mechanisms such as vascular ectasia, lack of neuronal control of blood flow, and the overexpression of vascular endothelial growth factor (VEGF) are thought to be involved.

Individuals with SWS possess somatic mosaic mutations in the CNAQ gene. This gene encodes a guanine nucleotide-binding protein that functions to regulate intracellular signaling pathways. Individuals who develop the CNAQ mutation earlier in development are more likely to acquire SWS, whereas individuals who acquire the mutation much later may only have a port-wine stain and no other complications.

Clinical

The PWS can occur anywhere on the body, though they are commonly found on the face and tend to follow the distribution of the trigeminal nerve branches. These lesions may extend onto the mucosal surfaces inside the mouth.

One of the most serious complications of a PWS-related capillary malformation is ocular involvement and secondary glaucoma. The development of glaucoma is believed to be caused by elevated episcleral venous pressure secondary to the obstruction of venous drainage around the eye.

If the patient has SWS, additional neurologic complications include early onset seizures in childhood, hemiparesis contralateral to the affected side of the brain, intellectual disability, and behavioral problems.

Treatment

Medical therapy for SWS includes anticonvulsants for seizure control, symptomatic and prophylactic therapy for headache, and intraocular pressure lowering agents and possibly laser therapy for glaucoma and laser treatments for the PWS. Epilepsy surgery may be necessary for medically refractory seizures, and glaucoma surgery is often needed for refractory glaucoma in SWS.

Prognosis

The prognosis for SWS depends on the extent of the leptomeningeal capillary-venous malformation and to what extent it effects perfusion of the cerebral cortex. The prognosis of the PWS depends upon its extent of ocular involvement.

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Clinically definite MS; Multiple sclerosis diagnosis

Definition

The Poser criteria are a set of diagnostic parameters determined by Charles Poser et al. in 1983 for the diagnosis and classification of multiple sclerosis (MS) (Poser et al. 1983). The four categories are clinically definite, laboratory-supported definite, clinically probable, and laboratory-supported probable multiple sclerosis (Poser et al. 1983). The purpose of deriving these criteria was to establish a reliable diagnostic definition of MS for research studies that incorporated both clinical evidence and laboratory data (Poser et al. 1983). The Poser criteria replaced a previous scheme that did not analyze laboratory data but has since been replaced by a newer method that incorporated a greater role for magnetic resonance imaging (MRI) (Fangerau et al. 2004; McDonald et al. 2001; Poser et al. 1983).

Under the Poser criteria, patients are classified into one of the four categories based on number of clinical attacks lasting more than 24 h they have had, number of separate lesions evoking clinical signs, supportive imaging studies or physician assessments (termed paraclinical evidence), and the presence of oligoclonal bands in the cerebrospinal fluid (CSF) (but not in the serum) plus an increase in CSF immunoglobulin G (Poser et al. 1983). Clinically definite MS requires two attacks with clinical or paraclinical evidence of two distinct lesions (Poser et al. 1983).

Poser's definitions do not allow for the classification of primary progressive MS or for the effective utilization of magnet resonance imaging. Newer MS criteria include the McDonald criteria which were published in 2001 and revised in 2005 and 2010 (McDonald et al. 2001; Milo and Miller 2014; Poser et al. 1983).

Definition

Positron emission tomography (PET) is a type of functional imaging which uses positron-emitting radiopharmaceuticals which, when emitted, will travel a few millimeters before encountering an electron in the surrounding area resulting in complete annihilation. The annihilation results in simultaneous emission of two gamma photons in opposite directions. These rays are received by the surrounding detector simultaneously at two different points (electronic coincidence) inferring that the decay took place somewhere along the line between the two simultaneously detected events. A great number of these events are recorded in order to produce a 2D horizontal cross-section image. Many of these images are collected and reconstructed to form a functional 3D image.

Like SPECT (see "► Single-Photon Emission Computed Tomography"), PET is a type of functional imaging and does not yield the most beneficial image of the anatomical features of the viewed area as in conventional structural imaging (e.g., CT or MRI). As a result, PET is often combined with conventional x-ray-based structural computed tomography (CT) for simultaneous functional and anatomical imaging. Thus this PET/CT dual-modality imaging results in increased speed, accuracy, and convenience allowing a physician to look at both the functional and anatomical/structural features of patients.

History

A few years after development in 1949 and early clinical use of a planar gamma-ray scanning device, a positron-annihilation imaging scanner was developed for use on human patients as early as 1956. The early positron-annihilating systems used opposing pairs of small detectors similar to today both with and without the use of electronic coincidence.

Basic Mechanism

Radiopharmaceuticals labeled with positron-emitting radioisotopes are injected into a patient who has been placed in an area surrounded by gamma-ray detectors. After traveling a few millimeters within the body, the positrons, which are emitted from the decaying radioisotope nuclei, encounter electrons in the surrounding area. These particles annihilate upon colliding, emitting two gamma photons in opposite directions. These two photons are collected by gamma-ray detectors which can infer the origin of the decay event, based on the premise that the emitted gamma rays traveling directly opposite each other will be detected simultaneously (electronic coincidence). Collected photon events pass through

amplifiers and a pulse-height analyzer to determine which events have high-enough energy signals for further analysis. These events are then analyzed for electronic coincidence to observe from where in the body various photons arose. An image is then reconstructed from the summation of points between two coincidental events from the many pairs of photons.

Clinical Uses

PET scans are used commonly to detect aberrant metabolic activity which may be indicative of cancer. PET can be used on lymph nodes to detect abnormal activity even prior to swelling, and it may be used on the heart to observe adequate blood flow and potential coronary artery disease. It can also be used as a diagnostic for brain disorders (e.g., Alzheimer disease, posterior cortical atrophy, epilepsy).

Comparison with SPECT

PET does produce images with higher resolution; however, availability for SPECT is more accessible due to the affordability and lower priced radiopharmaceuticals. PET system development may continue to lower the cost and increase the accessibility of the system. PET remains the preferred functional imaging method for research due to its high resolution.

PET/CT dual-modality imaging for oncological purposes has gained a great deal of clinical approval. In recent years, oncology clinics have been encouraged to replace stand-alone PET systems with dual-modality systems. In comparison, SPECT/CT dual-modality systems have not succeeded in the same way as there are lower clinical indications for this specific combined procedure.

Posner-Schlossman Syndrome

Friederike Mackensen
Interdisciplinary Uveitis Center, Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Synonyms

Glaucomatocyclitic crisis

Definition

Posner-Schlossman syndrome (PSS) is a rare form of recurring and remitting IOP elevations with associated/secondary mild inflammation.

Etiology

The clinical picture has been described and named by Posner and Schlossman in 1948 after the first reports by Kraupa in 1924. Not much is known about the etiology, although a possible role of herpes virus, especially CMV, has been postulated (Chee and Jap 2008). Reduction in aqueous outflow facility due to inflammation as well as augmented levels of prostaglandins leading to increased aqueous humor production has been reported. Some studies have even suggested an association with primary open-angle glaucoma (Mudumbai and Salim 2010). Most studies date

Friederike Mackensen: deceased.

back to the 1960s and 1970s with more recent publications linking PSS with non-arteritic anterior ischemic neuropathy (Irak et al. 2003).

Clinical Presentation

The pressure rise is typically unilateral and affects young to middle-aged individuals. The rise of IOP is out of proportion to the severity of the uveitis, up to 60 mmHg, and this rise in IOP precedes the identifiable inflammatory reaction, often by several days. The patient notes mild ocular discomfort and blurred vision of sudden onset. On examination mild iridocyclitis is seen with few cells and flare, with corneal edema and typical nonpigmented small- to midsized keratic precipitates in the center and lower half of the cornea that do not resemble the keratic precipitates seen in other uveitic entities. No synechiae formation is observed. The attack is usually short-lived and responds well to topical corticosteroids and carboanhydrase inhibitors topically and/or orally. Between attacks both the anterior chamber inflammation and IOP return to normal without the need of ongoing treatment (Grehn and Mackensen 1993; Mudumbai and Salim 2010).

Diagnosis

So far the diagnosis is a clinical one. It is important to recognize the clinical picture and educate the patient accordingly.

Differential Diagnosis

The differential diagnosis of PSS includes other conditions with unilateral raised IOP such as Fuchs uveitis syndrome (FUS) and herpetic uveitis or pigment dispersion syndrome. Iris hypochromia has been described already by the first describers as well as iris atrophy. The main distinguishers to FUS are the appearance of KPs, corneal, especially endothelial edema, flare in the anterior chamber, the patient describing symptoms, and the good response to topical corticosteroids. An FUS patient usually develops a pressure rise over time, not as a sudden occurrence. Herpetic uveitis usually shows pigmented granulomatous KP with more associated inflammation and needs more intensive and prolonged treatment. Gonioscopy finding of a normal angle structure helps in distinguishing pigment dispersion syndrome.

Prophylaxis

In between attacks treatment neither for glaucoma nor uveitis is needed nor would it prevent recurrences. In rare cases, the long duration of disease development of glaucoma has been described. Most important is to counsel the patient regarding his or her disease and educate them to seek appropriate care in the case of an acute attack.

Therapy

Topical corticosteroids are given to control inflammation. IOP in most cases normalizes with this treatment alone. Additional antiglaucomatous drops may be needed. Surgical treatment is only needed exceptionally. In cases where CMV is involved, ganciclovir can be considered, but relapse after cessation of treatment is frequent.

Prognosis

Prognosis is relatively good.

Epidemiology

PSS is extremely rare. It was seen in only 10 out of 1916 patients in a German tertiary center (Jakob et al. 2009). Looking at the literature published, it seems to be more frequent in Singapore than in other countries, where 74 presumed PSS patients of mostly Chinese race were seen in a 2-year period (Chee and Jap 2008). A mild male preponderance has been described.

There is some difficulty regarding the somewhat soft clinical definition which will have to be

sorted out, e.g., clarifying if CMV-associated uveitis should not be regarded as a uveitis entity different from PSS.

Posterior Capsule Rupture

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Posterior capsule rent; Posterior capsule tear

Definition

Posterior capsule rupture is defined as any breach in the integrity of the posterior capsule. Reason for this breach can either be congenital/traumatic (preexisting), spontaneous, or intrasurgical.

Epidemiology

Intraoperative capsule ruptures are the most common. They may occur accidentally or may be

planned, as in a primary posterior capsulorhexis. Between 1983 and 1997, the intrasurgical complication rate was reported between 1.5% and 11.4% dependent to the surgical technique, skill of surgeon, and stage of cataract. The incidence of intraoperative/traumatic posterior capsule tear has been reported to be higher in developing countries because of limited resources and delayed treatment, resulting in more advanced pathology. Spontaneous ruptures of posterior capsule tear are rare.

History

No detailed information exist about the history of posterior capsule rupture.

Clinical Features

Posterior capsule (PC) rupture during phacoemulsification cataract surgery remains an important complication because it may lead to poor visual outcome. Vitreous loss can occur in posterior capsule rupture and is associated with various complications including cystoid macular edema, glaucoma, retinal detachment, and infective endophthalmitis.

Tests

Visit with check of uncorrected and best corrected vision acuity and slit lamp examination with dilated and undilated pupil are important examinations to test the presence of a posterior capsular rupture.

Differential Diagnosis

Posterior polar cataract

Etiology

Intraoperative capsule ruptures may occur accidently or may be planned, as in primary posterior capsulorhexis. An increased intrasurgical capsule rupture rate is reported in patients with diabetes mellitus and pseudoexfoliation. Posterior polar cataracts, posterior lenticonus, cataract with persistent primary hyperplastic vitreous, and cataract following vitreoretinal surgery have also demonstrated increased propensity for the occurrence of posterior capsule rupture. Spontaneous capsule rupture is associated with hypermaturity, posterior lenticonus, intraocular tumors, and posterior polar cataracts. Traumatic capsule rupture can be caused by ocular or orbital injuries, and congenital posterior capsule rupture is related to posterior polar or infantile hypermature cataract. Intrauterine insults may be possible for both congenital cataract and congenital posterior capsule rupture.

Treatment

Prompt diagnosis and meticulous management are mandatory to prevent further enlargement of the tear and avoid consequent complications. The conventional management consists of prevention of mixture of cortical matter with vitreous, dry aspiration, and anterior vitrectomy, if required. In addition, during phacoemulsification low flow rate, high vacuum, and low ultrasound are advocated if a posterior capsule tear occurs. Dislocated nucleus or nuclear fragments require vitrectomy and the use of perfluorocarbon liquids. In the presence of a posterior capsule tear, the IOL can be placed in the sulcus, if the capsular rim is available, or in the bag, if the tear is small. Scleral fixated posterior chamber lenses and anterior chamber IOLs can be implanted when the posterior capsule tear is large. For prevention of posterior capsule rupture, viscodissection was reported to be a successful method.

Posterior Capsule Tear

► Posterior Capsule Rupture

Posterior Capsulorhexis

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Posterior capsulotomy; Posterior continuous circular capsulorhexis (PCCC)

Definition

A step of cataract surgery used in pediatric patients to avoid a late posterior capsule opacification. In adults, this technique is practiced in the presence of a central posterior capsular tear, posterior polar cataract, or in primary posterior capsular opacification.

Epidemiology

See "Epidemiology" section of "► Cataract Surgery" entry.

History

See "History" section of "Capsulorhexis" entry.

Clinical Features

Conducting instruments are either a cystotome or a bended needle.

Tests

See section "Tests" of "► Cataract Surgery" entry.

Differential Diagnosis

Another technique which is commonly applied is the continuous curvilinear capsulorhexis (CCC).

Other capsular opening methods in the following are, for example:

- Can-opener technique (letter-box technique): traditionally used in pediatric cataract surgery, for the planned extracapsular extraction, using a disposable or commercially available cystotome, several punctuations (60–80)
- Linear capsulotomy
- Capsulopuncture

Etiology

See "History" section above.

Treatment

After inflating the capsular bag with high-viscosity viscoelastic agents, a 1–2 mm relaxing capsulotomy is conducted at the center of the posterior capsule. To push the anterior vitreous face backward, 0.1 ml of the same agent is injected under posterior capsule. The resulting posterior capsule flap has to be teared outward while holding it with a forceps. Because of the nature of the

posterior capsule (thinner, more slippery, and elastic compared to the anterior capsule), a frequent and repeated regrasping of the capsular edge has been highly beneficial clinically.

The ideal size of this capsulorhexis should be approximately 4–5 mm.

A dye-enhanced posterior capsulorhexis may be adjuvant (0.1 ml of 0.1% trypan blue).

In case of pediatric surgery, the diameter of the posterior capsulorhexis is considered to be 1.0–1.5 mm smaller than the optic of the implanted intraocular lens.

Posterior Embryotoxon, Neurocristopathy

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Definition

Posterior embryotoxon is a prominent, anteriorly displaced Schwalbe's line that can extend 360° around the peripheral cornea or be isolated to a few clock hours, located most often, in the temporal aspect of the cornea. It can often be visualized on slit lamp exam, otherwise is seen gonioscopically.

Etiology

Dysgenesis of neural crest cells of the anterior chamber causes posterior embryotoxon. It can be isolated (i.e., considered normal) or be associated with a more extensive disease process such as Axenfeld-Rieger syndrome or Alagille's syndrome. Less commonly, it is seen in congenital glaucoma or iridocorneal endothelial syndrome. Histologically, it appears as a central core of collagen and ground substance covered by a layer of spindle shaped cells and basement membrane. In Axenfeld-Rieger syndrome, iris strands may extend to the posterior embryotoxon.

Occurrence

Posterior embryotoxon is present in 8–15% of normal individuals. It is most commonly seen in Axenfeld-Rieger syndrome, and seen in most, but not all, individuals with this disorder.

Classification

No classification system established.

Synonyms

Arteritic PION (A-PION); Nonarteritic PION (NA-PION); Perioperative PION; Retrobulbar optic neuropathy; Surgical PION

Definition

The optic nerve is divided into two segments based clinically on the presence or absence of disk edema anterior or posterior to the lamina cribrosa. Posterior ischemic optic neuropathy (PION) is defined as acute ischemia of the posterior segment of optic nerve (retrobulbar optic neuropathy).

Etiology

PION can be divided into three main categories based on etiology: (1) arteritic PION (A-PION) is ischemia due to giant cell arteritis (GCA), (2) non-arteritic PION (NA-PION) is ischemia due to causes other than GCA, and (3) postsurgical PION. NA-PION is rare compared with typical NA anterior ischemic optic neuropathy (NAION); the ischemic event is thought to be multifactorial in nature and is associated with a variety of systemic diseases, including diabetes mellitus, arterial hypertension, arteriosclerosis, atherosclerosis, and arterial hypotension. These systemic diseases may be risk factors in the development of PION, as their prevalence is much higher in patients with PION versus the control population. In general, systemic diseases with vascular risk factors and defective autoregulation may predispose patients to the development of PION. The last type of PION is surgical PION (typically spine or cardiac surgery) with pathogenesis also likely to be multifactorial in nature. Major reported associations include duration of surgery, face-down positioning, prolonged arterial hypotension, prolonged general anesthesia, massive blood loss and anemia, hemodilution from large amounts of IV fluids, use of colloid versus crystalloid fluid replacement, use of the Wilson frame in spine surgery, and postsurgical orbital and periorbital edema. Surgical PION is thus associated with prolonged systemic surgical procedures most commonly after spine surgery or cardiac surgery but has also been reported in multiple types of surgery including orthopedic procedures, radical neck dissection, venous graft procedures in extremities, and hip surgeries.

Clinical Presentation

The clinical presentation varies depending on the etiology of PION. Those with A-PION and NA-PION usually present with painless and acute visual loss in one or both eyes. Patients

with GCA typically have other constitutional symptoms including headache, scalp tenderness, jaw claudication, fever, or polymyalgia rheumatica. Patients with PION may discover visual loss upon waking up in the morning, and others may experience more acute and then progressive symptoms during waking hours. Patients with surgical PION often notice unilateral or bilateral visual loss or blindness immediately upon awakening postoperatively, but some patients with surgical PION do not report their visual complaints until later. Visual acuity and visual field defects are variable in PION. However, the most common visual field defects are nerve fiber layer type. Unilateral or asymmetric bilateral PION will likely present with a relative afferent pupillary defect, but the remainder of the ocular exam is typically normal. Generally within 6–8 weeks, disk pallor will develop in the affected eye(s).

Diagnosis of PION

PION is a diagnosis of exclusion as other forms of retrobulbar optic neuropathy can mimic the clinical presentation. A combination of the following findings are suggestive of PION: (1) sudden and acute onset of visual deterioration that may be accompanied by deterioration of central visual acuity, (2) visual field defect in the affected eye, (3) relative afferent pupillary defect in the affected eye, (4) initially normal optic disk and fundus on both ophthalmoscopy and perhaps concomitant fluorescein fundus angiography, (5) no other abnormalities that may explain the visual loss, and (6) optic disk pallor that develops within 6–8 weeks. However, the diagnosis of surgical PION can be based on drastic visual loss noted upon patient awaking from a major surgical procedure.

Differential Diagnosis

Nonarteritic AION, macular and retinal lesions, retrobulbar optic neuritis, compressive optic neuropathy, neurological lesions.

Prophylaxis

There is no prophylaxis beyond controlling vasculopathic risk factors for NPION, but some measures to reduce the risk of postsurgical PION have been proposed including monitoring for and avoiding excessive arterial hypotension or hemodilution, attention to fluid management (colloid versus crystalloid fluid replacement), avoiding direct pressure on the orbit, shortening the duration of surgery to a minimum and/or staging the procedure if necessary, avoiding vasoconstrictors, transfusion for anemia, and prone positioning with the head at the level of the heart. Unfortunately, no single countermeasure has proven to be effective as surgical PION which is likely multifactorial has no proven single proximate cause. In addition, treatment of one risk factor (e.g., hypotension) might worsen another risk factor (e.g., increased bleeding or surgical time). In terms of NA-PION, since it is associated with several systemic risk factors, reducing as many risk factors as possible may reduce the risk of eye involvement.

Therapy

Management of PION depends upon the etiology.

Prognosis

Visual prognosis in PION is variable. In general steroid therapy is given to GCA PION patients to prevent fellow eye involvement. Most patients with surgical PION do not recover their vision and the role of steroids is unproven. NA-PION has a variable rate of spontaneous recovery that may be better than GCA-related PION or surgical PION.

Epidemiology

PION is much less common than AION, and its true incidence is difficult to assess considering it is a diagnosis of exclusion. The exact incidence of

surgical PION is also unknown, but they are most frequently reported after cardiac and spinal surgeries.

Posterior Lenticonus

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Posterior lenticonus is a unilateral or bilateral thinning and posterior bowing of the posterior capsule of the crystalline lens.

Etiology

Sporadic cases of posterior lenticonus occur. In many cases, posterior lenticonus is inherited (x-linked, autosomal dominant trait or autosomal recessive inheritance). Posterior lenticonus has been associated with microcornea, hyperglycinuria, Duane's syndrome, Alport syndrome, and anterior lentiplanus.

Clinical Presentation

In a slit-lamp examination, a spheroidal or conical protuberance affecting the posterior lens surface can be observed. Opacification of the adjacent lens cortex may occur, and posterior lenticonus may manifest as a high degree of astigmatism.

Diagnostics

Posterior lenticonus can be diagnosed in a slit-lamp examination or with ultrasound biomicroscopy.

Differential Diagnosis

Posterior subcapsular cataract.

Therapy

Mild cases may be observed. More severe cases with progressive opacity of the lens lamellae or risk of amblyopia due to high astigmatism may require cataract surgery with a posterior capsulorhexis during the first months of life.

Prognosis

The prognosis is usually good if no amblyopia has developed.

Epidemiology

Posterior lenticonus is a rare disease.

Definition

Surgical technique during phacoemulsification for reduction of posterior capsule opacification.

Epidemiology

No epidemiologic data available for this topic.

History

In 2006, Menapace introduced this technique to preserve full capsular transparency and to evaluate it as a potential routine alternative to standard in-the-bag implantations of sharp-edged optic intraocular lenses. It has also been used in cataract surgery with children to prevent aftercataract.

Clinical Features

See Treatment section below.

Tests

Thorough examination of the anterior segment with the slit-lamp gonioscopy, measurement of uncorrected and best spectacle-corrected visual acuity and intraocular pressure, and biometry are mandatory to maintain best possible postoperative results.

Differential Diagnosis

Other surgical techniques for reducing posterior capsule opacification ARE:

– Anterior capsulorhexis fixation

Etiology

See History section.

Treatment

After topical anesthesia, standard anterior capsulorhexis and phacoemulsification are performed. Remaining opacifications of the anterior and posterior capsule are polished bimanually. Injection of viscoelastic is necessary to separate the capsule leafs from each other and to lift the posterior capsule from the vitreous surface.

After implantation of the intraocular lens and enclavation of the haptic in the chamber fornix, slight pressure is performed on the optic at 6 o'clock until it moves behind the posterior capsule. The same maneuver is done at 12 o'clock of the optic and the viscoelastic is removed. Finally, when observing the intraocular lens, the anterior rhexis shows a round form, whereas the posterior rhexis is oval.

Posterior Polar Cataract

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

A posterior polar cataract is a congenital or infantile subcapsular cortical opacification at the posterior pole of the crystalline lens.

Etiology

The opacification consists of abnormally developed lens fibers attaches to the posterior capsule. Posterior polar cataract occurs sporadically, but there is also an autosomal dominant familiar form which is in most cases bilateral. The sporadic form is sometimes associated with other abnormalities such as remnants of the tunica vasculosa lentis, lenticonus. or lentiglobus.

Clinical Presentation

As in other forms of cataract the disease causes variable degrees of decrease in visual acuity and contrast sensitivity as well as symptoms of glare depending on the size of the lesion. Because of the proximity to the nodal point of the eye posterior polar cataracts cause more visual impairment than anterior polar cataracts. Especially, unilateral cases can cause amblyopia.

Diagnostics

The posterior polar cataract is seen in slit-lamp microscopy as a central subcapsular opacification at the posterior lens pole in an otherwise clear lens.

Differential Diagnosis

Similar lesions may occur due to posterior capsule trauma, e.g., due to previous vitreoretinal surgery.

Prophylaxis

There is no known prophylaxis against this condition.

Therapy

As in other forms of cataract, the therapy is surgical. Because of a high incidence of increased capsular fragility or preformed posterior capsular openings cataract surgery in eyes with posterior polar cataract has a higher than average risk of posterior capsule rupture and care must be taken to minimize stress on the posterior capsule. In 20% of cases, a primary posterior capsule defect has been reported.

Prognosis

Usually, the condition is stable and does not progress. However, a progressive form which usually becomes symptomatic between 30 and 50 years of age has been described.

Epidemiology

It is generally agreed that posterior polar cataract is a rare disease. No publications about its incidence and prevalence are available.

Posterior Polymorphous Corneal Dystrophy

Andrew Nightingale and Anita Gupta
Department of Ophthalmology, New York Eye and Ear Infirmary of Mount Sinai, New York, NY, USA

Synonyms

Posterior polymorphous dystrophy (PPMD); Schlichting dystrophy

Definition

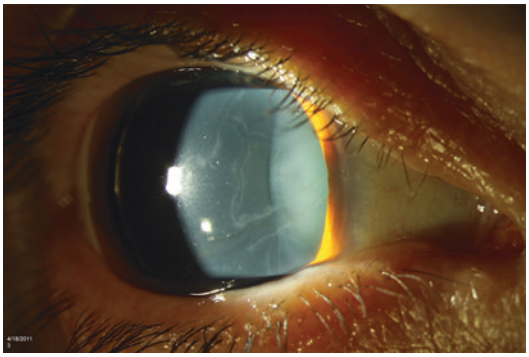
Endothelial corneal dystrophy.

Etiology

Posterior polymorphous corneal dystrophy (PPCD) is an autosomal dominantly inherited corneal dystrophy. Three genetic loci – PPCD 1 through 3 – have been isolated to chromosomes 20, 1, and 10, respectively. Mutations in *COL8A2* (collagen type VIII alpha 2) and *ZEB1* (two-handed zinc-finger homeodomain transcription factor 8) are responsible for PPCD 2 and PPCD 3. The gene implicated for PPCD 1 has not been isolated.

Clinical Presentation

The onset of PPCD is in early childhood. Patients often present with asymmetric, deep corneal lesions of various morphologies including nodular, vesicular, and blister-like lesions. Patients can also present with deep stromal broadbands with scalloped edges have been termed "railroad tracks" (Fig. 1a, b). Geographic-shaped lesions at the level of Descemet's membrane are often present. Stromal and epithelial edema can be variably present



Posterior Polymorphous Corneal Dystrophy, Fig. 1 Posterior polymorphous dystrophy showing deep stromal bands with scalloped edges ("Railroad tracks"). (**a**) Posterior polymorphous corneal dystrophy, displaying deep stromal bands with scalloped edges ("railroad tracks"). (**b**) Posterior polymorphous corneal dystrophy, retro-illumination view highlights deep stromal bands with scalloped edges ("railroad tracks")

due to endothelial decompensation. Peripheral iridocorneal adhesions can also be present. In about 15% of cases, intraocular pressure is elevated.

Diagnosis

The diagnosis of PPCD is often made on the basis of the clinical exam. Biopsy of corneal tissue can reveal the distinctive light microscopic finding of PPCD: the appearance of abnormal, multilayered endothelial cells that resemble epithelial cells or fibroblasts. Light microscopy can also reveal thickened Descemet's membrane with multiple layers of collagen on its posterior surface manifesting focal fusiform or nodular excrescences. Confocal microscopy reveals polymegathism of the endothelium. Vesicular lesions in PPCD appear as doughnut-like areas (rounded dark areas with some detail in the middle) on confocal microscopy.

Differential Diagnosis

Differential diagnosis includes Fuchs endothelial corneal dystrophy and congenital hereditary endothelial dystrophy 1.

Therapy

While most remain asymptomatic, some patients can develop stromal edema due to endothelial decompensation. Mild edema can be managed with sodium chloride drops and ointment. Advanced edema can be managed with either endothelial or penetrating keratoplasty. PPCD can recur in a graft. Concomitant glaucoma must be managed if present.

Prognosis

Patients are often asymptomatic. Endothelial signs of PPCD often remain unchanged over years. Rarely there is slow progression of these lesions leading to endothelial decompensation. Congenital corneal clouding is extremely rare.

Epidemiology

Rare

Posterior Vitreous Detachment

Shibo Tang, Jacey Hongjie Ma, Shangli Ji and Hua Fan
Aier School of Ophthalmology, Central South University, Changsha, China

Definition

Posterior vitreous detachment (PVD) is the most frequent and most important change of the vitreous, which is defined as the separation of posterior hyaloid membrane from the internal limiting membrane (ILM). Although PVD naturally resulted from aging and usually harmless, PVD can be the provoking event for numerous vitreoretinal pathologies. It has been shown that up to 24% of symptomatic PVD gives rise to retinal complications (Yonemoto et al. 1994; Hikichi and Trempe 1994; Chuo et al. 2006). According to the existence of adhesion at the vitreoretinal interface and its sequelae, PVD can be divided into complete or partial and innocuous or anomalous PVD.

Epidemiology

Studies have shown the incidence of PVD is 66% between the ages of 66 and 86 years and 53% after 50 years (Favre and Goldmann 1956). The average age of onset of PVD is approximately 61 years old (Yonemoto et al. 1994). In cases suffered from myopia, retinal vascular disorders, trauma, and retinitis pigmentosa, the onset may occur at a younger age (less than 40 years old) (Yonemoto et al. 1994; Sebag 1993; Akiba 1993; Hikichi et al. 1995; Morita et al. 1995). Female gender is one of the risk factors of development of PVD. The average age of onset for females has been shown to be statistically significantly earlier than males which have been attributed to postmenopausal loss of estrogen. The development of new technics, including clinical examination, ultrasonography, monochromatic photography, and optical coherence tomography, helps to improve the assessment of PVD.

Etiology

The vitreous, a transparent, avascular gel, contains 98% of water and 2% of low molecular weight solutes and macromolecules. The major molecular constituents are hyaluronic acid (HA), collagen, a wide range of soluble proteins, and some other components, including heparin sulfate, chondroitin sulfate, and opticin. These molecules are the main ingredients that maintain the gel-like and transparent appearance of the vitreous. However, under aged or pathologic condition, the architecture features of the vitreous experience dramatic changes as degeneration causes syneresis, cavity formation, and collapse of the vitreous gel.

Liquefaction and vitreoretinal interface weakening are the most important processes of vitreous aging that occur in parallel. Age-related liquefaction is called "synchysis senilis." However, the first appearance of liquid vitreous was observed at the age of 4 years; after age 40 years, there is a significant decrease in the gel volume and a concurrent increase in the liquid volume of the vitreous, and by the age of 80–90 years, more than half the vitreous is liquid (Foos and Wheeler 1982; Williamson and Williamson 2013). Actually, there is no consensus on the explicit reason of gel liquefaction. Myopia is a notable cause of vitreous liquefaction in younger individuals. Yonemoto et al. demonstrated that 0.91 years could be subtracted from the average age of PVD for each diopter of myopic refractive error (Yonemoto et al. 1994). Beside increase of liquid in the vitreous, the collagen malformation is also the etiology of liquefaction. Inherited collagen metabolic disorders such as Marfan, Ehlers-Danlos, Stickler, and Knobloch syndromes are

usually accompanied by advanced vitreous liquefaction. Along with the advancing vitreous liquefaction, cavities of liquid vitreous called lacunae arise within the gel-like architecture.

In the context of weakening of vitreoretinal adherence, chondroitin sulfate, opticin, and/or other components are lost or altered and at the same time will promote the aggregation of vitreous collagen fibrils into visible fibers called "aggregation of the vitreous," which eventually leads to the collapse of the vitreous body. Complete PVD dissects completely the posterior vitreous cortex and the inner limiting membrane of the retina; it usually has no abnormal adhesion at the vitreoretinal interface. It's clinically innocuous and has dominance in the elderly. When the vitreoretinal dehiscence is insufficient, the liquefied vitreous cannot pull away thoroughly. Some parts of the vitreous cortex at the posterior vitreoretinal interface will be detached, which is called partial PVD. One special situation is called vitreoschisis (VS), which means there is a split in the posterior vitreous cortex. Any factor that breaks the balance between the degree of gel liquefaction and the vitreoretinal adhesion can lead to PVD. Those factors can be congenital like Marfan, Ehlers-Danlos, and Stickler syndromes or secondary from systemic diseases such as proliferative diabetic vitreoretinopathy and diabetic macular edema. Likewise, numerous eye complaints such as trauma, inflammation, and myopia disturb the homeostasis of vitreous body and lead to PVD.

Posterior Vitreous Detachment, Table 1 Complications of posterior vitreous attachment

Origins	Retinal complications
Age-related posterior vitreous detachment	Retinal tears
	Rhegmatogenous retinal detachment
	Macular epiretinal membrane
	Vitreomacular traction syndrome
	Macular hole
	Vitreous hemorrhage
Pathological vitreous separation	Diabetic tractional retinal detachment
	Posterior uveitis
	Trauma

Clinical Presentation

Symptoms

Floaters

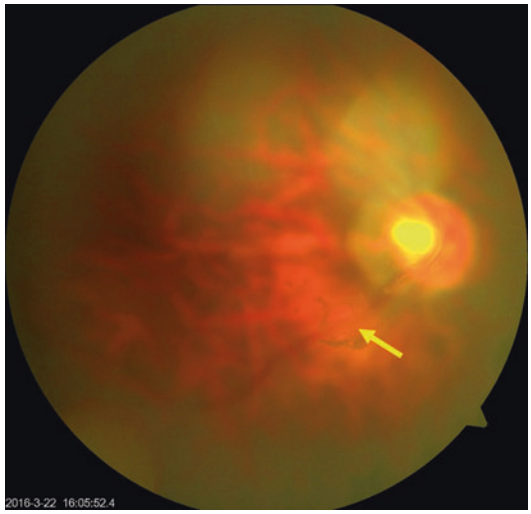
Though PVD is usually asymptomatic or without pathological complications, the most common symptom arising from PVD is floaters. Floaters can be resulted from the shadows casted by Weiss ring, intravitreal blood, or condensed vitreous fibers. A Weiss ring, a small ring of tissue in front of the optic disk, is the gliotic tissue avulsed from the disk margin during PVD, which indicates the development of posterior vitreous detachment. The patients with floaters often complain a cobweb, spider, veils, a ring, and a spot or multiple spots that move with the eye movements.

Flashes

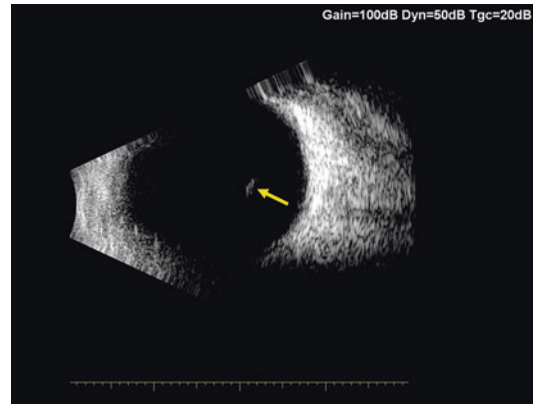
Photopsia or "lightning flashes," another distinguished clinical symptom of PVD, are described as "a light from non-photic stimulation or a flash-like appearance of the lights," which lasts typically a second at a time, usually vertical, and almost always in the temporal periphery of their visual field (Williamson and Williamson 2013). Their exact pathogenesis is obscure but thought to be resulted from either traction or impact exerted by the vitreous onto the retina. The traction retina existing upon the vitreoretinal interface during PVD can lead to sight-threatening complications (Table 1), such as retinal breaks, retinal detachments, and hemorrhages called anomalous PVD. Patients who experience symptomatic PVD have a 10% risk of retinal tears, which should be kept in mind by every health practitioner. Flashes from PVD may diminish in a few months with the relief of traction but may not vanish completely.

Signs

Complete PVD can be diagnosed by examining the eye with a 90-diopter lens as the detection of a Weiss ring (Fig. 1). Although the ring is often incomplete and absent in 13% of PVD (Akiba



Posterior Vitreous Detachment, Fig. 1 A Weiss ring (*yellow arrow*) in the posterior vitreous cortex following PVD in front of the optic disk (color fundus image) (Color fundus image was taken from a PVD patient and provide by Dr. Jacey Hongjie Ma.)



Posterior Vitreous Detachment, Fig. 2 Ultrasound B-scan of a posterior vitreous detachment showing a Weiss ring (*yellow arrow*) (Ultrasound B-scan was taken from a PVD patient and provide by Dr. Jacey Hongjie Ma.)

et al. 2001; Kakehashi et al. 1998), the posterior hyaloid membrane can be seen in these patients and an optically clear space, behind the membrane, suggesting the absent of the vitreous. Though in complete PVD, the vitreoretinal adhesion at the peripheral part of the retina, around the ora serrata, persistently exists. This adhesion is the reason of the formation of retinal tear usually within the first 6 weeks after onset of symptoms. Retinal tears are complicated in 10% of symptomatic PVD (van Overdam et al. 2001).

Another important sign of PVD, named Shafer's sign, can be observed as some pigment granules in anterior vitreous, owning to the retinal pigment epithelial (RPE) cells released through the retinal tear. The existence of Shafer's sign indicates the presence of a retinal tear from PVD (Tanner et al. 2000; Dayan et al. 1996; Byer 1994; Brod et al. 1991).

Besides Shafer's sign, vitreous hemorrhage should also raise suspicion of pathology. Though red blood cells are more difficult to be seen than RPE cells in the vitreous, 50% of patients with RBCs in the vitreous are having retinal tears (Williamson and Williamson 2013). Once RBCs are indicated, retinal tear should be examined carefully. If vitreous hemorrhage is severe and the retina is hard to be visualized, the B-scan ultrasonography should be taken, and a pars plana vitrectomy (PPV) may be chosen to remove the hemorrhage and fix the break when necessary.

Diagnosis

The diagnosis is mainly made after a careful clinical examination with a 90-diopter lens, and different imaging modalities aid with better performance in diagnosing, categorizing, and assessing the insult. B-scan ultrasonography is an established and helpful method to detect and characterize PVD (Fig. 2) and other possible complications such as vitreous hemorrhage, vitreous macular traction, and retinal detachment, which can be easily imaged by B-scan ultrasound when the posterior vitreous cortex is separated from the retina.

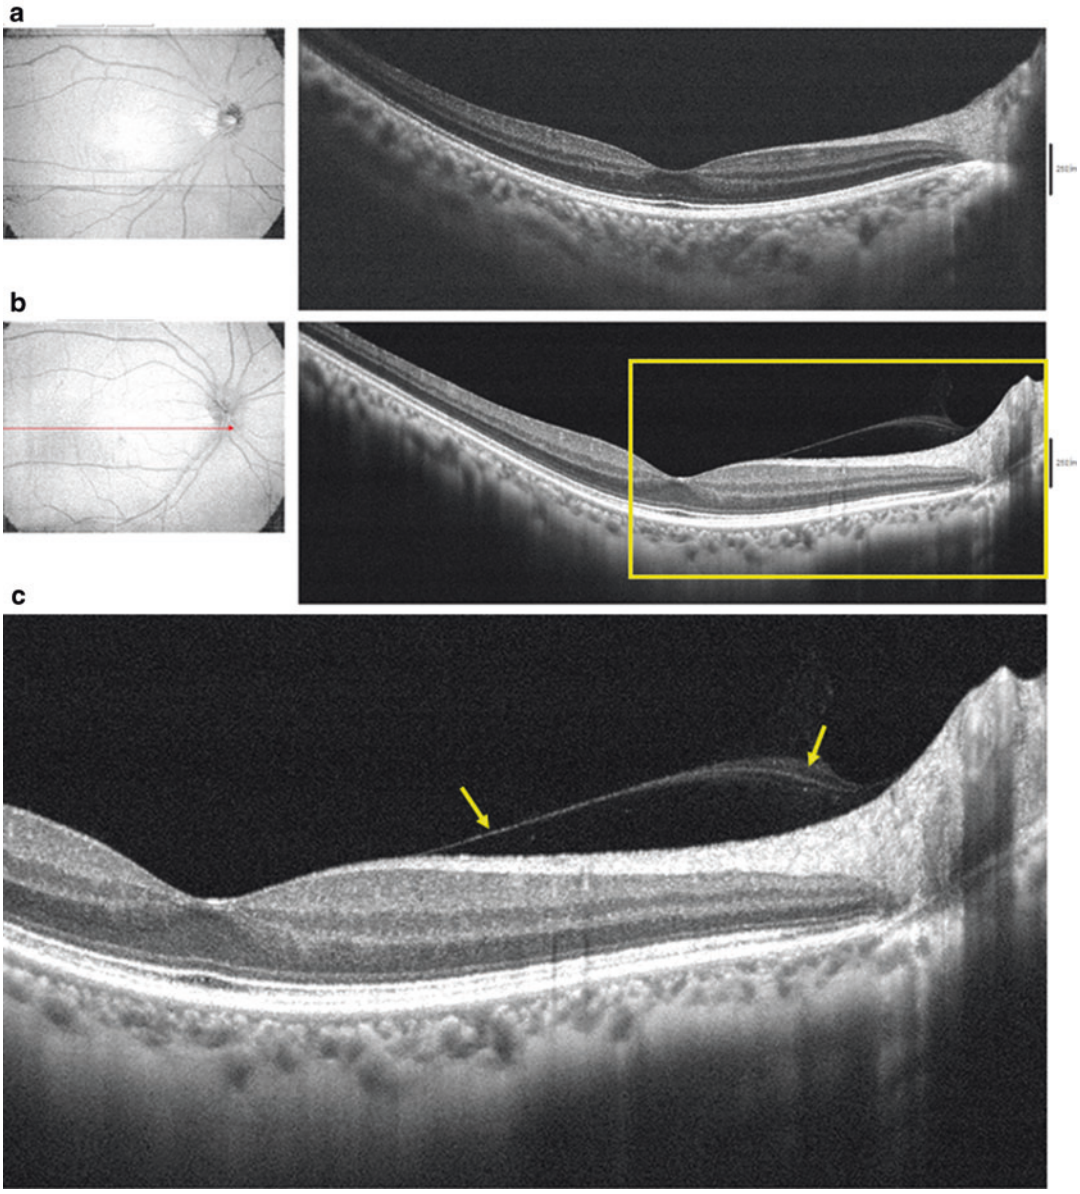
Newly developed optical coherence tomography technologies, such as spectral domain OCT (SD-OCT) and swept source OCT (SS-OCT), provide a detailed delineation of the posterior vitreous cortex, the inner limiting membrane (ILM), and the contour of macular and optic nerve (Fig. 3a), which often demonstrates a hyper-reflective line completely separating or partially adhering to the neurosensory retina from the vitreous (Fig. 3b, c).

Differential Diagnosis

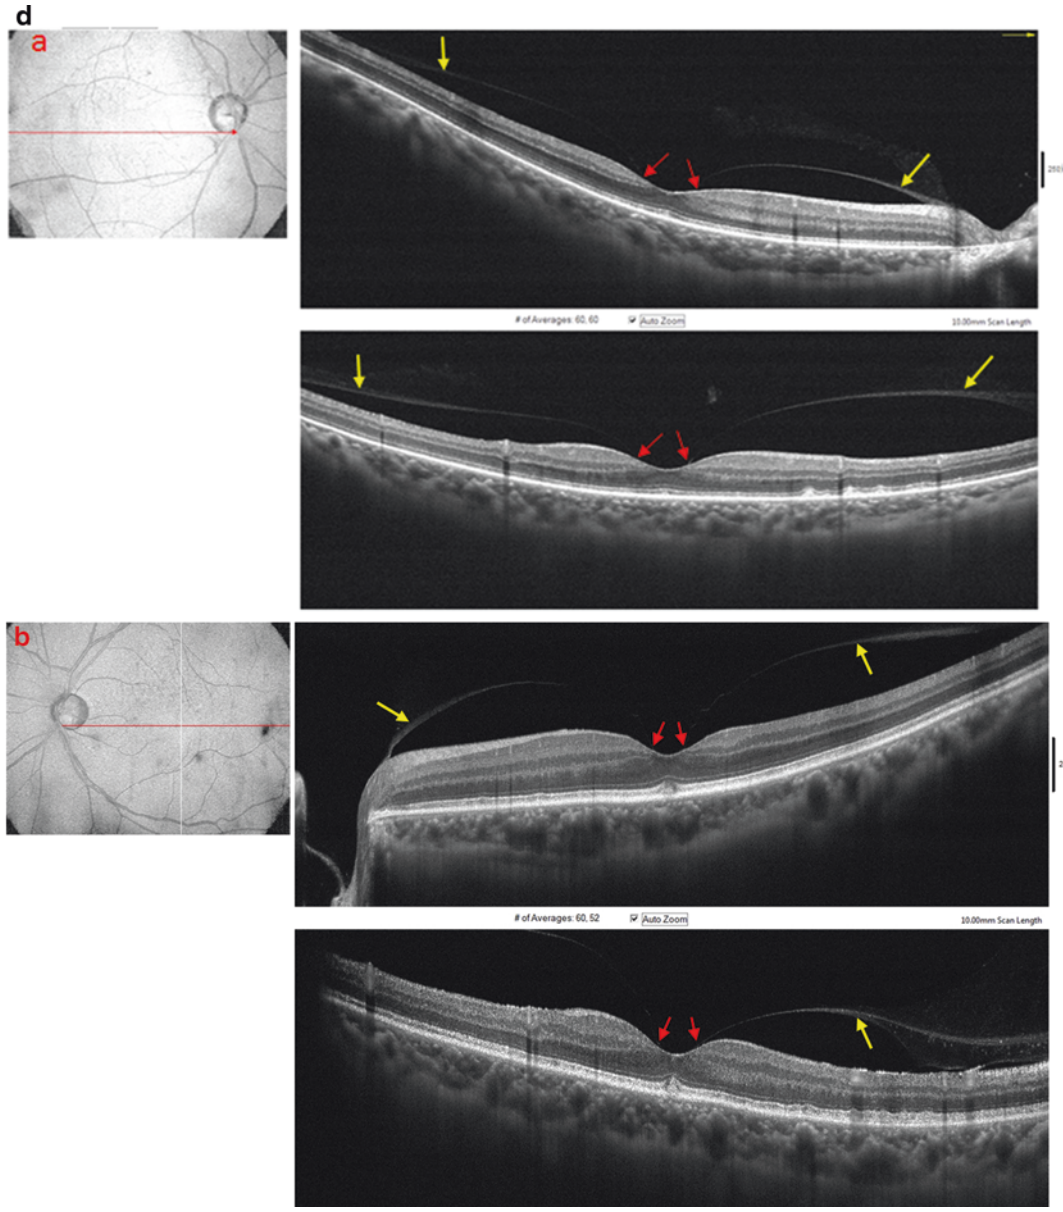
PVD should be discriminated from those diseases such as vitreous opacity, retinal detachment, zigzag lights of migraine, and flickering stars associated with occipital ischemia which have similar symptoms (floaters and lighting flashes). With the help of imaging modality aids, it can be easily discriminated.

Prophylaxis

Since the high incidence of retinal tears and macular disorders in symptomatic PVD, called anomalous PVD, may develop into sight-threatening diseases, such as rhegmatogenous retinal detachment, macular pucker, and macular hole, it should be taken seriously and checked intensively. The main prevention procedure is to examine the



Posterior Vitreous Detachment, Fig. 3 (continued)



Posterior Vitreous Detachment, Fig. 3 (**a**) SD-OCT image is showing normal interface between the vitreous and retina without PVD; (**b**) partial separation of the vitreous from internal limiting membrane. (**c**) Enlarge image of the yellow frame in (**b**) is showing the separation of the vitreous from internal limiting membrane (*yellow arrows*). (**d**) OCT images of a patient suffering PVD in both eyes (**a** right eye, **b** left eye). Posterior vitreous was separated from the retina (*yellow arrows*) except the macular fovea (*red arrows*) (SD-OCT images were provide by Dr. Jacey Hongjie Ma.)

complications of anomalous PVD, carefully, timely, and follow up regularly with a 90-D lens through a dilated pupil, especially in the cases with higher risks such as proliferative diabetic retinopathy, myopia.

Therapy

Though complete PVD, exempt from retinal tears or macular disorder, is clinically innocuous, routinely follow-up is recommended. In the cases

with visual disturbance caused by floaters, it can receive modern vitreolysis, also known as floater laser treatment. Vitreolysis is a noninvasive, pain-free procedure that can eliminate the opacity vitreous fibers or Weiss ring by YAG laser.

Anomalous PVD is usually accompanied by various complications, including retinal tears, retinal detachment, macular disorders, and the underlying diseases; therefore, further attention and appropriate treatment should be given when confronting those diseases.

Prognosis

For complete PVD which is usually caused by aging and is clinically innocuous, the prognosis is benign, while for anomalous PVD, visual acuity prognosis is often according to the extent of the complication and relies on the timely and appropriate intervention.

Postherpetic Neuralgia

Amit Sangave
Department of Ophthalmology, U Rochester, Rochester, NY, USA
Flaum Eye Institute, University of Rochester, Rochester, NY, USA

Synonyms

Nerve pain; Shingles

Definition

Postherpetic neuralgia (PHN) refers to pain, as well as associated itching and irritation, following acute herpes zoster infection. Reactivation of latent varicella zoster virus, which lies dormant in sensory ganglia, is the cause of herpes zoster.

This reactivation happens in about 30% of people over a lifetime. Of those with reactivation, a significant minority – roughly 10–20% – suffers from PHN. Resultant viral nerve damage, to both central and peripheral nervous systems, is thought to be the cause of PHN. More specifically, the generation of spontaneous neuronal discharges coupled with decreased activation threshold produces pain signals out of proportion to common stimuli. Symptoms localize to the skin and nerves affected by the herpes zoster rash. These can include burning, aching, or electric-shock-like pain. A spectrum of presentation is also common, ranging from mild dysesthesia to excruciating allodynia. The ophthalmic division of the trigeminal nerve is commonly involved. Other common areas of involvement are the thoracic, cervical, and lumbosacral dermatomes.

A precise definition of PHN is not agreed upon in the literature. In some clinical studies, a diagnosis of PHN is made 3 months after resolution of skin rash though other studies cite 120 days as the defining criterion. In practice, this definition is applied less conservatively and can be anywhere from 1 to 4 months after resolution of zoster. Additionally, it should also be noted that PHN can occur in the absence of rash (zoster sine herpete), making diagnosis even more difficult in some cases. At 1 month after the skin rash resolves, roughly 10% of patients have PHN.

Risk factors include increasing age, severe pain with initial infection, immunosuppression, and severe prodrome. Patients greater than 80 years of age carry a 35% risk of developing PHN as compared to a 20% risk for patients over the age of 50. PHN in those less than 50 years of age is rare – about 2%.

Due to the complex nature of this condition and an incomplete understanding of its pathophysiology, there are a wide variety of treatments that are available. First-line agents that have been shown to be effective include GABA agents and tricyclic antidepressants. Topical preparations such as 5% lidocaine are also reported to ease PHN. Furthermore, there are several other classes of drugs, like serotonin-norepinephrine uptake inhibitors and antiepileptic agents, which are the focus of investigation today. It is also interesting to note that, if given in the first 72 h of rash development, both antivirals and amitriptyline have been shown to decrease the intensity and duration of PHN probably secondary to the neuroprotective benefits they confer. Studies have shown that PHN has significant detrimental effects on quality of life including increases in insomnia, depression, fatigue, and cognitive impairment. Significant economic impact is another sequela of PHN given its effects on upwards of 2,000 individuals per year in the United States. A vaccine for herpes zoster is currently available and has been effective in reducing the burden of herpes zoster and in turn PHN. Fortunately, though no cure exists, symptoms associated with PHN often fade over time.

Potential Acuity Meter

Oliver K. Klaproth and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Purpose

The marco Guyten-Minkowski potential acuity meter (PAM) projects an eye chart directly on

the retina and bypasses the cataract. This allows the examiner to test for visual acuity without interference from the cloudy lens (Minkowski et al. 1983).

Principle

Mounted on a slit lamp, the PAM projects a Snellen visual acuity chart into the eye via a narrow beam of light converging to a minute aerial aperture of 0.1 mm in diameter. The examiner aims the narrow beam through "windows" in the cataract, avoiding blockage or scattering of the light that would otherwise occur. Without diffraction from the edges of the aperture or loss of illumination, this allows for determination of retinal acuity (Minkowski et al. 1983).

The potential acuity meter (PAM) must not be mixed up with a retinometer (Visometer), which uses interference for projection of sinusoidal patterns o the retina, while the PAM projects an image of, e.g., a Snellen letter or number chart on the retina (Faulkner 1983; Reid et al. 2007). Current models of both devices, however, seem to provide the same quality of results, if used properly (Reid et al. 2007).

Indication

The PAM is used for fast estimation of potential postoperative visual acuity, when classical visual acuity testing due to a blurred lens (e.g., in cataract) is not possible. It can furthermore be used for fast visual acuity screening without refraction in vitreoretinal, retinal vascular, or neurophthalmic patients as well as in patients with large and/or irregular refractive errors.

Contraindication

Some limitations that may cause more tedious testing or even may make testing impossible are: poor pupillary dilation, dense media (finger counting), poor patient posture, communications problem, alphabet illiteracy, nystagmus, senility, or fatigue.

Advantage/Disadvantage

The major advantage of the PAM is the option to measure visual acuity in dense, though not intransparent, optical media. However, optical distorsions caused by, e.g., irregular corneal astigmatism (keratoconus) remain undetected, if no additional corneal diagnostic is performed. PAM measurements of visual acuity should thus always be performed in combination with slit-lamp imaging and corneal topography to exclude other causes of potential postoperative visual acuity impairment.

Precorneal Tear Film

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Synonyms

Lacus lacrimalis; Tear lake; Tear meniscus

(These terms refer specifically to the collection of tears at the lower lid – globe interface.)

Definition

Layer of tears overlying the cornea and ocular surface.

Structure

The tear film was traditionally conceptualized as having three discrete layers: a mucin layer, an aqueous layer, and an outer lipid layer. It has subsequently become clear that the constituents of the tear film interact more dynamically, but it is still useful to discuss the structure and function of these layers individually (Colby 2006).

The innermost layer abutting the cornea is formed of high molecular weight glycoproteins known as mucins. Some of these are bound to the outer microvilli-laden surface of the epithelial cells. The secreted mucins, which also interact with the aqueous phase of the tear film, easily slide over their membrane-bound counterparts due to electrostatic repulsion. The majority of mucins are produced and secreted by conjunctival goblet cells, but the lacrimal gland and squamous epithelial cells may generate some as well. The aqueous layer of the tear film contains water, electrolytes, proteins such as albumin, growth factors, immunoglobulins, and antimicrobial molecules such as lysozyme and lactoferrin. Lipid secretions from the meibomian glands, as well as the glands of Zeiss and Moll, constitute the outer oily layer of the tear film.

Function

The integrity of the tear film is critical to creating a clear refractive surface as well as to protecting the cornea from dessication, breakdown, and infection. It is constantly replenished, and the dynamic flow from the lacrimal gland to the drainage system serves to clear foreign materials, inflammatory mediators, and microbes.

Mucins facilitate interactions between hydrophobic cell membrane components and the aqueous phase, as well as help to bind and clear debris. Electrolytes in the tear film serve to buffer the pH and to create a favorable environment for the epithelial cells. Growth factors and cytokines are critical to promoting epithelial cell turnover and migration. Immunoglobulins and other antimicrobial molecules are an important component of the host defenses. The lipid layer protects against rapid evaporation of the tear film.

Clinical Relevance

The tear film is adversely affected in a variety of dry eye conditions, which are broadly categorized as either aqueous tear deficiency (ATD) or evaporative tear deficiency (ETD), although the two frequently overlap (Peng et al. 2014). Aqueous tear deficiency is further subdivided into Sjögren's- and non-Sjögren's-related groups.

Schirmer tests have traditionally been used to measure aqueous tear production and can be performed with our without anesthesia. Vital dyes such as fluorescein, lissamine green, and rose bengal are often used to assess the tear film and ocular surface. In addition to highlighting epithelial defects or areas of punctate keratopathy, fluorescein is useful for assessing tear breakup time (TBUT) and for approximating the height of the tear meniscus (Chen et al. 2010).

More recently, techniques such as tear osmolarity measurement, interferometry, and high-resolution optical coherence tomography (OCT) have gained popularity for quantitative assessments of the tear film (Hosaka et al. 2011; Werkmeister et al. 2013).

Presbyopia

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Presbyopia is the loss of the accommodating ability of the eye that occurs with advancing age.

Course

The loss of accommodative ability begins at a young age. At the age of 35 years already two thirds of the accommodative amplitude has been lost. At 60 years of age, the ability for accommodative change in the dioptric power of the eye has completely disappeared (Duane 1912).

Possible Causes

Accommodation is effected by a change in shape of the crystalline lens. Therefore, it is conceivable that presbyopia is caused by hardening of the lens substance. This means that with advancing age the

ciliary muscle action occurring with an accommodative effort is not accompanied by the corresponding changes in lens power. Experimental studies in vitro found that the ability of the human crystalline lens to change its shape under the influence of mechanical stretching diminishes continuously with advancing age up to the age of 60 years. After that no change occurs at all (Glasser and Campbell 1998). Corresponding to these results are other studies showing evidence for progressive hardening of the lens substance with age (Weeber et al. 2007). The lens capsule, on the other hand seems to keep most of its elasticity even into advanced age. The insertion of the anterior zonule near the lens equator shifts anteriorly with advancing age while the distance to their origin at the ciliary body remains constant. This could in connection with the increasing thickness of the lens play a role in the development of presbyopia. The loss of elasticity of the posterior tendons of the ciliary muscle as well as the age-related degeneration of muscle and nerve fibers with consecutive changes in ciliary muscle configuration could as well potentially contribute to the age-related loss of accommodation. Several studies show a decrease of the ciliary muscle ring diameter and the movement of the muscle with accommodation. There are also existing hypotheses that the vitreous body has a stabilizing effect on the lens during accommodation and that the age-related liquefaction of the vitreous is a contributing factor to the loss of accommodation.

Lenticular and ciliary origins of presbyopia are not mutually exclusive. Most probably presbyopia has multifactorial causes, but so far the hardening of the lens substance seems to play the most important role among the factors responsible for the age-related loss of accommodation (Glasser et al. 2003).

Primary Angle Closure and Angle Closure Glaucoma

Cornelia Hirn
Eye Clinic, City Hospital Triemli, Zurich, Switzerland

Synonyms

Narrow angle glaucoma; Narrow drainage angle

Definition

Primary angle closure is defined by iridotrabecular contact in eyes with an anatomic predisposition but no further pathology causing narrow angle or peripheral anterior synechiae (PAS).

In primary angle closure, elevated intraocular pressure (IOP) or PAS are present, but no evidence for glaucomatous optic neuropathy (GON) is seen. Features indicating that trabecular obstruction by the peripheral iris has occurred, as well as symptoms suggestive of episodes of primary ▶ acute angle closure, may be found.

The term primary ▶ angle closure glaucoma is used if GON is present, although elevation of IOP or PAS may be absent at the time of initial examination.

Primary ▶ acute angle closure is defined by an excessive rise of IOP with acute symptoms, whereas intermittent primary angle closure is a condition in which ▶ angle closure occurs with abortive symptomatic.

Chronic primary angle closure is defined as synechial closure (▶ angle closure), usually without typical clinical symptoms, unless severe GON is present.

Etiology

Relative pupillary block is considered to be the most common underlying cause of primary angle closure and angle closure glaucoma. Due to an anatomic predisposition, trans-pupillary aqueous flow resistance is increased, followed by forward bowing of the peripheral iris and iridotrabecular contact with occlusion of the anterior chamber angle. Lens-block mechanisms, where changes of the crystalline lens with age, as increasing thickness and forward movement, result in increased iridolenticular contact with increased trans-pupillary aqueous flow resistance, may contribute to this phenomenon.

In ▶ acute angle closure, circumferential apposition of the iris to the trabecular meshwork causes rapid and excessive increase in IOP.

In contrast, in intermittent angle closure, clinical symptoms are milder as the iridotrabecular apposition is transient and resolves spontaneously.

Chronic angle closure may develop after an acute attack in which synechial closure persists or may also develop when the chamber angle closes gradually with slow formation of PAS, which advance circumferentially. In such creeping ▶ angle closure, multiple mechanisms are suspected to be involved, including pupillary block and ▶ plateau iris.

Clinical Presentation

▶ Acute primary angle closure presents with unilateral ocular pain and headache, red eye, mild dilated and non-reactive pupil, iris bombé, photophobia, decreased or blurred vision and halos, disc edema, and splinter hemorrhages, but also with nausea and vomiting, and occasionally abdominal cramps and palpitations.

Typically, patients who develop primary angle closure have symmetric small, "crowded" anterior segments, a shallow anterior chamber, and short axial lengths. Hyperopia may also be present. Asymmetry of anterior chamber depth is highly suspicious of secondary angle closure.

Intermittent or subacute angle closure is characterized by recurrent episodes of blurred vision, halos, and mild pain due to elevated IOP. In contrast to acute angle closure, these symptoms resolve spontaneously – often during sleep – and can therefore be misinterpreted as headache or migraine. Between episodes, the IOP may be normal. Otherwise, there may be signs of previous

attacks including a permanently fixed, mid-dilated pupil, sector iris atrophy, pigmentary dusting of the corneal endothelium, anterior subcapsular lens opacities (so-called glaukomflecken), PAS, and manifest GON.

Intermittent angle closure may also progress to chronic angle closure.

Chronic angle closure is typically asymptomatic. In the course of disease, mild to moderate elevation of IOP results in GON and corresponding visual field defects.

Diagnosis

▶ Angle closure is diagnosed on gonioscopy, preferably by dynamic gonioscopy to distinguish between appositional angle closure and peripheral synechiae.

In primary angle closure, gonioscopy reveals a narrow anterior chamber angle in both the affected and fellow eye; a significant difference in anterior chamber depth is suggestive of ▶ secondary angle closure glaucoma.

In chronic angle closure, dynamic gonioscopy may reveal PAS in patients with modest elevation of IOP and GON.

▶ Ultrasound of the anterior segment may reveal additional structural changes of the peripheral iris or ciliary body.

Tonometry reveals elevated IOP.

Biomicroscopy with accurate assessment of the anterior chamber as well as the posterior segment is mandatory in classifying the various forms of angle closure and angle closure glaucoma. Previous ocular and medical history, family history as well as subjective symptoms should be inquired to exclude or confirm previous attacks in case of acute or intermittent angle closure.

▶ Visual field examination, retinal nerve fiber layer assessment, and optic disc imaging should be performed to assess the stage of disease.

Differential Diagnosis

For differential diagnosis, consider any secondary angle closure with elevated IOP, either neovascular glaucoma, ▶ uveitic glaucoma, ▶ lens-induced angle closure, and angle closure due to aqueous misdirection (▶ malignant glaucoma) or to choroidal pathologies (e.g., ▶ uveal effusion).

Also consider any ▶ secondary open-angle glaucoma with acute rise of IOP like inflammatory, ▶ corticosteroid glaucoma, ▶ Posner-Schlossman syndrome, ▶ pseudoexfoliative glaucoma, ▶ pigmentary glaucoma, ▶ ghost cell glaucoma, ▶ phacolytic glaucoma, or open-angle glaucoma due to intraocular malignant tumors.

Prophylaxis

There is clear evidence for prophylactic treatment in fellow eyes of acute angle closure.

Therapy

Therapy of primary angle closure and angle closure glaucoma depends on the clinical presentation and stage of disease.

In acute primary angle closure, medical treatment includes mild topical ▶ miotic agents; topical hypotensive medication like ▶ beta-blocker, alpha agonists, and ▶ prostaglandin analogues; topical steroids to prevent PAS formation; and systemic aqueous humor suppressants, either ▶ carbonic anhydrase inhibitors or hyperosmotic agents. Indentation of the cornea may open the anterior chamber angle by shifting the fluid in the anterior chamber into the periphery.

The definitive treatment for acute primary angle closure is iridectomy either laser or surgical. In some cases, peripheral laser iridoplasty may be necessary prior to iridectomy to flatten the peripheral iris.

Another approach is surgical lens extraction, especially in cases where a lens-block mechanism is involved.

In intermittent and chronic angle closure, a laser iridotomy may relieve a pupillary block component and reduce the risk of further permanent synechiae. Nevertheless, the disease may progress, and long-term use of topical hypotensive medication or even filtering surgery may be indicated to lower IOP.

Prognosis

Angle closure glaucoma accounts for 50% of all glaucoma blindness worldwide and is probably the most visually destructive form of glaucoma.

Besides the above-described mechanism of direct obstruction, often with rapidly developing peripheral anterior synechiae, primary angle closure may impair aqueous outflow also by causing irreversible degeneration and damage of the trabecular meshwork during phases of raised IOP.

After an acute attack, IOP may be lowered due to reduced aqueous humor production after ischemia of the ciliary body. Therefore, repeated gonioscopy is mandatory to confirm a persistent open angle.

There is a 40–80% risk of acute angle closure in the fellow eye.

Prognosis for intermittent and chronic primary angle closure depends on the extent of optic nerve damage and subsequent IOP control.

Epidemiology

Primary angle closure is rare in individuals younger than 40, and the prevalence increases with each decade after 40 years of age. It is 2–4 times more common in women than men. The prevalence of primary angle closure in patients older than age 40 varies depending on ethnicity and is highest in Inuit with 2.1–5.0%, followed by East Asians (0.3–1.4%) and Japanese (0.3%), whereas it is only 0.1–0.6% and 0.1–0.2% in Caucasian and black populations, respectively. The prevalence is also increased in first-degree relatives of patients with primary angle closure, with the highest relative risk in Chinese, followed by Inuit.

Caucasians present more commonly with acute forms, whereas Africans and Asians present more frequently with asymptomatic chronic disease. Chronic open-angle glaucoma is the major cause of irreversible blindness in Asia.

Primary Color Vision Deficiency

Ido Perlman and Shadi Safuri
Ruth and Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel

Synonyms

Inherited color vision disorders; Inherited dyschromatopsia

Definition

Normal color vision in human observers is trichromatic, depending upon three populations of cone photoreceptors, each containing a visual pigment with a different absorption spectrum. Primary inherited color vision deficiency arises from mutation in one or more of the genes coding the three types of cone visual pigments. There are several characteristics typical to primary inherited color vision deficiency which separate it from acquired color deficiency: (i) the color vision defect is present from birth and does not change with age, (ii) it is symmetrical in the two eyes, (iii) it is well defined by the commonly used color vision tests, and (iv) in most cases, there is no additional retinal involvement.

Structure

Primary inherited color vision deficiency arises from a mutation in one or more of the genes coding the protein part of the cone visual pigments. There are three genes involved; two of them, the genes coding the long-wavelength and the medium-wavelength visual pigments, are located on the X chromosome (L-gene and M-gene, respectively) and are arranged in a head-to-tail tandem. The short-wavelength visual pigment is coded by the S-gene, located on chromosome 7.

On the X chromosome, a single L-gene is followed by one or more M-genes. The number of M-genes is polymorphic; approximately 25% of male Caucasians have a single M-gene, 50% have two M-genes, and the remainders have three or more M-genes. Regardless of the number of M-genes, only the first two genes coding visual pigments are expressed (L-gene and M-gene).

The L-cone opsin gene and M-cone opsin gene contain six exons, which are highly homologous and share 96% amino acid identity, while their homology to the S-cone opsin gene and to the rod opsin gene is approximately 40%. Due to their proximity and high similarity of their sequences, the genes coding for the L-cone opsin and the M-cone opsin are highly subject to unequal recombination resulting in chimera (hybrid) genes. When one of the first two cone opsin genes on the X chromosome is a chimeric gene, color deficiency in the red-green part of the spectrum is present. A color vision disorder in the blue region of the spectrum requires mutation in the S-cone opsin gene located on chromosome 7. Mutations in the S-cone genes are transmitted by autosomal dominant inheritance mode, characterized by either complete penetrance, or almost complete penetrance or incomplete penetrance depending upon the exact mutation.

The majority of patients with inherited color vision defects suffer from absence or abnormality in one or both of the cone opsin genes on the X chromosome, leading to inactive or abnormal light absorption by the corresponding cones. Therefore, color vision disorders in the red-green part of the visible spectrum are more prevalent in males than in females. A total of about 8% in males and 0.01% in females suffer from red-green color vision deficiency. Color vision deficiencies in the blue part of the spectrum is equally divided between males and females and are rare, appearing in about 1 out of 10,000 of the population.

Function

Trichromatic color vision means that a mixture of three primary colors can reproduce any color. When color vision is tested in the laboratory, the subject is seated in front of a colorimeter and observes a bipartite visual field. One half contains a monochromatic light of any wavelength within the visible range (400–700 nm) having a fixed intensity, while the other half contains a mixture of three primaries (e.g., 450 nm, 540 nm, and 600 nm for blue, green, and red primaries, respectively). The observer is instructed to adjust the intensities of the three primaries (one of them can be moved, if needed, to the other half of the field), until the two halves of the field appear indistinguishable from one another. This is called metameric color matching. An observer with normal color vision (trichromatic) needs to adjust the intensity of all three primaries in order to reach a

metameric color match, and the relationships between the intensities of the three primaries is remarkably similar between observers with normal trichromatic color vision. Metameric color matching means that the total numbers of photons absorbed by the L-cones, by the M-cone, and by the S-cones are identical in both sides of the visual target. Therefore, metameric color matching depends only upon the spectral properties for light absorption by the cone visual pigments, and not upon the relative number of L-cones to M-cones to S-cones. Patients suspected of suffering from primary inherited color vision deficiency are tested on the colorimeter in order to define their type of color vision defect. There are three major types of inherited color vision defects:

i. *Anomalous trichromacy*: The anomalous trichromats need to adjust the intensities of the three primaries in order to obtain a metameric match to any test wavelength, but their match differs from that of the normal trichromat. If the long-wavelength pigment differs from the normal one (protanomaly), the patient will need a different intensity for the red primary for a match compared to the normal observer. The deuteranomalous, whose medium-wavelength cone visual pigment differs slightly from that of the normal one, will need a different intensity of the green primary for a match, and the tritanomalous will need a different intensity for the blue primary to achieve a metameric color match compared to the normal trichromat. In general, the anomalous trichromat will not accept the color match of a normal trichromat, and a normal trichromat will not accept the color match of the anomalous trichromat.

   These patients have three functional cone opsin genes, but one of them differs and codes an abnormal cone opsin. Chimeric visual pigments genes in the X chromosome are associated with two types of anomalous trichromacy, deuteranomaly, and protanomaly. Thus, if the first gene is a normal L-cone gene, and the second is an L-chimeric gene, coding for a visual pigment that differ slightly in peak absorption from the normal L-cone gene, the individual will be a deuteranomalous. In contrast, when the L-cone gene is missing and the first two genes code a normal M-cone gene and a chimeric one that codes for an M-cone gene, having different peak absorptions than the normal M-cone gene, the individual will be a protanomalous. The degree of anomalous trichromacy in the red-green part of the visible spectrum ranges from very severe to mild depending upon the distance between the peak absorptions of the two existing cone visual pigments, the larger the difference the milder is the defect. In tritanomaly, the visual pigments in L-cones and M-cones are normal, while the absorption spectrum of the S-cone visual pigment differs slightly from that of the normal color vision observer. Protanomaly appears in 1.08% and deuteranomaly in 4.63% of the male population. Tritanomaly is a rare defect appearing in 1 of 10,000 of the general population.

ii. *Dichromacy*: These individuals miss one of the cone visual pigments, but the existing two pigments are normal. Protanopes miss the long-wavelength cone visual pigment, deuteranopes miss the medium-wavelength cone visual pigment, and tritanopes miss the short-wavelength cone visual pigment. These individuals are called dichromats because they need to adjust the intensity of two primaries in order to make a metameric color match to any monochromatic light of fixed intensity. Since they have normal two cone visual pigments, they will accept the color match of a normal trichromat, but the trichromat will not accept the metameric color match of the dichromat because one of the primaries has not been adjusted. Protanopia is present in 1.01% and deuteranopia in 1.27% of the male population, while tritanopia is more rare, appearing in 1 out of 10,000 of the normal population. In fact, because the center of the fovea, to foveola, lacks short-wavelength cones, every individual with normal trichromatic color vision behaves as a tritanope when colored objects illuminate only the foveola.

iii. *Monochromacy*: These are divided into cone monochromats and rod monochromats. Cone

monochromats possess two types of functioning photoreceptors, one spectral type of cones and rods. Rod monochromats contain only one type of functioning photoreceptors, the rod photoreceptors. Cone monochromats can slightly distinguish between colors under mesopic conditions (dusk) when both cones and rods function in parallel and therefore are said to suffer from incomplete achromatopsia. Rod monochromats suffer from complete color blindness and see only shades of gray. Therefore, they are said to suffer from achromatopsia. The big difference between the two types is expressed in daytime vision. Cone monochromats can function under wide range of background luminance, and they are not photophobic. Red-cone monochromats and green-cone monochromats enjoy relatively good visual acuity, while blue-cone monochromats have poor visual acuity because the foveola, the center of the fovea, lack blue cones, and thus there are no functioning cones in the center of the fovea of blue-cone monochromats. Rod monochromats suffer from photophobia, they are "afraid of light" under background conditions, and they have poor visual acuity. Monochromats are very rare; the most prevalent type is the blue-cone monochromat, appearing in about 1 in 100,000 affecting mainly males, since they suffer from mutations in the red-opsin and green-opsin genes located next to each other on the X chromosome. Red-cone monochromats and green-cone monochromats require mutation in one of the cone opsin genes on the X chromosome, and mutation of the blue-opsin gene in both alleles of chromosome 7. This is a very rare situation and some estimate as 1 in 1,000,000 while others believe it is even more rare, 1 in 100,000,000. Rod monochromats, caused by mutations in all three cone opsin genes are very rare, more rare than the red-cone monochromats and the green-cone monochromats. The most common cause of rod monochromatism (achromatopsia) is a mutation in a specific gene that code proteins specific for the phototransduction process of cones and not of rods. Mutations in GNAT2 (the cone transducin), PDE6C (the cone phosphodiesterase), or CNGB3 (the cone cGMP-dependent cationic channels) were found to be associated with achromatopsia, with the latter being the most prevalent one. Individuals, suffering from one of the above mutations, have all three spectral types of cones containing normal visual pigments, but light absorption is not translated to electrical activity, and therefore, there is no visual perception from the cone system. The prevalence of rod monochromatism (achromatopsia) is 1 in 33,000–50,000.

Clinical Relevance

Color vision deficiency may impose a disadvantage when performing visual tasks, requiring distinction between the colors of an object embedded in its background, such as the detection of fruit among foliage. Subjects with red-green color defects complain on difficulties navigating in the color-coded world of Internet; they have difficulties distinguishing traffic lights and also choosing clothing of matching colors. For certain professions where safety of people or quality of products may be affected, specific vocational tests are used to assess for normal color vision. Thus, children with inherited color vision defects need to be discouraged from planning on becoming police officers, sailors, pilots, and more. Young children with inherited color defects may encounter difficulties during their education since colors play an important role as cues during reading or math teaching. The most serious problems arise when color vision disorders are misinterpreted as learning difficulties.

In medical practice, though there is no evidence of adverse outcome, there are reports of physicians misdiagnosing clinical signs such as rashes and jaundice and ophthalmologists confusing blood and pigment on ophthalmoscopy.

Despite these disadvantages, primary color deficiency is maintained at high rate in the population, suggesting it may also confer an advantage. Some evidence suggests that patients suffering from anomalous trichromacy can break

camouflages, which confounds subjects with normal trichromatic color vision.

Primary Congenital Glaucoma

Sarwat Salim
Medical College of Wisconsin, Milwaukee, WI, USA

Definition

Primary congenital glaucoma (PCG) is the most common type of developmental glaucoma in infants and children and results from an isolated abnormality in the filtration angle during gestation in the absence of other ocular anomalies.

Synonyms

Developmental glaucoma; Infantile glaucoma; Isolated trabeculodysgenesis

Etiology

Although it is generally accepted that abnormal development of the anterior chamber angle results in obstruction of aqueous outflow facility and elevated intraocular pressure (IOP), the exact pathogenesis of PCG remains unclear. Initial suggestion of a Barkan's membrane lining the anterior chamber angle recess has not been histopathologically proven. There appears to be a developmental arrest of anterior chamber angle tissues derived from neural crest cells. The high insertion of the ciliary body and iris may compress the underlying trabecular meshwork beams (Anderson 1981). The trabecular beams have also been described to be thickened, affecting aqueous outflow facility. In addition, immaturity of the juxtacanalicular meshwork and underdevelopment of Schlemm's canal have been described.

Epidemiology and Genetics

The incidence varies widely from 1 in 10,000 live births in the United States to about 1 in 1250 live births in Romanian gypsies, with overall incidence increasing with consanguinity. Most cases are sporadic with 10–40% reported to be familial. In familial cases, autosomal recessive inheritance with variable expression is the most common mode of transmission. Several chromosomal loci for PCG have been identified: GLC3A (chromosome 2), GLC3B (chromosome 1), GLC3C (chromosome 14), and GLC3D (14q24). However, only two genes have been identified: cytochrome P4501 subfamily 1B1 (CYP1B1) on the GLC3A locus and latent transforming growth factor beta-binding protein 2 (LTBP2) on the GLC3D locus (Mauri et al. 2016). The CYP1B1 protein is a membrane-bound monomeric monooxygenase that is thought to be involved in the metabolism of a yet-unidentified compound that regulates development of the anterior chamber angle, particularly the trabecular meshwork. Several mutations in CYP1B1 gene have been identified, including point missense, nonsense, frameshift, terminator mutations, deletion, and

insertion with significant heterogeneity (Abdolrahimzadeh et al. 2015). Mutations in one gene, CYP1B1, on locus GLC3A were reported in 87% of familial cases of PCG in contrast to 27% in sporadic cases (Sarfrazi and Stoilov 2000). LTBP2 mutation is rare and has been reported in few families in Pakistan, Iran, and European Gypsies. Autosomal dominant inheritance caused by hypo- and hypermorphic FOXC1 has also been reported (Medina-Trillo et al. 2016).

Clinical Presentation

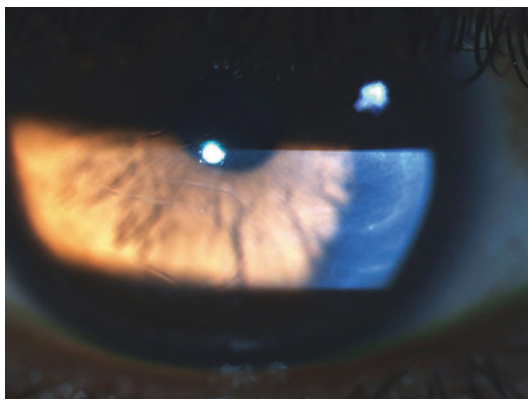
These cases are typically bilateral with male predominance and are usually diagnosed at birth or within the first year of life. The classic symptoms include epiphora, photophobia, and blepharospasm. These symptoms result from horizontal breaks (Fig. 1) in Descemet's membrane (Haab striae) and associated corneal edema, which in turn result from elevated IOP. The distensibility of the neonatal globe results in enlargement of the cornea, sclera, optic nerve, and lamina cribrosa (Allingham et al. 2005). Once buphthalmos develops (Fig. 2), the globe does not return to its normal size with normalization of IOP. The increased axial length results in myopia, which can lead to amblyopia in unilateral and asymmetric cases.

Clinical Examination

Key examination components include vision assessment, tonometry, measurement of central corneal thickness (CCT) and corneal diameter, anterior segment examination (with emphasis on cornea, anterior chamber depth, iris, and pupil), gonioscopy, ophthalmoscopy, ultrasonography, and retinoscopy. The IOP should be measured soon after induction of anesthesia to avoid influence on measurements by various anesthetic agents. Corneal diameter and CCT are usually inversely related. Gonioscopy is critical for both diagnostic and therapeutic decisions. Typical findings include a high iris insertion with limited view of the angle recess, peripheral iris hypoplasia, and thickened and stippled appearance of the trabecular meshwork. In infants and children, the cup enlarges circumferentially with enlargement of the scleral canal, and optic nerve cupping may be reversible.

Differential Diagnosis

Differential diagnoses include nasolacrimal duct obstruction, conjunctivitis, megalocornea, axial myopia, obstetric trauma, corneal opacification from infections and dystrophies, inborn error of metabolism (mucopolysaccharidosis), physiologic optic nerve cupping, optic nerve coloboma, and optic nerve atrophy.



Primary Congenital Glaucoma, Fig. 1 Haab striae – horizontal breaks in Descemet's membrane

Primary Congenital Glaucoma, Fig. 2 Buphthalmos, enlarged globes with megalocornea

Management and Prognosis

PCG is a surgical condition with medical therapy serving as a temporizing measure before surgery or playing an adjunctive role after surgery (Allingham et al. 2005). Beta blockers and carbonic anhydrase inhibitors are generally effective. Alpha agonists should not be used in infants and young children, given reports of bradycardia, apnea, hypothermia, hypotension, and hypotonia. Cholinergic agents may paradoxically increase IOP because of high insertion of the ciliary muscle into the trabecular meshwork. Literature is limited on the use of prostaglandin analogues in infants with better efficacy reported in older children. Angle surgery, either goniotomy or trabeculotomy, creates a direct communication between the anterior chamber, and SC and is reported to be successful in 70–80% of cases in the United States (Salim and Walton 2008), but with lower success rates in developing countries. Other surgical alternatives include trabeculectomy with or without antimetabolites, combined trabeculotomy and trabeculectomy, glaucoma drainage implants, and cyclophotocoagulation for intractable cases with poor visual potential. Associated amblyopia should be aggressively treated. Life-long follow-up is needed, because IOP elevation may recur at any age.

Primary Endothelial Failure, After Penetrating Keratoplasty

Deepak Raja
Department of Ophthalmology, University of Central Florida, College of Medicine, Orlando, FL, USA
Orlando Eye Institute, Orlando, FL, USA

P

Synonyms

Primary graft failure

Definition

Corneal graft edema starting on the first postoperative day which does not clear within 2 months (Mannis et al. 2013).

Etiology

The most common etiology is usually a low endothelial cell count, often from manipulation of the graft during surgery (Wilhelmus et al. 1995). Other causes include postoperative inflammation, hypotony, glaucoma, and vitreous and iris adhesions to the endothelium. For endothelial

keratoplasties, poor adhesion at the graft-host interface is another cause.

Occurrence

Occurs in approximately 1% of graft failures (Mannis et al. 2013).

Classification

For penetrating keratoplasties, primary failure consists of grafts that do not clear postoperatively. For endothelial keratoplasties, they are grafts that do not reattach or never clear postoperatively (Oster et al. 2009). Both present with microcystic edema, often with Descemet's folds. Patients often complain of blurry vision and may have foreign body sensation and photophobia.

Primary Posterior Capsulorhexis

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Primary posterior continuous curvilinear capsulorhexis

Definition

An operative technique in cataract surgery to prevent posterior capsule opacification (PCO). It is based on the theory that by removing the scaffold

for the migration of lens epithelial cells, a permanently clear optical zone can be provided. Primary posterior capsulorhexis can be performed in combination with anterior vitrectomy and is a common procedure in the treatment of congenital cataract. A planned primary posterior capsulorhexis is also useful in removing posterior capsular plaques and can also be attempted when a small posterior capsular rupture occurs to prevent radial extension of the tear.

History

In 1990 Gimbel et al. suggested that a posterior capsulorhexis is useful in three different situations: for the prevention of a posterior capsule tear, in the presence of a posterior capsule plaque, and in infants because the risk of development of a posterior capsule opacification is high. In such cases it is difficult to perform laser. In 1993 Galand et al. began performing a technique of primary posterior capsulorhexis in adult eyes with intact and clear posterior capsules. Recently Menapace used this method combined with optic buttonholing in a large series of patients to prevent posterior capsule opacification with budding results.

Clinical Features

Posterior capsule opacification is a common problem in cataract surgery. The effect of this opacification is a severe decrease in vision acuity. The treatment of posterior opacification is a postoperative neodymium: YAG (Nd:YAG) capsulotomy of which the rate of retinal detachment has been reported from 0.50% to 4.16%. This side effect led to the idea of preventing a posterior capsular opacification by removing a part of the posterior capsule intraoperatively.

Tests

In order to achieve best postoperative results, thorough slit-lamp examination with dilated pupil, Scheimpflug imaging and measurement of uncorrected and best spectacle-corrected visual acuity are essential.

Etiology

See "History" section above.

Differential Diagnosis

Another nonsurgical type of treatment of posterior capsular opacification is:

– Neodymium: YAG (Nd:YAG) capsulotomy

Treatment

At the end of cataract or refractive lens removal, the posterior capsulorhexis can be performed. A layer of sodium hyaluronate (Healon) should be placed on the posterior capsule after which a central opening of the posterior capsule can be performed. Through this opening a generous layer of sodium hyaluronate is injected to separate the posterior capsule of the anterior vitreous. Then a central piece of the capsule can be excised to obtain a posterior capsulorhexis of 3–4 mm in diameter. Sodium hyaluronate can then be used to separate the anterior and posterior capsule and the intraocular lens can be implanted.

PRL Phakic Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Phakic refractive lens; Posterior chamber phakic intraocular lens; PRL

Definition

A phakic IOL that is placed between the iris and the crystalline lens floating freely over the crystalline lens.

Epidemiology

Today, the number of implanted PRLs is not high in relation to the latest anterior chamber phakic IOL model (AcrySof) and the iris-supported phakic IOL models (Artisan/Verisyse and Artiflex/Veriflex) (Güell et al. 2010).

History

Complications from anterior chamber angle-supported implants led to the idea of moving toward the posterior chamber. This location theoretically provided lower incidence of halos and glare as the margins of the pupil cover the border of the optical zones. Additionally, the risk of corneal endothelial damage was also theoretically minimized, due to the greater distance between the implant and the corneal endothelium. One of the first posterior chamber phakic IOL designs, the "collar-button" or "mushroom" configuration, is attributed to Fyodorov in 1986 (Hardten et al. 2003). He developed a one-piece silicone lens, with a 3.2-mm optic and a concave anterior surface that projected anteriorly through the pupil. The lens was fixated behind the iris plane by two haptics and had a total length of 8.0 mm. Initial complications included corneal touch, decentration, pupillary block glaucoma, iridocyclitis, and cataract formation (Kohnen and Koch 2006). Since then, evolution in design and materials has led to the emergence of several different models, including the Adatomed lens. However, cortical opacities and decentration frequently occurred after surgery, and this lens was also withdrawn from the market. Currently, there are only two posterior chamber models available on the market: the "implantable contact lens" (ICL, STAAR Surgical, Monrovia, USA) and the "phakic refractive lens" (PRL, Carl Zeiss Meditec, Jena, Germany).

Clinical Features

The foldable PRL can be used for the correction of myopia and hyperopia and is made of hydrophobic silicone. It has a concave posterior base curve of 10-mm radius that mimics the anterior curvature of the crystalline lens. Central thickness is less than 0.5 mm and is constant for myopic lenses but varies with hyperopic lenses. Edge thickness is always less than 0.2 mm, and it is constant in hyperopic and varies in myopic lenses. There are two models of myopic lenses available: overall diameter of 10.8 mm (PRL 100) and 11.3 mm (PRL 101). Diameter of the optic is 4.5–5.5 mm, depending on the lens power, which ranges from −3.0 to −20.0 D - (maximum correction at the spectacle plane of −28 D). Hyperopic lenses (PRL 200) have an overall diameter of 10.6 mm, a 4.5-mm optic, and power ranges from +3.0 to +15.0 D. Because this type of PIOL lacks fixation, stability of centration and rotation is of concern. Thus, this lens is unsuitable for the correction of astigmatism.

Tests

Anterior chamber depth for PRL implantation must be at least 2.5 mm. Other inclusion criteria for phakic IOL implantation must be considered (see also "► Phakic Intraocular Lens").

Differential Diagnosis

The other posterior chamber phakic IOL is the ICL that is fixated in the ciliary sulcus.

Etiology

Other currently available types of phakic IOLs are anterior chamber angle- (AcrySof) or iris-supported phakic IOLs (Artisan/Verisyse and Artiflex/Veriflex).

Treatment

Implantation procedure for the PRL is almost the same as for the ICL. Two opposed paracentesis ports are created on either side of a 3.2-mm clear cornea incision. The PRL is inserted with a specially designed forceps or with an injector system. As the lens unfolds slowly in the anterior chamber, its haptics initially lie anterior to the dilated iris. Each haptic corner then is gently placed behind the iris through the pupil with a long spatula or an intraocular hook. When proper horizontal lens orientation is verified, a miotic agent is injected. As spontaneous rotation of the PRL may easily occur, two peripheral iridotomies, 90° apart, are mandatory to prevent pupillary block situation.

Steele-Richardson-Olszewski Syndrome

Definition

Progressive supranuclear palsy (PSP) is a neurodegenerative disease characterized by a progressive, bilateral supranuclear ophthalmoplegia and postural instability. The clinical and neuropathological features of this disease were first described in a nine patient study by Steele, Richardson, and Olszewski in 1964. It is considered to be the most common of the atypical Parkinsonian syndromes, which include multiple systems atrophy (MSA) and corticobasal degeneration (CBD).

Etiology

The underlying cause of PSP is unknown, but a combination of genetic, environmental, and inflammatory factors likely contributes. The pathogenesis involves neuronal loss, gliosis, and accumulation of neurofibrillary tangles in various regions of the brain, most commonly the basal ganglia, diencephalon, brainstem, and cerebral cortex. PSP is considered to be a tauopathy, a group of neurodegenerative diseases that includes CBD, Pick disease, frontotemporal dementia, and Alzheimer disease. Tauopathies are defined by the pathological aggregation of tau proteins, which normally function in the central nervous system to stabilize microtubules and facilitate axonal transport. Abnormal phosphorylation of these tau proteins leads to misfolding and subsequent self-aggregation into neurofibrillary tangles. The exact role of neurofibrillary tangles in tauopathies like PSP is still unclear, but in general, they seem to be correlated with disease progression. In PSP, the neurofibrillary tangles are uniquely composed of straight filaments of tau protein, which distinguishes it from other tauopathies.

While PSP is considered to be a sporadic disease, some studies have identified familial aggregations of PSP with autosomal dominant inheritance pattern. Other studies have indicated that certain mutations in the microtubule-associated protein tau gene (MAPT) may be a significant risk factor for the sporadic form of the disease.

Clinical Presentation

Classic PSP is the most common and well-known form of PSP. The most common initial manifestation of classic PSP is gait disturbance, which leads to frequent falls and traumatic injuries. Approximately 69% of patients report mobility issues at

disease onset. Many patients will also develop some kind of personality or cognitive change within 2 years of disease onset. The progressive, supranuclear ophthalmoplegia (the hallmark of PSP) generally develops within 3–4 years of disease onset but can take as long as 10 years. The slowing of vertical saccades is often the first visual manifestation seen in PSP and helps contribute to initial diagnosis. Other prominent features of classic PSP include axial rigidity, dysarthria, dysphagia, and sleep disturbances. In contrast to the more common and often age-related, supranuclear upgaze palsy, a supranuclear downgaze palsy in an older patient is always pathologic and should raise the suspicion for PSP.

Several different clinical subtypes of PSP have been described, including PSP-Parkinsonism (PSP-P), PSP-pure akinesia with gait freezing (PSP-PAGF), and PSP-primary progressive freezing gait (PSP-PPFG). These atypical subtypes of PSP typically do not satisfy all of the diagnostic criteria for classic PSP and have their own unique features. The atypical subtypes of PSP also tend to have a better prognosis than classic PSP.

Diagnostics

The National Institute of Neurological Disorders and Stroke (NINDS) and the society for PSP (SPSP) proposed a set of diagnostic criteria for PSP in 1996, which includes different criteria for "possible, probable, and definite" PSP as well as mandatory exclusion criteria. Important inclusion criteria for PSP include gradually progressive disorder, age of onset greater than 40 years, and vertical supranuclear palsy and/or prominent postural instability within the first year of disease onset. Definitive diagnosis however requires neuropathological examination (although it is generally not performed). Exclusion criteria are designed to rule out iatrogenic, inflammatory, infectious, and structural disease as well as other neurodegenerative diseases that can mimic PSP.

Unfortunately, there are no established laboratory or imaging findings for the diagnosis of PSP. Magnetic resonance imaging (MRI) or computed tomography (CT) of the brain may however demonstrate atrophy of the affected areas, especially the midbrain ("the hummingbird sign"), and may support diagnosis of PSP.

Differential Diagnosis

PSP is most commonly confused with other Parkinsonian disorders. The differential diagnosis of PSP includes idiopathic Parkinson disease, corticobasal degeneration, multiple system atrophy, dementia with Lewy bodies, vascular Parkinsonism, Alzheimer disease, Creutzfeldt-Jakob disease, and central nervous system (CNS) whipple disease.

Therapy

There is currently no effective therapy for PSP.

Prognosis

The prognosis for PSP is quite poor, as median survival from time of diagnosis ranges from 6 to 12 years. Shorter time to certain clinical milestones, including frequent falls, cognitive disability, unintelligible speech, and wheelchair dependence, is associated with poorer prognosis. Patients also experience significant decline in quality of life as the disease progresses, with symptoms like immobility and cognitive impairment being especially debilitating. The atypical PSP syndromes tend to progress slower and have a better prognosis than classic PSP.

Epidemiology

The prevalence of PSP is disputed due to the diagnostic challenges it presents, but studies from the UK in 1999 show rates as high as 6.4 per 100,000. An earlier study from the USA in 1988 demonstrated prevalence of 1.39 per

100,000, but it is believed that the real number is actually higher with the recent discovery of the PSP subtypes. The mean age of onset for PSP is about 62 years old.

Proptosis

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Synonyms

Exophthalmos (when associated with thyroid eye disease)

Definition

Proptosis is defined as the forward protrusion of one or both globes.

Etiology

The most common cause of proptosis is thyroid eye disease. Other causes of proptosis include infection (orbital cellulitis, mucormycosis, concurrent sinus disease), inflammatory disease (orbital inflammatory pseudotumor, posterior scleritis), vasculitis (Wegener's granulomatosis, polyarteritis nodosa), neoplasm (lacrimal, lymphoma, leukemia, meningioma, glioma, rhabdomyosarcoma, metastatic), orbital vascular disease (orbital varix, carotid-cavernous sinus fistula, arteriovenous malformation), and trauma (retrobulbar hemorrhage, orbital or facial fractures).

Occurrence

Proptosis can be diagnosed with exophthalmometry, which measures the distance between the lateral angle of the bony orbit and the cornea. A difference of at least 2 mm between the two eyes of any given patient is considered abnormal. Normal upper limits for proptosis are approximately 22 mm in Caucasians and 24 mm in African-Americans. The amount of proptosis

can also be quantified by measuring globe protrusion on CT scan.

Proptosis occurs in both adults and children at any age. Thyroid orbitopathy and the resultant exophthalmos in 60% of patients show a female preponderance with a female to male ratio of 6:1 and a predilection for middle-aged adults (30–50 years).

Classification

Proptosis can be classified by unilateral or bilateral involvement. The most common cause of unilateral and bilateral proptosis in adults is thyroid eye disease. Most tumors present as unilateral proptosis. However, bilateral orbital involvement from lymphoma, vasculitis, idiopathic orbital inflammatory disease, metastatic tumor, or leukemia can also produce bilateral proptosis. In children, unilateral proptosis is often due to infectious causes, and in bilateral cases, metastatic neuroblastoma, leukemia, or idiopathic orbital inflammatory disease is more likely.

Proptosis can also be classified by axial or nonaxial displacement of the globe. Axial displacement is caused by retrobulbar lesions such as cavernous hemangioma, glioma, meningioma, metastases, and any other mass lesions within the muscle cone. Nonaxial or eccentric displacement is caused by extraconal lesions in which the direction of proptosis is determined by the site of the mass including maxillary sinus tumors, lacrimal gland tumors, and frontoethmoidal mucoceles.

Pseudoaccommodation

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Pseudoaccommodation is a name for optical phenomena which increase the depth of focus and can enable a presbyopic or pseudophakic eye to see in more than one distance without real accommodation, i. e., without a dynamic change in the dioptric power of the eye. Among these optical effects are pupillary constriction, bi- and multifocality, caused e.g., by a multifocal intraocular lens, astigmatism, or higher-order optical aberrations.

Synonyms

PEX; *Pseudoexfoliatio lentis*; PXF

Definition

Elastic microfibrillopathy as an ocular manifestation of a systemic disorder is characterized by the deposition of whitish material on and within the structures of the anterior eye segment and is

frequently associated with severe chronic secondary open-angle glaucoma and cataract.

Histology

The hallmark of PEX syndrome is a pathologic production and accumulation of an abnormal fibrillar extracellular material in the anterior segment tissues. The characteristic PEX fibrils appear to be multifocally produced by various intraocular cell types including the preequatorial lens epithelium, nonpigmented ciliary epithelium, trabecular endothelium, corneal endothelium, vascular endothelial cells, and virtually all cell types of the iris (Naumann et al. 1998). Accordingly, clinical-histopathologic correlations focus on the involvement of the lens, the zonular apparatus, the ciliary body, the iris, the trabecular meshwork, and the cornea.

Immunohistochemistry

Immunohistochemistry shows that zonular disintegration may be facilitated by proteolytic mechanisms of lysosomal enzymes, particularly cathepsin B and metalloproteinases, within the PEX material.

Electron Microscopy

Scanning electron micrograph shows an accumulation of PEX material on the ciliary processes and the zonular fibers in the region of the pars plicata **and** loosened zonular lamella on the anterior lens capsule by accumulation of PEX aggregates. Transmission electron micrograph shows separation of the zonular lamella from the capsular surface by PEX material produced by the lens epithelium and erupting through the capsular surface and rupture of zonular lamella at sites of PEX material infiltration. Electron microscopy of the trabecular meshwork shows that the main deposition of PEX material appears to occur in the juxtacanalicular tissue adjacent to Schlemm's canal. Progressive accumulation of PEX material leads to a swelling of the juxtacanalicular tissue and a marked disorganization of Schlemm's canal architecture (e.g., narrowing of the canal lumen, collapse of the inner and outer walls, disruption of its endothelial lining, fragmentation into smaller channels, and partial obliteration by PEX material and degenerating endothelial cells) in advanced stages (Schlötzer-Schrehardt and Naumann 2006).

Molecular Diagnosis

PEX has a strong familial association. Single nucleotide polymorphisms (SNPs) in exon 1 of the lysyl oxidase-like 1 (LOXL1) gene have been identified as strong genetic risk factors for PEX syndrome and PEX glaucoma. LOXL1 is a pivotal cross-linking enzyme in extracellular matrix metabolism and seems to be required for elastic fiber formation and stabilization. Available data suggest that LOXL1 is differentially regulated dependent on the phase of progression of the fibrotic process. While increased levels of LOXL1 participate in the formation of abnormal PEX fiber aggregates in the initial phase of fibrogenesis, inadequate tissue levels may promote elastotic processes in advanced stages of the disease (Schlötzer-Schrehardt 2009).

Differential Diagnosis

- Pigment dispersion syndrome (PDS) is more often clinically bilateral and more common in young myopic males. PDS displays characteristic peripupillary iris transillumination defects and pigmentation of the chamber angle (Yanoff and Duker 2009).
- Capsular delamination (true exfoliation) is a rare condition that shows splitting of the anterior lens capsule without any deposition of fibrillary material. It may occur after heat exposure, trauma, irradiation, or inflammation (Yanoff and Duker 2009).
- Primary familial amyloidosis is a rare systemic disease with an abnormal deposition of a particular protein, called amyloid, in various

tissues of the body. In the anterior chamber, the disease displays white flocculent material in the pupillary margin and flaky substance on the surface of the lens (Yanoff and Duker 2009).

Pseudoexfoliative Glaucoma

Ursula Schlötzer-Schrehardt
Universität Erlangen-Nürnberg, Augenklinik mit Poliklinik, Erlangen, Germany

Synonyms

Exfoliative glaucoma

Definition

Secondary open-angle glaucoma associated with pseudoexfoliation (PEX) syndrome, a generalized disorder of the extracellular matrix. PEX syndrome has been characterized as a specific elastosis associated with the production and deposition of abnormal fibrillar PEX material deposits within intra- and extraocular tissues.

Etiology

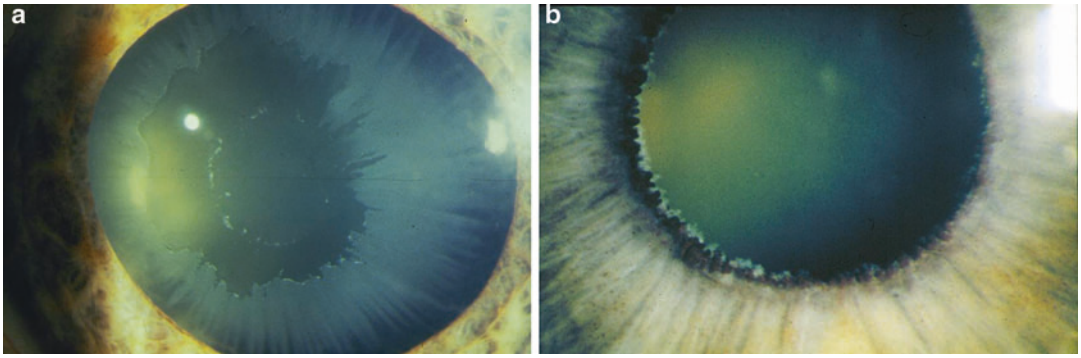
The underlying condition, PEX syndrome, represents a complex, multifactorial, late-onset disease of worldwide significance involving both genetic and nongenetic factors in its etiopathogenesis. Single nucleotide polymorphisms in exon 1 of the lysyl oxidase-like 1 *(LOXL1)* gene, coding for a cross-linking enzyme, have been identified as principal genetic risk factors for PEX syndrome/glaucoma. External factors including oxidative stress, hypoxia, low-grade inflammatory processes, and pro-fibrotic growth factors may act as co-modulating factors.

Clinical Presentation

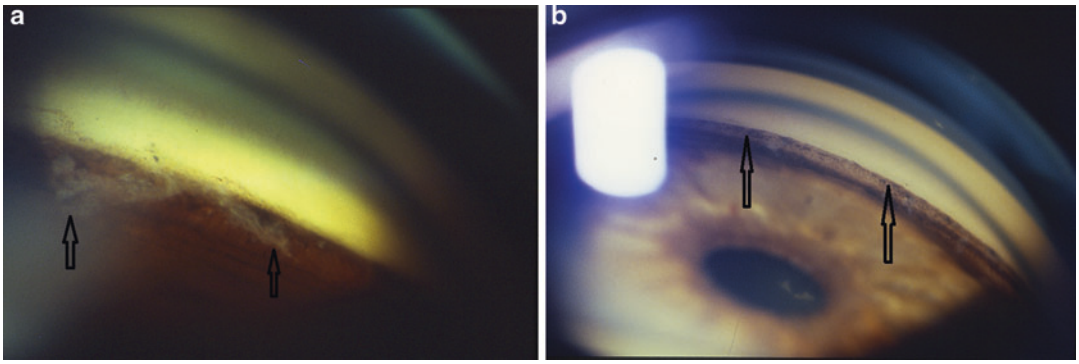
PEX glaucoma typically represents a high-pressure open-angle glaucoma with asymmetric presentation and pronounced chamber angle pigmentation. It is associated with high mean intraocular pressure levels, great diurnal pressure fluctuations and spikes, and rapid rates of progression. Pigment dispersion from the iris pigment epithelium may cause acute pressure rises after pupillary dilation. Narrowed chamber angles and smaller anterior chamber volumes due to a slight anterior movement of the lens may also induce angle-closure glaucoma via a pupillary block mechanism.

Diagnosis

Whitish flake-like deposits of PEX material can be observed on anterior segment structures, particularly on the anterior lens surface and the pupillary margin, occasionally also on the posterior surface of the cornea and on intraocular lens implants, as well as in the chamber angle by gonioscopy. The characteristic target-shaped



Pseudoexfoliative Glaucoma, Fig. 1 Clinical appearance of pseudoexfoliation syndrome. (**a**) Characteristic target-shaped pattern of PEX deposits on the anterior lens surface after pupillary dilation. (**b**) PEX material at the pupillary border



Pseudoexfoliative Glaucoma, Fig. 2 Typical appearance of the chamber angle as viewed by gonioscopy. (**a**) Accumulation of flakes of PEX material (*arrows*). (**b**) Irregular pigmentation (*arrows*) of the trabecular meshwork

pattern of PEX material accumulation on the lens can be only seen after pupillary dilation. PEX material deposition is usually accompanied by ancillary clinical signs, including pigment dispersion, peripupillary atrophy and pupillary ruff defects, pigment deposition on iris sphincter region, corneal endothelium, and trabecular meshwork as well as phacodonesis, iris hemorrhages, posterior synechiae, and insufficient pupillary dilation, particularly if asymmetrically present (Figs. 1 and 2).

Differential Diagnosis

Differential diagnosis of PEX syndrome/glaucoma includes true exfoliation of the lens, pigment dispersion syndrome and pigmentary glaucoma, and primary open-angle glaucoma.

Prophylaxis

Frequent consumption of fruit and vegetables was associated with a reduced risk of PEX syndrome in the Reykjavik eye study, suggesting that antioxidants may be protective against PEX syndrome/glaucoma.

Therapy

Since intraocular pressure is the main risk factor for progression, rigorous reduction and stabilization of

mean and diurnal 24-h intraocular pressure by means of medical, laser, or surgical therapy are crucial. A target IOP of <17 mmHg and lower was shown to prevent or slow progressive damage.

Prognosis

The prognosis of PEX glaucoma is more severe than that of primary open-angle glaucoma. There are greater 24-h pressure fluctuation, greater visual field loss and optic disk damage at the time of detection, poorer response to medications, more rapid progression, greater need for surgical intervention, and greater proportion of blindness.

Epidemiology

PEX syndrome occurs in all geographic regions worldwide with reported prevalence rates averaging about 10–20% of the general population over age 60. In all populations, the frequency rises with increasing age, with its incidence doubling every decade after the age of 50. PEX glaucoma accounts for approximately 20–25% of all open-angle glaucomas.

Pseudoguttatae

▶ Pseudoguttatae: Inflammatory Disease

Pseudoguttatae: Inflammatory Disease

Neema Nayeb-Hashemi
Department of Ophthalmology, Loyola University Medical Center, Maywood, IL, USA

Synonyms

Inflammatory pseudoguttatae; Pseudoguttatae

Definition

Transient, reversible endothelial edema that looks clinically identical to the guttatae classically associated with Fuchs endothelial dystrophy (Zantos and Holden 1981).

Etiology

When inflammatory pseudoguttatae occur, they are typically noticed within hours to days from the onset of anterior segment inflammation. The most common causes include infectious keratitis, iritis, toxins, and thermokeratoplasty, though it has also been described in cases of viral conjunctivitis, trauma, and tight-fitting contact lenses (Zantos and Holden 1977).

Clinical Presentation

Inflammatory pseudoguttatae are visible under direct illumination as regions of focal thickening representing endothelial edema (Krachmer et al. 2011). In specular reflection, these areas appear as enlarged darkened patches with irregular contours against a hyperreflective endothelial mosaic (Nakashima et al. 2007). On occasion fine dustlike particles over the posterior surface of the endothelium can be seen.

Diagnosis

Typically pseudoguttatae can be diagnosed with serial simple slit-lamp examination confirming resolution of endothelial edema after appropriate management of the anterior segment disease. However, specular microscopy can also be useful for confirmation. Specular microscopy can demonstrate enlarged black patches (both discrete and confluent) within the endothelial mosaic. Endothelial cell counts obtained using this technique after the disappearance of pseudoguttatae show no difference from before the onset.

Differential Diagnosis

Transient endothelial blebs consist of increased separation between endothelial cells and circumscribed black zones obscuring the endothelial mosaic which form within minutes of contact lens insertion and resolve within an hour.

Guttatae are excrescences within the Descemet's membrane associated with adjacent endothelial dysfunction or loss. It is the hallmark of Fuchs endothelial dystrophy and are both progressive and irreversible, ultimately leading to stromal edema.

Chandler's syndrome, one of the three manifestations of iridocorneal endothelial (ICE) syndrome, may possibly be confused with corneal guttatae given the beaten-bronze appearance of the endothelium and associated corneal edema; however the endothelial changes are much finer in quality. It also is most common unilaterally, which would mimic pseudoguttatae more than the endothelial dystrophies. This condition, however, is more likely to occur in women, and intraocular pressure tends to be higher due to obstruction of the trabecular meshwork.

Herpetic disciform keratitis often presents with focal endothelial changes appreciable in specular reflection at the slit lamp; however keratic precipitates are often present in the area involvement; in pseudoguttatae, fine endothelial dusting can be seen, but keratic precipitates are not present. Additionally corneal edema is usually much more severe, requiring administration of topical steroids concurrent with antiviral medication.

Prophylaxis

Unclear

Therapy

Pseudoguttatae are treated by addressing the primary cause of inflammation.

Prognosis

Inflammatory pseudoguttatae have an excellent prognosis once the inflammation causing it has resolved.

Epidemiology

Unlike true guttatae which are more commonly seen in women, the limited data from the literature suggests there is no sex-related difference in the incidence of pseudoguttatae. As contact lens-related keratitis has been described as one of the leading causes of pseudoguttatae, the age at which pseudoguttatae is seen is typically much younger than in Fuchs endothelial dystrophy.

Pseudo-Hurler Polydystrophy

Steven Agemy
Department of Ophthalmology, SUNY Downstate Medical Center, Brooklyn, NY, USA

Disease

Pseudo-Hurler polydystrophy, also known as mucolipidosis III (ML III), is a lysosomal storage disease resulting from a deficiency of the enzyme UDP-*N*-acetyl glucosamine *L*-phosphate transferase (C1cNAcPT) (Chen 2006). Symptoms usually appear at 3–5 years of age and are less severe and progress slower than Hurler syndrome. Non-ophthalmic features include no or mild mental retardation, skeletal abnormalities, coarse facial features, and short height (Yannuzzi 2010). Ophthalmic manifestations include corneal clouding, optic nerve head swelling, maculopathy, and retinal vascular tortuosity. Patients often survive beyond the fifth to sixth decade of life (Chen 2006).

Pseudomembrane, Conjunctival

Allen O. Eghrari
Johns Hopkins University School of Medicine, Baltimore, MD, USA
Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Pseudomembranous conjunctivitis

Definition

Pseudomembrane is composed of gray fibrin and inflammatory material and is avascular. Pseudomembranes can be peeled without bleeding due to their deposition on an intact conjunctival epithelium and lack of vascularity, in contrast to true membranes which contain highly concentrated fibrin deposited within conjunctival epithelium and stroma. These are most commonly seen in viral infections, including adenovirus and herpes viruses. However, potential etiologies include bacterial infections such as beta-hemolytic streptococcus, fungal infections including *Candida albicans*, chemical burns, and immunological diseases including ligneous conjunctivitis.

[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Congenitally anomalous disk; Pseudoneuritis

Definition

Normal variant elevation of the optic disk, disk drusen, disk abnormalities, or congenital fullness of the optic nerve without vessel leakage or optic disk edema can mimic papilledema and is referred to as pseudopapilledema.

Etiology

Pseudopapilledema is a familial condition that can be caused by a congenitally narrow scleral canal, myelinated fibers, anomalous disks, or optic disk drusen. Pseudopapilledema in contrast to true papilledema is not caused by elevation in intracranial pressure.

Clinical Presentation

Most patients with pseudopapilledema will not report any visual or systemic symptoms, although visual field defects (e.g., nerve fiber layer defects, enlarged blind spot) are detectable upon examination.

Diagnostics

Pseudopapilledema is sometimes difficult to differentiate from true papilledema (a true swelling of the optic disk). Typically, ophthalmoscopic analysis will reveal a normal color to the optic disk (e.g., yellow or yellowish pink) with blurred margins but no obscuration of the retinal nerve fiber layer from true edema and no obligatory signs of increased intracranial pressure. Optic disk drusen (hyaline bodies) either visible or buried may be present. Hemorrhage is not usually present in pseudopapilledema but if present will be of the subretinal, retinal, or vitreous variety (rather than the splinter hemorrhages seen in true papilledema). The peripapillary retinal nerve fiber layer typically appears clear without obscuration of the underlying retinal blood vessels as they cross the disk margin. There is usually an absence of cupping of the optic disk in pseudopapilledema from disk drusen or anomalous disks. The condition can be unilateral (one-third of patients) or bilateral and may be asymmetric. Fluorescein angiography will show no vessel leakage of dye unlike in true papilledema. A spontaneous venous pulse may be present but may be absent in up to 20% of normal individuals.

Differential Diagnosis

True papilledema, optic disk drusen, vitreopapillary traction, hypertropia, myelinated nerve fiber, and optic nerve hypoplasia.

Prophylaxis and Therapy

There is no prophylaxis or therapy for pseudopapilledema.

Prognosis

Although pseudopapilledema has been associated with nerve fiber layer-type visual field defects, there is typically no decrease in visual acuity because the papillomacular bundle is not usually affected by pseudopapilledema (e.g., disk drusen). If however macular hemorrhage or choroidal neovascular membrane occurs, central visual loss may result. In pseudopapilledema with the presence of optic disk drusen, visual field defects may slowly progress with age, but most patients are usually only modestly affected or are asymptomatic.

Epidemiology

Pseudopapilledema with optic disk drusen is present in approximately 2% of the general population and is more common among Caucasians compared to those of African American descent.

Definition

Optic disc drusen (ODD) are congenital or developmental optic disc abnormalities that tend to become more noticeable and superficial by

ophthalmoscopy over time. These yellowish depositions have a "globular lumpy-bumpy" appearance on and around optic nerve head distorting the edges of optic disc and producing an anomalous, elevated appearance with loss of the physiologic optic cup and may be mistaken for true disc edema. ODD are mostly asymptomatic and can be an incidental finding during routine eye examination. It is important to evaluate patients with ODD and appropriately document the findings in order to avoid unnecessary neurological testing as it can be misdiagnosed true disc edema later. There is no proven treatment for ODD but many patients even with abnormal visual fields remain asymptomatic.

Etiology

ODD is believed to be an abnormal accumulation of protein and calcium salts in the optic disc due to disturbances in axonal metabolism in the presence of small scleral canal. ODD are composed of mucopolysaccharides, amino acids, ribonucleic and deoxyribonucleic acid, calcium, and iron.

Epidemiology

The incidence of ODD is 3.4–24 per 1000 in general population. Bilateral ODD had been reported in approximately 75–85% but ODD can be markedly asymmetric or even strictly unilateral. They are more common in Caucasians. Most cases are sporadic but an inheritance pattern when present is often autosomal dominant pattern with incomplete penetrance. ODD is typically an isolated finding but may be associated with other conditions (e.g., pseudoxanthoma elasticum, angioid streaks, retinitis pigmentosa).

Clinical Presentation

Most patients with ODD are asymptomatic and many are incidentally found during routine eye examination in childhood. Some patients, however, may experience transient visual obscurations (TVOs) lasting seconds at a time and can be described as flickering or graying of vision as seen in true papilledema. Although nerve fiber layer visual field defects are common, central vision is usually preserved. Loss of visual acuity has been reported in cases with concomitant retinal vein occlusion, nonarteritic anterior ischemic optic neuropathy, or juxtapapillary choroidal neovascularization.

ODD produce an elevated optic disc and the presence of the visible superficial refractile yellow bodies in optic discs is usually diagnostic. Signs of true disc edema such as exudates, cotton wool patches, and flame hemorrhages are absent in ODD. In younger patients, ODD are often buried and are not obviously visible on the surface of the disc. As patients get older, however, increased calcium and protein accumulation occur and ODD move more superficially and can then be more easily observed on funduscopic examination.

Up to 70% of patients with ODD have visual field defects with the most common patterns being nonspecific enlargement of the blind spot, inferior or less commonly superior retinal nerve fiber layer defects, or generalized constriction, increased retinal vascular tortuosity, dilated veins, and abnormal branching with trifurcation, and crossing of horizontal midline by temporal branches of central retinal arteries have been documented in discs with ODD. There is also a reported increase in the incidence of cilioretinal arteries in up to 20–40% of ODD in contrast to the general population of 15%.

Diagnosis

Although most cases of ODD can be diagnosed by clinical exam alone, B-scan ultrasonography can be useful for the detection of ODD especially when buried. The classical finding of ODD on B-scan ultrasonography is a highly reflective round structure in the optic disc head with acoustic shadowing. Due to their high concentration of calcium, the hyperechoic lesion can still be

detected even with a low-gain scan. B-scan is the most sensitive method to detect ODD which are calcified but do not have good sensitivity for noncalcified ODD (Atta 1988; Kurz-Levin and Landau 1999).

Although computed tomography (CT) scan is almost as sensitive as B-scan in detection of calcified ODD, ultrasound is cheaper, easier to perform, and has better resolution. In addition, exposure to radiation and the higher cost associated with CT scan make B-scan ultrasonography a more suitable method for routine diagnosis of ODD. We do not typically image ODD but patients with central visual loss, progressive and rapid visual defects, non-nerve fiber layer defects (e.g., homonymous or bitemporal hemianopsia), concomitant optic disc edema, or optic atrophy might benefit from further evaluation including neuroimaging as ODD does not protect one from the development of alternative etiologies for visual loss.

ODD may exhibit autofluorescence on the pre-injection fluorescein angiogram. Fundus fluorescein angiography (FFA) can also be used to help differentiate difficult cases of ODD from true papilledema, as disc leakage occurs in true disc edema versus late staining in ODD. Optical coherence tomography (OCT) is a newer noninvasive optical technique for ODD. The advantage of OCT is the ability to detect concomitant RNFL loss with high reproducibility. The nasal RNFL tends to be the first quadrant to be affected in ODD. Newer generation OCT can also show the underlying ODD ("boot sign") but it remains to be seen if OCT will replace FFA and B-scan ultrasonography in differentiating true disc edema from ODD.

Differential Diagnosis

1. Papilledema
2. True optic disc edema secondary to other causes (e.g., inflammatory, infectious, ischemic, hereditary etc.)

Therapy

There are no proven treatment modalities for ODD. In presence of visual field defect, routine tonometry and visual field tests are reasonable as well as baseline photos or OCT. Antiglaucomatous therapy in selected cases can be considered if there is clear evidence of elevated or borderline intracranial pressure elevation or in cases of severe RNFL loss. The clinical challenge lies in determining if the RNFL loss is due to glaucomatous damage or ODD alone. In small and congested optic disc, it is difficult to determine glaucomatous cupping since it is masked by crowding of optic nerve head. Furthermore, the visual field defects secondary to ODD mimic those of glaucoma (Auw-Haedrich et al. 2002). It has been our practice to consider IOP lowering agents in patients with ODD who are glaucoma suspects.

Prophylaxis

Nonapplicable.

Prognosis

Patients with ODD typically have mild or no symptomatic vision loss. In one study, the average vision loss rate was about 1.2% per year (Lee and Zimmerman 2005).

Pseudoproptosis

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Definition

Pseudoproptosis is the simulation of abnormal prominence or a true asymmetry that is not associated with displacement of the globe.

Etiology

Causes of pseudoproptosis result from asymmetries of the bony orbit, globe, and eyelid including:

Enlarged globe (high myopia, buphthalmos)
Contralateral enophthalmos (contralateral enophthalmos, contralateral small globe, contralateral cicatricial tumor)
Asymmetric orbital size (congenital, post-irradiation, postsurgical)
Asymmetric palpebral fissures (ipsilateral eyelid retraction, scarring or facial nerve paralysis, or contralateral ptosis)

Occurrence

Pseudoproptosis is most commonly seen in eyelid retraction, high myopia, and contralateral enophthalmos. Eyelid retraction, which is associated with thyroid eye disease, produces a more prominent appearing eye and can coexist with true proptosis. Unilateral high axial myopia can mimic proptosis owing to the increased length of the myopic eye. Acute enophthalmos, often secondary to orbital blow-out fracture, may cause apparent proptosis of the contralateral eye. However, the diagnosis of pseudoproptosis should not be made until the possibility of a mass lesion has been ruled out.

Classification

Pseudoproptosis can be classified into three broad categories including abnormalities of the globe (asymmetric myopia, buphthalmos), altered lid position (ptosis, lid retraction, surgical recession of the muscles, third nerve palsy), and structural lesions (facial asymmetry, contralateral enophthalmos, posttraumatic disorders).

Synonyms

Functional ptosis; Nonorganic ptosis

Definition

Pseudoptosis is apparent but not true drooping of the eyelid (see ptosis). Pseudoptosis is typically unrelated to neurological or musculoskeletal defects of the eyelid.

Etiology

Pseudoptosis may be the result of abnormal size of the eye such as the absence of eye development (anophthalmos); a shrunken, non-functional eye (e.g., phthisis bulbi); a small eye (microphthalmos); and posterior placement of the eyeball (enophthalmos), which all present as apparent ptosis without defect to the eyelid mechanisms themselves. Abnormal growth or placement of eyelid tissue such as excessive loose skin of the eyelid (dermatochalasis), contralateral retraction of the eyelid, or prolapse of orbital fat (blepharochalasis) might also result in the pseudoptosis. Bulging of one eye (proptosis) or lid retraction due to thyroid eye disease may result in the diagnosis of possible ptosis in the contralateral eye when in reality it is pseudoptosis. Similarly, an eye with a hypotropia might also result in pseudoptosis. When the patient attempts to fixate on objects with the hypertropic eye, the contralateral eye (the hypotropic eye) might appear to have ptosis. Patients who are unable to infraduct (e.g., downgaze paralysis) might also exhibit bilateral pseudoptosis.

Narrowing of the eyelid fissure due to unilateral facial spasms (hemifacial spasm) or eyelid spasms (blepharospasm) may also give the appearance of ptosis. Overactivity of the orbicularis oculi muscles is also common and is usually proportional to the amount of eyelid fissure narrowing and eyebrow depression from frontalis muscle inactivity.

Pseudoptosis has also been observed in conversion disorder (psychogenic pseudoptosis), revealed by normal pathology findings and positive effect with a placebo.

Clinical Presentation

Pseudoptosis presents as ptosis without defects related to eyelid position. It may be secondary to one of the following primary manifestations: anophthalmos, microphthalmos, enophthalmos, phthisis bulbi, dermatochalasis, blepharochalasis, facial spasms from narrowing of the eyelid, lid retraction of the contralateral eye, or chronic Bell's palsy.

History

At the beginning of the twentieth century, there was considerable debate about the presence of functional weakness in the face as part of "hysteria" (modern day conversion disorder). For example, in 1889, Charcot stated that out of the many cases he had seen of functional limb weakness as a result of hysteria, the face remained absent of that weakness; however, Janet in 1907 claimed to have seen numerous cases of "hysterical facial paralysis." Janet's early descriptions likely included functional facial weakness of the eyelid, which is known today as psychogenic pseudoptosis. Today it is known that pseudoptosis can have other causes such as dermatochalasis and blepharochalasis.

Diagnosis

In order to distinguish pseudoptosis from organic ptosis, appropriate facial muscle movements should be examined for hemifacial spasm or blepharospasm. Characteristically, pseudoptosis patients with orbicularis spasm have a depressed eyebrow with variable ability to elevate the frontalis muscle, compared to organic ptosis patients who generally exhibit frontalis muscle overactivity to compensate for true ptosis. Patients should also undergo evaluation for proptosis, ocular misalignment (e.g., hypertropia), contralateral eyelid retraction, or mechanical causes (e.g., dermatochalasis) for pseudoptosis.

Differential Diagnosis

Ptosis, anophthalmos, microphthalmos, enophthalmos, phthisis bulbi, dermatochalasis, blepharochalasis, and Bell's palsy.

Treatment

Treatment should be directed at the etiology of the pseudoptosis, for example, botulinum toxin injections for lid spasm, treatment of lid retraction or proptosis in thyroid eye disease, or treatment of ocular misalignment in strabismus. In some cases positive reinforcement or psychologic therapy is sufficient for cases of psychogenic pseudoptosis.

Prognosis

Full recovery is expected for most patients depending on treatment of the underlying etiology. In the case of psychogenic disorders, spontaneous resolution may occur with positive assurance, but some cases have also shown continuation of psychogenic pseudoptosis for a few years following initial diagnosis.

Epidemiology

The frequency of organic ptosis has not been officially reported in the United States or worldwide. As a result, the frequency of pseudoptosis is also unknown.

Pterygium

Ben Janson[1] and Shameema Sikder[2]
[1]School of Medicine, Johns Hopkins University, Baltimore, MD, USA
[2]Wilmer Eye Institute, Johns Hopkins University School of Medicine, Bethesda, MD, USA

Definition

A fibrovascular growth of conjunctiva that extends from the bulbar region of the conjunctiva onto the cornea

Etiology

Pterygia are not well understood and the pathogenesis is mostly unknown (Tan and Chan 2011). However, many studies have shown that UV exposure is a risk factor for pterygium (Chow et al. 2009; Tan and Chan 2011). This may produce a limbal stem cell dysfunction and deficiency due to the UV exposure, which shows the typical pterygium characteristics of fibrovascular growth and inflammation (Tan and Chan 2011). Historically, pterygia were described as a degenerative disorder, but current opinion labels pterygia as a proliferative growth disorder (Tan and Chan 2011). Pterygia's high propensity for recurrence and the similar treatment to that of anti-cancer therapy support this classification (Tan and Chan 2011).

There are changes in the pterygium cells that make them behave differently. Pterygium fibroblasts respond to TGF-beta differently than normal fibroblasts and may play a role in pathogenesis (Tan and Chan 2011). They also have increased levels of matrix metalloproteinases and greater levels of bFGF and IGF-II, which may contribute to this altered response (Tan and Chan 2011).

Clinical Presentation

Pterygia grow gradually and typically present in an individual's 20s to 40s (Chow et al. 2009). The name refers to the characteristic winglike growth, and the morphology of the fibrovascular growth is divided into the head, neck, and body (Coroneo and Chui 2013). The head is attached to the cornea and extends onto the cornea and includes a white avascular cap. The neck is a narrowed portion of tissue extending from the bulbar region of the eye to the peripheral cornea. The body is the thicker tissue that lies on the sclera and is continuous with the conjunctiva (Chow et al. 2009; Coroneo and Chui 2013). The pterygium can appear as low-grade avascular pterygium or as high-grade fleshy pterygium. They also may show iron lines near the pterygium head called a Stocker line (Coroneo and Chui 2013).

A pterygium typically appears nasally, but can arise temporally too (Chow et al. 2009). They present unilaterally or bilaterally, and in some cases of double pterygium, one eye can have a nasal and a temporal pterygium (Chow et al. 2009).

Pterygium may cause significant irritation and foreign body sensation due to the irregular shape or dry eye symptoms induced (Rich 2008; Tan and Chan 2011). It often produces a with-the-rule astigmatism and in advanced cases can grow far enough onto the cornea to obstruct vision (Tan and Chan 2011; Coroneo and Chui 2013). They also can advance enough to restrict ocular motility.

Diagnostics (Lab Diagnostics)

Pterygia have a characteristic appearance, and clinical observation alone is often sufficient to make a diagnosis. In cases with uncertainty, an excisional biopsy is appropriate.

Differential Diagnosis

- Pinguecula – Unlike pterygium, these do not invade the cornea.
- Pseudopterygium – These arise from trauma or chemical insult and do not adhere to the limbus (Chow et al. 2009).
- Conjunctival tumors including papilloma, lymphoma of the conjunctiva, nonpigmented nevi, squamous cell carcinoma, and melanoma
- Leukoplakia

Prophylaxis

The major prevention of pterygium is the reduction of UV exposure, especially for outdoor workers. Sunglasses, glasses, and hats have proven to reduce the incidence of pterygium (Rich 2008; Chow et al. 2009; Coroneo and Chui 2013). Other preventable risk factors like smoking and alcohol use remain controversial in their preventative or incidence role (Chow et al. 2009).

Therapy

Therapy can begin in the early stages of the disease and include lubricating drops and when needed steroid and vasoconstrictive drops (Rich 2008; Coroneo and Chui 2013). These can alleviate symptoms, but do not prevent progression.

In cases with significant irritation, astigmatism, obstruction of visual acuity, or loss of ocular motility, surgical intervention is recommended (Chow et al. 2009). Also, in cases of cosmesis, the patient may elect to have pterygium excision. Surgical management includes many types of surgical procedures and adjuvants, but there is no consensus on the best procedure. Surgeons must evaluate each case by the resources available, the risk of recurrence, and the safety. The procedures include bare sclera, simple conjunctival closure, conjunctival autografting, and amniotic membrane grafting. These procedures can be done under local anesthesia, but in the more complicated techniques, a peribulbar or retrobulbar anesthesia is recommended (Rich 2008; Chow et al. 2009). In procedures utilizing grafts, sutures or fibrin glue can serve as attachment methods. Additionally, adjunctive medical therapies of beta-irradiation, mitomycin C, or 5-fluorouracil can supplement the procedure.

Bare sclera was the first technique developed and involves excising the pterygium and leaving the sclera bare to epithelize on its own. It is a quick and simple procedure, but alone is not recommended due to its high recurrence rates ranging 24–89% (Tan and Chan 2011). With any of the procedures excising the pterygium, some surgeons will use a technique to balloon the conjunctiva with fluid before excision (Chow et al. 2009).

Another simple and quick procedure is the simple conjunctival closure after pterygium excision. This technique uses sutures to apposition the conjunctiva superior and inferior to the defect and closes them over the sclera. While not well studied, unfavorable recurrence rates of 29% and 37% have diminished its use (Tan and Chan 2011).

The conjunctival autograft is a popular procedure. It uses a donor graft taken from bulbar conjunctiva, typically in the superior portion of

the patient's eye, to cover the defect made after pterygium excision. It benefits from low complications, low recurrence, and excellent cosmesis (Chow et al. 2009; Coroneo and Chui 2013). The procedure's drawbacks are greater technical demands, longer operation times, and more patient pain (Chow et al. 2009). A related procedure, the conjunctival limbal autograft, extends the donor graft into the limbus to transfer limbal stem cells. This is believed to restore anatomical function and relieve the local stem cell deficiency (Chow et al. 2009). It also has low recurrence rates, but debate exists to whether it improves outcomes compared to the less complicated conjunctival autograft. Both kinds of autografts have historically been attached to the sclera using sutures, and these produce excellent outcomes. Recent studies have shown that fibrin glue is a competitive alternative that provides quicker surgical times, less postoperative discomfort, and, in many studies, lower recurrence rates (Chow et al. 2009; Tan and Chan 2011; Coroneo and Chui 2013).

The amniotic membrane graft is another promising procedure with good outcomes and low recurrence rates. Amniotic membranes are available frozen or dried and have anti-inflammatory and antifibroblast properties (Chow et al. 2009). Additionally, it matches the conjunctiva's alpha-subunit layout of collagen IV (Tan and Chan 2011). Some studies show higher recurrence rates than the conjunctival autograft, but still much better than bare sclera (Tan and Chan 2011). The amniotic membrane graft is most useful in sparing the conjunctiva for other procedures that may be needed like glaucoma surgery. Also in large pterygia requiring large grafts, an amniotic membrane can be used. Some patients with scarred conjunctiva or insufficient remaining conjunctiva from multiple recurrent pterygium may also benefit from the amniotic membrane transplant (Rich 2008; Tan and Chan 2011).

Complications of surgery are generally not severe or vision threatening. Conjunctival autografts may have graft edema, hemorrhage, retraction, necrosis, or dellen formation (Tan and Chan 2011). Intraoperative complications can include perforation of the sclera or cornea and excessive bleeding (Chow et al. 2009). With the grafts, the graft may become flipped from the anatomical orientation. Postoperatively, graft dehiscence, granulomas, symblepharon, and inclusion cysts can arise (Chow et al. 2009).

In addition to surgery, adjunctive medical therapy can also lower the rates of recurrence. Beta-irradiation from strontium-90 has been used for a long time and can lower recurrence (Rich 2008). Dosing is typically 1000–3000 rad doses in single or fractionated doses (Chow et al. 2009). The recurrence rates after beta-irradiation are in the 10% range, but the technique is not well studied (Chow et al. 2009; Tan and Chan 2011). However, serious complications with some latency periods of greater than 10 years do occur and include scleral and corneal necrosis, corneal ulceration, symblepharon, iritis cataract, infectious scleritis, and secondary glaucoma (Rich 2008; Chow et al. 2009; Tan and Chan 2011).

5- 5-Fluorouracil is another adjunctive therapy and works by inhibiting DNA synthesis. Intraoperative use has shown to lower recurrence to 10–20%, but more studies are needed on its effects (Chow et al. 2009).

Mitomycin C is a popular adjunctive treatment for many procedures. This adjuvant works by inhibiting DNA, RNA, and protein synthesis, and it is most effective on rapidly growing cells (Chow et al. 2009; Tan and Chan 2011). Mitomycin C lowers the recurrence rates of each procedure compared to without mitomycin C and can be administered preoperatively, intraoperatively, or postoperatively (Chow et al. 2009). Recurrence rates are roughly less than 10% for primary cases and 20% for recurrent cases (Chow et al. 2009). The earliest use was in postoperative drop regimens typically lasting 4–14 days with 0.2–0.4 mg/mL drops 2–4 times daily (Chow et al. 2009). The use of mitomycin C does have risks of scleral melting, corneal edema, necrotizing scleritis, corneal and scleral perforation, sudden onset mature cataract, photophobia, and secondary glaucoma, and the reports of these vision threatening complications are highest in postoperative drop regimens (Chow et al. 2009; Tan and Chan 2011). Intraoperative use is more favored today and dosed in 0.2–0.4 mg/mL for

2–5 min once the pterygium has been excised (Chow et al. 2009). It is widely used, but it should be used judiciously in knowledge of the known complications and possible unknown long-term adverse affects.

Prognosis

A pterygium is gradually progressive. In some cases, a pterygium may be small and stable and will require no intervention. This is why photographing can be important in evaluating the changes of the pterygium. When surgical intervention is required, recurrence is the major outcome of interest. The rates of recurrence depend on the type of procedure, grade of pterygium, and patient history. Recurrence is highest in the bare sclera and simple conjunctival closure techniques, and the conjunctival autograft and amniotic membrane grafts have much lower recurrence rates (Chow et al. 2009; Tan and Chan 2011). These procedures can have their recurrence rates lowered through the use of adjunctive therapies like mitomycin C commonly, or 5-fluorouracil or beta-irradiation, but may carry additional side effects.

Recurrence is associated with higher-grade pterygium. The higher-grade fleshy pterygium recurs more often than the lower-grade atrophic pterygium (Rich 2008; Tan and Chan 2011). Additionally, patients with a history of recurrence are also more likely to recur than patients presenting with primary pterygium (Rich 2008).

The time to recurrence is typically within 6 months and almost all cases within 1 year (Chow et al. 2009). Pterygium that recur typically are more aggressive and larger than the previously excised pterygium (Tan and Chan 2011).

Epidemiology

Pterygium is found worldwide, but rates have been reported highest near the equator and tropical regions (Rich 2008; Coroneo and Chui 2013). There is a pterygium belt 37° above and below the equator where the highest prevalence is found (Tan and Chan 2011). The highest rates include the study in Barbados that found a prevalence rate of 23.7% in black individuals (Chow et al. 2009). That is in comparison to the study in Victoria, Australia, which found a prevalence rate of 1.2% in urban residents (Chow et al. 2009).

Pterygium prevalence is highest in older ages, but most importantly those with the greatest UV exposure (Coroneo and Chui 2013). Another factor, rural residence, is also associated with higher prevalence of pterygium, although this may be due to other factors associated with rural residence (Coroneo and Chui 2013). Controversy exists whether male gender, race, and smokers have higher prevalence rates (Chow et al. 2009). Genetics may also play a role in pterygium prevalence, but this is not strongly established.

Synonyms

Orbital pain

Definition

Orbital pain can be caused by many different disorders of the orbit. Typically it is described as a deep, dull ache behind or in the eye.

Occurrence

Although orbital pain is not a feature of many orbital processes, it may be a significant and characteristic symptom of acute inflammation and infection. Pain may also be a feature of malignant tumors that have perineural spread.

Classification

Many different orbital diseases cause pain and can be broadly classified by etiology including infection, inflammation, hemorrhage, and neoplasm. This includes infection such as orbital cellulitis where pain is typically with extraocular movement. Acute inflammation such as orbital inflammatory syndrome and Tolosa-Hunt can also cause orbital pain, ophthalmoplegia, and decreased vision. In Wegener's granulomatosis, painful proptosis as well as reduced ocular motility is caused by necrotizing vasculitis and granulomatous inflammation. Retrobulbar hemorrhage may cause significant pain as well as optic nerve compression and is considered an ocular emergency. Most of the slow growing benign tumors typically do not cause significant pain. However, malignant tumors may cause orbital pain due to perineural spread such as adenoid cystic carcinoma of the lacrimal gland and invasion from adjacent nasopharyngeal carcinoma or metastatic lesions.

Punctate Epithelial Defects

▶ Punctate Epithelial Defects/Erosions

Punctate Epithelial Defects/Erosions

Stephen Winkler
Krieger Eye Institute, Baltimore, MD, USA

Synonyms

PEEs; Punctate epithelial defects

Definition

A breakdown of healthy corneal epithelium resulting in pinpoint defects with positive fluorescein, lissamine green, or rose bengal staining seen via a slit-lamp examination.

Etiology

Tear film instability, desiccation, or inflammatory changes of the cornea resulting in a breakdown of

the healthy epithelium. Causes include infectious, allergic, neurologic, toxic, or autoimmune diseases. Inflammation from these diseases leads to a secondary tear deficiency that may then lead to further epithelial disruption.

Occurrence

PEE is a nonspecific sign that occurs in many disease processes, usually as a result of instability of the tear film. The location and pattern of the PEE are important to determine the causative agent.

Classification

A full medical history should be conducted targeting autoimmune disorders, infiltrative processes, infectious causes, neuropathic disorders, and endocrine dysfunction. During examination, one of the aforementioned stains should be instilled into the eye. The location of the PEE will aid in the diagnosis. Diffuse PEE may be caused by viral conjunctivitis, early bacterial conjunctivitis. or medicamentosa. PEE across the lower one third of the cornea may be due to staphylococcal blepharoconjunctivitis, trichiasis, or eyelid malposition. PEEs confined to the intrapalpebral zone are usually related to drying of the cornea secondary to exposure. On the superior one third of the cornea, PEEs are generally related to superior limbic keratoconjunctivitis, vernal conjunctivitis, or floppy eyelid syndrome. Other patterns include vertical linear PEE from foreign bodies lodged underneath the lid and areas where inappropriately fitting contact lenses touch the cornea.

One must differentiate PEE from punctate epithelial keratitis (PEK) and superficial punctate keratopathy (SPK). PEK will have corneal infiltrates associated with the negative staining pattern and is thought to be a progression of the PEE to becoming subepithelial infiltrates (SEIs). SPKs generally have a negative staining pattern with associated positive staining apex and are found in Thygeson's keratopathy.

Punctate Inner Choroidopathy

Victor Menezo[1] and Simon R. J. Taylor[2]

[1]Uveitis Service, Institut Catala de Retina, Barcelona, Spain

[2]Department of Ophthalmology, University of Surrey, Guildford, Surrey, UK

Introduction

Punctate inner choroidopathy is an uncommon posterior multifocal chorioretinopathy first described by (Watzke et al. 1984). It is characterized by the presence of small, focal, yellow lesions at the posterior pole occurring at the level of the inner choroid/retinal pigment epithelium in the absence of vitreous inflammation. It usually affects young, myopic females (who may also be fair haired with blue- or light-colored irides).

The usual presenting symptoms include blurred vision, scotomata, and/or photopsia. These usually occur due secondary to inflammatory foci at the time of presentation, but can be caused by choroidal neovascularization (CNV) complicating the inflammatory focus or by scarring consequent to the inflammation.

Despite having such a distinct clinical phenotype, there remains some controversy as to whether this disease simply represents part of a larger spectrum of chorioretinal disorders of unknown origin, including idiopathic multifocal

choroiditis (MFC), the white dot syndrome (WDS) spectrum, and idiopathic or myopia-associated CNV formation.

Although the majority of cases run a self-limited course, up to 69% of eyes may develop CNV, and furthermore about half of eyes develop subretinal fibrosis with consequent visual loss often characterized by enlarging and new scotomata and in some cases further impairment of vision.

Immunogenetics

There remains some speculation as to whether the WDS share a common immunopathogenic pathway, given their overlap in clinical phenotype, and a preceding infection as their trigger to an innate immune dysregulation (Jampol and Becker 2003). However, despite several studies having demonstrated an association between the HLA-B7 and DR2 haplotypes and patients with POHS, these findings have not been consistently reproduced in other types of chorioretinal disorders within the WDS. Nevertheless, the HLA-DR2 haplotype is more common in British patients with PIC compared to similar clinical phenotypes such as MFC with panuveitis. Genome-wide association studies have provided new insights into the genetics of uveitis and suggest that in most circumstances any inherited predisposition is likely to involve non-HLA genes. There is an association between the IL-10 gene and susceptibility to develop WDS, and some IL-10 haplotypes are more common in patients with PIC and MFC with panuveitis (Atan et al. 2011). In addition to this, dysregulation of the complement system, a key component of the innate immune system, has also been linked with the development of different immune-related disorders, including CNV proliferation, and a strong link between the Y402H allele and IVS1 in the CFH locus and MFC has been described.

Imaging

Traditionally, colour fundus photography has provided the gold standard for documenting and classifying the clinical phenotype of PIC lesions into typical (less than one quarter of the disk diameter, located within the arcades, and absent around the papillary margin) and atypical (more than one quarter of the disk diameter, outside the arcades, and including a peripapilly distribution). Furthermore, retinal photographs are still extensively used to monitor disease progression (Table 1).

More recently, optical coherence tomography (OCT) technology provides real-time, noninvasive imaging of retinal tissues. High-resolution SD-OCT demonstrates the presence of elevated lesions in the sub-RPE space and outer retina during the acute inflammatory phase. Serial imaging with SD-OCT demonstrates the progressive and uneven changes of choroid, RPE, and retinal lesions and allows for the monitoring of disease progression (Zhang et al. 2013) (Table 1).

The use of enhanced depth image optical coherence tomography (EDI-OCT) provides high-resolution cross-sectional images of deeper regions in the eye, enabling the evaluation of inner choroidal thickness. Although this imaging modality may be of greatest use in inflammatory or vascular disorders with more diffuse choroidal involvement, it has shown a small increase of choroidal thickness beneath active PIC lesions. Furthermore, in patients with "presumed" quiescent disease, localized RPE elevation with underlying hyporeflectivity may be an early marker of subclinical activity (Spaide et al. 2013).

Accumulation of metabolic waste products from the outer segments of photoreceptors in the RPE can be visualized by means of fundus autofluorescence (FAF), allowing this technique to assist in the evaluation of the status of the photoreceptor-RPE complex. FAF has very low specificity for characterizing PIC lesions but can be useful in monitoring disease activity as hyperautofluorescence is not only as an indicator of disease activity, due to the displacement of lutein pigment, but is also associated with CNVM formation. In contrast, hypoautofluorescence may indicate RPE death/loss, as well as being an indicator of disease remission (Fig. 1).

Finally, angiography remains a very useful tool in order to detect subclinical lesions that are not

Punctate Inner Choroidopathy, Table 1 Clinical phenotypical stages of PIC with corresponding imaging findings

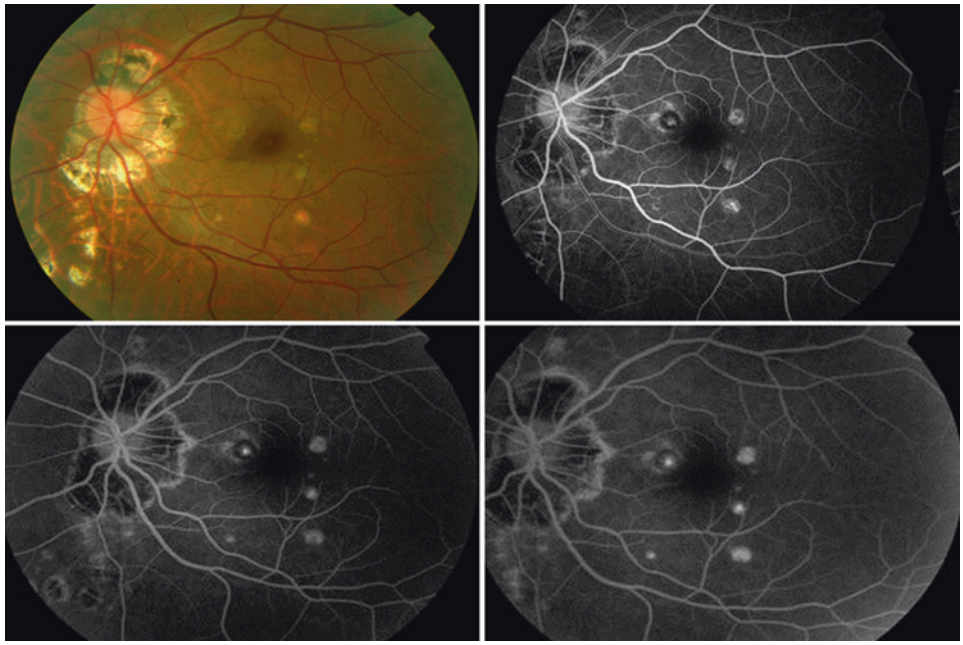
Stage	Fundus examination	FFA	ICG	SD-OCT
I	Normal	Normal	Blurring choroidal vessels and mild to moderate hypofluorescence spots	Slight irregularities in the outer nuclear layer
II	Normal or mild spot discoloration	Normal to mild window defect	Better demarcated hypofluorescence spot	Focal elevation of the RPE with corresponding inner/outer segment interface disruption
III	Yellow-cream spot with blurred margins	Early hyperfluorescent spot with late staining	Halo of hyperfluorescence surrounding hypofluorescence spot	Nodular lesions of moderate reflectivity breaking through RPE
IV	Deep, punched-out, atrophic lesions	Early hyperfluorescence due to window defect	Dark spot	Regression of nodular lesions followed by incarceration of the outer plexiform layer and inner retina through RPE and Bruchs' membrane defects
V	Expanding atrophic lesion with increasing pigmentation	As above	Dark spot with surrounding late hyperfluorescence	Gradual loss of photoreceptor layer around the lesion and disappearance of the outer plexiform layer and inner retina

Punctate Inner Choroidopathy, Fig. 1 Autofluorescence in inactive disease shows typical patches of hypoautofluorescence

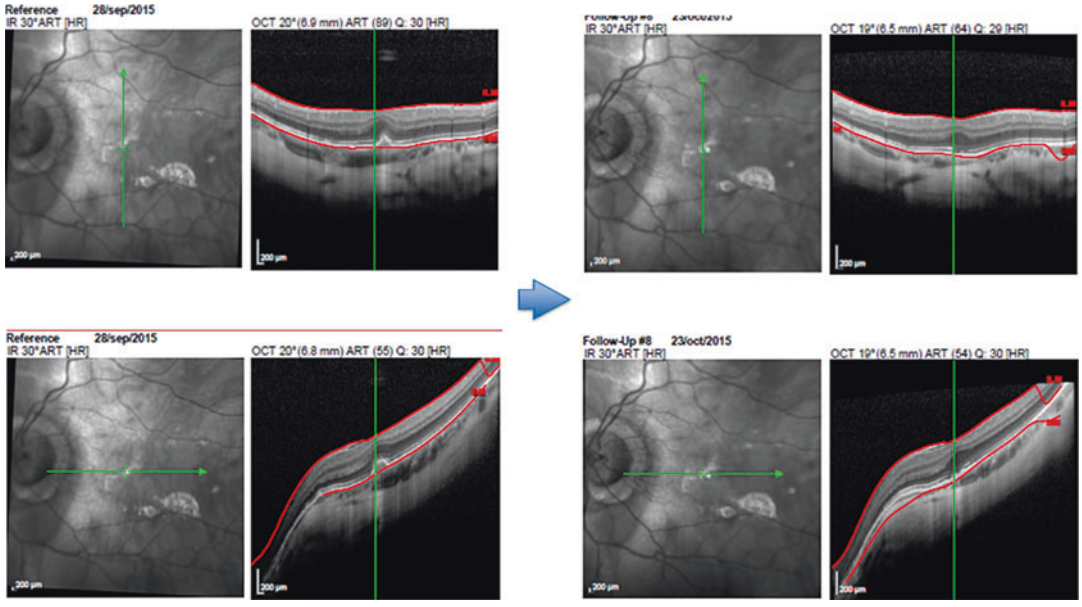
visible on clinical examination (Fig. 2), cystoid macular edema, and also to confirm CNVM formation. The features of PIC lesions on fundus fluorescein angiography (FFA) differ depending upon the stage of the disease: acute lesions are usually hyperfluorescent in the arterial and early arteriovenous phases, with late leakage, although a small proportion of eyes in the very acute stages of the disease may show early hypofluorescence and late staining; older or inactive lesions often demonstrate retinal pigment epithelium window defects, with central atrophic early hyperfluorescence. In cases where CNV develop, they appear as focal areas with a typical irregular lazy pattern, with early hyperfluorescence and late leak. Indocyanine green angiography (ICG) may be more sensitive than FFA: active lesions show early hypofluorescence that persists throughout the angiogram and becomes more apparent in the late phases and that may represent localized areas of choroidal hypoperfusion during the acute phases of inflammation. In addition to this, hyperfluorescence points seen along large choroidal vessels may be the result of a much larger widespread vasculitic process.

Treatment

Controversy still remains over what constitutes the optimal treatment for the majority of patients



Punctate Inner Choroidopathy, Fig. 2 Fluorescein angiography of atypical PIC. The small central lesions are typical, although the extensive peripapillary changes are not. The lesion superonasal to the fovea is clearly apparent on angiography but less obvious on the colour photograph



Punctate Inner Choroidopathy, Fig. 3 Typical PIC pre- (*left* hand images) and post- (*right* hand images) 60 mg/day prednisolone for 7 days

with PIC in the absence of secondary CNV (Fig. 3). As with other noninfectious uveitis, corticosteroids remain the mainstay of therapy. However, given the relapsing nature of the PIC lesions, patients often remain symptom-free for extended periods of time. Periocular or intravitreal corticosteroids may also be sufficient to control the initial inflammatory response and limit the extent of RPE disturbance and posterior subretinal fibrosis formation.

Steroid-sparing agents such as T cell inhibitors or antimetabolite agents have been used in patients with multiple recurrences as maintenance therapy, although data regarding their efficacy remains limited.

Similarly, there is no standard protocol for the management of secondary CNV. Since its introduction in the early 2000s, photodynamic laser therapy (PDT) has been used for CNV associated with PIC, given its "classic"-type morphology on FFA. Other treatment options have included steroid either oral, periocular, or intravitreal, used either in isolation or in combination with PDT. Surgical removal of CNV (characterized as type 2 by Gass) has also been employed, with varying degrees of success. Anti-VEGF agents have been used in PIC-associated CNV on the basis that these drugs are useful in treating CNV in exudative age-related macular degeneration (AMD) and there is now strong evidence in the literature for the use and efficacy of bevacizumab and ranibizumab such that these drugs now form the mainstay of treatment.

Pupil Center

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Pupillary center

Definition

Center of pupillary aperture.

Basic Characteristics

The pupil of the eye is a critical limiting factor in the optics of the visual system. When the pupil changes its size, it controls not only the amount of light available to the visual system but also the optics of the eye.

The exact size and location of the pupil are important in corneal refractive surgery.

In keratorefractive procedures, the relationship between the size and location of the optical zone and the pupil is crucial for a successful visual outcome. If the corneal ablation becomes decentered with pupils of large diameter, the patient may complain about glare, halos, or starbursts under low illumination.

There have been several studies of the change in centration of the pupil with changing size,

with the center of the pupil moving slightly nasally and superiorly as the pupil constricted (Yang et al. 2002).

According to the recommendations of the Optical Society of America working group and the American National Standards Institute, wavefront errors (WFE) are quantified with respect to the pupil center (Applegate et al. 2010).

Pupil Diameter

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Pupil width

Definition

Measurement across pupillary aperture.

Basic Characteristics

In healthy subjects, pupils are circular and equal in size (3–5 mm). A variety of influences may cause variation in pupil size ranging between 1.5 mm (miosis) and 8 mm (mydriasis). A difference in size of more than 1 mm between the pupils of both eyes is called anisocoria (Schünke et al. 2007).

Pupil diameter can be affected by neurologic conditions such as an afferent pupillary defect or Horner's Syndrome as well as by sleepiness, pharmaceutical side effects, psychiatric disorders, or autonomic neuropathy in diabetes mellitus or trauma (Wilhelm and Wilhelm 2003).

Pupil diameter is a determinant of outcome after refractive surgery. Visual symptoms such as halos, star bursts, and glare may emerge after keratorefractive procedures with a small optical zone or implantation of phakic intraocular lenses (IOLs) in patients with large scotopic pupils. The eye has numerous optical aberrations that increase as the pupil dilates (Yang et al. 2002).

Precise pupil diameter measurement can be performed accurately by binocular simultaneous measurements using pupillometers (Kohnen et al. 2004; Schnitzler et al. 2000).

Pupil Dilator

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Device for pupil extension during ocular surgery.

Indication

The use of pupil dilators should be considered in cataract surgery with small nondilating pupils, iris prolapse, and intraoperative floppy iris syndrome.

Contraindication

None.

Use and Dosage

Different devices are currently available for intraoperative pupil dilation. Iris hooks are applied for four to five point iris retraction. Iris hooks are placed in sideports 1 mm posterior of the corneoscleral junction. Alternatively, ring expanders may be used for pupil expansion. Ring expanders reduce the risk of iris-sphincter damage due to a circumferential expansion of the pupil. Different devices are available and should be used according to the surgeon's preference.

Adverse Reactions

Excessive stretching of the pupil may result in iris sphincter damage. Improper positioning and removal of pupil dilators may result in tears of the anterior capsule or iridodialysis.

Definition

The pupil can be irregular or show anisocoria from trauma to the iris itself or damage to the parasympathetic pathway from the ciliary ganglion, the third cranial nerve or central oculomotor nuclei, or damage to the oculosympathetic pathway to the dilator muscle.

Basic Characteristics

Evaluating for Abnormalities

The first step in evaluating anisocoria is to determine if the anisocoria is worse in the light or in the dark. If the anisocoria is worse in the light, then this suggests a problem in either the parasympathetic innervation to the sphincter pupillae or the iris. Normal adult pupils should be of equal size and depending on age are variable sized in diameter but typically 2–4 mm when observed in the light. In up to 20% of the population, there is a 1 mm or less anisocoria that is the same in the light and in the dark and is not pathologic. In trauma patients, however, unequal pupils should be evaluated as pathologic until proven otherwise.

Tonic Pupils

Tonic pupils are characterized by a large pupil that reacts sluggishly or not at all to light and better tonically to accommodation. Tonic pupils can result from trauma to the intraorbital ciliary ganglion or short ciliary nerves which results in parasympathetic denervation of the sphincter pupillae. On slit lamp biomicroscopy, there may be constriction of some segments of the pupil (i.e., vermiform movement) with absent constriction in other segments (i.e., sector paresis). Topical testing with low dose pilocarpine 1/10% might demonstrate denervation supersensitivity in the tonic pupil.

Hutchinson Pupil

Hutchinson pupil is characterized by anisocoria and ipsilateral mydriasis typically associated with other oculomotor nerve deficits. Rarely, isolated pupillary involvement in trauma cases may precede other signs of damage to the oculomotor nerve since the parasympathetic nerves are located peripherally to the oculomotor nerve (CN III). Hutchinson pupil commonly results in trauma patients due to increased intracranial pressure and secondary herniation of the uncus of the temporal lobe. The pupillary changes are usually seen on the same side as the herniation occurred but can occur as a false localizing sign on the contralateral side (Kernohan notch phenomenon). A fixed and dilated Hutchinson pupil in trauma is often associated with a higher risk for mortality.

Iris Sphincter Injury

Trauma to the iris sphincter pupillae can result from blunt or penetrating trauma to the eye

which causes mydriasis, dilation of the pupil, and a poor or no response to light and accommodation. Traumatic sphincter tears might be seen at the pupil margin. Traumatic uveitis can also lead to posterior synechiae that can cause a poorly reactive or fixed and dilated or miotic pupil. Slit lamp biomicroscopy should be able to differentiate these etiologies.

Horner Syndrome

Horner syndrome (HS) is characterized by sympathetic dysfunction that is associated with the classic triad of ipsilateral ptosis (eyelid drooping), miosis (pupillary constriction), and facial anhidrosis. A lesion anywhere along the three neuron sympathetic pathway can result in HS, although anhidrosis will only be present if the injury occurs at the level of the first or second-order neurons. The pupil that is experiencing these symptoms will also be slow to dilate in response to dark. Trauma often results in injury to the second-order neuron (e.g., carotid artery dissection) and may not have any additional signs or symptoms aside from other injuries sustained with the head or neck trauma. Horner syndrome in children is most often congenital and often is seen with birth trauma. There may be concomitant brachial plexus injury in patients with birth trauma.

Bilateral Mydriasis

When the pupils of both eyes are dilated and are sluggish to react to light or do not react at all in a patient with known or suspected trauma, this can be a poor prognostic sign of diffuse and severe brain and brainstem injury or secondary anoxia.

Pupil Stretch

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Pupil dilation; Pupilloplasty

Definition

Pupil stretch is a surgical technique to mechanically stretch small pupils and thus allow phacoemulsification in poorly dilated eyes (maximum pupil size 4 mm). Several surgical techniques are described to mechanically stretch small pupils. Techniques include the use of flexible iris hooks, mechanical dilating devices such as Beehler pupil dilator (Moria), the Perfect Pupil expansion ring (Becton Dickinson Ophthalmic Surgical), and performance of multiple partial iris sphincterotomies. Additional substances as ophthalmic viscosurgical devices are used for pupil stretch.

History

In 1992 Masket listed traditional methods for pupil enlargement such as synechiolysis by sector iridectomy, inferior or radial sphincterotomies, multiple incomplete sphincterotomies, and post-paced suture of iris defects. However, these surgical approaches are all due to aesthetically deformed or functionally deficient pupils. So in the following years, new surgical techniques for atraumatic pupil dilation were developed such as preplaced inferior iris suture (Masket), small pupil enlargement with self-retaining retractors and repositors (Mackool), or pupilloplasty (Fine). In modern cataract surgery with undilated pupils, most surgeons perform phacoemulsification through a small pupil using minimal iris manipulation.

Clinical Features

Intraoperative miosis due to aging, pseudoexfoliation, diabetes, uveitis, or chronic miotic therapy has been described as a risk of conversion from phacoemulsification to extracapsular cataract extraction. To avoid complications during the operation caused by miosis, different methods of pupil stretch have been developed.

Tests

Intra- and postoperative thorough examination of the anterior segment with the slit lamp or operating microscope, as well as postoperative pharmacological dilation of the pupil, and measurement of uncorrected and best spectacle-corrected visual acuity are mandatory to maintain best possible postoperative results.

Differential Diagnosis

There are no data available in this topic.

Etiology

See section "History" above.

Treatment

As described above there exist multiple techniques for pupil stretch. One surgical technique uses Rappazzo scissors. The procedure includes eight tiny sphincterotomies measuring 0.5–0.75 mm that are cut at equal intervals around the pupillary border and results in a considerable increase in pupil size. Another method incorporates the combination of a superior radial full sphincterotomy with preplacement of a superior iris suture. This technique with preplacement of the permanent iris suture assures proper alignment of the iris papillars and results in a physiologic pupil. Mackool designed for pupil stretch two new instruments – self-retaining iris retractors and an iris repository – and his method allows the iris to be securely and reversibly retracted in several meridians simultaneously.

▶ Pupil Diameter

Pupil, Characteristics

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Definition

The pupil is the aperture at the center of the iris which normally enlarges during low lighting conditions and contracts during bright lighting conditions to control the amount of light admitted to the eye.

Basic Characteristics

Aqueous flows through the pupil from the posterior chamber to the anterior chamber. Restriction of this normal flow at the pupil can result in pupillary block and related narrow angle with or without elevation in intraocular pressure.

The iris sphincter muscle constricts the pupil in response to light. This pathway involves the optic nerve and optic tract, the Edinger-Westphal (oculomotor) nuclei, the oculomotor nerve, and the ciliary ganglion. The sympathetic system controls the dilator muscle of the iris.

When a light is shined into one eye, there is direct constriction of the pupil in that eye as well as a consensual constriction in the contralateral eye (because of bilateral stimulation of the Edinger-Westphal nucleus). The intensity of this response is proportionate to the light-carrying ability of the directly stimulated optic nerve.

If a lesion of the optic nerve is present, there may be an afferent pupillary defect (APD). An APD is present when the direct light pupillary response in the involved eye is less intense than its consensual response.

Not only does pupil size vary with lighting conditions, it also varies with age, between individuals, and with emotional states and alertness. The normal pupil also becomes smaller with accommodation.

Assessing pupil size and response to light and near stimuli can be used to measure optic nerve function and localize lesions along the visual pathway. For example, abnormal pupillary responses can identify problems along the afferent light pathway, the parasympathetic or sympathetic pathways, or a lesion in the brain. Pupils are normally similar in size but can be about 0.5 mm different from each other in 20–40% of normal individuals. Asymmetry greater than this is considered anisocoria.

Pupillometers

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Device for pupil size measurement.

Purpose

Assessment of pupil size under defined illumination levels prior to refractive surgery.

Principle

For pupil size measurement, either comparison charts (pupil cards), rulers, or infrared pupillometers may be applied. Currently, different infrared pupillometers are commercially available. The devices differ in measurement period, pupil margin detection (observer or software based), and monocular or binocular measurement and illumination level.

Indication

In refractive surgery, the optical zone should ideally exceed the pupil diameter under any level of ambient illumination in order to minimize the risk of night vision problems. Pupillometers enable the definition of minimum optical zones in refractive surgery.

Advantage/Disadvantage

Modern infrared pupillometers provide highly accurate and reproducible measurements of pupil size under standardized conditions. However, results may be influenced by retinal dark adaption, accommodation, alertness, emotional status, and different medications. Further difficulties arise since pupils are often asymmetric and highly dynamic.

► Aspheric Profile Photorefractive Keratectomy

Q-Factor Customized Ablation Profile

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Aspheric ablation profile; Wavefront-optimized ablation profile

Definition

An ablation profile that aims at minimizing postoperative spherical aberration, by maintaining preoperative corneal asphericity (q factor).

Basic Characteristics

Corneal laser refractive surgery with conventional ablation profiles changes corneal asphericity (q factor). Myopia treatment changes the shape from prolate ($q < 0$) to oblate ($q > 0$). The optical result is an induction of positive spherical aberration which was found to be proportional to the attempted spherical equivalent (Applegate and Howland 1997; Moreno-Barriuso et al. 2001; Oshika et al. 2002). The fact that spherical aberration significantly deteriorates retinal image quality prompted the development of aspheric ablation profiles with less induction of spherical aberration than conventional profiles (Mrochen et al. 2004). Q-factor customized ablation profiles aim at maintaining the preoperative corneal q factor (Koller et al. 2006). The profile is calculated individually ("customized") based on preoperative corneal shape, the attempted treatment, and the programmed optical zone. A "fudge factor" for anticipating the loss of laser fluence in the corneal periphery can be included in the treatment algorithm.

A preoperative corneal topography to determine the preoperative corneal asphericity (q factor) is mandatory. Together with other data like refraction and aberrometry, programmed optical zone, and corneal pachymetry, these data are integrated in a proprietary treatment algorithm. The treatment itself is identical to a treatment with a conventional profile. The predictability of the ablation can be assessed with postoperative corneal topography or aberrometry.

Radial Keratotomy

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Anterior radial keratotomy

Definition

Corneal incision performed to flatten the cornea and reduce myopia.

Epidemiology

Radial keratotomy was the most commonly performed refractive procedure in the late 1970s and 1980s.

History

Sato first described this procedure in 1939.

Clinical Features

No clinical feature data available for this topic.

Tests

Preoperative evaluation includes slit lamp examination, pachymetry and topography of the cornea, as well as BCVA refraction.

Differential Diagnosis

Corneal relaxation procedures for correction of myopia:

- Astigmatic keratotomy
- Arcuate keratotomy
- Transverse keratotomy
- Trapezoidal keratotomy
- Hexagonal keratotomy
- Limbal relaxing incisions

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

Etiology

Due to unstable results, radial keratotomy has been replaced by the far more accurate excimer laser.

Treatment

There are two methods for radial keratotomy. In the "American-style incision," the incisions are performed from the optical zone toward the limbus. The Russian centripetal technique described incisions starting at the limbus and continuing toward the optical zone. The "genesis technique" was a combined technique from the two others.

Ranibizumab

Francesco Bandello[1], Niccolò Castellino[2] and Maurizio Battaglia Parodi[1]
[1]Department of Ophthalmology, University Vita-Salute, IRCCS San Raffaele Hospital, Milan, Italy
[2]Department of Ophthalmology, Ospedale San Raffaele, University Vita-Salute, Milan, Italy

Definition

Ranibizumab (Lucentis; Genentech, South San Francisco, California) is the fragment of a recombinant humanized antibody Fab which binds and neutralizes the human vascular endothelial growth factor A (VEGF-A). Ranibizumab binds to VEGF-A with high affinity, thus preventing the interaction of VEGF-A to both its receptors VEGFR-1 and VEGFR-2. Ranibizumab binds to all VEGF molecules with a one-to-one ratio. Ranibizumab has a molecular weight of 48 kDa, is produced in *Escherichia coli*, and presents no glycosylation sites. It contains only the Fab fragment of the entire parental antibody bevacizumab (149 kDa) that is an entire humanized recombinant antibody and therefore contains both the Fab and Fc fragments of the molecules.

In vitro and in vivo studies have demonstrated a 5- to 20-fold higher activity of ranibizumab in comparison to bevacizumab and a shorter half-life, estimated in approximately 9.8 days. Because of the smaller molecular weight in comparison to the entire antibody, ranibizumab has a higher diffusive capacity from the vitreous to the retina and the choroid tissues.

VEGF-A has been demonstrated to play a pivotal role in the regulation of angiogenesis both under physiologic and pathologic conditions (Ferrara et al. 2003). As far as the eye is concerned, VEGF-A is produced by various cell populations, such as retinal pigment epithelial cells, neurons, glial cells, ganglion cells,

endothelial cells, Muller cells, and smooth muscle cells. The primary target of VEGF-A is vascular endothelial cells, although all cell populations are at least in part affected by its action. VEGF-A synthesis is regulated by variations of ocular oxygen tension. Under condition of normal oxygen pressure, the hypoxia-inducible factor 1alpha, which is the cell's oxygen sensor, is hydroxylated and degraded via the ubiquitin-proteasome intracellular proteolytic pathway. Under the condition of low intracellular oxygen tension, however, the rate of hydroxylation is reduced, and stabilized hypoxia-inducible factor 1alpha is capable to interact with nuclear VEGF-A genes, thereby inducing VEGF-A synthesis. The major effects of VEGF-A are the increase in hydraulic conductivity via the induction of fenestration of cell bodies and the activation of metalloproteinases and phosphorylation of various intracellular and junctional proteins which eventually lead to a loss of intracellular tight junctions. The final effects of VEGF-A are an impairment of blood/retinal barrier. Ranibizumab binds to VEGF-A, which becomes unavailable for the interaction with its receptors VEGFR-1 and VEGFR-2 and prevents the onset of the abovementioned molecular mechanisms which eventually would lead to the development of retinal edema, endothelial cell proliferation, and neovascularization.

Indications

Intravitreous ranibizumab injections are a valid therapeutic strategy for several retinal diseases.

Ranibizumab is the first VEGF-A inhibitors approved by the FDA for the treatment of diabetic macular edema (DME), which represents a prominent cause of visual loss in patients with diabetes mellitus and the most frequent cause of legal blindness among adult individuals in developed countries. In DME visual loss is caused by diabetes-induced microvascular damages which cause the thickening and structural alteration of the basal membrane and the loss of the pericytes and vascular endothelial cells. These events lead to microaneurysm formation and the impairment of the blood/retinal barrier. The consequent vascular leakage results in the development of DME. VEGF concentration was found to be increased in ocular fluid of patients with DME, and it was hypothesized that ranibizumab via its binding and inactivation of VEGF-A may stop the evolution of these pathological events. The clinical effects of ranibizumab in DME were evaluated in randomized clinical trials. The DRCR Network showed that patients treated with 0.5-mg ranibizumab plus prompt laser or deferred laser therapy had significantly better visual acuity outcomes at 1 year than those treated with sham injection plus prompt laser. The results were confirmed at 2-year follow-up. The RESTORE trial randomized patients with DME to either 0.5-mg ranibizumab monthly for 3 months and then as needed plus sham laser (group A), 0.5-mg ranibizumab monthly for 3 months and then as needed plus laser therapy (group B), or sham injections plus laser therapy (group C). At 1 year, visual acuity improved of six ETDRS letters with ranibizumab alone (group A), 5.9 letters with ranibizumab combined with laser (group B), and only 0.8 letters with laser alone (group C) ($P < 0.0001$, A and B vs. C). Mean central retinal thickness also significantly decreased in both ranibizumab groups compared with laser alone. Lately the RISE and RIDE trials confirmed the positive effects of ranibizumab for the treatment of DME (Aiello et al. 1994).

Another approved indication for ranibizumab is the treatment of neovascular age-related macular degeneration (AMD), characterized by a new vessel formation which takes origin from the choroid (Rosenfeld et al. 2006). Choroidal neovascularization development has been correlated to the elevated intraocular VEGF-A concentrations. Choroidal neovascularization is characterized by structural and functional alterations which lead to intraretinal bleeding and exudations, with subsequent impairment in retinal oxygen perfusion and focal hypoxic areas. In turn, focal hypoxia determines further VEGF-A synthesis with a self-perpetuating pathologic cycle.

The effect of anti-VEGF therapy was demonstrated by the MARINA trial involving patients with minimally classic/occult choroidal neovascularization, who were treated with fixed monthly intravitreal injections, gaining more letters of vision with respect to the sham-injected controls (improvement of 7.2 letters vs. loss of 10.4 letters). Approximately 95% of patients treated with ranibizumab maintained or improved visual acuity compared to 62% of eyes in the control group. Similarly, the ANCHOR trial demonstrated the superiority of ranibizumab over standard therapy (verteporfin photodynamic therapy) in the treatment of classic choroidal neovascularization. In particular, at 1-year follow-up, 94.3% of patients given 0.3 mg of ranibizumab and 96.4% of those given 0.5 mg lost less than 15 letters, as compared with 64.3% of those in the verteporfin photodynamic therapy group ($P < 0.001$). Visual acuity improved by 15 letters or more in one third of both ranibizumab subgroups, as compared with marginal improvement (5.6%) of the verteporfin group ($P < 0.001$). Mean visual acuity increased by 8.5 and 11.3 letters in the 0.3- and 0.5-mg ranibizumab group, respectively, as compared with a decrease of 9.5 letters in the verteporfin group ($P < 0.001$). The HARBOR trial enrolled four groups. For 12 months, two groups received monthly ranibizumab at doses of either 0.5 mg or 2.0 mg, and two groups received the same doses, but each on an as-needed basis after three monthly loading doses of ranibizumab. All subgroups showed a clinically meaningful visual gain over the first year of the study, ranging from a gain of 10.1 letters in the 0.5-mg monthly group to 8.2 letters in the 0.5-mg PRN group. At 12 months, the mean change in visual acuity was similar in the four treatment subgroups, although it was slightly lower in the 0.5-mg as-needed subgroup. At 24 months, most patients had lost approximately one letter from month 12, but patients in the 0.5-mg as-needed group lost only 0.3 letters. These data suggest that there is an individualized response to treatment and a need to individualize it in this patient cohort.

The National Institutes of Health funded a head-to-head trial to compare bevacizumab and ranibizumab, the "Comparison of Age-Related Macular Degeneration Treatments Trials (CATT)" study. The drugs performed comparably in both the monthly (ranibizumab, 8.5 letters gained; bevacizumab, 8.0 letters gained) and as-needed (ranibizumab, 6.8 letters gained; bevacizumab, 5.9 letters gained) treatment arms. Results at 1 year were confirmed at 2-year follow-up. Similar results were also achieved by another head-to-head trial, the IVAN trial, which was performed in the United Kingdom.

Meaningful results were obtained also with the ranibizumab treatment of retinal vein occlusions.

Branch retinal vein occlusions (BRVOs) and central retinal vein occlusions (CRVOs) afflict 1.8% and 0.5%, respectively, of the population over 50 years. Intravascular obstruction occurs at the arteriovenous crossings in BRVO and the lamina cribrosa in CRVO. The pathophysiologic mechanisms leading to retinal vein thrombosis are multifactorial and include both local and systemic factors including hypertension, diabetes mellitus, hypercoagulability as well as local hemodynamic changes (stasis and turbulence), and endothelial injury. Impaired venous outflow determines retinal ischemia.

Vitreous levels of VEGF-A in eyes affected by retinal vein occlusion are very elevated, suggesting that VEGF-A plays an important role in the pathogenesis of its complications, in particular of macular edema and retinal or iris neovascularization. Recently, two separate trials have evaluated the effects of monthly injection ranibizumab (0.3–0.5 mg) versus sham injections in the treatment of macular edema in patients with branch retinal vein occlusion (BRAVO) study or central retinal vein occlusion (CRUISE) study. Both studies demonstrated the efficacy of anti-VEGF treatment.

In the BRAVO study, ranibizumab determined a gain of 16.6 (at the dose of 0.3 mg) to 18.3 letters (at the dose of 0.5 mg) compared with a gain of 7.3 letters in the sham group at 6 months. Approximately 60% of eyes treated with ranibizumab gained at least 15 letters compared to 29% in the sham group. In the CRUISE study, results were also impressive. Ranibizumab resulted in a gain of 13 (at the dose of 0.3 mg) to 15 (at the dose of

0.5 mg) letters compared to a not significant change in the sham group. Approximately 50% of eyes treated with ranibizumab gained at least 15 letters from baseline compared with only 17% in the sham group. At 6 months, intravitreal anti-VEGF significantly improved visual acuity in both BRVOs (20/125 baseline vs. 20/55) and CRVOs (20/270 baseline vs. 20/135). Improvements in visual acuity were associated to a significant reduction in foveal thickness. Following the initial 6-month BRAVO and CRUISE study period, all groups, including the control groups, received ranibizumab on an as-needed basis for macular edema with persistent clinical improvement.

An additional clinical indication for intravitreal injection of ranibizumab is choroidal neovascularization secondary to degenerative myopia. Several trials studies have shown that intravitreal injection of ranibizumab is effective for primary treatment myopic subfoveal and non-subfoveal choroidal neovascularizations, leading to a remarkable visual gain.

Finally, it has been demonstrated that VEGF-A is highly expressed in vascular endothelial cells and retinal pigmented epithelium of patients with polypoidal choroidal vasculopathy, a retinal disorder with multiple aneurismal and polypoidal lesions in the choroidal vasculature. Anti-VEGF-A administration reduces the subretinal exudation, leading to a visual acuity improvement. A combined therapy with intravitreal ranibizumab injection and photodynamic therapy seems to provide further synergistic effects in the treatment of polypoidal lesions.

Contraindication

Well-established contraindications to the intraocular use of ranibizumab are previous episodes of hypersensitivity against anti-VEGF agents or against one of the additive components of the injectable preparation. In addition, ranibizumab should not be used in patients with active intraocular or periocular infections, either diagnosed or suspected. Similarly, ranibizumab is contraindicated in patients with septic or aseptic endophthalmitis. The systemic administration of other anti-VEGF agents represents a contraindication to its intraocular use. At present it is unclear whether macular ischemia, which may be concomitant to macular edema in various clinical conditions, is a contraindication for prolonged anti-VEGF treatment, because a worsening of macular ischemia in the long term cannot be definitely excluded.

Clinical Use and Dosage

Ranibizumab is administered through intravitreal injection in two different dosages of 0.3 and 0.5 mg. In general, the recommended dose is 0.5 mg in an injected volume of 0.05 ml. The minimal interval between ranibizumab administrations is 1 month, with a treatment strategy based on the characteristics of the underlying disease. The treatment is continued with monthly injection until there is a stabilization of visual acuity. If there is no significant effect on visual acuity within the first 3 months of treatment, discontinuation of treatment is recommended. Therefore it is of great clinical importance to monthly monitor the visual acuity of patients during treatment, in order to resume the administration whenever visual acuity decline is registered. Over the follow-up, optical coherence tomography plays an important role to achieve an accurate monitoring of changes of intraretinal fluid and edema in response to treatment and to detect a relapse of the disease.

Side Effects and Adverse Reactions

After the intravitreal injection of 0.5 mg of ranibizumab, the systemic concentrations of the antibody are extremely lower than the intravitreal ones (90.000 lower according to the manufacturer) and well below the level required to inhibit 50% of the systemic activity of VEGF. All studies reported that the rates of systemic events which have been associated with the systemic use of anti-VEGF inhibitors such as thromboembolism, hemorrhage, gastrointestinal perforation, systemic

hypertension, and proteinuria, following intravitreal administration of ranibizumab, are very low. In a recent large Medicare analysis, treatment with ranibizumab was not associated with increased risk of mortality, myocardial infarction, stroke, or bleeding in comparison to pegaptanib or phototherapy. Similar data were also reported by a pooled analysis of various European registries based on ranibizumab use in everyday clinical practice and by a systematic review of reported side effects with all anti-VEGF agents. For ranibizumab the calculated cumulative incidences for heart disease are reported to be less than 0.10% per 100 injections. The incidence rates of stroke and transient ischemic attack (TIA) were below or equal to 0.07 per 100 injections for both ranibizumab and bevacizumab. It should be pointed out, however, that patients undergoing ranibizumab treatment, because of the advanced age and high prevalence of diabetes and hypertension, have an elevated absolute risk profile for cardiovascular and cerebrovascular events which is to a large extent independent of the intraocular treatment. Therefore more than the absolute risk of events, the relative risk should be taken into account.

As far as systemic hypersensitivity reactions are concerned, very few cases with oral angioedema and generalized urticaria have been reported, all resolved with steroid therapy.

The CATT study reported a significant prevalence of various minor side effects during therapy with ranibizumab and bevacizumab; however, the relationship between side effects and anti-VEGF doses is unclear, with higher prevalence of side effects in lower treatment groups.

Data from the European registry (Holz et al. 2011) and systematic reviews (Van Der Reis et al. 2011) showed that ranibizumab is associated with a low rate of ocular events that could be either caused by intravitreal injection per se or by the use of VEGF inhibitors.

Less than 1% of patients experienced retinal pigment epithelial tear or intraocular pressure-related events, and $<0.3\%$ of patients developed traumatic cataract, vitreous hemorrhage, deterioration of retinal blood flow, endophthalmitis, intraocular inflammation, or retinal detachment. Annual incidence of endophthalmitis from European registry was lower than in controlled clinical trial. Endophthalmitis was reported after ranibizumab injections with incidence rates below or equal to 0.04 per 100 injections; both infectious and non-infectious endophthalmitis were reported. For retinal detachment, a cumulative incidence rate of 0.01 per 100 injections has been reported. The occurrence of RPE tears has also been related to an anti-VEGF injection; the incidence rates for ranibizumab were equal to or below 0.14 per 100 injections. The overall incidences of mild anterior chamber reactions and anterior chamber inflammations (including any events described as anterior chamber inflammation, iritis, iridocyclitis, uveitis, or vitritis) were 1.06 per 100 injections of ranibizumab. Subretinal and vitreous hemorrhage occurred for ranibizumab at a rate of 0.03 per 100 injections. It should be pointed out that intraocular hemorrhages are a complication that may also be associated with the natural course of the underlying neovascular retinal diseases. An increased intraocular pressure (IOP) may be caused by the intraocular injection per se or by the pharmacologic properties of the intravitreal drugs used. The rise in IOP may be transient or sustained. The cumulative incidence rate of increased IOP reported for ranibizumab was below 0.50 per 100 injections.

Synonyms

Marcus Gunn pupil

Definition

A relative afferent pupillary defect (RAPD) is a clinical sign used to detect a lesion/defect in the pupil pathway on the afferent side. The direct response of the pupil to light can be compared to the contralateral consensual response by swinging the light stimulus between the two pupils. The detection of the RAPD requires two eyes but only one working pupil (see reverse RAPD below). When shining light into each eye, the affected eye (i.e., with the RAPD) demonstrates a diminished direct response to light, and when the light swings to the normal unaffected eye, the abnormal pupil dilates. The presence of an RAPD typically indicates a problem in the ipsilateral afferent pathway involving the retina or the optic nerve but also may occur in lesions of the optic tract or the pretectal neurons connecting the afferent pathway of the pupil to the efferent pathway in the midbrain (i.e., a tectal RAPD).

Etiology

Any lesion of the anterior visual pupil pathway (pregeniculate) can cause an RAPD.

Retinal lesions (e.g., retinal detachment, retinoblastoma, central retinal artery, or vein occlusion), optic nerve lesions (e.g., optic neuritis, anterior ischemic optic neuropathy, optic atrophy), and suprasellar lesions (e.g., pituitary adenoma, meningioma, craniopharyngioma) can all produce an RAPD.

Occurrence

The epidemiology of an RAPD depends on the underlying etiology of the lesion.

Classification

Signs and Symptoms

An ipsilateral RAPD might be associated with loss of visual acuity or visual field if the retina, optic nerve, chiasm, and tract are affected. A tectal RAPD might not be associated with visual loss if the visual afferent pathway is

unaffected, and only the pupillary afferent fiber is affected in midbrain.

Ray Tracing

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Laser ray tracing

Definition

Technique to measure optical aberrations of the human eye.

Purpose

To objectify wavefront aberrations.

Principle

In ray tracing, a sequentially delivered laser beam coming from a point object enters the eye through different pupil locations to form a spot on the retina. The local aberrations in the beam's entry position in the pupil cause a focal shift of the retinal image.

The retinal spot pattern is captured by a charge-couple device (CCD) camera, and the displacement of each spot from the location of the reference ray is computed. These displacement data are used to provide information about the local wavefront slopes for the whole pupil area (Moreno-Barriuso et al. 2001; Rozema et al. 2005; Yoon et al. 2006).

Indication

To measure optical aberrations of the human eye, correlation with visual symptoms, wavefront sensing for preoperative evaluation of refractive surgical procedures.

Advantage/Disadvantage

Ray tracing relies on a good retinal reflection, which can compromise measurement accuracy in patients with retinal pathologies; sequential measurement limits the application for real-time dynamic measurements.

[1]Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA
[2]Jules Stein Eye Institute, David Geffen School of Medicine at UCLA, University of California Los Angeles, Los Angeles, CA, USA

Synonyms

Eyelid reconstruction; Eyelid repair

Definition

Surgical correction of partial or full thickness defects of the upper and/or lower eyelids.

Indication

Reconstruction of the eyelid is indicated in defects that may lead to secondary complications such as exposure keratopathy, epiphora, lagophthalmos, eyelid malpositions, and/or eyelid notching if left untreated. The most common indications for repair are defects resulting from cancer resection surgery, including Mohs surgery, and trauma. Involvement of the lacrimal outflow system necessitates surgical repair and reconstruction.

Contraindications

Surgery should be deferred until the patient is medically stable and a suitable candidate for surgery in cases of trauma. Also more serious injuries, such as a ruptured globe, take precedence and should be repaired prior to the eyelid injuries. In patients with monocular vision or in children at risk of amblyopia development, techniques that obstruct vision such as lid-sharing techniques should be avoided.

Techniques and Principles

The goals of eyelid reconstruction are to recreate a maximally functional eyelid, with a stable eyelid margin, while maximizing symmetry and aesthetic outcome. In reconstruction of eyelid defects, the surgeon must consider several factors: the size and orientation of the defect, the depth of the defect and the structures involved, the patient's age and laxity of their tissues, and any history of previous surgeries or a history of radiation to the region. General principles of eyelid reconstruction include: choosing the least disruptive technique to properly reconstruct the eyelid, minimizing vertical eyelid tension to avoid eyelid malpositions particularly ectropion, maintenance of proper canthal position and tension, attention to the diagnosis and treatment of any lacrimal outflow system injuries, and preference for local flaps for reconstruction as opposed to full thickness skin grafts.

Eyelid defects not involving the eyelid margin can sometimes be repaired by direct closure if vertical tension on the eyelid, which can result from closure in the horizontal plane, can be avoided. Direct closure of circular anterior lamellar defects not involving the eyelid margin should be closed with a vertical scar to avoid vertical tension and potential for ectropion. Advancement flaps, rotational flaps, and/or transposition flaps can be utilized if direct closure is not feasible. The flaps are mobilized as a composite of skin and muscle and incisions are hidden in relaxed skin tension lines when feasible. Large defects not amenable to closure with local advancement flaps may warrant full thickness skin grafting. Appropriate donor sites for full thickness skin grafts to the eyelids include: redundant skin from the upper eyelid, postauricular skin, supraclavicular skin, and preauricular skin.

Direct full thickness layered closure may be used for upper and lower eyelid defects involving usually less than 33% of the eyelid margin. Depending on the degree of tissue laxity, addition of a canthotomy and cantholysis can provide improved mobilization allowing for direct closure in wounds involving up to 50% of the eyelid margin. The wound is converted to a pentagonal wedge to allow closure without bunching of tissues. The defect is closed in layers. The keystone sutures are those which reapproximate the tarsus, which are passed in a lamellar fashion facilitated by the use of a spatulated needle. The eyelid margin is then realigned and the edges of the eyelid margin everted with sutures passed in a vertical mattress fashion. Everting the eyelid margin with this vertical mattress suture helps to avoid subsequent healing with notch formation. The skin/muscle is then directly closed with sutures.

Larger defects involving greater than on average 33–50% of the eyelid margin often require independent reconstruction of the anterior and posterior lamellar defects, one of these surfaces must provide vascularized tissue. Techniques that may be utilized for the repair of large upper eyelid defects include the Tenzel semicircular flap, Cutler-Beard flap, tarso-conjunctival transposition flaps, or free tarso-conjunctival grafts under anterior lamellar advancement flaps. Repair of large lower eyelid defects can be achieved with the use of the modified Hughes procedure, Tenzel semicircular flaps, free tarso-conjunctival grafts, or other tarso-conjunctival substitutes such as ear cartilage or hard palate graft under a vascularized skin/muscle flap.

Outcome

A reconstructed functioning eyelid able to provide protection to the globe is the desired outcome.

Complications

Eyelid malpositions such as ectropion or entropion with their inherent problems may result. Excess tension or inadequate alignment may result in lid notching or wound dehiscence. Limited eyelid mobility secondary to myogenic or neurogenic injury may occur including blepharoptosis or lagophthalmos. Cosmetic deformities may result after any extensive eyelid reconstruction.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Cancer-associated retinopathy (CAR) antigen

Definition

Recoverin is a neuronal calcium-binding protein in the photoreceptor cells of the eye involved in the recovery phase of visual excitation and adaptation to background light. It modulates the life of photoexcited rhodopsin by inhibiting rhodopsin kinase, the regulator of rhodopsin phosphorylation. Reducing this inhibition of the kinase regulates sensory adaptation in the retina and prolongs the light sensitivity of rhodopsin. Closing photoreceptor channels is light dependent and causes calcium to decrease and keeps calcium-bound recoverin from inhibiting rhodopsin kinase, causing faster inactivation of activated rhodopsin. When not bound to calcium, recoverin remains in the cytosol, but when bound migrates to the disk membrane using its amino terminal myristoyl group as an anchor.

Clinical Presentation

Patients with cancer-associated retinopathy (CAR), a rare retinal degenerative disease, have elevated antibodies against recoverin-like proteins. Its mechanism is not clearly elucidated, but suggests a series of autoimmune reactions against components of the retina, primarily CAR antigen. CAR serum antibodies have been used to construct the CAR antigen cDNA library, which shares 90% homology to a bovine recoverin amino acid sequence.

Recurrent Corneal Erosion

Marcus Neuffer
Department of Ophthalmology, Keesler Medical Center, Biloxi, MS, USA

Synonyms

Dystrophia smolandiensis variant; Franceschetti hereditary recurrent erosion; Hereditary recurrent corneal erosion

Definition

A disease characterized by poor adhesion of the epithelial cell layer to the basement membrane resulting in localized sloughing of the epithelium causing. The erosions may be secondary to trauma or occur spontaneously (Krachmer et al. 2011).

Etiology

Inheritance is autosomal dominant. Erosions can be secondary to minor trauma or occur spontaneously. Sometimes dust, smoke, dryness, and lack of sleep precipitate erosions (Weiss et al. 2008).

Clinical Presentation

Patients can present with foreign body sensation, photophobia, and ocular pain and redness. Blebs and haze are seen on examination of the cornea. Symptoms develop in the first decade of life and become less frequent and intense over time (Weiss et al. 2008).

Diagnosis

Diagnosis is made with clinical presentation and family history. Slit lamp examination reveals blebs and haze on the cornea. No changes consistent with epithelial basement membrane disease are seen with light microscopy (Weiss et al. 2008).

Differential Diagnosis

Differential diagnosis includes epithelial basement membrane disease, map-dot-fingerprint dystrophy, anterior membrane dystrophy, Cogan microcystic dystrophy, corneal abrasion, dry eye syndrome, corneal foreign body, herpes simplex, and Fuchs' corneal dystrophy.

Prophylaxis

Prevention is to avoid precipitating factors such as trauma, dust, smoke, or dryness. When precipitating factors cannot be avoid, hypertonic saline drops and ointments or topical lubricants are used (Krachmer et al. 2011).

Therapy

Various therapies are used in preventing and treating corneal erosions. The objectives of the treatments are the same, which is to promote corneal healing. Common treatments are topical lubricants, topical cycloplegics, antibiotic ointments, autologous serum tears, bandage contact lenses, and pressure patching. When conservative measures do not work, then epithelial debridement, corneal micropuncture, or phototherapeutic keratectomy can be performed (Krachmer et al. 2011). In severe cases that lead

to significant corneal scarring, a keratoplasty may be necessary to restore vision.

Prognosis

In the first few decades of life, prevention of recurring attacks of pain and foreign body sensation can be difficult to treat. However, attacks decline over time and often cease by the age of 50 years old (Weiss et al. 2008).

Epidemiology

The prevalence of recurrent erosion is unknown. Onset is usually the first decade of life.

Synonyms

Achromatopsia

Definition

Dyschromatopsia is a congenital or acquired disorder of color vision. The human retina has three types of cones, each optimally responding to one of the primary colors: blue-sensitive cones (coded on chromosome 7), red-sensitive cones, and green-sensitive cones (both coded on the

X-chromosome). The different colors of the spectrum are perceived by different mixtures of these three colors. Normal individuals are called *trichromats* (three-color system). In contrast, *dichromats* have only two functioning cone types, and monochromats only have one. The term "protanopia" refers to a defect in red perception, whereas "deuteranopia" is a defect in green perception and "tritanopia" is a defect in blue perception (Barrett et al. 2012).

Etiology

Mutations in the genes coding for the cones can cause congenital color blindness. The most common mutations occur in the X-chromosome and thus affect males much more commonly than females (see "Epidemiology").

Color blindness can also be an acquired condition resulting from lesions in the afferent visual pathway in one or both eyes (e.g., from optic nerve damage (such as in multiple sclerosis or advanced glaucoma), chiasm, optic tract to brain lesions (e.g., radiations or in the occipital lobe, specifically in the V8 region (Barrett et al. 2012). Optic nerve lesions tend to affect red-green, while retinal lesions affect blue-yellow more often (Ropper and Samuels 2009). However, the other conditions usually affect all colors (not necessarily to the same extent) and sometimes show other symptoms depending on the size and location of the damage.

Some medications can cause acquired dyschromatopsia (e.g., ethambutol used against mycobacteria. Erectile dysfunction agents (e.g., Sildenafil), a phosphodiesterase inhibitor, can also cause a reversible, transient blue-green change in vision. The drug can affect the retinal phosphodiesterase as well as the penile form (Barrett et al. 2012).

Clinical Presentation

Hereditary (congenital) colorblindness is usually noticed in childhood, when children use inappropriate colors in their artwork and other activities, for example, using brown instead of red for flowers. In acquired forms, patients may complain that colors look "washed out."

Diagnostics

Ishihara color plates (pseudoisochromatic plates) can be used to diagnose color blindness in the clinic. They consist of numbers or shapes made up of colored spots on a background of similar colored spots. The colors are ones that would be difficult for an affected person to distinguish from the background.

Differential Diagnosis

- Congenital Colorblindness
- Medication-induced color deficiency
- Optic neuritis
- Occipital lobe stroke (V8 region)

Prophylaxis

There is no known prophylaxis.

Therapy

Congenital red-green colorblindness cannot be cured. In acquired forms, the underlying problem should be treated.

Prognosis

Congenital color blindness-affected individuals may have variable limitations in certain occupations but in general can use environmental cues to guide them in leading a normal life. For example: a vertical traffic light has red as the top color and green as the bottom color. If the color blindness is acquired, then the prognosis depends on the severity and type of disease or lesion.

Epidemiology

Since this is commonly an X-linked-inherited and recessive disorder, males are affected if they get the affected X-chromosome and females become carriers and may pass the gene onto half of their sons. If however the gene on both X-chromosomes is mutated, a female can be affected. About 8% of the Caucasian male US population and 0.4% of the female population are affected (Barrett et al. 2010) by congenital color blindness. The epidemiology of acquired dyschromatopsia is dependent upon the specific etiology.

Secondary blepharospasm

Definition

Blepharospasm is spasm of the eyelids. Bilateral benign essential blepharospasm (BEB) can be an adult-onset localized dystonia involving spontaneous contractions of the periocular muscles, namely, the orbicularis oculi, procerus, and corrugator muscles. This results in bilateral eye closure that ranges in severity from a benign increase in blink frequency to severe impairment from sustained eyelid closure. Blepharospasm typically has a gradual and intermittert onset occurring during midlife after age 30. Reflex blepharospasm is a type of secondary blepharospasm triggered by dry eyes, blepharitis,

intraocular inflammation, meningeal irritation, and light sensitivity.

Etiology

In contrast to reflex blepharospasm, BEB has no known etiology.

Clinical Presentation

Clinical manifestations of blepharospasm include an increase in blink frequency and spastic involuntary closure of the eye. Though it can present asymmetrically, blepharospasm is typically bilateral, synchronous, and symmetric. The criteria suggested for diagnosing blepharospasm are synchronous orbicularis oculi spasms resulting in bilateral eyelid narrowing/closure as well as either an increase in blink frequency and/or a "sensory trick" maneuver that decreases the dystonia. Patients with reflex blepharospasm usually have worsening of symptoms with bright light or stress, with onset typically beginning with dry eye or ocular irritation due to photosensitivity. Reflex blepharospasm may be triggered by photosensitivity and surface disease.

Diagnostics

Blepharospasm is a clinical diagnosis made by a thorough history and physical examination.

Differential Diagnosis

Blepharospasm should be distinguished from Meige syndrome or craniocervical dystonia, which includes both the focal dystonic eyelid closure of blepharospasm in addition to contractions of the lower face, jaw, and neck. Meige syndrome involves bilateral contractions of the face. Though most cases of Meige syndrome are due to an unknown etiology, it can result from prolonged neuroleptic medication use. Blepharospasm should also be distinguished from hemifacial spasm (HFS) which is involuntary unilateral facial spasms that often start with the eyelid. HFS is typically transitory and clonic movements and, unlike blepharospasms, is usually unilateral, with less than 5% being bilateral. Irregular, brief clonic movements begin in the orbicularis oculi and then spread to other muscles innervated by the facial nerve, gradually over months to years. Both BEB and HFS are most effectively treated by botulinum injections. EEG may be required in atypical cases where seizure is suspected but usually BEB and HFS are clinical diagnoses.

Therapy

In secondary causes instigating the reflex blepharospasm, the underlying etiology should be treated. Botulinum toxin is a potent neurotoxin made by *Clostridium botulinum* resulting in regional muscle weakness. Botulinum toxin may be further enabled through its zinc endopeptidase disrupting fusion proteins, thus interfering with acetylcholine release at the neuromuscular junction and causing localized muscle weakness. Botulinum toxin treatment is effective for up to 50–85% of patients with blepharospasm.

Prognosis

If the underlying secondary etiology is treated, symptoms may resolve.

Epidemiology

Age seems to be the most significant risk factor in blepharospasm development compared to other causes of focal dystonia. The mean age at onset of blepharospasm together with cranial dystonia was 55.7 years. One case control study in Italy showed that coffee drinking was associated with decreased development of blepharospasm compared to controls with the strength of the relationship increasing with average numbers of coffee cups per day. Patients with blepharospasm are also more likely to experience spread of the dystonia to other body parts (31% past the head) than other types of dystonias, with the greatest risk being present in the first 5 years of the disorder.

Reflex Tear Arc

B. Ranjodh Singh[1], Allison J. Chen[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Lacrimation reflex

Definition

The reflex tear arc is responsible for production of tears in response to irritation of the ocular surface and in maintaining a tear film for adequate lubrication of the eye.

Structure

The reflex tear arc is triggered by ocular surface irritation and consists of the lacrimal glands, ophthalmic branch of the trigeminal nerve, and parasympathetic fibers from the superior salivary nucleus. The lacrimal gland is located in the superior lateral corner of the orbit, within the lacrimal fossa of the frontal bone. Inferiorly, it is in contact with the globe, and superiorly it is split into the upper (orbital) and lower (palpebral) lobes by the lateral horn of the levator aponeurosis. Approximately 8–12 lacrimal gland ducts empty into the superior cul-de-sac approximately 5 mm above the lateral tarsal border. The ducts from the orbital lobe join with the ducts from the palpebral lobe.

The ophthalmic branch of the trigeminal nerve serves as the afferent (sensory) pathway for detecting ocular surface irritation. The efferent pathway is composed of parasympathetic fibers originating from the superior salivary nucleus of the pons and traveling with the facial nerve. The lacrimal fibers leave the greater superficial petrosal nerve (branch of the facial nerve) and pass to the sphenopalatine ganglion. The fibers then enter the lacrimal gland via the superior branch of the zygomatic nerve through an anastomosis between the zygomaticotemporal nerve and the lacrimal nerve.

Along with the primary lacrimal gland, the accessory lacrimal glands of Krause and Wolfring are also responsible for aqueous tear secretion. These glands are smaller than the primary lacrimal gland; the glands of Krause are located in the upper fornix, while the glands of Wolfring are situated further down on the eyelid, above the tarsus.

Function

The reflex tear arc primarily produces tears from the main lacrimal gland in response to ocular

surface irritation. The accessory lacrimal glands of Krause and Wolfring provide nonreflexive, basal tear secretion. Aqueous secretion from the main and accessory lacrimal glands is composed of water, electrolytes, and proteins. This aqueous secretion combines with mucin from goblet cells to produce an evenly distributed tear film, which is coated by oily outer layer produced by the Meibomian glands that reduces evaporation of the tear film.

Clinical Relevance

Lacrimal gland tumors, although rare, require a thorough workup to differentiate benign from malignant lesions. Approximately half of lacrimal gland tumors are malignant, which often warrants obtaining a lacrimal gland biopsy of suspicious masses. Since the ducts from the orbital lobe join with the ducts from the palpebral lobe prior to emptying, lacrimal biopsy of the orbital lobe should be performed as biopsy of the palpebral lobe may seriously reduce secretion from the entire gland.

Keratoconjunctivitis sicca, i.e., dry eyes, is a common condition that can occur with reflex tear arc malfunction (Dartt 2004). Autoimmune diseases, e.g., Sjogren's disease, can affect the nerve innervation of the lacrimal glands, leading to inefficient tear production and ocular surface irritation. The ocular surface and the afferent limb of the reflex tear arc may be injured during corneal procedures, e.g., refractive surgery, leading to an abnormal reflex tear arc.

Crocodile tears syndrome, a.k.a., gustolacrimal reflex, is a unilateral lacrimation that occurs when a patient eats or drinks (Montoya et al. 2002). Crocodile tears syndrome usually follows a Bell's palsy or traumatic facial paralysis or can occur congenitally after a Duane's retraction syndrome. The underlying mechanism of this abnormal reflex is largely due to the misdirection of regenerating gustatory fibers from either the facial or glossopharyngeal nerves. While debilitating for patients, injection of botulinum toxin type A into the affected lacrimal glands may provide symptomatic relief.

Refraction

▶ Refractive Ametropia

Refraction Law

▶ Law of Refraction (Snell's Law)

Refractive Ametropia

Achim Langenbucher
Institute of Experimental Ophthalmology, Saarland University, Homburg, Saar, Germany

Synonyms

Refraction; Refractive errors

Definition

In the ideal eye, an object located at infinity is sharply imaged to the retinal plane in the absence of accommodation. If the optics of the eye do not focus properly to the retina, it shows refractive ametropia. The most common forms of ametropia are myopia (nearsightedness)/hyperopia

(farsightedness), where the image plane is located in front of/behind the retinal plane or astigmatism. Ametropia refers to all refractive vision disorders or errors.

Refractive Astigmatism

Achim Langenbucher
Institute of Experimental Ophthalmology, Saarland University, Homburg, Saar, Germany

Synonyms

Nonstigmatic refraction

Definition

Astigmatism is an optical disorder in which vision is blurred due to the inability of the optics of the eye to focus a point object into a conjugated image on the retina due to an irregular (mostly toric) curvature of the cornea or lens. The two types of astigmatism are regular (which can be compensated with optical corrections, e.g., glasses) and irregular (which cannot be compensated). Refractive astigmatism is caused by a difference in degree of curvature refraction of the two different meridians.

Refractive Lens Exchange

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Clear lens exchange (CLE); Clear lens extraction; Refractive lens extraction (RLE)

Definition

Refractive lens exchange (RLE) is an essential ▶ cataract surgery without any cataract. The ▶ crystalline lens is removed and replaced with an artificial ▶ intraocular lens (IOL). The IOL is of a power to correct the underlying ▶ refractive error.

Epidemiology

RLE accounts for a marked amount of refractive surgeries in the presbyopic age group.

History

Early in the year 1890, Fukala reported on refractive lens extraction in eyes with high myopia

(Fukala 1890). This procedure was subsequently abandoned due to the tenfold increase of postoperative retinal detachment in comparison to unoperated myopic eyes. Since 1890, ophthalmic surgery has undergone steady changes by means of innovations in intraocular lens design, application of ophthalmic viscoelastic substances, and development of phacoemulsification and microincisional surgical techniques. These innovations improved the safety and efficacy of refractive lens exchange, making it an integral part of refractive surgery today.

Clinical Features

Implanted IOL are the same as used for cataract surgery. In the scope of RLE, toric and multifocal/accommodative IOL are especially in the focus of interest.

Tests

Indications for RLE are high myopia or hyperopia with coexistent presbyopia. The reason for the inclusion of presbyopia is the fact that RLE always leads to a complete loss of accommodation. Correction of underlying regular astigmatism in scope of RLE, which cannot be managed by corneal incisional techniques, is best accomplished by implantation of toric lens implants. Border indications for RLE are presbyopia without ametropia implying implantation of a multifocal lens implant, presbyopia with underlying astigmatism, and prepresbyopic patients with high hyperopia of +5 to +10 D not amenable for keratorefractive surgery or phakic IOL due to shallow anterior chamber situation (Kohnen 2011).

Differential Diagnosis

If any clinically relevant clouding of the crystalline lens is present prior to surgery, one should better declare surgery as cataract surgery.

Etiology

Compared to excimer and femtosecond laser surgery for refractive surgery, RLE is by far an older surgical procedure.

Treatment

Surgery and complication spectrum of RLE are similar to that following cataract surgery with some differences. Phacoemulsification is much more easy to perform and requires less phacoenergy as the lens does not incorporate a hard nucleus. Regarding the anatomy of the treated eyes, RLE is implemented in very short or very long eyes. From this specific situation, certain risks emanate the postoperative retinal pathologies after myopic RLE and typical intraoperative difficulties induced by short anterior segment in hyperopic RLE. Myopic RLE may be difficult due to instability of the capsular bag. This bears an increased risk for tear of the capsule. Insertion of a capsular tension ring might alleviate the intraoperative situation, especially in cases of weak zonules or lysis of the zonules. In eyes with high axial length, the risk of an intraoperative subchoroidal hemorrhage is markedly increased as compared to that in normal eyes. In eyes with an axial length of more than 25 mm, rare capsular block syndrome appears more frequently. Hyperopic RLE surgery in eyes with an axial length below 21 mm is hampered by the narrow spatial situation and shallow anterior chamber. Compared to eyes with normal axial length, the risk of choroidal effusion syndrome is markedly increased.

Synonyms

Refractive eye surgery

Definition

Eye surgery used to correct refractive and eliminate or reduce a patients' need for wearing eyeglasses or contact lenses.

Basic Characteristics

One must differentiate between laser (flap and surface procedures) and non-laser refractive surgery.

Laser eye surgery can be divided into flap and surface procedures. Flap procedures include automated lamellar keratoplasty (ALK) and laser-assisted in situ keratomileusis (LASIK).

Surface procedures are Epi-LASIK, laser-assisted subepithelial keratomileusis (LASEK), and photorefractive keratectomy (PRK).

Non-laser refractive surgery includes implantable lenses, intrastromal corneal ring segments (Intacs), conductive keratoplasty (CK), astigmatic keratotomy (AK), radial keratotomy (RK), and limbal relaxing incisions (LRI). RK, AK, and LRI are counted among corneal incision procedures.

Reis-Bücklers Dystrophy

Marcus Neuffer
Department of Ophthalmology, Keesler Medical Center, Biloxi, MS, USA

Synonyms

Anterior limiting membrane dystrophy, type I (ALMD I); Atypical granular corneal dystrophy; Corneal dystrophy of Bowman's layer, type

I (CDB I); Geographic corneal dystrophy; Granular corneal dystrophy, type III; Superficial granular corneal dystrophy

Definition

A corneal dystrophy of Bowman's layer characterized by geographic opacities and recurrent erosions that lead to ocular pain and early visual loss (Figs. 1, 2, and 3).

Etiology

Inheritance is autosomal dominant.

Clinical Presentation

Patients have decreased vision at a young age (first or second decade of life) accompanied with pain and erythema from recurrent erosions. Confluent central geographic-like opacities involving Bowman's layer and the anterior stroma are seen on slit lamp examination (Krachmer et al. 2011).

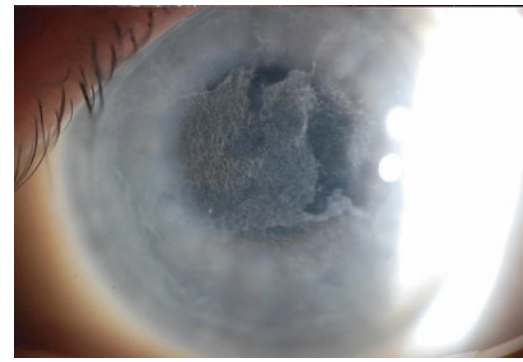
Diagnostics

Transmission electron microscopy helps distinguish Reis-Bücklers dystrophy from Thiel-Behnke by identifying rodlike granules instead of curly fibers (Krachmer et al. 2011). In light microscopy Masson trichrome stain reveals sheet-like connective tissue substance replacing Bowman's layer. Confocal microscopy demonstrates highly reflective deposits in and replacing Bowman's layer (Weiss et al. 2008).

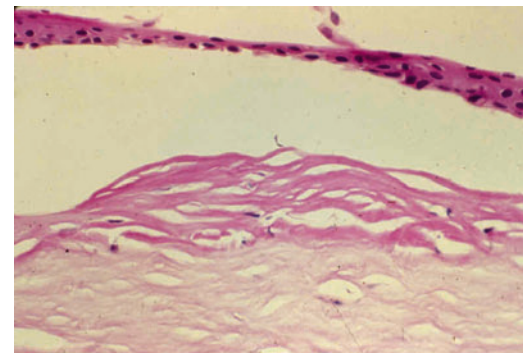
Differential Diagnosis

Differential diagnosis includes Thiel-Behnke corneal dystrophy, map-dot-fingerprint dystrophy disease, recurrent corneal erosion disease,

Reis-Bücklers Dystrophy, Fig. 1 Geographic opacities most prominent centrally



Reis-Bücklers Dystrophy, Fig. 2 Magnification of geographic opacities



Reis-Bücklers Dystrophy, Fig. 3 Histology – connective tissue-like substance replacing Bowman's layer

macular corneal dystrophy, Fuchs' corneal dystrophy, and herpes simplex.

Prophylaxis

No prophylaxis is known; however, topical lubricants are used to prevent corneal erosions.

Therapy

Treatment is initially focused on recurrent erosions that begin in the first or second decade of life. Topical lubrications, contact lenses, and patching are used during this time. Eventually, as corneal scarring develops, superficial keratectomy or phototherapeutic keratectomy (PTK) may be performed. Keratoplasty, lamellar or penetrating, is reserved for when the scarring becomes severe and deep. The dystrophy frequently recurs in the graft (Krachmer et al. 2011).

Prognosis

Recurrent erosions lessen with time. Vision slowly and progressively deteriorates until surgical treatment is necessary (Weiss et al. 2008).

Epidemiology

The condition is rare and prevalence unknown.

Residual Stroma Bed

▶ Residual Stroma Thickness

Residual Stroma Thickness

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Residual stroma bed

Definition

The amount of corneal tissue which is left, i.e., after LASIK. According to the Food and Drug Administration, a minimum of 250 μm of residual stroma thickness should be left under the LASIK flap in order to avoid corneal ectasia.

Epidemiology

No epidemiological data available.

History

Since LASIK has been performed in the late 1980s, the residual stroma thickness also became a term in refractive surgery.

Clinical Features

No clinical feature data available for this topic.

Tests

The residual stroma thickness can be measured by ultrawave pachymetry, anterior segment optical coherence tomography, or corneal topography.

Differential Diagnosis

Corneal treatment procedures which are dependent on the stroma thickness are as follows:

- LASIK
- LASEK
- PRK

Etiology

See History section above.

Treatment

See cross-references for an exact description of the different treatment methods involving the stroma thickness.

Retina, Structure of

William J. Wirostko
Eye Institute- Medical College of WI, Milwaukee, WI, USA

Definition

A highly organized and specialized structure consisting of alternate layers of cell bodies and synaptic junctions that captures and transduces light images into a pattern of neuronal activity ultimately conveying visual information to the brain (Chen et al. 2006; Loewenstein and Green

1999; Miller 2006). It is located on the interior posterior surface of the eye.

Basic Characteristics

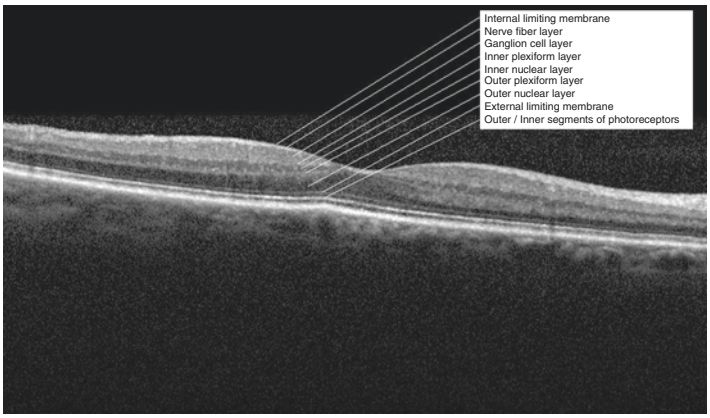
Histologically, the retina is composed of nine layers. These include (progressing from the outer retina to inner retina):

1. Layer of the outer and inner segment of the photoreceptors
2. External limiting membrane
3. Outer nuclear layer
4. Outer plexiform layer
5. Inner nuclear layer
6. Inner plexiform layer
7. Ganglion cell layer
8. Nerve fiber layer
9. Internal limiting membrane

All layers function together for the purpose of converting light images into neuronal signals, which can be interpreted by the brain as vision.

Layers 1 through 4 are in the deepest levels of the retina and involve the photoreceptor rod and cone cells of the retina. In the human eye, there are approximately 100 million retinal rod cells and five million retinal cones cells. The outer segments of these photoreceptor cells (layer 1) contain visual pigment stacked on disk membranes. When as little as one photon of light is absorbed by these light-sensitive pigments, the photoreceptor undergoes hyperpolarization and begins the process of transducing light energy into a neuronal signal. Retinal rod cells are far more sensitive to absorbing light than cones, likely due to their large content of the visual pigment rhodopsin, but are insensitive to color and have low special acuity. Outer segments of both rod and cone cells receive support from surrounding villous processes of the retinal pigment epithelium. They also receive support from their respective inner segments, which contain the protein synthesis and metabolic machinery for that photoreceptor cell. Both the outer segment and the inner segment lie distal to the external limiting membrane (layer 2). The outer nuclear layer (layer 3) is composed of nuclei of both retinal cone and rod cells. The outer plexiform layer (layer 4) involves the proximal ends of the photoreceptor cells. It is here that the photoreceptors connect with horizontal cells, bipolar cells, and second-order neurons via glutamate neurosynaptic junctions, to complete the transduction of light energy to a neurological signal. Horizontal cells are interneurons of the outer retina. They receive input from certain photoreceptor terminals, travel laterally, and reconnect to other photoreceptors terminals.

The inner nuclear layer (layer 5) contains nuclei of bipolar cells, amacrine cells, and interplexiform cells. Bipolar cells conduct signals from photoreceptors to ganglion cells in the inner plexiform layer (layer 6). Amacrine cells are the horizontal cells of the inner nuclear level and



Retina, Structure of, Fig. 1 Optical coherence tomography demonstrating nine layers of the retina

conduct signals between ganglion cells and other amacrine cells. Two types of bipolar cells exist, namely, depolarizing and hyperpolarizing. These cells for the basis for the on and off ganglion cell receptive field. Amacrine cells employ a variety of neurotransmitters, including peptides, gamma-aminobutyric acid (GABA), glycine, acetylcholine, and dopamine. Interplexiform cells are a relatively newly discovered type of cell and likely function to carry information from the inner retinal to the outer retinal, which is opposite to the direction of most signals in the retina.

The ganglion cell layer (layer 7) involves ganglion cells whose axon extends from the retina to the brain. These cells constitute the final common pathway for transduction of light from the photoreceptors of the retina to the brain.

The nerve fiber layer (layer 8) contains axons from ganglion cells on their way to the brain. These axons are unmyelinated in the human retina since myelination ceases at the lamina cribrosa during embryologic development. Rarely, some axons may appear myelinated in the retina.

The most internal layer of the retina is the internal limiting membrane (layer 9). This layer is composed of the basal lamina of Muller cells. It is thickest in the posterior fundus and becomes thinner as one moves more anterior. It is absent both over the foveola and the optic nerve (Fig. 1).

Retinal Arteries and Retinal Veins

► Retinal Blood Vessels

Retinal Blood Vessels

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Retinal arteries and retinal veins

Definition

The retinal blood vessels originate from the central retinal artery and permeate the retina from the internal limiting membrane to the inner nuclear layer to nourish and remove waste from the inner two thirds of the retina. This blood supply is completely independent of the choroidal vasculature.

Structure

The central retinal artery, a branch off of the ophthalmic artery, enters the eye by way of the optic nerve and branches into four retinal arteries that each supplies a different quadrant of the retina. Retinal arteries and veins remain in the nerve fiber layer of the retina. Smaller arterioles and venules extend deeper into the retina and create two microvascular networks: (1) a more superficial capillary bed in the ganglion cell and nerve fiber layer and (2) a deeper network in the inner nuclear layer. These capillary networks thin to one layer near the fovea and in the periphery. In the peripapillary region of the retina, a distinct layer of radial capillaries can be found in the inner nerve fiber layer, making these the most anterior of all capillary networks.

Capillary-free zones exist around larger retinal arteries, likely due to increased oxygenation of the retina in these locations. Retinal capillaries are also absent in the 400–500 μm foveal avascular zone and in the far periphery.

After the first retinal branch, the retinal arteries do not contain any elastic fibers or internal elastic membrane. Retinal capillaries consist of endothelial cell that are surrounded by pericytes. Retinal vein and venules generally follow their associated retinal arteries and arterioles. Where retinal arteries and veins cross, the artery usually is more anterior, and the arteries and veins share a common adventitial sheath.

After the ophthalmic artery enters the lamina cribrosa, there is no evidence of nerve fiber endings in retinal blood vessels. Therefore no central regulation of blood flow occurs within the retina but instead blood flow regulation is a result of autoregulation due to changes in the retinal vascular microenvironment.

Function

The retinal vessels supply blood to the inner most 2/3 layer of the retina from the internal limiting membrane to the inner nuclear layer. Tight junctions located in the retinal capillary endothelial cells create a blood-retinal barrier.

Clinical Relevance

Many retinal pathologies are a result of disorders in the retinal circulation. Examples include diabetic retinopathy, retinal vascular occlusions, hypertensive retinopathy, sickle-cell retinopathy, and HIV retinopathy. Macular edema from retinal vascular dysfunction can also result from many different causes including diabetes, vein occlusions, radiation retinopathy, secondary to ocular surgery, uveitis, and hereditary retinal degenerations. Retinal vascular diseases also exist such as Coats' disease, juxtafoveal telangiectasias, and retinal arterial macroaneurysms. Inflammation of retinal blood

vessels, retinal vasculitis, can be associated with certain systemic diseases and types of uveitis.

Synonyms

Retinal tears

Definition

A full-thickness defect in the neurosensory retina

Etiology

Retinal breaks are full-thickness breaks that occur secondary to vitreous traction, more frequently at site of strong vitreal adhesion as a consequence of a posterior vitreous detachment (PVD), especially at the vitreous base. The posterior edge of the tear is its apex, and the anterior extensions are its base.

Lattice degeneration of the retina is another risk factor for the development of a retinal break. This is a condition in which peripheral retinal thinning is associated with liquefaction and separation of the overlying vitreous, associated with a pronounced vitreoretinal adhesion at the margin. When PVD occurs, traction at the margin of the lattice degeneration can lead to retinal tears.

Blunt trauma can also induce many varieties of retinal breaks, which include horseshoe tears, retinal dialysis, and macular holes. The major mechanism of peripheral break formation is hypothesized to be compression of the globe with subsequent distortion and expansion at the area of the ora serrata and equator. This expansion produces an acute increase in vitreoretinal traction, which often results in a retinal dialysis.

Horseshoe or flap tears with persistent traction often avulse the base of the tear to leave a small, round defect in the neural retina with an overlying operculum of retinal tissue. This generally indicates complete relief of vitreoretinal traction in this area.

Atrophic holes in the retina occur secondary to retinal thinning. Vitreous traction is not the pathogenic mechanism of atrophic retinal holes. Although these can occur in isolation, they often present within areas of lattice degeneration.

Open-globe injury with penetrating foreign body may cause retinal break immediately at the time of impact with two mechanisms: a direct retinal trauma, with disruption of the retina and necrotic breaks, or as result of latter vitreous traction. This retinal defects are typically irregular (Ryan 2013).

Clinical Presentation

Symptoms associated with acute horseshoe tears include floaters secondary to vitreous debris

(hemorrhage, retinal pigment epithelium cells) and flashes that result from persistent vitreous traction.

A significant visual loss could occur when retinal breaks are associated with vitreous hemorrhage.

Marfan's syndrome, Ehlers-Danlos syndrome, and homocystinuria can predispose to retinal break formation (Yanoff and Jay 2013).

Diagnosis

The diagnosis is typically clinical. A careful examination of the peripheral retina must be carried on by using a Goldmann three-mirror lens or with indirect ophthalmoscopy and scleral depression.

Differential Diagnosis

Pars plana cysts
Enclosed oral bays
Meridional folds/complex
Ora serrata pearls
Granular tags
Paving-stone degeneration
Chorioretinal scars
Peripheral cystoid degeneration
White with/without pressure
Retinal erosion

Prophylaxis

Upon the discovery of a retinal break, many factors should be considered: the presence or absence of symptoms; age and systemic health of the patient; refractive error of the eye; location, age, type, and size of the break; status of the fellow eye; and whether the patient is aphakic or pseudophakic or will soon undergo cataract surgery.

The presence or absence of symptoms in association with the onset of the break is the most important prognostic criterion for progression to retinal detachment.

In phakic patients who have no previous history of retinal disease or of high myopia and who develop *asymptomatic* horseshoe tears, atrophic holes, or holes with opercula, prophylactic treatment is rarely indicated.

Patients should be made aware of the symptoms of vitreous traction and retinal detachment and should be instructed on how to assess the peripheral visual field.

By contrast, in phakic patients, it is recommended that nearly all acute, *symptomatic* retinal breaks be treated to prevent retinal detachment.

Long-standing tears often have retinal pigment epithelial changes adjacent to them. These changes indicate to the clinician the decreased likelihood of retinal detachment; by contrast, supero-temporal breaks are more frequently associated with retinal detachment.

Retinal dialyses, whether traumatic or idiopathic, have a high association with the development of retinal detachment. In these cases, prophylaxis is usually indicated (Yanoff and Jay 2013).

Therapy

Aim of therapy is to provide a chorioretinal adhesion between the tear and the adjacent retina, which prevents liquid vitreous access through the hole and into the subretinal space. Most common first choice therapy is laser photocoagulation or cryotherapy.

Laser could be achieved indifferently with the argon green laser, krypton red laser, or diode laser, and it is delivered by slit lamp or indirect ophthalmoscopy. Slit lamp is preferred for posterior retinal break, while indirect ophthalmoscopic laser photocoagulation is preferred for anterior retinal breaks because of difficulty in treatment of the anterior margin at the slit lamp. The tear should be surrounded completely by three to four rows of laser burns. Although the spots need not be confluent, there should be no more than half a spot size of untreated retina between burns. Chorioretinal adhesion occurs the instant that the laser photocoagulation is applied, but maximal adhesion occurs 7–10 days later. Topical anesthesia alone is

enough in the majority of cases. If multiple large breaks are present and the patient is unable to tolerate the treatment, retrobulbar anesthesia may facilitate completion of the procedure.

Cryotherapy destroys the choriocapillaris, retinal pigment epithelium (RPE), and outer retina to provide a chorioretinal adhesion. One week is required to achieve partial adhesion and up to 3 weeks for the full adhesive effects to occur. Cryopexy can be delivered adequately despite the presence of extensive cataract, anterior or posterior capsular opacity, relatively dense vitreous hemorrhage, or anterior breaks. Transconjunctival cryotherapy under topical anesthesia (cotton-tipped applicators soaked in 4% lidocaine) is usually adequate. In some cases, 2% lidocaine injection subconjunctivally via a 30-gauge needle may be necessary. In eyes that fail prophylactic therapy, retinal detachment repair by pneumatic retinopexy, scleral buckling, or vitrectomy is usually successful in the anatomic reattachment of the retina (Kanski 2003; Ryan 2013; Yanoff and Jay 2013).

Prognosis

Failure rates for prophylactically treated retinal breaks depend on many factors, which include the type of retinal break, indications for treatment, length of follow-up, and definition of failure.

Risk factors for failure included aphakic or pseudophakic status, acute symptoms, retinal detachment in the fellow eye, and male gender.

Epiretinal membrane and macular pucker are other visually significant complications associated with prophylactic treatment of a retinal break; they occur in 1–5% of treated eyes. More rare complications that can occur include Adie's pupil, subretinal and vitreous hemorrhage, and breaks in Bruch's membrane. An exceedingly rare, but potentially devastating, complication in patients who have staphylomatous sclera and eyes treated with cryotherapy is scleral rupture (Ryan 2013).

Epidemiology

The incidence of retinal breaks at autopsy in individuals over 20 years of age is in the range 6–11%.

The annual incidence of retinal detachment is approximately 12 per 100,000 people per year.

The occurrence of retinal breaks increases with increasing age. Myopia is considered a risk factor for retinal breaks that lead to retinal detachment; however, prevalence of retinal breaks in myopic eyes is similar to that in eyes of general population (Ryan 2013).

Ablatio retinae

Definition

Detachment of the neurosensory from the underlying retinal pigment epithelium.

Histology

Diagnosis of retinal detachment (RD) is usually made upon clinical or sonographical examination. Nevertheless, there are some specific changes found in histology. Like clinical findings, these depend highly upon stage of RD and are therefore dependent on time passed since acute RD.

At early stages, only little changes may be found within the retina. In animal models, the earliest sign is intraretinal edema. Photoreceptors show a loss of the horizontal orientation of the discs within the outer segment. Swelling of the nucleous may represent hypoxic condition of various retinal cells. Retinal pigment epithelium cells (RPE) present a swelling, and at later stages these cells partly separate from Bruch's membrane. Clumps of proliferating RPE cells and macrophages are later found on both surfaces of the detached retina.

At later stages, the detached retina shows signs of degeneration in outer retinal layers and general thinning. With more time passing, the retina shows changes with cell loss and large cystoid spaces at the inner and outer nuclear layer. In some cases persisting longer than 3 months, RPE cells proliferate at the junction of detached and attached retina.

As also can be found upon clinical examination, most retinal detachments develop proliferative vitreoretino pathy. This disease is characterized by sub-, epi-, or intraretinal formation of membranes. Upon histologic examination, hypocellular membranes can be found consisting of RPE cells, glia cells, and myofibrocytes – most likely dedifferentiated RPE cells. These cells produce collagen and other extracellular matrix (ECM) proteins. Among many others, transforming growth factor beta contributes to transformation of RPE cells and increased production of ECM proteins.

Immunohistochemistry

For diagnosis of RD, immunohistochemistry is of no relevance. However, for research, this technique is widely used as it allows detection of ECM proteins and constellation thereof in PVR.

Electron Microscopy

For diagnosis of RD, electron microscopy is of no relevance.

Molecular Diagnostics

There is no specific molecular diagnostics for RD. However, some syndromal genetic disorders are associated with increased incidence of RD (for example, stickler syndrome, FEVR).

Differential Diagnosis

RD – especially longstanding RD – may clinically be confounded with retinoschisis.

Department of Ophthalmology, Sidney Kimmel Medical College of Thomas Jefferson University, Philadelphia, PA, USA

Synonyms

Retinal detachment

Definition

Detachment of the neurosensory retina from the underlying retinal pigment epithelium due to a full-thickness retinal break or breaks (Fig. 1).

Etiology

Rhegmatogenous retinal detachment (RRD) is caused by the passage of mobile, liquefied vitreous gel through a full-thickness retinal break, commonly a retinal tear, retinal hole, or retinal dialysis. It is generally agreed that vitreous traction must be present on or near the retinal break for rhegmatogenous retinal detachment to occur. Conditions that may be associated with rhegmatogenous retinal detachment include posterior vitreous detachment (PVD), trauma, high myopia, lattice degeneration, retinoschisis, infectious retinitis, uveitis, inherited vitreoretinal dystrophies, and prior history of retinal detachment.

Retinal Detachment Rhegmatogenous, Fig. 1 Inferior rhegmatogenous retinal detachment. Two adjacent retinal breaks are visible with bullous, subretinal fluid extending into the macula

Interventions associated with higher risk of rhegmatogenous retinal detachment include cataract extraction and Nd: YAG capsulotomy.

Rhegmatogenous retinal detachment may also be found in combination with tractional retinal detachment, which is characterized by vitreoretinal traction that mechanically detaches the neurosensory retina. Combined rhegmatogenous-tractional detachments may occur in patients with proliferative diabetic retinopathy, proliferative sickle cell retinopathy, proliferative vitreoretinopathy, and ocular trauma.

Clinical Presentation

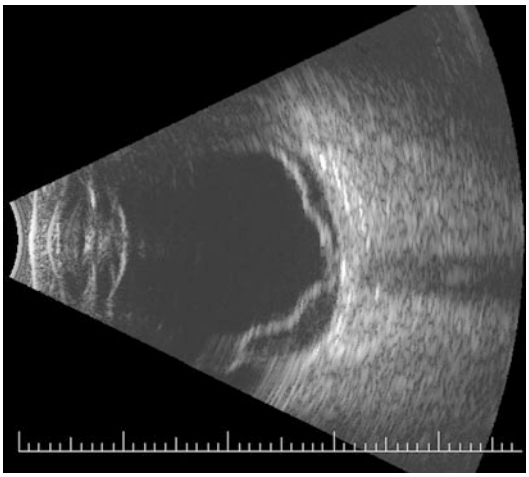
Patients may report symptoms of vitreoretinal traction and posterior vitreous detachment, including the sudden appearance of floaters and/or photopsias (flashes). Progressive accumulation of subretinal fluid ultimately results in a symptomatic visual field defect as more of the retina posterior to the equator is detached. Macular and particularly foveal involvement of the detachment results in central vision loss. Elevated intraocular pressure and inflammation may result, termed Schwartz-Matsuo syndrome.

Rhegmatogenous retinal detachment may be asymptomatic, however, when dissection of subretinal fluid is limited in area and the vitreous gel is less liquefied. Young, myopic patients with atrophic retinal holes or breaks associated with lattice degeneration without PVD, for example, may have subclinical detachments.

Diagnostics

Binocular indirect ophthalmoscopy with scleral depression remains the mainstay of diagnosis of rhegmatogenous retinal detachment and identification of causative retinal breaks.

When view of the fundus is obscured, B-scan ultrasonography (Fig. 2) can be used to characterize the location and extent of retinal detachment and to identify areas concerning for retinal break. Optical coherence tomography (OCT) may be used to confirm presence of subretinal fluid, particularly in cases when macular involvement may be in question, or to differentiate from retinoschisis.



Retinal Detachment Rhegmatogenous, Fig. 2 B-scan ultrasonography revealing retinal detachment. Shallow subretinal fluid is present superior and inferior to the optic nerve

Differential Diagnosis

Differential diagnosis includes tractional retinal detachment, exudative (serous) retinal detachment, and retinoschisis.

Prophylaxis

Prophylaxis targets prevention of the factors causing rhegmatogenous retinal detachment, namely: preventing passage of fluid vitreous through a full-thickness retinal break and/or relieving vitreoretinal traction.

Laser photocoagulation, cryotherapy, and far less commonly a scleral buckling procedure or vitrectomy may be used as prophylaxis of rhegmatogenous retinal detachment via prevention of fluid vitreous from passing through a retinal break (laser photocoagulation and cyrotherapy) or relief of vitreoretinal traction (scleral buckle or vitrectomy).

Treatment of symptomatic retinal tears, especially in the presence of posterior vitreous detachment, with laser photocoagulation or cryotherapy is recommended to prevent

rhegmatogenous retinal detachment. In regard to asymptomatic lesions or precursors of retinal tears, particularly atrophic retinal holes or lattice degeneration, data from prospective, randomized trials is unavailable to guide clinical practice. Prophylactic treatment of these asymptomatic lesions may be considered in high-risk patients such as those with vitreoretinal degenerations or a history of retinal detachment in the fellow eye. Patients should be counseled on symptoms of retinal traction or detachment, including photopsias, vitreous floaters, and visual field loss, and therapy should be individualized.

Therapy

Multiple options are available for treatment of rhegmatogenous retinal detachment. Comorbid ocular and systemic pathology, lens status, and surgeon preference may affect decisions regarding chosen method of repair.

Pars plana vitrectomy with intravitreal tamponade and scleral buckling procedure, used alone or in combination, are the mainstays of primary rhegmatogenous retinal detachment repair. Concurrent endolaser photocoagulation and cryotherapy are performed to seal retinal breaks. Injection of perfluorocarbon liquid, retinotomy/retinectomy, membrane peeling, and external or endo-drainage are surgical techniques that may be utilized to achieve anatomic reattachment.

In selected patients, pneumatic retinopexy and demarcation with laser photocoagulation or cryotherapy are appropriate office-based therapeutic approaches.

Prognosis

Visual acuity improves after successful retinal reattachment, but the degree of visual acuity may vary pending duration of detachment and involvement of the fovea. Failure of primary surgery, poor preoperative visual acuity, extensive detachment, and the presence of PVR have been associated with poorer visual outcome.

Single surgery anatomic success rates vary in prior reports but may be achieved in approximately 90% of patients, with final retinal reattachment achievable in approximately 95% of patients. Proliferative vitreoretinopathy is the most common cause of retinal detachment surgery failure and occurs in up to 10% of patients.

Epidemiology

The annual incidence of rhegmatogenous retinal detachment has been reported to be between 6.3 and 17.9 per 100,000 population, with a median incidence of 10.5 per 100,000 population. Risk of detachment in the fellow eye has been reported to be between 5% and 15%.

Retinal Hemangioblastomas

► Hemangioblastomas, with Retinal Angiomatosis (von Hippel Lindau Disease)

Retinal Hemangioma

Shahar Frenkel and Jacob Pe'er
Department of Ophthalmology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel

Synonyms

Retinal capillary hemangioma; Retinal cavernous hemangioma

Definition

Capillary hemangioma is a benign developmental tumor in which proliferating endothelial cells form a primitive capillary network usually fed by feeder vessels originating from the central retinal artery.

Cavernous hemangioma is a benign congenital collection of multiple thin-walled dilated vessels lined by non-fenestrated endothelium without feeder vessels (Singh et al. 2007).

Etiology

Capillary hemangioma results from a proliferation of endothelial cells, which is why some authors consider it a hemangioblastoma. In up to 60% of patients with either solitary or multiple retinal capillary hemangiomas, especially if there is a family history, there is association with von Hippel-Lindau (VHL) disease which has an autosomal dominant etiology.

Cavernous hemangioma could not be consistently linked with a systemic condition.

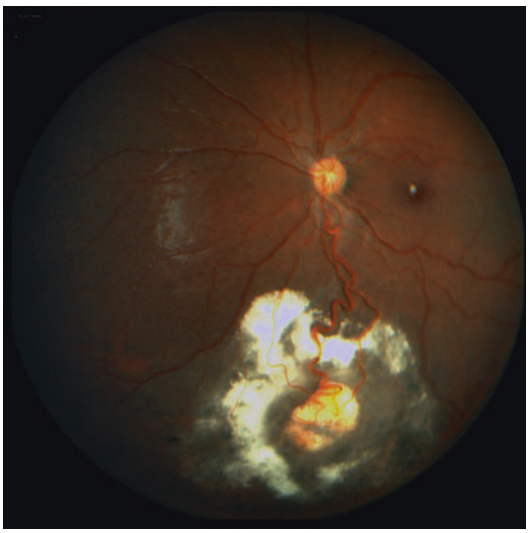
Clinical Presentation

Capillary hemangiomas can be detected by 25 years of age, when patients are screened due to a known VHL family history. In two-thirds of the cases, there is a red-orange intraretinal solitary lesion, while in one-third there are multiple lesions. In VHL, there may even be bilateral lesions. The lesions are usually found in the temporal periphery with feeder vessels or they may be found juxtapapillary without feeder vessels. The capillaries leak fluid causing exudative detachment and a decrease in the patients' visual acuity (Fig. 1).

Cavernous hemangiomas appear at any age from birth to 60 years of age. They can be solitary, but there are usually multiple grape-like blood-filled lesions appearing in the retina juxtapapillary area or over the optic nerve head. They usually do not leak fluid and thus do not cause a reduction in visual acuity.

Diagnostics

Clinical examination should be complemented by ultrasonography and fundus photography, along



Retinal Hemangioma, Fig. 1 Color fundus picture of a left eye with dilated tortuous vessels leading from the optic disk toward a typical peripheral retinal yellow lesion surrounded by subretinal fluid and white exudates

with optical coherence tomography (OCT) imaging. OCT can detect fluid accumulation resulting from leakage from the abnormal vessels within the hemangioma. Still, the most important imaging for these vascular lesions is fluorescein angiography. It can detect the feeder vessel leading from the disk to the capillary hemangioma and stain the exudation. OCT can detect both subretinal and intraretinal fluid. If the fluid does not extend into the central macular area, it should not cause a visual disturbance and can remain untreated.

Systemic correlations should be evaluated and may help in the diagnosis: VHL in patients with capillary hemangiomas. Patients with a cavernous hemangioma may have a similar brain lesion (a cerebral cavernous malformation).

Differential Diagnosis

Differential diagnosis includes ▶ malignant choroidal melanoma (amelanotic), ▶ Coats' disease, ▶ arterial macroaneurysm, ▶ and other vascular malformations.

Melanoma has a different ultrasonic internal reflectivity than hemangiomas, with medium-low internal reflectivity vs. high internal reflectivity, respectively. Coats' disease is usually diagnosed earlier in life and has telangiectatic vessels and significant exudation. Macroaneurysms are diagnosed later in life and are usually diagnosed after a bleeding event that results in blood under the retina, within the retina, and above it (preretinal hemorrhage and vitreal hemorrhage). There is no feeder vessel, but rather the macroaneurysm extends from a retinal arteriole. Lastly, vasoproliferative tumors do not have feeder vessels as do capillary hemangiomas.

Prophylaxis

There are currently no methods to avoid formation of retinal hemangiomas. However, patients with VHL disease should be followed carefully for early detection.

Therapy

Small non-leaking hemangiomas can be followed in cooperative patients. Photodynamic therapy has replaced laser photocoagulation in the treatment of capillary hemangiomas. Although more efficient in treating lesions smaller than 1.5 mm, when the lesions are more than 3 mm in diameter, one should use cryotherapy over laser photocoagulation. These larger lesions would also respond to brachytherapy. If a large lesion causes a retinal break, one should resort to vitreoretinal surgery in the treatment of the hemangioma.

Cavernous hemangiomas usually need no treatment as they do not progress. They may even spontaneously close with a thrombus. Other than a few reports of the use of laser photocoagulation, there is no known treatment for the retinal cavernous hemangiomas.

Prognosis

As a benign tumor, retinal hemangioma threatens patients' sight rather than their lives. A quarter of the patients will lose some of their vision permanently; a fifth retain only 20/100 in at least one eye.

Epidemiology

This is a rare condition with an unknown incidence.

Retinal Hole

Francesco Boscia
A.O.U Sassari, Sassari, Sardegna, Italy
Department of Surgical, Microsurgical, and Medical Sciences, Section of Ophthalmology, University of Sassari, Sassari, Italy

Synonyms

Atrophic retinal holes; Atrophic retinal tears

Definition

Retinal holes are full-thickness breaks in the sensory retina not associated with vitreoretinal traction.

Etiology

Atrophic retinal holes are not caused by vitreoretinal traction, but atrophic changes in the sensory retina are supposed to be the main cause of these lesions. There appears to be no sex predilection.

Retinal holes are the result of chronic atrophy of the sensory retina. These lesions often take a round or oval shape. It has been postulated that the pathogenesis of this lesion stems from an atrophic pigmented chorioretinopathy that is associated with retinal vessel sclerosis and a disturbance of the overlying vitreous. As the blood supply to the retina is shut down, the retinal tissue subsequently dies in conjunction with degeneration of the surrounding vitreous. This pathology precludes traction of the vitreous to the underlying sensory retina.

Idiopathic atrophic retinal hole is the most common presentation. There are no generally accepted risk factors for this condition, but lesions have been cited more often in younger myopic patients. It has been estimated about 5% of the general population has atrophic holes. Atrophic holes often present in the peripheral (temporal or superior) retina.

Large, irregular retinal holes sometimes occur in an area of blunt impact (post-traumatic retinal holes) where there are fragmentation of the retina and hemorrhagic necrosis of the choroid.

Clinical Presentation

Retinal hole are full-thickness breaks in the sensory retina, round or oval in shape, with or without a perilesional subretinal fluid accumulation. Most rounds holes are solitary, although multiple holes may be present within a lattice lesion. Retinal holes are more common in myopic eyes, most often asymptomatic. They are usually detected during routine fundus examinations or in patients complaining of photopsia and myodesopsia due to other coexisting peripheral retinal lesions. Retinal holes can become symptomatic (photopsia) if a vitreoretinal traction acts on the edges of the lattice degeneration, which they are associated to. In post-traumatic retinal holes, portions of retina sometimes appear to be missing in the area of contusion, and these defects can be quite large. The irregular edges of large retinal breaks are frequently rolled, and pieces of necrotic retina may be present in the vitreous cavity overlying the irregular breaks. Small, atrophic retinal holes may appear later in areas of less severe commotion retinae.

Diagnosis

The diagnosis is typically clinical. A careful examination of the peripheral retina must be carried on by using a Goldmann three-mirror lens or with indirect ophthalmoscopy and scleral depression. In case of blunt trauma, a fundus examination must be repeated some days after the event, since retinal holes can develop late after trauma.

Differential Diagnosis

Horseshoe retinal tear, lattice degeneration, operculated retinal hole, snail track degeneration, and retinoschisis

Prophylaxis

Usually, in simple asymptomatic retinal holes, a prophylactic treatment is not required and a periodic fundus examination is recommended. Retinal hole with subretinal fluid, evidence of vitreoretinal traction on the edges of large areas of lattice degeneration in symptomatic patients, and history of retinal detachment in the fellow eye represent typical indications for a prophylactic argon laser photocoagulation.

Therapy

Therapy is rarely necessary.

Prognosis

Prognosis is good, with a low incidence of retinal detachment.

Epidemiology

Round atrophic retinal holes within areas of lattice degenerations are typically small measuring less than 0.3 mm. Round holes have been reported in 16–18% of lattice lesions in clinical studies. Atrophic holes within lattice lesions occur more frequently in older patients, and their prevalence increases in a linear fashion with increasing age to 43% at ages 50–59. The inferotemporal quadrant is the most common side of this retinal breaks. The clinical importance of atrophic holes is that they occasionally cause or contribute to retinal detachment.

[2]Department of Ophthalmology, Croix-Rousse University Hospital, University of Lyon, Lyon, France

Synonyms

Some types of degenerations may have several names:

Microcystoid degeneration – Cystic retinal tuft; Paving stone degeneration – Cobblestone degeneration

Definition

A large family of pathologies, in which there is a degenerative process in one of the retinal layers of the anterior neuroretina or ora serrata. These pathologic processes may be grossly divided to three subfamilies:

1. Intraretinal degenerations which include the microcystoid degenerations, senile retinoschisis, and pars plana cysts
2. Retinovitreal degenerations which include the snail track degeneration, the lattice degeneration, and the white degeneration
3. Chorioretinal degeneration which include the paving stone degeneration

Etiology

The exact etiology of most of the peripheral retinal degenerations is not known. Most of the degenerations are due to aging, others are familial disorders, and some are associated with high myopia as lattice degeneration and snail track degeneration. Pars plana cysts may by associated in some cases with multiple myeloma or other diseases with abnormal protein production. White-without-pressure degeneration is considered to be a manifestation of peripheral vitreous traction.

Clinical Presentation

Intraretinal Degenerations

Microcystoid degeneration is characterized by small bubble-like lesions near the ora serrata. The lesions are visualized very well with scleral depression. They occur in the outer plexiform and inner nuclear layers of retina. Usually these degenerations are found in both eyes and more frequently are located in the supero-temporal quadrant of retina. Inner wall of the bubble may be absent, giving an impression similar to retinal hole, which is actually a pseudohole. The bubbles are filled with hyaluronidase-sensitive mucopolysaccharide. The reticular cystoid degeneration tends to occur in inner retinal layers and is located posterior and continuous with microcystoid degeneration in most of cases. It appears as linear or reticular lesions that follow the retinal blood vessels. Its histologic appearance is different from that of the microcystoid degeneration.

Expansion of both microcystoid and reticular degeneration may lead to senile retinoschisis, which is a bullous elevation of peripheral retina. It occurs mainly in the inferotemporal quadrant. It may be caused because of traction by zonular fibers or poor peripheral vascularization. Retinoschisis is usually asymptomatic and remains immobile with the eyeball movement. Sometimes it may produce an absolute field defect. With time it may enlarge toward the posterior pole, and further it may even lead to retinal detachment (RD). Retinoschisis may be classified into two subgroups: typical, which is a consequence of microcystoid degeneration, and reticular, which is a consequence of reticular degeneration. In the typical type, the retina splits in the outer plexiform layer. The inner retinal layers appear as smooth, oval lesions, whereas the outer layers are irregular and pockmarked with small "snowflakes-like" white dots, which may be seen on it. These dots represent the neurons and the Muller cells, which bridge or formerly bridged between the inner and the outer layers of the retina. In the reticular retinoschisis, the splitting occurs in the nerve fiber layer, and thus the inner, detached retinal layer is very thin and may be markedly elevated. Reticular degeneration is more prone to further RD than the typical one. The risk of RD remains rare nevertheless. Treatment is recommended only in the presence of holes in external layer.

Another type of intraretinal degeneration is the pars plana cysts. These cysts are clear, bullous elevations of nonpigmented ciliary epithelium of pars plana. They are usually seen underneath the temporal part of vitreous base. The cysts contain a clear fluid with high concentration of hyaluronic acid. In patients with multiple myeloma or other disease with abnormal protein production, an abnormal protein may accumulate in cysts that show a typical turbid appearance. These are harmless lesions not associated with serious eye complications.

Retinovitreal Degenerations

Snail track degeneration is a complex of shiny white dots, which may resemble salt grains.

These lesions are found in the area of or just in front of the equator. The pathological feature is an atrophy of retinal neural elements and deposition of lipids in the internal layers of retina. It is considered the early stage of lattice degeneration.

Lattice degeneration appears as one or several linear bands of thin retinal tissue at the equator of the eye. The lesion may be represented as fine white line or pigmentary changes within a band of retinal thinning. The bands may sometimes be traced to larger sclerosed or sheathed vessels. Histologically, there is an atrophy of the inner retinal layers and blood vessels with thick walls, which may accumulate irregular pigment. The overlying vitreous is liquefied, condensated, and adhered to the area of the margins of the degeneration process. In most cases, the degenerative area is covered with an internal limiting membrane, which protects it from RD. Actually, only 5–10% percent of patients with lattice degeneration will actually develop RD. These will be usually young patients with high myopia. Nevertheless, at eye examinations of patients with rhegmatogenous RD, lattice degeneration may be found in up to 30% of them. The tear will usually occur by means of traction of posterior or lateral margins of the lesion. In some cases, an atrophic hole in the middle of the lesion may be formed.

White degeneration is defined by white-appearing lesions of the peripheral retina. Some of such lesions are visualized with indirect ophthalmoscopy only and are called white degeneration without pressure. When retina appears normal without depression, but the white lesions are visualized with retinal indentation, these lesions are considered white-with-pressure degeneration. White-with-pressure degeneration has opalescent or milky white appearance. It may be found in 30–35% of normal eyes. Without depression, the retina appears absolutely normal. It is considered a benign condition, but the subclinical peripheral RD must be ruled out. White-without-pressure degeneration has a distinctive white color, which is brighter than the appearance of white-with-pressure degeneration. In this lesion, the choroid is almost absolutely obscured. If the sclera depression is performed, the whiteness is accentuated even more. The lesion borders are sharply demarcated. Some intervening areas of normal retina may be seen. These areas should not be confused with retinal holes. As in the white-with-pressure degeneration, the lesion may resemble RD, but after the indentation of the suspected area, it is clearly visualized that the retina is attached to the RPE. White with or without pressure presents no risk of retinal detachment. No treatment is recommended.

Chorioretinal Degeneration

Paving stone degeneration is a slowly progressive form of retinal degeneration, which is usually asymptomatic and do not lead to any complications, although it has a very dramatic appearance of multiple rounded punched-out lesions. They appear as patches of choroidal and retinal atrophy of half to several disc diameters. These lesions are located between the ora serrata and equator, in inferior quadrants of the retina. The color is yellow to white, which actually represents the sclera that lies just beneath the atrophic lesions. It is possible to see the choroidal blood vessels running through the base of the degenerative patch. The margins of the lesions are sharp and may be pigmented because of a surrounding rim of hypertrophic pigment epithelium. Several patches may merge and become confluent.

Diagnostics

The lesions are diagnosed with direct and indirect ophthalmoscopy. As it was mentioned before, parts of them have to be indentated for better visualization.

Differential Diagnosis

Retinoschisis has to be differentiated from the retinal detachment. In retinoschisis there is absolute scotoma. Usually there are no signs of

intraretinal hemorrhage or tobacco dust. The surface is very smooth and the detached layer appears thin and opaque. Underlying retinal pigment epithelium appears normal. In retinal detachment the scotoma is relative, "tobacco dust" and hemorrhages may be seen, and the surface will usually appear corrugated. If a pigmented demarcation line is present in the setting of retinoschisis, concomitant rhegmatogenous retinal detachment is present. Scleral depression is essential in distinguishing retinoschisis from retinal detachment. In contrast to retinal detachment, scleral indentation fails to collapse the cavity in retinoschisis.

Prophylaxis

Lattice degeneration is relatively common in general population (6–8%) and is prone to cause symptomatic tear with further RD in about 5–10% of patients with this lesion. Even though there is no indication for prophylactic treatment in a patient with incidental finding of lattice degeneration, in patients with lattice and risk factors for RD (the presence of a tear inside the lattice degeneration, retinal detachment in fellow eye, aphakia or pseudophakia, flap tears, future ocular surgery planned), preventive treatment may be indicated. Treatment is prophylactic laser retinopexy around the lesion. Although 6% of patients with RD have degenerative retinoschisis, for the vast majority of patients with this degeneration, there is no indication for prophylactic treatment, and the natural course of this lesion is to remain stable over years. Retinoschisis is treated if it is symptomatic or progressive and if threatens the macula. Laser demarcation of retinoschisis or treatment of margins of outer retinal layer breaks should be avoided.

Although microcystoid degenerations present some risk for development of RD, being associated with posterior vitreous detachment, these lesions are not recommended for prophylactic treatment in otherwise healthy eyes.

Prophylactic treatment of the fellow eye is doubtful in most types of degenerations. Although some of the patients who developed RD in one eye as a complication of degenerative process are in increased risk for RD in the fellow eye, there are not sufficient prospective, evidence-based studies to show that prophylactic treatment of the fellow eye will actually prevent RD. In lattice degeneration there are only some indications for preventive laser treatment of the fellow eye, but studies showed a modest treatment benefit. Current indications for prophylactic intervention are poor surgical results in the first affected eye and treatment of patients unable to recognize symptoms of RD and of patients who live in areas with limited access to ophthalmologic care. Myopic patients with atrophic holes in lattice lesions have to be evaluated periodically. During the evaluation, they have to be counseled about loss of peripheral vision, because slowly progressive retinal detachments can occur. In patients with degenerative retinoschisis and RD in one eye, there is no absolute indication for prophylactic treatment of the fellow eye. The prophylactic treatment is indicated only for unusual cases, in which breaks in outer layer of retina are responsible for retinal detachment in the first eye, while outer layer breaks and retinoschisis are present in the fellow eye.

Treatment

Treatment of degenerative processes is usually designed to prevent RD, and thus only lesions with appropriate prophylactic indications are treated. The main treatment techniques are laser photocoagulation and cryotherapy. Laser treatment is very effective for more posterior lesions, the greatest advantage of this procedure being an almost immediate effect on the tissue with proper visualization (by laser burns) of the already treated area. During the procedure, the margins of the degenerative lesion are demarcated with laser-applied burns. Eyes with small pupil or variable media opacities (e.g., partial cataract, mild vitreous hemorrhage) are not good candidates for this treatment. Cryotherapy is very effective in treating especially anterior

lesions farther located and of eyes with partial opacities of the ocular media, such as mild vitreous hemorrhages and cataract. During this procedure, cold burns are applied on or near the lesion area (depending on the lesion size), using a cryoprobe applied from the outer sclera side of the eye. One of the main disadvantages of this technique is the limited visualization of already treated areas during the procedure, since the effect of the cold burn is visualized only after several days.

Prognosis

Most degenerative lesions remain stable over time. However, some types may render the patients' eyes at higher risk for retinal breaks and further on for rhegmatogenous retinal detachment.

Microcystoid and paving stone degenerations usually do not predispose to retinal detachment. Most cases of retinoschisis are asymptomatic and nonprogressive over years. Snail track degeneration and lattice degeneration commonly lead to the development of retinal holes and in up to 10–20% of cases may lead to RD.

Epidemiology

Peripheral cystoid degeneration is present in almost all individuals over 20 years of age. Paving stone degeneration is very common, occurring in up to 22% of adult eyes, and it is bilateral in 30% of cases. Lattice degeneration is not a rare form of peripheral retinal degeneration. Its prevalence is about 10% of the general population and may be bilateral in 50%. Pars plana cysts are seen in 5–10% of general population, affecting both genders. The cysts are bilateral in 1/3 of cases. Senile retinoschisis occurs in 2–4% of population above age of 40 years. Snail track degeneration is more typical in young patients.

The incidence of white-with-pressure degeneration as well of paving stone degeneration increases with age.

RPE

Definition

RPE is one of the layers of retina formed by epithelial cells of neuroectodermal origin. The cells are hexagonally or cuboidally shaped cells which contain pigment. This single cuboidal epithelium layer is situated at the outer segments of the retina between the photoreceptors, at their apical part, and Bruch's membrane at their basal part. It extends from the margin of the optic disc to the ora serrata and is continuous with the pigment epithelium of the ciliary body. RPE cells play an important role in retinal function.

Structure

The apical portion of the RPE has villous processes that envelop the basal part of the photoreceptor cells. RPE are short, cuboidal cells, with a diameter at the periphery of about 16 μm. Macular RPE cells are much more dense and taller. In the area of fovea, RPE cell density is highest. Lateral surfaces of adjacent epithelial cells are closely

joined with each other by junctional complexes (tight junctions) and the adherens junctions. These junctional complexes form the outer blood-retinal barrier (BRB) and contribute to the RPE layer integrity and stability. The basal surface of the cells shows a rich enfolding of the plasma membrane. This surface is firmly attached to its basement membrane – the innermost layer of Bruch's membrane. RPE cells contain high amount of melanin-rich granules. These granules contribute to the typical brownish appearance of the fundus. The highest concentration of the pigment is found in the peripheral retina, while the lowest in the area of the macula.

The RPE is represented by two highly reflective lines in the optical coherence tomography (OCT) images: the Verhoeff's membrane, also called in the new terminology "interdigitation zone" (where the tips of the cone photoreceptor outer segments are enveloped by microvilli) and the RPE/Bruch's complex.

Function

The RPE cells perform essential functions:

- Absorb light
- Provide phagocytosis of the shed photoreceptor membranes
- Ensure retinol metabolism
- Form the outer BRB
- Ensure retinal attachment
- Transport nutrients to photoreceptors
- Heal and form scar tissue
- Perform an immune function

Light absorption: Each RPE cell has number of melanosomes – cell particles with melanin molecules distributed on protein fibers – that are located at the apical portion of the RPE. Melanin is a biologic light absorber, which is able to react differently on light according to variations in wavelength. Blue light with shorter wavelength is absorbed much more than red light with longer wavelength (Rayleigh absorption). Proper light absorption is important for the formation of better image as received by the retina.

Phagocytosis: RPE cells are macroglia, and as such, they continuously ingest debris from photoreceptors, cell membranes, cell discs, and other shed cell segments. Each RPE cell provides "cleaning services" to about 30–45 photoreceptors. The waste material is processed by certain phagocytized enzymes located within the RPE cells lysosomes. RPE dysfunction is supposed to explain the formation of drusen, an extracellular, amorphous deposit of material on Bruch's membrane in the macula.

Retinol metabolism: Retinal and polyunsaturated fatty acids are found in the outer segment discs. These acids play an important role in photoreceptors function and the visual cycle, thus have to be recycled. II-cis-retinaldehyde is reduced to the II-trans-retinaldehyde during the reaction with light in the photoreceptors. Most of the steps of regeneration to the II-cis configuration occur in the RPE.

Form the outer BRB: The blood-retina barrier prevents diffusion of metabolites between the choroid and the subretinal space and so contributes to the separation of the neurosensory retina from the outer environment. The RPE cells are important for the regulation of the photoreceptors' environment. This regulation is done by proper control of molecules and proteins that cross the BRB. RPE barrier functions by the way of two major components, the tight junctions and the polarized distribution of the RPE membrane proteins. Tight junctions are dynamic structures that can modify the BRB permeability by different physiological and pharmacological conditions. One of the important functions of the RPE is to "dehydrate" the inner layers of retina. These cells are capable to pump out water molecules and so prevent the formation of edema in neurosensory retina.

Retinal attachment: Dehydration of the inner retinal layers contributes to the close attachment of the photoreceptors to the RPE. Apical expression of neural cell adhesion molecules (N-CAM) by the RPE cells helps as well to keep the integrity between the neural retina and the RPE. Separation of the retinal outer segments from the RPE may lead to decreased phagocytosis and consequently accumulation of outer segments in the subretinal space.

Nutrient transport: Different pumps, transporters, and cotransporters are located on the apical and basolateral membrane surfaces. These, together with close control of the tight junctions, contribute to selective transport of nutrients, ions, and other molecules to the neural retina.

Heal and form scar tissue: External stimuli may cause trauma or inflammation of the retina. RPE have an important role in the healing process. Epithelial cells are able to proliferate, migrate, and transform to macrophages and fibroblast-like cells, and so they are contributing to the healing of the damaged tissue. Unfortunately, this property of the RPE sometimes contributes to pathologic processes of the retina. For instance, hypoxia-enhanced production of vascular endothelial growth factors (VEGF) by the transformed RPE cells may play a role in induction of choroidal neovascularization. Enhanced collagen production may cause a contraction of cellular retinal membranes and so lead to retinal detachment.

Immune function: As a crucial part of the BRB, RPE cells have an important role in the regulation of local immune response. In the presence of the inflammatory response, RPE may inhibit the action of inflammatory mediators. RPE cells secrete the tumor necrosis factor α (TNF α) receptors, which inhibit the action of proinflammatory TNF α molecule. They are also able to suppress the neutrophil superoxide generation, thus limiting tissue injury during inflammation. Breakdown of the BRB may initiate T cell activation with signaling through RPE cells, resulting in non-antigen specific lymphocytic infiltration. These epithelial cells have an important role in the synthesis of many immune modulating molecules and immunomodulatory cytokines and so control the local immune reaction of T cells and other immune system components.

Clinical Relevance

RPE has an important role in regulation of different processes in the retina. Any RPE anomaly may cause retinal pathology.

Hypertrophy of the RPE cells may result from a variety of causes, including trauma. Congenital hypertrophy of the RPE (CHRPE) produces slate gray-black flat lesions, usually in the periphery of the retina. These lesions often have depigmented lacunae, particularly in older individuals, and are often surrounded by a depigmented halo.

Hyperplasia of the RPE may contribute to epiretinal membrane (ERM) formation following rhegmatogenous retinal detachment.

RPE degeneration and atrophy play an important role in the pathogenesis of age-related macular degeneration (AMD).

In Best vitelliform dystrophy, the mutation in the Best1 gene causes production of a novel, transmembrane chloride channel at the basolateral plasma membrane of the RPE. It causes abnormal ion flux and subsequently accumulation of lipofuscin at the basal part of RPE. This lipofuscin accumulation contributes to the typical yellow, yolk-like macular lesion.

Albinism is a congenital disorder of melanin production. It is associated with decreased vision, photophobia, and nystagmus.

Definition

Retinal migraines (more properly retinal vasospasm) were defined in 1988 by the International Headache Society (IHS) as at least two attacks of fully reversible, transient monocular visual loss or disturbances associated with migraine headache. The complete diagnostic definition, as outlined by the IHS is detailed in the "Diagnostics" section below. However, recent literature challenges the notion that monocular visual loss is physiologically associated with migraine headaches. Instead, some researchers propose that "presumed retinal vasospasm" with or without associated migraine would be a more accurate diagnosis for most patients.

Etiology

The pathophysiology of retinal migraine/vasospasm remains controversial. The two main criteria are monocular visual disturbance and migraine headache. Some cases of retinal vasospasm however do not have the migraine headache (acephalgic migraine equivalent). Proposed causes of migraine headache related neurologic deficit including visual loss include spreading depression or vasospasm. Retinal vasospasm is the predominant theory for "retinal migraine," and the cortical spreading depression in bilateral migraine aura would be difficult to prove in the human retina causing monocular visual loss.

Clinical Presentation

Patients with retinal migraine/retinal vasospasm typically present after rather than during the visual symptoms. Rare patients with transient retinal vasospasm has been imaged and photographed. Unfortunately, some patients may have difficulty defining strictly monocular versus bilateral visual defects which can make the diagnosis more difficult. Typical migraine associated with aura (bilateral) is more common than monocular retinal migraine/vasospasm.

Diagnostics

Retinal migraine/vasospasm is generally considered to be a diagnosis of exclusion. The diagnostic criteria for a retinal migraine are strictly defined by the IHS as:

(A) At least two attacks fulfilling criteria **B** and **C.**
(B) Fully reversible monocular positive and/or negative visual phenomena (scintillations, scotomata, or blindness) confirmed by examination during an attack or (after proper

instruction) by the patient's drawing of a monocular field defect during an attack.

(C) Headache, fulfilling the following criteria for a "migraine without aura" begins during the visual symptoms or follows them within 60 min.
- Headache attacks lasting 4–72 h (untreated or unsuccessfully treated).
- Headache has at least two of the following characteristics:
  - Unilateral location, pulsating quality, moderate or severe intensity, aggravation by or causing avoidance of routine physical activity
- During headache at least one of the following:
  Nausea/vomiting or photophobia/phonophobia

(D) *Normal ophthalmologic examination between attacks.*

(E) *Not attributed to another disorder (other causes of monocular vision loss excluded).*

Differential Diagnosis

The monocular manifestation of visual disturbances in retinal migraines is the primary characteristic which distinguishes this rare condition from several other types of migraines associated with aura visual disturbances (e.g., familial/sporadic hemiplegic migraine, basilar-type migraine). Aura, believed to be caused by spreading depression in the occipital cortex, typically affects a visual hemifield and is thus bilateral in nature. Transient ischemia from other etiologies should be considered in the differential diagnosis (e.g., thrombosis, emboli, vasculitis).

Prophylaxis

Identifying and avoiding environmental triggers such as stress and sleep deprivation is one method of reducing subsequent migraines. Upon initiation of visual symptoms, patients may try to abort the event by the use of nonsteroidal anti-inflammatory drugs (NSAIDs).

Therapy

Little data exists to guide effective treatment of retinal migraines. Migraine treatments are often tailored to what is most effective on a patient by patient basis. Historically, effective treatments have included aspirin, other NSAIDS, and some epilepsy drugs. Prophylactic therapy with tricyclic antidepressants, beta-blockers, and calcium channel blockers has also been advocated with variable success.

Prognosis

Variable depending on severity and frequency of attacks.

Epidemiology

True retinal migraine/vasospasm as defined by the IHS criteria is probably rare. In a review of reported cases, it was asserted that the frequency of retinal migraines has been historically overstated as most of the diagnosed patients do not meet the full IHS criteria.

Definition

Retinitis is an inflammation of the retina, most commonly related either to an infectious or an inflammatory cause. It is a nonspecific sign that accompanies many diverse causes of ocular inflammation and indicates the inflammation is involving the retina, either in isolation or in association with other structures, such as the choroid (chorioretinitis) or the optic nerve (neuroretinitis).

Etiology

Retinitis has inflammatory and infectious causes, which are either parasites, bacteria, viruses, or fungi.

The most common cause of infectious retinitis is related to *Toxoplasma gondii* which is an obligate intracellular protozoan parasite. Ocular toxoplasmosis may be congenital due to transplacental transmission of tachyzoites or acquired following consumption of raw or undercooked meat containing cysts or by ingestion of fruits, vegetables, or water contaminated by cat feces rich in oocysts. Other parasites that may can cause retinitis include toxocariasis, onchocerciasis, and diffuse unilateral subacute neuroretinitis can be caused by several different parasites.

Cytomegalovirus (CMV) retinitis is seen predominantly in immunocompromised patients and especially those with acquired immunodeficiency syndrome (AIDS). It may also occur following organ transplantation in patients receiving systemic immunosuppression or following chemotherapy for malignant disease. Following a primary CMV infection, which is usually asymptomatic in immunocompetent people, the virus remains latent and only reactivates when the immune system is suppressed.

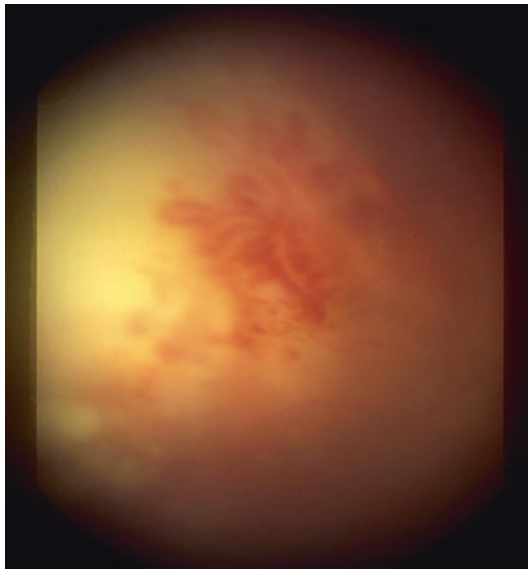
Acute retinal necrosis (ARN) is caused by herpes simplex or varicella zoster virus (VZV) infections. In immunocompetent patients these viruses result in a progressive peripheral necrotizing retinitis. In immunocompromised patients infections can cause a rapidly progressive disease, progressive outer retinal necrosis (PORN), which can involve the posterior pole and has a very poor visual prognosis.

Noninfectious retinitis can be related to systemic diseases such as Behçet disease and sarcoidosis.

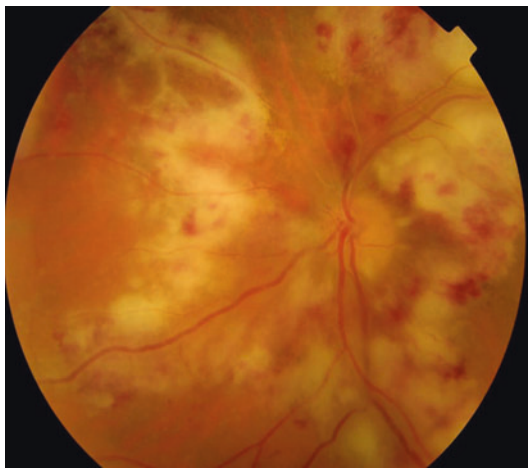
Clinical Presentation

Retinitis manifests as either focal or diffuse areas of pale-white retina accompanied by retinal hemorrhages, vascular sheathing, retinal ischemia, and retinal necrosis. In ARN, lesions are white yellow, small, and multifocal located in the peripheral retina which progressively enlarge and coalesce spreading circumferentially toward the posterior pole (Fig. 1). In PORN at the time of diagnosis, the retinitis may already involve the posterior pole and is rapidly progressive, leading to severe vision loss in most cases.

In CMV retinitis, the lesions are white and granular in appearance and may be surrounded by retinal hemorrhages. Because CMV retinitis occurs in immunocompromised patients, there is little vitritis, even in the presence of extensive retinal involvement. Progression of the lesions is slow and in a characteristic "brushfire" pattern, resulting in atrophic retina behind the active edge (Fig. 2). Toxoplasma retinitis occurs either in primary disease or adjacent to an existing scar in disease reactivation (Fig. 3). In primary infection, retinitis appears as a white, raised area with

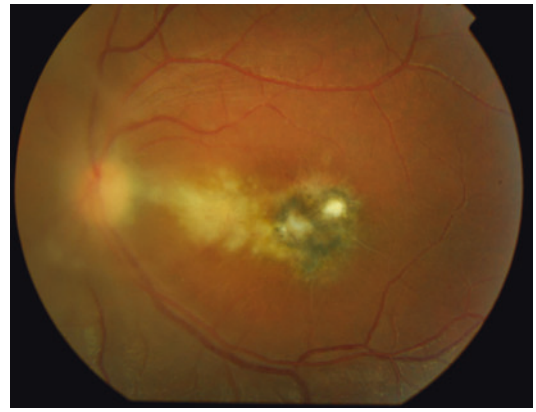


Retinitis, Fig. 1 Patient with VZV-related ARN with peripheral necrotizing retinitis

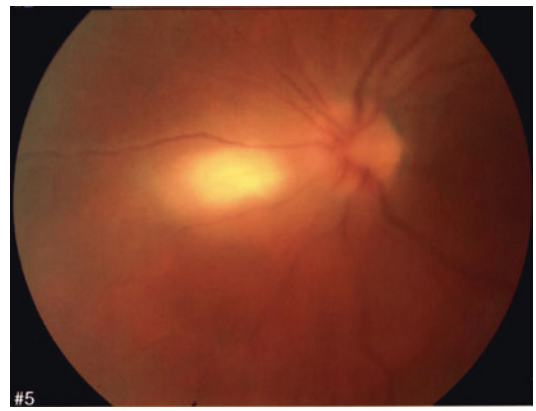


Retinitis, Fig. 2 Retinal image of an HIV patient with CMV retinitis. Note the extensive involvement of the posterior pole with widespread retinal hemorrhages and the brush border

indistinct borders (Fig. 4) and may involve nearby retinal vessels resulting in retinal artery or vein occlusion. Retinitis in Behçet disease is ischemic in type, can be isolated or multifocal, and usually occurs with significant vitritis (Fig. 5).



Retinitis, Fig. 3 Toxoplasmic reactivation at the border of an old pigmented chorioretinal scar



Retinitis, Fig. 4 Primary toxoplasmosis causing retinitis near the optic disk

Diagnosis

As retinitis is a nonspecific sign related to many conditions, a detailed history and clinical examination are important in guiding the diagnostic work-up, particularly with regard to infectious etiologies. Retinal imaging tests, such as fluorescein angiography, may be helpful in identifying the extent of retinal involvement and areas of retinal ischemia. Depending on the clinical presentation, systemic work-up, including blood tests, may be warranted. Table 1 lists the recommended systemic investigations in cases of retinitis. In cases when a viral cause is suspected, a vitreous biopsy should be obtained

Retinitis, Fig. 5 Patient with Behçet disease with a patch of retinitis associated with vitritis

Retinitis, Table 1 Recommended systemic investigations to identify etiology of retinitis

Etiology	Systemic investigations in retinitis
Sarcoidosis	Serum angiotensin-converting enzyme (ACE), chest X-ray
Syphilis	Specific treponemal (FTA-ABS) and nonspecific treponemal antibody (VDRL)
Toxoplasmosis	Toxoplasma serology
Cat scratch disease	Bartonella serology
HIV infection	HIV serology
Behçet disease	HLA-B51
Birdshot chorioretinopathy	HLA-A29
Tuberculosis	Interferon-gamma release assay (QuantiFERON Gold, Mantoux, or T-spot tests), chest X-ray

and polymerase chain reaction (PCR) testing performed for the presence of viral deoxyribonucleic acid (DNA).

Differential Diagnosis

In most cases the clinical appearance and history can direct the investigations to identify the etiology (Davis 2012). Other retinal lesions that should be distinguished from retinitis include cotton-wool spots, related to infarcts of the retinal nerve fiber layer and hard exudates. In cases of immunosuppressed patients, the clinical appearance may be atypical, and accompanying signs such as vitritis and anterior chamber reaction may be missing. Masquerade syndromes, for example, malignancy, should be considered in the presence of systemic involvement or if the ophthalmic signs are atypical.

Therapy

Cases of inflammatory retinitis are treated with local or systemic immunosuppressive therapy. Corticosteroids are the mainstay of systemic treatment, with the addition of second-line immunosuppressive agents as required. Local treatment is also predominantly corticosteroid-based and may be administered in the form of periocular or intravitreal injections or longer-acting intraocular implants.

Sight-threatening infectious retinitis must be treated promptly with appropriate antimicrobial therapy. In all cases of a suspected infectious cause, antimicrobial treatment must be given with the steroid treatment, and local steroid injections should not be used.

Not all cases of toxoplasmosis in immunocompetent individuals require treatment as the disease is self-limiting. Treatment should be given in cases of immunocompromised patients or when vital retinal structures are involved such as the fovea, optic disk, or main blood vessels. There are several treatment regimens including: (1) sulfadiazine and pyrimethamine together with folinic acid to reduce the bone marrow toxicity of pyrimethamine, (2) trimethoprim-sulfamethoxazole (co-trimoxazole), and (3) clindamycin in cases of individuals with allergies to sulfur-containing drugs (Harrell and Carvounis 2014). High-dose prednisolone is usually given with the antibiotic therapy to reduce the inflammation.

In cases of CMV retinitis, oral or intravenous ganciclovir or intravenous foscarnet may be used

initially in induction doses for 2–3 weeks followed by long-term maintenance therapy. Foscarnet or ganciclovir can also be administered intravitreally (Huynh et al. 2011). The underlying cause of immunodeficiency, for example, HIV infection, should be managed in conjunction with other physicians.

ARN is commonly treated using intravenous aciclovir for 7–10 days, followed by oral aciclovir for 6–12 weeks. Alternatively, oral valaciclovir for 6 weeks may be used. Systemic steroids may be used in immunocompetent patients to help control the inflammation. In the case of immunosuppressed or immunodeficient patients, management of disease in close liaison with other physicians is advised, and steroids are contraindicated (Wong et al. 2013). Following resolution of the acute inflammation, areas of extensive retinal necrosis are at a high risk of developing retinal tears and retinal detachments. These are related to posterior vitreous detachments that happen following the extensive vitritis in these cases and typically occur within the first 6 weeks after the beginning of the retinitis. Barrier laser to try and prevent any retinal detachment affecting the posterior pole may be considered. In cases of non-clearing dense vitreous opacities, vitrectomy may be required several months later when the eye is quiet (non-inflamed). For retinal detachment, vitrectomy surgery with silicon oil tamponade is usually required.

Prognosis

The prognosis of retinitis depends on the etiology, the visual acuity at the time treatment is started, the degree of involvement of the macula and the optic disk, and the development of subsequent complications, such as retinal detachment.

In cases of noninfectious retinitis, prompt treatment and long-term immunosuppressive control of the disease result in a stable long-term visual outcome, with most patients maintaining the vision at presentation. Causes of vision loss include macular scarring and atrophy, chronic cystoid macular edema, epiretinal membranes, and macular ischemia (Tomkins-Netzer et al. 2014).

In cases of ARN, the extensive retinal necrosis can lead to the development of retinal detachment, posterior pole involvement, and vitreous hemorrhages, all of which result in a poor long-term visual outcome (Wong et al. 2013). In CMV retinitis, treatment is effective in arresting the progression of retinitis and minimizing the complications related to that. Anti-retroviral therapy is required to control CMV replication in the long term and prevent further recurrence. However, patients may develop significant visual impairment secondary to large areas of retinal involvement, recurrent disease, epiretinal membranes, cystoid macular edema, cataract, or retinal detachment.

In toxoplasmosis, the visual prognosis depends on the location of the retinal involvement. Posterior pole involvement in the form of macular scars, optic nerve involvement, or vascular occlusion can lead to severe vision loss.

Definition

Retinitis pigmentosa (RP) is a class of genetic degenerative retinal disorders that affect the photoreceptor cells (rods and cones) as well as the retinal pigment epithelium. Over 35 different genes have been identified, and modes of inheritance for RP include autosomal recessive, autosomal dominant, and X-linked transmission. This family of disorders typically results in painless, bilateral, and progressive vision loss due to dysfunction and eventual atrophy of rods, cones, and retinal tissue. Disease onset and manifestation of symptoms can be highly variable as a wide number of hereditary abnormalities can result in RP. In most cases appreciable deficits develop over the course of 1–3 years. The severity and patterning of visual dysfunction is dependent on the distribution of cell and tissue damage, but loss of vision is irreversible.

Nyctalopia

Loss of night vision or night blindness (nyctalopia) is a cardinal sign of RP and results from a progressive loss of light-sensitive rod cells. Rod cells function in the detection of objects and movements in low-light settings and are found throughout the retina with the exception of the macula. Patients with RP generally lose rod cells first, thus loss of night vision is often the first clinical sign of disease. Night blindness is not a symptom exclusive to RP and can also be seen in other retinal disorders, myopia, and age-related macular degeneration. In RP, night blindness usually manifests in the first one to two decades of life. Earlier onset of night blindness has been linked to autosomal recessive disease types, while later onset is often seen in autosomal dominant modes of inheritance.

Visual Field Defects

Patients with RP will experience a peripheral narrowing of the visual field over time due to the loss of rod function. As with the deficits in night vision, visual field defects also usually manifest in early adolescence. Earlier onset has been linked to increased disease severity. Defects are usually seen first in the superior visual field, suggesting damage occurs initially in the inferior portion of the retina. Patients may not initially detect these changes, but appreciable deficits are seen over the course of years or decades. In some cases, visual fields may be altered within months; however, with central vision intact, these more drastic changes can go unnoticed by the patient.

Central acuity is usually maintained until middle age (age 40–50). In less severe forms of disease, central visual acuity can be preserved

beyond age 60 or can be retained for all of a patient's life. Peripheral vision is usually lost first in RP; however, loss of central acuity is not uncommon and can occur during early stages of disease. Cases with loss of central acuity before peripheral loss are referred to as "inverse retinitis pigmentosa" and are usually found in older patients. Defects in central acuity result from damage to the fovea of the retina. This can be caused by damage to the retinal pigment epithelium localized to the fovea, retinal vascular leakage, or cystoid macular edema.

Cone cells, responsible for high visual acuity and color vision, are initially maintained in RP. Most patients do not report difficulty with differentiating colors. Cone cells are highly concentrated in the fovea; damage to the fovea results in deficits in color vision as well as sensitivity to bright sunlight.

Diagnostic Findings

On fundoscopic exam, retinitis pigmentosa is characterized by the presence of retinal pigment epithelium changes (bone spicules). The amount of bone spicules is variable among patients and may be less prominent in young children. Thinning of the retinal pigment epithelium (RPE) and a loss of photoreceptor cells can be detected using fundus autofluorescence and optical coherence tomography (OCT). Other ocular manifestations of the disease include optic nerve gliosis, loss of choriocapillaries, and attenuation of retinal arterioles. The extent of these findings, including the amount of pigment and degree of optic nerve gliosis, increases with age. In RP, electroretinography (ERG) may also indicate loss of photoreceptor cell function. Some patients with RP have optic disk drusen that can mimic papilledema or can have waxy pallor of the optic disk.

Prognosis and Treatment

Retinitis pigmentosa is characterized by deficits in night vision and visual fields that progress over the course of 1–3 years. The progressive loss of rod and cone cells results in these irreversible defects, and although uncommon, complete blindness can occur.

There is currently no proven effective treatment for retinitis pigmentosa; however, there are some therapies that have been suggested to alleviate associated symptoms. Oral acetazolamide may be used to treat cystoid macular edema. Many causative genes have been identified in RP, and gene therapy clinical trials are under investigation. Patients with RP are advised to take vitamin A supplements and use UV-protective eyewear.

Retinitis Punctata Albescens

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Synonyms

Atypical retinitis pigmentosa (RP)

Definition

Variant of retinitis pigmentosa characterized by numerous punctate whitish-yellow flecks at the level of the retinal pigment epithelium.

Etiology

Although the exact etiology of retinitis punctata albescens remains unclear, studies suggest the pathogenesis involves an abnormal RLBP1 gene. This gene encodes cellular retinaldehyde-binding protein (CRALBP), which is vital to the normal cycling between all-trans retinal and 11-cis-retinol. Dysfunction of this protein leads to the characteristics symptoms of the disease (Carr and Noble 1999; Gass 1997; Weleber and Gregory-Evans 2006).

Clinical Presentation

Similar to patients with retinitis pigmentosa, patients with retinitis punctata albescens present with night blindness, peripheral visual field loss, photopsias, and decreased central visual acuity. Fundus exam demonstrates numerous whitish-yellow flecks at the level of the retinal pigment epithelium which extend in a radial pattern, are most prominent at the equator, and typically spare the macula. Retinal changes also often include the typical findings of retinitis pigmentosa, including attenuation of the retinal arterioles, waxy pallor of the optic nerve, and peripheral bone-spicule formation.

Diagnostics

The diagnosis of retinitis punctata albescens begins with a thorough history, inquiring about any night blindness, peripheral visual field loss, photopsias, and central visual acuity loss. Slit lamp biomicroscopy should investigate the presence of subcapsular cataracts, waxy or pale optic nerves, attenuated retinal arterioles, or any whitish-yellow flecks at the level of the retinal pigment epithelium. Formal visual field testing is helpful for documenting visual field loss, while an electroretinogram (ERG) will demonstrate severely decreased retinal amplitudes.

Differential Diagnosis

The differential diagnosis of retinitis punctata albescens includes other causes of flecked retina, including fundus albipunctatus, dominant (familial) drusen, fundus flavimaculatus, abetalipoproteinemia, oxalosis, cystinosis, talc emboli, Alport's syndrome, fleck retina of Kandori, and canthaxanthine retinopathy. Retinitis punctata albescens can be distinguished from fundus albipunctatus in that the ERG will be severely depressed and will not show improvement with dark adaption (as opposed to fundus albipunctatus which shows normalization in the rod response after a variable amount of dark adaption).

Prophylaxis

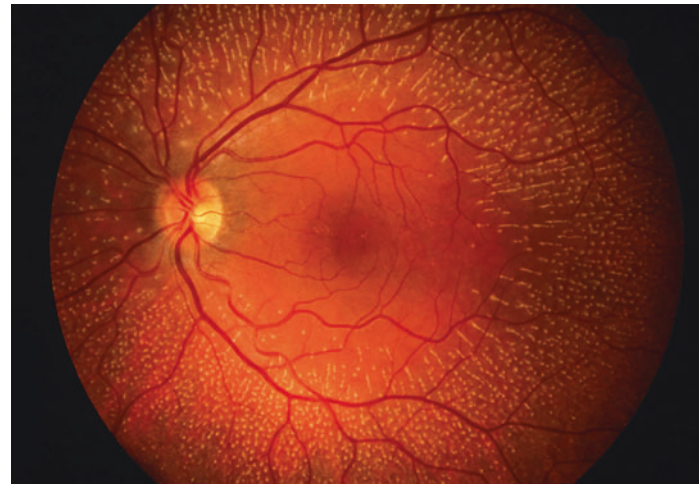
Although no prophylactic treatment is available for retinitis punctata albescens, routine screening of patients with a family history of retinitis pigmentosa allows early diagnosis and counseling.

Therapy

No cure exists for retinitis punctata albescens. Management involves treating associated causes of vision loss, including cataract and cystoid macular edema. Low vision aids and genetic counseling may also prove beneficial.

Prognosis

Retinitis punctata albescens behaves clinically like classic retinitis pigmentosa with the majority



Retinitis Punctata Albescens, Fig. 1 Color fundus photograph demonstrating typical fundus changes of retinitis punctata albescens, including numerous whitish-yellow flecks at the level of the retinal pigment epithelium (Photo courtesy of Dennis P. Han)

of patients experiencing progressive night blindness and loss of peripheral vision. Loss of central and color vision occur at more advanced stages of the disease.

Epidemiology

While the prevalence of retinitis pigmentosa as a group is estimated to be 1 in 5000, the prevalence of retinitis punctata albescens is not known. Retinitis punctata albescens tends to affect males and females equally and is most often inherited in an autosomal recessive pattern (Fig. 1).

Retinoblastoma

Jonathan Schell
STL Vision, Saint Louis, MO, USA

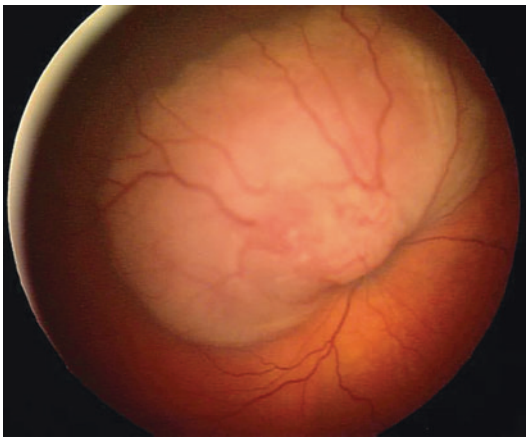
Definition

Retinoblastoma is a malignant neuroblastic tumor derived from the embryonic retinal cell.

Etiology

Retinoblastoma develops following mutations in both alleles of a cell's RB1 gene. The RB1 gene is

located on the long arm of chromosome 13 (13q14) and produces a nucleoprotein that regulates the transition of a cell from G1 to the S phase of the cell cycle. Loss of both RB1 alleles allows uncontrolled cellular proliferation. In approximately 40% of patients with retinoblastoma, loss of the first RB1 allele is inherited from either an affected parent (10%) or from a spontaneous mutation in one of the gametes (90%), and the loss of the second is spontaneous. In the remaining 60% of patients with retinoblastoma, loss of both RB1 alleles in the same cell is spontaneous (Murphree et al. 2006; Gass 1997; Shields 1999; Conway et al. 2005).



Retinoblastoma, Fig. 1 Color fundus photograph demonstrating a retinoblastoma tumors appear as yellow-white vascular masses of the retina with various growth patterns

Clinical Presentation

Retinoblastoma commonly presents as leukocoria (white pupil) or strabismus in a young child. Other less common signs include vitreous hemorrhage, hyphema, red eye, glaucoma, proptosis, and pseudohypopyon. Average age at diagnosis is 12 months for patients with hereditary retinoblastoma and 24 months for patients with non-hereditary retinoblastoma. Patients with hereditary retinoblastoma can develop multiple and bilateral tumors.

Diagnostics

Retinoblastoma is principally a clinical diagnosis made with fundus ophthalmoscopy using scleral depression during an exam under anesthesia. Retinoblastoma tumors appear as yellow-white vascular masses of the retina with various growth patterns (Fig. 1). Exophytic tumors grow into the subretinal space and induce an exudative retinal detachment. Endophytic tumors grow into the inner retina, where they can breakthrough into the vitreous and produce vitreous tumor seeds. Diffuse infiltrative tumors grow laterally within the retina and often display no discrete mass effect. Trilateral retinoblastoma involves concurrent growth of a tumor in the pineal gland.

Various ancillary tests are helpful for supporting a diagnosis of retinoblastoma. Ocular echography of the retinal tumor can suggest intralesional calcium by demonstrating tumor shadowing. Intralesional calcium is fairly specific for retinoblastoma. Computed tomography (CT) can also demonstrate the presence of intralesional calcium but does involve radiation exposure which can increase the risk of secondary cancers, especially in patients with hereditary retinoblastoma. Magnetic resonance imaging (MRI) of the orbit and head is valuable for excluding the presence of extraocular tumor extension and presence of a pineal tumor (trilateral retinoblastoma).

Histopathological diagnosis of retinoblastoma in enucleated eyes involves indentifying fleurettes and Flexner-Wintersteiner rosettes, both of which represent early degrees of retinal cellular differentiation.

Differential Diagnosis

The differential diagnosis of retinoblastoma includes persistent hyperplastic primary vitreous, Coat's disease, ocular toxocariasis, retinopathy of prematurity, cataract, chorioretinal colobomas, congenital retinal folds, retinal dysplasia, vitreous hemorrhage, uveitis, and other tumors (e.g., retinoma, astrocytic hamartoma, choroidal hemangioma, and diktyoma).

Prophylaxis

There is no true prophylaxis against retinoblastoma formation. Nonetheless, individuals carrying the RB1 mutation who are trying to have children can undergo preimplantation genetic testing with subsequent in vitro fertilization. Routine screenings with exams under anesthesia are recommended during the first several years of life for all babies with a family history of retinoblastoma.

Therapy

Treatment of retinoblastoma varies according to size and extent of tumor formation. Local therapy with transpupillary thermotherapy laser photocoagulation, cryotherapy, or plaque brachytherapy is appropriate for small tumors. Chemoreduction followed by local therapy may be necessary when a tumor is too large to be managed with local therapy alone. Often, one to six cycles of chemotherapy using a combination of vincristine, etoposide, and carboplatin can shrink a tumor enough so that local therapy is then appropriate. External beam radiation teletherapy, once a mainstay of treatment, is currently falling out of favor due to its association with secondary malignancies and craniofacial deformities in the field of radiation. Nonetheless, it can still be valuable for some advanced tumors. Primary enucleation remains standard of care for eyes with advanced retinoblastoma and no useful vision potential.

Treatment of extraocular retinoblastoma is complex and often involves a combination of systemic chemotherapy, external beam radiation teletherapy, and bone marrow transplantation. Gamma knife radiation therapy with intrathecal chemotherapy may be helpful for intracranial trilateral retinoblastoma.

Prognosis

Overall survival prognosis for patients with retinoblastoma confined to the eye is good with estimates greater than 90%. Poor prognostic indicators include tumor invasion of the optic nerve posterior to the lamina cribrosa, massive choroidal involvement, trilateral disease, and distant metastatic disease at the time of presentation. Individuals with heritable disease display a 1% chance per year during their lifetime of developing a secondary neoplasm.

Epidemiology

Retinoblastoma remains the most common malignant intraocular tumor of childhood with an estimated incidence of 1 in 15,000 live births (range 1:14,000–1:20,000). Most patients are diagnosed before 5 years of age. Males and females are equally affected and there is no predilection for any particular race.

Retinopathy of Prematurity

Barbara Gold
Department of Ophthalmology, Tel Aviv University, Tel Aviv Medical Center, Tel Aviv, Israel

Definition

Retinopathy of prematurity (ROP) is a disease seen in premature infants having incomplete, vascularized retinas with a peripheral avascular zone. At gestational age earlier than 30 weeks, vascular endothelial growth factor (VEGF) and insulin-like growth factor I (IGF-I) influence abnormal growth of the retinal blood vessels as they develop from the optic disk toward the nasal ora serrata and finally reaching the temporal ora serrata.

Etiology

Smaller weight babies (1,250 g or less) and those with early gestational age (30 weeks or earlier) are at the highest risk for development of ROP.

Exposure to oxygen is a poorly understood risk factor. Currently, it is thought that the pathogenesis of ROP is biphasic. In the first phase seen at 22–30 weeks, the retina is hyperoxic. VEGF levels are low and the retinal blood vessels stop growing. The decrease blood vessel growth is thought to be due to low levels of IGF-I, low birth weight of less than 1,500 g as well as exposure to oxygen.

In the second phase seen around 32 weeks, neovascularization begins due to rising VEGF levels responding to the hypoxic avascular retina.

Clinical Presentation

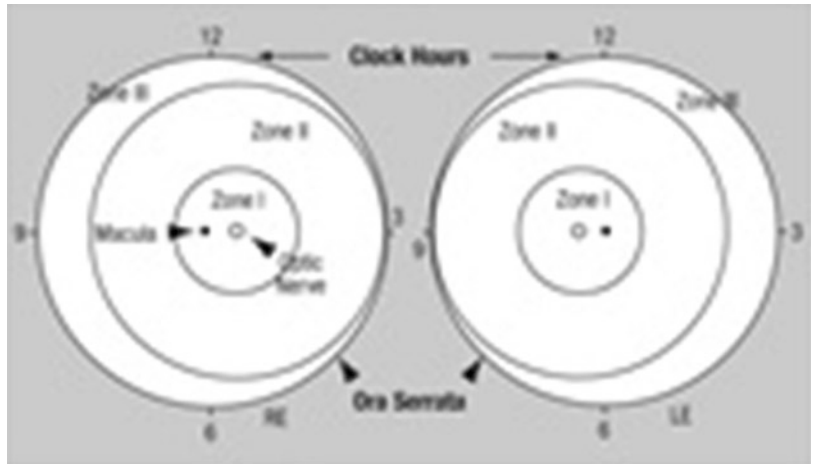
Not all premature babies who are premature develop ROP. About 90% of all infants with ROP are in the mild category and do not need treatment; only periodic ophthalmic observation. Weekly observation beginning at the fourth week of birth is to detect any disease progression to the more advanced stages of ROP and/or pre-plus disease as to prevent blinding eye disease.

ROP is classified in five stages, ranging from mild (stage I) to severe (stage V):

Stage 1 – mildly abnormal blood vessel growth that usually resolves without treatment. Children go on to develop normal vision and there is no further disease progression.
Stage II – moderately abnormal blood vessel growth that usually resolves without treatment. Children have normal vision and no further disease progression.
Stage III – severely abnormal blood vessel growth. Often plus disease develops requiring treatment
Stage IV – partially detached retina. Traction from the scar produces bleeding; abnormal vessels pull the retina
Stage V – completely detached retina and the end stage of the disease. If the baby is not treated, there is severe damage and even blindness.

Diagnostics

At 4–6 weeks of age, pupil dilation is performed using phenylephrine (1–2% combined with cyclopentolate (0.2–0.5%) or tropicamide (0.5–1%)). Using a lid speculum, the sclera is gently depressed while performing a thorough examination wearing binocular indirect ophthalmoscope. There is an international classification of ROP into anterior and posterior zones based on the optic nerve position. The degree of disease



Retinopathy of Prematurity, Fig. 1 International Classification of ROP

involvement is divided into 30° clock hours. Disease is staged depending on observation of the following problems. See Fig. 1.

Signs and symptoms include optic nerve pallor, enlarged cup in the optic nerve, retina detachment, dragged folds, attenuated or dilated or tortuous vessels, hemorrhage, neovascularization, pigment changes, and retrolental mass. In the vitreous, there may be haze or traction. There may be the appearance of myopia, strabismus, glaucoma, cataract, or anisometropia.

ETROP Classification of Disease (Early Treatment for Retinopathy of Prematurity)

Type 1 ROP – need prompt treatment within 48 h

Zone 1: any stage with plus disease
Zone 1: stage 3 without plus disease
Zone II: stage 2 or 3 with plus disease

Type 2 ROP – not severe enough to require treatment

Zone 1: stage 1 or 2 without plus disease
Zone II: stage 3 without plus disease

Stage 1 ROP signifies development of a demarcation line between the normal retinal vessels and avascular retina. The line has significant height and width and extends above the retina surface.

Stage 2 ROP signifies development of a demarcation ridge between the normal retinal vessels and avascular retina.

Stage 3 ROP signifies neovascularization in the stage 2 demarcation line and leads to extraretinal proliferation of tissue. The ridge may bleed and cause traction on the ridge. Due to retinal ischemia, vessels grow into the vitreous gel, causing fibrous proliferation, traction over the ridge, and eventually retinal detachment. At this point, the classification is considered type 1 ROP requiring immediate laser intervention to arrest disease progression.

Stage 4 ROP defines retinal detachment sparing the macula as 4A and involving the macula as 4B.

Stage 5 ROP signifies complete retinal detachment and necessitates an immediate and very difficult surgery to attempt to reattach the retina. Stage 5 has a very poor prognosis.

(Lab Diagnostics)

Prophylaxis

Timely detection of ROP depends on examination by a trained pediatric ophthalmologist beginning at week four.

Therapy

In type 1, laser photocoagulation treatment is currently and strongly recommended. 100–3,000 laser spots may be needed depending on the extent of zone involvement; whereas in type 2 it is preferable to observe and see if there progression to type 1, then treat. In the study (BEAT-ROP) bevacizumab versus laser treatment was tried but the disease recurred. The advantage of bevacizumab is that there appears to be a lower incidence of very high myopia (>8 diopters). Despite the trial outcome, presently, there is concern using anti-VEGF agents on the developing vasculature of premature infants. In later stages of ROP, other treatment options include a scleral buckle and vitrectomy. In post-laser treatment, lubricant and anti-inflammatory eye drops are prescribed.

Prognosis

Myopia can develop in both treated and untreated infants. With high myopia, strabismus can occur.

Epidemiology

The incidence of ROP is rising, given the fact there are many more surviving premature infants. Also, babies requiring treatment is lower among African American than non-African American babies.

Synonyms

Capsulopalpebral fascia; Inferior tarsal muscle; Müller's muscle

Definition

The lower eyelid retractors consist of the capsulopalpebral fascia and the inferior tarsal muscle. The inferior tarsal muscle is occasionally referred to as Müller's muscle of the lower eyelid.

Structure

The capsulopalpebral fascia arises proximally as the capsulopalpebral head, which comprises fascial extensions from the terminal muscle fibers and tendon of the inferior rectus muscle (Hawes and Dortzbach 1982). The fibroelastic capsulopalpebral head then splits into two and straddles the inferior oblique muscle before reuniting as Lockwood's ligament. The tissue anterior to Lockwood's ligament has traditionally been termed the capsulopalpebral fascia. The majority of the capsulopalpebral fascia extends anterosuperiorly to insert on the inferior tarsus, inferior fornix, and Tenon's capsule on the surface of the globe, while the inferior portion extends through the orbital fat to the orbital septum.

The lower eyelid retractor has often been thought of as a single layer that incorporates the smooth muscle fibers of the inferior tarsal muscle, which are most prevalent near the inferior fornix (Hawes and Dortzbach 1982). More recently, however, the lower eyelid retractor has been described to be in a double-layer configuration (Kakizaki et al. 2006; Kakizaki et al. 2009). The double-layer configuration is also present in Asian eyelids, where there is often a higher or more indistinct line of fusion of the orbital septum to the capsulopalpebral fascia (Kakizaki et al. 2009). The posterior layer of the retractor consists of a dense fascial layer that includes the smooth muscles that comprise the inferior tarsal muscle, while the anterior layer extends from Lockwood's ligament and merges with the orbital septum and suborbicularis fascial layer, before extending through the orbicularis oculi to the anterior lamellae of the lower eyelid. The ability to separate the anterior and posterior lower eyelid retractor layers may have clinical implications in the treatment of eyelid malposition, especially as the posterior layer has been reported to be responsible for the main tractional forces on the lower eyelid.

The lower eyelid retractor functions in tandem with the inferior rectus, which is in turn innervated by the inferior division of the oculomotor nerve. The smooth muscles of the inferior tarsal muscle are sympathetically innervated, analogous to the Müller's muscle of the upper eyelid.

Function

The lower eyelid retractors effectuate inferior movement of the lower eyelid, as well as widening of the interpalpebral fissure in conjunction with the upper eyelid retractors. The lower eyelid retractors exert rotational forces on the tarsus and play a role in normal and abnormal eyelid margin positioning.

Clinical Relevance

The lower eyelid retractors are intrinsically involved in disorders of lower eyelid position as they contribute to the vertical stability of the eyelid. Lower eyelid retractor atrophy, loosening, or dehiscence results in decreased vertical stability of the eyelid, allowing eyelid margin rotation resulting in entropion or ectropion. Lower eyelid retractor dehiscence or disinsertion may be reversed with surgical advancement and reattachment of the retractors to the inferior tarsus (Tse et al. 1991). The Jones entropion procedure is a commonly performed method of involutional entropion repair where the anterior surface of the lower eyelid retractor is identified without separating the posterior aspect of the retractor from the conjunctiva. Isolated advancement of the posterior layer of the lower eyelid retractor has also been reported to be effective in entropion repair.

In lower eyelid retraction, there is often a relative or absolute shortening of the posterior lamella and eyelid retractors. Common causes of lower eyelid retraction include thyroid ophthalmopathy, chemical burns, cicatrizing conjunctival diseases, and trauma. Lower eyelid retraction is frequently managed by recession of the lower eyelid retractors and interposition of a spacer graft to provide increased length. Autologous tissue grafts such as hard palate mucosa have been reported to be effective donor tissue (Kersten et al. 1990).

Knowledge of the anatomy of the lower eyelid retractors is also important in strabismus surgery that involves the inferior rectus. Manipulation of the inferior rectus concurrently alters the lower eyelid retractor complex, resulting in increased lower eyelid retraction after inferior rectus recessions and vice versa. Careful dissection of the fascial and connective tissues surrounding the inferior rectus is important to minimize undesired eyelid positional changes after strabismus surgery.

As a consequence of the sympathetic innervation of the smooth muscles of the inferior tarsal muscle, medical conditions that potentiate sympathetic innervation such as thyroid dysfunction can lead to increased eyelid retraction and inferior scleral show. Increased exposure of the ocular surface and cornea may lead to secondary dry eyes or keratopathy.

Retrobulbar Block

Adiel Barak, Oded Ohana and Eyal Cohen
Tel Aviv Sourasky Medical Center, Tel Aviv-Yafo, Israel

Definition

Retrobulbar block is a regional anesthetic nerve block used in intraocular procedures. In retrobulbar injection, local anesthetic is injected behind the eye, into the muscle cone of the extraocular muscle, which is located inside the orbital space, the area located behind the globe of the eye. Injection of local anesthesia provides akinesia of the extraocular muscles by blocking cranial nerves II, III, and VI, which prevents movement of the globe. Retrobulbar block also provides sensory anesthesia of the cornea, uvea, and conjunctiva by blocking the ciliary nerves.

Usual retrobulbar block includes either 1–2% lidocaine (Xylocaine) and 0.5–0.75% bupivacaine (Marcaine). Lidocaine enables quick anesthesia but has shorter duration, whereas bupivacaine has a longer duration but also takes longer time to achieve anesthesia. A mixture of both compounds is ideal to achieve quick and long-lasting (up to 2–3 h) anesthesia. The volume of liquid injected is between 4 and 6 cc, and up to 8 cc is considered safe. It is important to avoid bupivacaine mixture with epinephrine, because epinephrine may cause vasoconstriction and may cause central retinal artery occlusion. In the past, hyaluronidase – an enzyme – was frequently used as an adjuvant to the anesthetic solution, as it accelerates and improves dispersal of the agent, but in recent years, the enzyme is rarely used and hard to find. The injection is performed using a needle (22–27 Gauge, 3 cm long) – either special retrobulbar needle with blunt-end or regular hypodermic needle. By using a blunt-end needle, there is less likelihood of causing globe perforation, but insertion of the blunt needle is more painful as compared to sharp-end needle. The needle is inserted at the 1/3 inferolateral border of the bony orbit and directed straight back until it has passed the equator of the globe. It is then directed medially and upward toward the apex of the orbit. Occasionally a "pop" is felt as the needle tip passes through the muscle cone delineating the retrobulbar space. Following a needle insertion, gentle aspiration is performed to ensure that the needle is not situated inside an artery or vein, and then anesthesia solution is slowly injected. Proptosis of the globe is usually the first sign that the injection is in its proper position.

This block was previously employed abundantly for cataract surgery, but in recent years, its use has decline due to the widespread use of topical anesthesia and currently is used predominantly in complicated vitreoretinal procedures.

Retrobulbar block is associated with serious vision and life-threatening complications. Ocular adverse events include hematoma formation, optic nerve damage, and perforation of the globe with possible blindness. Systemic complications include local anesthetic toxicity, brainstem anesthesia, and stimulation of the oculocardiac reflex.

Definition

Retrobulbar hemorrhage is an uncommon, vision-threatening complication of the orbit that in some instances can lead to irreversible loss of vision. The loss of vision can be attributed to the development of orbital compartment syndrome with secondary ischemia, increased intraocular pressure, or direct compression of the optic nerve.

Epidemiology

One study reported 115 cases of nontraumatic orbital hemorrhage over a 24-year period (Sullivan and Wright 2000). Retrobulbar hemorrhage can affect any age, either gender, and any race depending on underlying etiology although trauma and surgery are common causes.

Clinical Features

The most common symptoms and signs of retrobulbar hemorrhage include ipsilateral orbital pain, pressure, ophthalmoplegia, proptosis, and loss of vision. Patients may complain of headache, diplopia, nausea, and vomiting (Lewis and Perry 2007). Signs of an acute retrobulbar hemorrhage are usually obvious and include a tense orbit, rapidly progressive proptosis, ophthalmoplegia, increased intraocular pressure, visual loss, and a relative afferent pupillary defect. Funduscopy might show a normal or swollen optic disk and retinal vascular occlusive disease (Lewis and Perry 2007).

Tests

Due to the emergent nature of the sight-threatening acute retrobulbar hemorrhage, a surgical decompressive treatment (e.g., lateral canthotomy and cantholysis) is often initiated before the orbital imaging studies to confirm the diagnosis (Goodall et al. 1999).

Typically orbital computed tomography (CT) scans are preferred because of their faster acquisition time and better visualization of the bony anatomy and the retrobulbar hemorrhage (Lewis and Perry 2007).

Differential Diagnosis

(a) Diplopia
(b) Proptosis
(c) Hyperthyroid
(d) Cavernous sinus thrombosis

Etiology

Retrobulbar hemorrhage has many different etiologies. Some of these etiologies include trauma, retrobulbar anesthetic injection, and periocular surgery or may rarely occur spontaneously (Lewis and Perry 2007).

Diagnosis

The diagnosis is primarily made by the typical clinical signs and symptoms of the retrobulbar hemorrhage. In some cases, however, it may be necessary to utilize an orbital CT to confirm the diagnosis.

Treatment

The treatment regimen will depend on the urgency of the situation. Although oxygen therapy, intravenous (IV) mannitol, oral or IV acetazolamide, steroids, and topical beta-blockers (Wolfort et al. 1999) have been used, the mainstay of acute treatment is surgical decompression.

The preferred methods to decrease the elevated orbital and intraocular pressure are urgent lateral canthotomy and cantholysis (Goodall et al. 1999).

Synonyms

Lateral geniculate lesion; Occipital lobe lesion; Optic tract lesion; Parietal radiations lesion; Temporal radiations lesion

Definition

The retrochiasmal pathway begins posterior to the optic chiasm with the optic tracts then travels to the lateral geniculate nuclei, the temporal lobe optic radiations (i.e., Meyer's loop), the parietal lobe optic radiations, and ends in the occipital cortex. At the optic chiasm, fibers from the nasal retina cross over to the contralateral side, while temporal fibers remain on the ipsilateral side creating visual field defects that are on the same side (i.e., homonymous) and respect the vertical meridian (hemianopic). As the optic fibers course posteriorly along the visual pathway, they become more organized so that fibers from a similar origination of the retina run in closer and closer proximity to one another. In general, the further posterior the lesion (e.g., occipital) along the retrochiasmatic pathway the more congruous (the same size, shape, and density on each side) is the homonymous hemianopic defect. Thus, occipital lobe lesions demonstrate the most congruity and optic tract lesions the least congruity. Unfortunately, the specificity of congruity for occipital lobe lesions is not 100% and highly congruous visual field defects can also occur in more anterior retrochiasmal lesions.

Etiology

1. Ischemic
2. Hemorrhagic
3. Traumatic
4. Neoplastic
5. Demyelinating
6. Infectious
7. Inflammatory
8. Degenerative

Clinical Presentation

Retrochiasmal lesions typically present with a contralateral HH. The patients typically complain of a problem with their "side vision," but the complaint may be more vague (e.g., "blurry vision", "difficulty reading") and some patients only notice the temporal visual field loss in their HH. For a right HH, there is often difficulty finding the next word during reading and for left homonymous hemianopsia there may be more difficulty finding the next line while returning to the left side of the text. The patient or their spouses or family may complain that the patient hits the curb or garage or has hit the side-mirror on the side with temporal visual field loss. Some patients, especially if in long-standing or in cases of degenerative disease, do not realize that they have a visual field defect and it may be found incidentally on routine eye exam.

In retrochiasmal lesions, patients will not complain of decreased visual acuity (regardless of macula sparing or splitting HH) unless they have another visual pathway lesion (e.g., cataract, retinopathy, or optic neuropathy) affecting the central vision or the retrochiasmal lesion is bilateral (i.e.,. juxtaposed bilateral HH). In addition, depending on the underlying etiology (e.g., cerebral tumor, brain hemorrhage or edema, AVM, etc.), the patient might have headache or other focal neurologic symptoms or signs in association with their HH. Occipital cortex lesions typically have no other signs or symptoms however.

- Occipital lobe lesions: Typically occipital lesions produce HH in isolation. Lesions of the occipital lobe can, however, produce unformed visual hallucinations, such as blotches of color or light. These hallucinations typically appear in a constant homonymous hemianopic distribution and do not alternate sides (which helps to distinguish them from migraine with aura). Association cortex involvement, however, might produce visual processing defects and agnosias.
- Temporal lobe lesions: May be characterized by cortical deafness; loss of ability to comprehend music or language; Wernicke type aphasia; memory loss; complex, multimodal hallucinations; or seizures (i.e., temporal lobe epilepsy).
- Parietal lesions: A patient with a lesion to the nondominant parietal lobe may experience

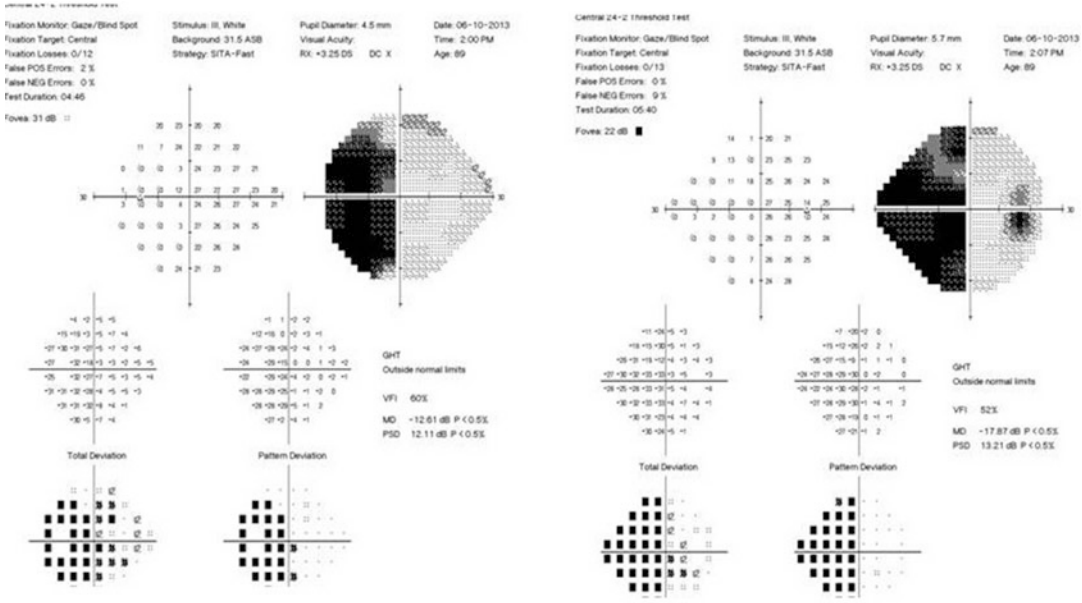
contralateral neglect and constructional apraxia. Damage to the dominant parietal lobe can result in Gerstmann Syndrome, which includes right-left confusion, difficulty with writing (agraphia), difficulty with mathematics (acalculia), and disorders of language (aphasia). In addition, the ipsilateral parietal lobe provides supranuclear control of smooth pursuit and thus in a patient with a complete HH there might be asymmetric impairment of the optokinetic nystagmus (OKN) response, indicating a parietal localization over occipital lobe lesions which would be expected to have a symmetric OKN response.

Diagnostic

1. The optic tract carries the visual fibers from the chiasm to the lateral geniculate body but also the afferent pupil fibers to the midbrain. Thus patients with an optic tract lesion might also have a relative afferent pupillary defect and band type optic atrophy in the eye with the temporal visual field loss (i.e., nasal fiber loss). The HH tends to be incongruous in optic tract lesions.
2. The lateral geniculate body (LGB) is a highly organized structure where the retinal fibers in the optic tract synapse. LGB lesions are rare but may produce characteristic and localizing visual field defects due to the unique blood supply of the LGB. Both the lateral choroidal artery (a branch of the posterior cerebral artery) and the anterior choroidal artery (a branch of the internal carotid artery) supply the LGB. With lateral choroidal artery disruption, the patient will have a contralateral homonymous hemianopsia in a wedge-shaped distribution, with sparing of the most superior and inferior aspects of that field. In contrast, with anterior choroidal disruption, the patient will have a contralateral homonymous hemianopsia with loss of the upper and lower quadrants that spares a symmetrical inner wedge, termed a quadruple sectoranopia.
3. Damage to the temporal lobe radiations (Meyer's loop) gives a contralateral homonymous hemianopsia that is denser superiorly (i.e., "pie in the sky quadrantanopia") because these radiations include the more inferior retinal fibers (which correspond to the superior aspect of the visual field). These HH may be incongruous suggesting a more anterior localization in the retrochiasmal pathway. The optic tract lesion can be distinguished sometimes from temporal lobe by the presence of an RAPD and band type optic atrophy in the optic tract lesion.
4. The parietal lobe radiations typically produce an incongruous homonymous hemianopsia that is denser inferiorly (from superior fiber involvement).
5. Occipital lobe lesion – depending upon whether the inferior or superior calcarine cortex is involved, the homonymous hemianopsia can be denser superiorly or inferiorly (see Fig. 1). The HH in occipital lesions tends to be congruous and macular sparing. There might also be selective involvement or sparing of the monocular temporal crescent. This temporal crescent (60–90° temporally) of contralateral visual field (crossed nasal fibers) has no correlate in the nasal field of the fellow eye and is represented monocularly in the anterior portion of the calcarine cortex.

Differential Diagnosis

Patients with unexplained HH should undergo a full neurologic exam looking for localizing features. A careful pupil and fundus exam in addition to formal visual field testing should be performed to look for an RAPD or band atrophy in an optic tract lesion and to define localizing features of the HH including laterality, congruity, macular sparing or splitting, and the presence or absence of the monocular temporal crescent. Neuroimaging (preferably MRI with and without contrast of the head) is recommended for unexplained HH. In the acute setting, a non-contrast CT scan might be superior to look for acute blood or to expedite the evaluation and treatment of the underlying etiology (especially for acute stroke).



Retrochiasmal Disorders, Fig. 1 Retrochiasmal lesion with left homonymous hemianopsia

Prophylaxis

Not applicable

Therapy

Treatment depends upon the etiology of the lesion.

Prognosis

Prognosis depends upon the etiology of the lesion.

Epidemiology

The retrochiasmal lesion can occur in any age, any race, and either gender. In most pooled large aggregate studies, the most common etiology of a HH in adults is ischemic or hemorrhagic stroke but any structural lesion of the retrochiasmal pathway may produce a HH. Older vasculopathic patients presenting with an acute HH should be evaluated for stroke or hemorrhage. Patients with optic tract lesions often have a compressive lesion.

Retro-Orbicularis Oculi Fat (ROOF)

Allison J. Chen[1], B. Ranjodh Singh[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Brow fat pad, superior extension of the sub-brow fat pad; Submuscular fibroadipose tissue; Suborbicularis fibroadipose tissue

Definition

Retro-orbicularis oculi fat (ROOF) is a superficial fat layer existing between the orbicularis oculi muscle and the periosteum of the supraorbital bone, superior to the orbital septum.

Structure

ROOF is a superior extension of the sub-brow fat pad and is a layer of fibroadipose tissue that is situated deep to the orbicularis oculi and superficial to the periosteum of the supraorbital bone. It extends medially beyond the midsupraorbital rim and laterally beyond the lateral orbital rim (Zide 2006). The superior portion of ROOF extends upward under the frontalis muscle and contributes to the galeal fat pad over the superolateral orbital rim (Prendergast 2013). Although ROOF consists of the same tissue as the sub-brow fat pad, it is thicker than the sub-brow fat pad and can contribute to the bagginess and bulky hood of the lateral upper eyelid in some patients (Kakizaki et al. 2009).

Function

ROOF contributes to the fullness (in youth) and heaviness (in senescence) of the lateral brow and lid.

Clinical Relevance

With age, deflation of the ROOF contributes to the hooding that occurs in the eyebrow and upper eyelid region. Endoscopic brow lift, which may include reinflation via fat transfer in the ROOF plane, can restore the more youthful three-dimensional contour of the eyebrow (Hoenig 2010).

ROOF resection alone is often efficacious in improving the thickness and heaviness of the upper eyelid in Caucasians (Kakizaki et al. 2009). However, because Asians often have a more substantial sub-brow fat pad, it is often necessary to additionally resect the sub-brow fat pad in Asians to produce an aesthetic "double eyelid" (Kakizaki et al. 2009; Tan et al. 2011).

A large venous channel often passes from the area of the supraorbital region laterally to the ROOF region. This vessel may lead to bleeding and should be anticipated during surgery (Zide 2006).

ROOF's corresponding adipose tissue in the lower eyelid is called the "suborbicularis oculi fat" (SOOF).

Rhabdomyosarcoma of Orbit

Kira L. Segal[1], Apostolos J. Tsiouris[2] and Gary Joseph Lelli[3]
[1]Department of Ophthalmology, Weill Cornell Medical College, New York, NY, USA
[2]Weill Cornell Medical College, New York, NY, USA
[3]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

Orbital rhabdomyosarcoma (RMS) is the most common primary orbital malignancy of childhood and accounts for 8% of all cases of primary RMS. The tumor arises from undifferentiated mesenchymal cells and most commonly presents with rapidly progressive, unilateral proptosis and globe displacement. With greater than 90% cure rate if discovered prior to orbital invasion, prompt recognition and treatment are essential.

Etiology

The majority of cases of RMS are sporadic. Reported risk factors include germline p53 mutations, ionizing radiation, associated central nervous system anomalies, maternal/paternal use of marijuana and cocaine, and first-trimester prenatal X-ray exposure. Additionally, familial cancer syndromes (e.g., Li-Fraumeni) have been associated with RMS.

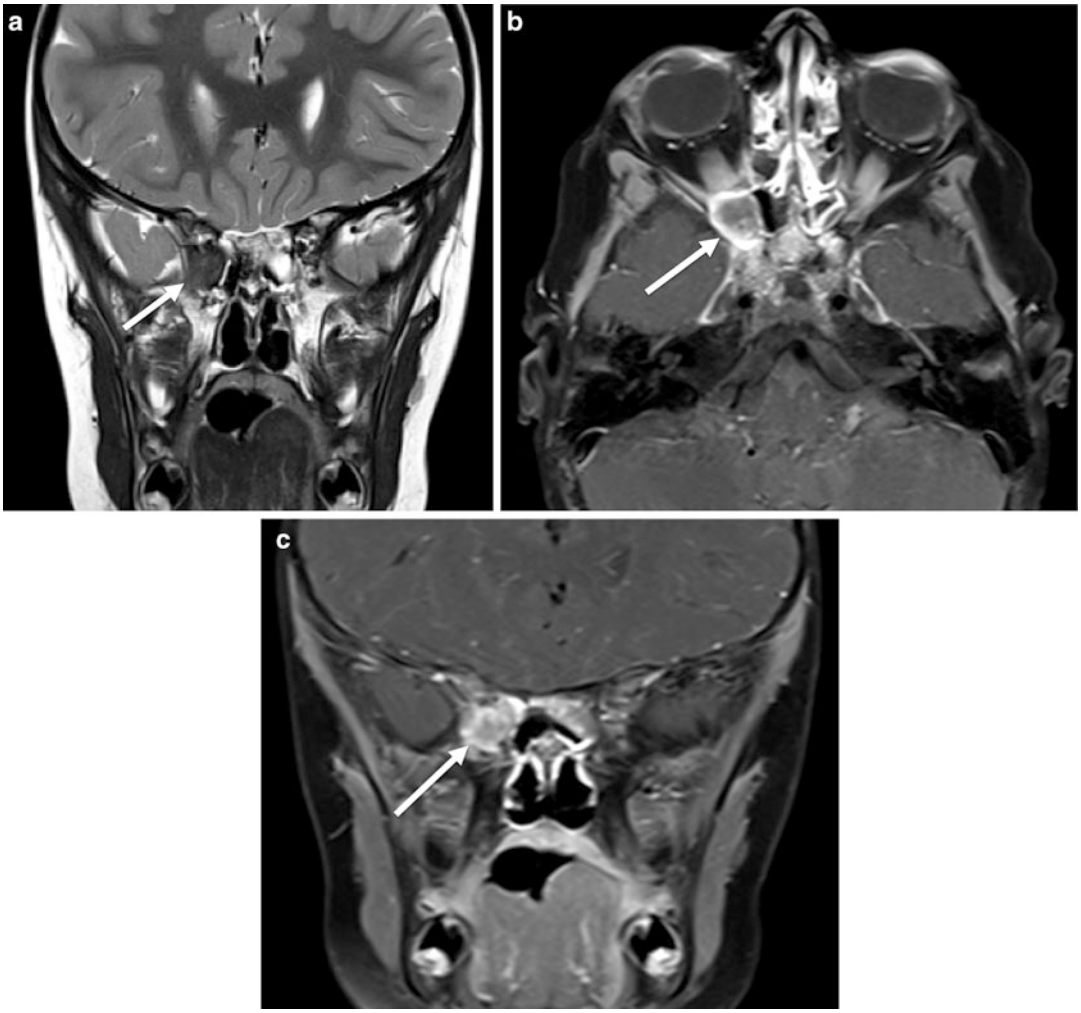
RMS is currently classified based on histologic subtype, with the embryonal subtype (ERMS) representing the most common variant (70–80% of cases). ERMS most often occurs in the head, neck, and genitourinary tract of young patients. Loss of heterozygosity at the 11p15.5 locus with resulting dysfunction of tumor suppressor genes has been implicated in the etiology of ERMS. Alveolar RMS (ARMS) is the second most common histopathologic subtype identified. A characteristic translocation of FKHR(FOX01A) gene at chromosome 13 with PAX3 or PAX7 results in tumorigenic behavior. The botryoid variant, a rare subtype of ERMS, invades the orbit secondarily by extension from the paranasal sinus or conjunctiva. Grossly, the botryoid variant appears grapelike.

Clinical Presentation

Classic presentation for RMS is rapidly progressive, unilateral proptosis. In older patients, proptosis can be more gradual, occurring over weeks to months. With superior orbital tumors, the globe is typically displaced downward, often with associated blepharoptosis, diplopia, or extraocular motility dysfunction. In 25% of cases, a firm mass is palpable; however, tumors may present in the retrobulbar space or conjunctiva. ARMS has propensity for the inferior orbit. With an anterior orbital location, significant soft tissue edema, eyelid dislocation, or chemosis may occur. Large tumors can cause choroidal folds or disc edema/optic neuropathy. Pain is reported in 10% of cases on presentation. History of unrelated trauma may confuse the clinical picture and can lead to delay in diagnosis and treatment.

Diagnostics

When concern for RMS arises, workup should proceed urgently. Both CT and MRI can be used to identify the lesion and determine the preliminary extent of invasion. Appearance on CT is of an extraconal mass that is isodense to muscle. The majority of tumors (2/3) are located in the superonasal quadrant, and half extend into the intraconal space. Bony destruction is found with large and/or aggressive lesions. More commonly, the tumor conforms to the bony walls of the orbit or the globe. Enhancement is always present and may be uniform or heterogeneous if there is necrosis or hemorrhage within the mass. Internal hemorrhage may produce focal areas of increased signal on both T1- and T2-weighted images and focal areas of hyperdensity on CT scan. MRI is useful to identify invasion of the surrounding soft tissues or intracranial extension (Fig. 1).



Rhabdomyosarcoma of Orbit, Fig. 1 (**a**) T2-weighted coronal image of an embryonal rhabdomyosarcoma in a young child demonstrates a focal T2 hypointense mass (*arrow*) at the orbital apex extending to the superior orbital fissure. (**b**) Fat-saturated T1-weighted post-gadolinium (**b**) axial and (**c**) coronal images demonstrate heterogeneous enhancement within this lesion (*arrows*)

When a pseudocapsule is present, prompt excisional biopsy should be undertaken, usually via an anterior orbital approach. Fine needle aspiration will be insufficient to provide tissue needed for frozen section, permanent light microscopy, electron microscopy, and immunohistochemistry. If the entire tumor cannot be reasonably removed due to location near vital structures or extent of invasion, as much tumor should be excised as is safe. There is suggestion that minimizing residual tumor burden will optimize subsequent radiation and chemotherapy and limit future treatment burden.

By histology, ERMS is composed of loose fascicles of undifferentiated small round or spindle-shaped cells. ARMS tumor cells are arranged in fibrovascular strands or nests, similar in appearance to lung alveoli. Electron microscopy may be necessary to identify cross-striations. Immunohistochemical markers of rhabdomyosarcoma include desmin, myoglobin, myogenin, MyoD1, vimentin, caveolin-3, and

muscle-specific actins. Cytogenetics helps differentiate and classify the primary orbital tumor type.

Referral to pediatric oncology is appropriate upon first suspicion of malignancy as concomitant diagnostic procedures may be necessary at the time of orbital biopsy. Any palpable nodes require biopsy to rule out regional metastasis. Lab testing including complete blood count, comprehensive metabolic panel, liver function testing, and urinalysis should be obtained. Rarely, tumor-induced disseminated intravascular coagulation (DIC) may be present, and coagulation profile is therefore necessary. Metastatic workup may further include CT chest, bone scan, bone marrow sampling, and PET scan. Metastatic spread occurs hematogenously, most commonly to the lung and bone.

Differential Diagnosis

Orbital RMS should be on the differential for any child presenting with progressive proptosis. Additional clinical findings of globe displacement, eyelid edema, and conjunctival congestion stimulate a broad differential in the pediatric population. Inflammatory (idiopathic orbital inflammation, allergy), infectious (orbital cellulitis, conjunctivitis, dacryocystitis), or neoplastic (capillary hemangioma, Langerhans cell histiocytosis, lymphangioma) alternatives must be considered.

Therapy

Treatment involves multimodal therapy including surgical excision followed by chemotherapy and/or radiation. All patients receive chemotherapy, the regimen dependent on Intergroup Rhabdomyosarcoma Study Group (IRSG) system and histologic subtype. The IRSG system is largely determined by the degree of residual tumor following surgical excision. Radiotherapy is performed on all cases except IRSG group I patients (those with completely resected localized lesions) with embryonal subtype.

Prognosis

IRSG staging and prognosis depend on primary site, histologic type, tumor size, degree of regional spread, nodal involvement, distant metastatic disease, and residual tumor following pre-chemotherapy surgical excision. Of all RMS types, an orbital primary location portends the best prognosis with an overall survival of over 90%. Children older than 1 and less than 10 years of age carry a more favorable prognosis. Alveolar tumors and distant metastases present at diagnosis are associated with worse prognosis.

Epidemiology

RMS represents 3% of all childhood cancers and is the third most common solid extracranial tumor behind neuroblastoma and Wilms' tumor. The incidence is reported to be 4–5 per million in children less than 15 years of age, and there is a slight male predominance (male/female ratio 1.4:1). Average age of onset is 6 years of age and there are two age peaks between 2–6 and 15–19 years. The 15–19 age peak presentation is more common in males. This malignancy can also develop in adults.

Riley-Day Syndrome (Familial Dysautonomia)

Mona Kaleem
Department of Ophthalmology, Euclid Hospital, Cole Eye Institute, Cleveland Clinic Foundation, Cleveland, OH, USA

Synonyms

Hereditary sensory and autonomic neuropathy (HSAN) III

Definition

A hereditary sensory autonomic neuropathy primarily affecting the sympathetic nervous system.

Etiology

Familial dysautonomia is an autosomal recessive disorder found predominantly in the Ashkenazi Jewish population. It is due to a mutation in the IkB kinase-associated protein (IKBKAP) gene which codes for the IKAP/hELP1 protein on the 9q31-q33 locus. This leads to the downregulation of genes involved in the expression of neurotransmitters critical for the development, differentiation, and survival of unmyelinated and small myelinated peripheral sensory and autonomic neurons. The sympathetic afferent and efferent pathways are both involved leading to impaired transmission of baroreceptor, visceral, and chemoreceptor information. There may also be a reduced number of parasympathetic ganglion cell complexes.

Clinical Presentation

Signs and symptoms of familial dysautonomia appear early in life and are generally identified in the pediatric population. They are related to loss of small sensory and autonomic fibers as well as supersensitivity to cholinergic and adrenergic agents. These include:

- Decreased pain and temperature
- Preservation of proprioception and touch
- Hemodynamic instability and dysautonomic crises:
  - Physiologic or psychologic stress leading to inappropriate cardiovascular response
  - Insensitivity to hypoxemia and hypercarbia leading to pulmonary insufficiency
- Hyporeflexia
- Corneal hypoesthesia:
  - Alacrima
  - Neurotrophic ulcers
- Poor oropharyngeal coordination (feeding difficulty, aspiration, reflux)
- Absence of fungiform papillae
- Erythematous skin blotching and hyperhidrosis
- Developmental delay but normal intelligence
- Ataxia
- Scoliosis

Diagnosis

Familial dysautonomia is largely a clinical diagnosis of the pediatric population.

Genetic testing is available at selected centers in the USA and Israel.

Clinical testing:

EMG (nerve function)
EEG (evaluation of seizures)
EKG (prolonged QT intervals and cardiac conduction)
Chest radiographs (atelectasis and pulmonary changes)

Urinary vanillylmandelic acid levels (decreased)
Homovanillic acid levels (increased)
Plasma dopamine β-hydroxylase (decreased)
Sural nerve biopsy

Differential Diagnosis

Hereditary sensory autonomic neuropathy, types I, II, IV, and V.

Prophylaxis

- Avoid medications that interact with the autonomic nervous system.
- Anxiolytic medications.
- Perioperative risk assessment and preparation.

Therapy

Treatment of familial dysautonomia consists of preventative and supportive care. These include maintaining eye moisture to prevent keratopathy, feeding strategies, and administration of agents to prevent dysautonomic crises (anxiolytics such as benzodiazepines, clonidine, etc.) and cardiovascular instability (fluid, plasma, blood products, and mineralocorticoids).

Prognosis

Dysautonomic crises begin around age 3 with attacks of cyclical vomiting, hypertension, sweating, and agitation. Fifty to 60% of children die before the age of 20 but there are reports of patients surviving until their 40s. The cause of death is usually related to aspiration, pulmonary failure, or cardiovascular instability.

Epidemiology

Occurs almost exclusively in the Ashkenazi Jewish population:

Ring Sign, in Idiopathic Orbital Inflammation

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Definition

The radiographic finding shows scleral uveal rim thickening with contrast enhancement and edema extending into Tenon's space producing the "ring sign" in nonspecific orbital inflammation.`

Etiology

In idiopathic orbital inflammation, an inflammatory infiltrate can affect the posterior portion of the globe and the retrobulbar fat pad. Scleral uveal thickening and enhancement may be caused by tenonitis with fluid in Tenon's space, producing a lucent area or "ring sign" on computed tomography (CT). On B-scan ultrasonography, an acoustically hollow area corresponding to an edematous Tenon's capsule can be seen.

Occurrence

Idiopathic orbital inflammation or orbital pseudotumor is a benign inflammatory syndrome of the orbit, although extra-orbital involvement can occur. It can cause symptoms of periorbital edema, erythema, proptosis, ptosis, diplopia, and pain with eye movements. Imaging with ultrasonographic (CT) and radiologic (MRI) examination plays an important role in the diagnosis of nonspecific orbital inflammation. Patients typically respond dramatically to high-dose corticosteroid therapy.

Classification

Orbital pseudotumor can be subclassified on the basis of the anatomic target areas within the orbit. It may be a diffuse process or more localized affecting the extraocular muscles (myositis), the lacrimal gland (dacryoadenitis), or the sclera and posterior tenons (scleritis). It is important to differentiate orbital pseudotumor from infection, neoplasm, and other causes of orbital inflammation including thyroid-associated orbitopathy, Wegener's granulomatosis, and lymphoproliferative disorders.

Acne rosacea

Definition

Ocular rosacea is ocular and eyelid inflammation due to rosacea, a chronic inflammatory condition that affects the skin on the face, nose, and forehead.

Etiology

The exact pathophysiology of rosacea is unknown, though it seems to be comprised of both innate and environmental factors. Recent research has shown an upregulation of proinflammatory and vasoregulatory genes in these patients (e.g., cathelicidin, kallikrein-5, and toll-like receptor 2). Various microbial organisms including *Helicobacter pylori*, *Demodex folliculorum*, *Demodex brevis*, and *Staphylococcus epidermidis* have also been implicated in the disease.

Clinical Presentation

Patients with ocular rosacea may complain of nonspecific symptoms, such as foreign body sensation, dryness, itching, photophobia, and tearing. Symptoms are usually bilateral. Ocular rosacea symptoms are usually not related to the severity of the cutaneous form of rosacea. In fact, in 20% of ocular rosacea patients, symptoms may occur before any cutaneous manifestations. Patients' eyelids, corneas, and conjunctiva can be affected depending on the severity of the condition.

Patients with ocular rosacea have also been found to have recurrent hordeolum and chalazion secondary to meibomian gland dysfunction which is common in this condition. Slit-lamp examination of the eyelid margins can reveal telangiectases, dilated meibomian glands, excessive seborrheic secretion, and collarettes around the eyelashes. There may be a soapy aspect of the inferior tear meniscus and debris in the tear film. Dry eyes, with abnormal Schirmer's test, and diminished tear breakup time (TBUT) were reported in a large majority of patients with ocular rosacea. Chronic conjunctivitis characterized by interpalpebral bulbar conjunctival hyperemia may be present, and cicatricial conjunctivitis involving the lower lid is one of the most common ocular surface findings in rosacea. Corneal manifestations, including keratitis and recurrent corneal epithelial erosions, may also occur in up to 33% of patients with rosacea.

Diagnosis

Ocular rosacea is diagnosed clinically, and laboratory studies are not implicated.

Differential Diagnosis

Staphylococcal and seborrheic blepharokeratoconjunctivitis; sebaceous gland carcinoma; cicatricial pemphigoid; allergic, bacterial, and viral conjunctivitis; corneal erosion; atopic dermatitis; dry eye syndrome; episcleritis; bacterial keratitis; atopic keratoconjunctivitis; sicca keratoconjunctivitis; corneal ulcer.

Prophylaxis

Broad spectrum sunscreen for photoprotection, regular eye exams.

Therapy

It is important to avoid trigger factors, which are highly individualized. Mild ocular rosacea requires

local remedies such as warm compresses, lid hygiene with neutral baby shampoo, and instillation of lubricating drops. Topical cyclosporine 0.05% can assist with tear production and quality. Antibiotic ointments applied nightly can decrease eyelid flora and help soften collarettes. Moderate ocular rosacea may require systemic treatment, such as tetracycline, doxycycline, or azithromycin, in addition to topical therapy. For persistent ocular inflammation, topical corticosteroids or cyclosporine has proven to be beneficial. However, due to the adverse side effects of long-term steroid use, such as glaucoma and cataracts, cyclosporine is preferable. Surgical intervention may be required in certain instances, such as chalazia, corneal thinning, and corneal perforations.

Prognosis

Prognosis depends on the severity of the condition.

Epidemiology

Out of the 10% of the general population, up to 60% experience ocular complications. Ocular rosacea affects both sexes equally.

Rosengren-Doane Tear Pump

Kristen E. Dunbar[1], B. Ranjodh Singh[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Lacrimal pump

Definition

A mechanism theorized by Rosengren-Doane thought to be responsible for the active excretion of the tears through the nasolacrimal drainage system.

Structure

The nasolacrimal system is comprised of multiple parts measuring approximately 32 mm in its entirety. There are two puncta, one at the medial aspect of each lid, approximately 5 mm from the medial canthus. They are apposed to the globe yet slightly inverted to allow them to rest in the tear lake. Each punctum is approximately 0.2 mm in diameter and surrounded by the ampulla perpendicular to the lid margin.

Each puncta ends in the canaliculi which course perpendicular to the lid margin approximately 2 mm before turning at a 90 angle medially. They then run approximately 8–10 mm before combining to form a common canaliculus in 90% of patients.

The tears then pass through the valve of Rosenmüller, a mucosal fold at the juncture of the common lacrimal canaliculus and superior aspect of the lacrimal sac (see "▶ Rosenmüller, Valve of"). The lacrimal sac extends for approximately 10 mm inferiorly within the bony fossa in the medial orbit. It is bordered by the anterior and posterior lacrimal crests.

The lacrimal sac then becomes the nasolacrimal duct extending inferiorly

approximately 12 mm and terminating in an ostium just beneath the inferior turbinate. This ostium is covered by another mucosal fold (the valve of Hasner).

Important to understanding the tear pump is the orientation of the orbicularis muscles. The pretarsal orbicularis is just anterior to the tarsus. Its fibers run horizontally and are the innermost ring of orbicularis tissue. Just surrounding the preseptal orbicularis is the preseptal orbicularis. The preseptal component overlies the orbital septum and originates from the superficial and deep heads of the medial canthal tendon. It has attachments to the lacrimal sac that contribute to the Rosengren-Doane tear pump mechanism.

Function

The Rosengren-Doane tear pump is the predominate theory of the active excretion of tears through the nasolacrimal system. In this theory, the pretarsal and preseptal orbicularis muscles work together to create concomitant positive and negative pressure propelling the tears from the tear lake into the nose.

At rest, when the eyelids are fully open, the puncta pop open, and the negative pressure allows the canaliculi to fill with tears. As the upper eyelid closes, both portions of the orbicularis contract. The horizontal fibers of the pretarsal orbicularis squeeze closed the canaliculi thus forcing the tears into the lacrimal sac and occluding the puncta to prevent reflux. The preseptal orbicularis attached to the lacrimal sac pulls the lacrimal sac laterally creating a negative pressure and allowing the tears to flow into the lacrimal sac. As the lid reopens and the orbicularis relaxes, the lacrimal sac then closes creating a positive pressure on the sac pushing the tears into the nasolacrimal duct and into the nose.

Clinical Relevance

Normal tear drainage relies on a fully functioning Rosengren-Doane tear pump. Understanding the active mechanism of active tear elimination and anatomy of the lacrimal system can help one appropriately diagnose and pinpoint diseases of this system.

Reduced drive to blink, incomplete blink, lid deformity, or involutional laxity can all contribute to malfunction of the lacrimal pump. This can result in epiphora or corneal exposure if not appropriately identified and treated.

Poor anatomic apposition of the puncta to the globe or punctal stenosis can lead to insufficient tear drainage into the canaliculi resulting in epiphora.

Infections of the nasolacrimal system (i.e., dacryocystitis or canaliculitis) can also cause obstruction and malformation.

[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Rosenmüller fold; Valve of Hanske

Definition

The valve of Rosenmüller is not a true valve, but rather a mucosal fold at the juncture of the common canaliculus and the lacrimal sac. It separates the palpebral portion of the lacrimal drainage system from the lacrimal sac and nasolacrimal duct. The valve of Rosenmüller is named after the German anatomist, Johann Christian Rosenmüller (May 25, 1771–February 28, 1820), who first described the structure.

Structure

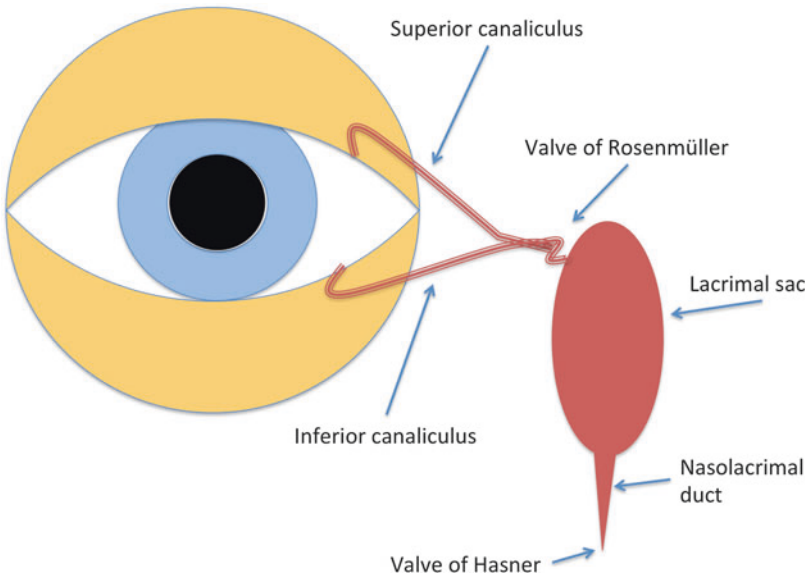
The valve of Rosenmüller is a mucosal fold at the juncture of the common lacrimal canaliculus and the superior aspect of the lacrimal sac (Fig. 1). According to cadaveric studies, there is a consistent pattern of angulation within the canalicular system. The canaliculi bend first posteriorly as they travel behind the medial canthal tendon and then bend anteriorly at an acute angle to enter the lacrimal sac (Tucker et al. 1996). This pattern of bending is consistently observed in a majority of specimens, and a mucosal fold corresponding to the valve of Rosemüller is observed in approximately 60% of persons (Zoumalan et al. 2011).

Function

Lacrimal drainage must transit the valve of Rosenmüller from the common canaliculus to the lacrimal sac and nasolacrimal duct. The physiologic role of the valve of Rosenmüller is to prevent reflux of tears from the lacrimal sac into the canalicular system. It is postulated that the fold of tissue functions as a one-way valve to enable flow from the common canaliculus into the lacrimal sac, but preventing retrograde flow (American Academy of Ophthalmology 2015).

Clinical Relevance

In lacrimal probing, the valve of Rosenmüller is felt as a "soft stop" as the probe is advanced through the common canaliculus and into the lacrimal sac, prior to the "hard stop" felt as the probe contacts the bony lacrimal fossa (Schmidt 1996).



Rosenmüller, Valve of, Fig. 1 Schematic of nasolacrimal anatomy

On punctal irrigation for the evaluation of potential nasolacrimal obstruction, an obstruction at the level of the valve of Rosenmüller will cause reflux of the irrigated saline out of the opposite punctum.

In dacryocystitis or nasolacrimal duct obstruction, palpation or massage over the lacrimal sac may produce reflux if the valve of Rosenmüller and canalicular system are patent (Cohen et al. 2014).

A dacryocystocele requires blockage of the valve of Rosenmüller proximally as well obstrcution of the nasolacrimal duct distally in order to form a cystic enlargement of the lacrimal sac (Cohen et al. 2014).

In dacryorhinocystostomy (DCR) surgery, the adherent mucosal tissue forming the valve of Rosenmüller may need to be excised if causing an obstruction at the entrance to the lacrimal sac (Cohen et al. 2014).

Miescher-Melkersson-Rosenthal syndrome

Definition

Melkersson-Rosenthal syndrome (MRS) was first described by Melkersson in 1928. MRS is characterized by the clinical triad of recurrent swelling, facial nerve palsy, and fissured tongue.

Etiology

While the exact etiology for MRS is unknown, it has been postulated to be associated with adverse

reactions to infection, allergy, or foreign material such a silicates, gold, and mercury; more recently, it has been theorized to have hereditary occurrence and genetic predisposition (autosomal dominant, locus: 9p11) (Gorlin et al. 1990; Laskaris 2003).

Clinical Presentation

Symptoms and signs of MRS include unilateral/bilateral facial paralysis, gingival edema, fissured tongue, and chronic and recurrent facial swelling in regions of face, lips, palate, cheeks, and tongue. MRS has also been associated with migraine, megacolon, and stress, implicating vasomotor instability and autonomic dysfunction (Laskaris 2003; Weedon et al. 2010).

Diagnosis

The diagnosis of MRS can be confirmed by characteristic biopsy showing noncaseating granulomas and/or lymphedematous alteration (Laskaris and George 2005; Grewal and Grewal 2012).

Differential Diagnosis

Hughes syndrome, Crohn disease, sarcoidosis, cheilitis granulomatosa, tuberculosis, angioneurotic edema, and allergic gingivostomatitis.

Therapy

Treatment of this syndrome is symptomatic, targeted toward therapy of facial palsy and correction of facial disfigurement due to edema. Facial palsy is managed by warm compresses, analgesics, oral corticosteroids, antibiotic eye drops, and ointment and usually recovers completely; however recurrences may occur. Facial decompression has been used in severe cases. Recent advances in therapeutic modalities have broadened to include the use of laser beam acupuncture and oral clofazimine to reduce swelling and avoid permanence (Laskaris and George 2005; Grewal and Grewal 2012).

Prognosis

MRS may recur or progress and may develop into a chronic disorder.

Epidemiology

MRS has been found in childhood or early adolescence and is three times more common in females than males but affects less than 200,000 people in the USA (Gorlin et al. 1990).

Rotational Flap for Eyelid Repair

Ronald Mancini[1] and Nicole Khadavi Kohan[2]
[1]Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA
[2]Jules Stein Eye Institute, David Geffen School of Medicine at UCLA, University of California Los Angeles, Los Angeles, CA, USA

Synonyms

Mustarde rotational flap; Simple rotational flap

Definition

A technique utilized in eyelid repair surgery to reconstruct a defect in the anterior lamellar (skin and muscle) of the eyelid, in which tissue from an area of relative excess is rotated in an arc around a fixed pivot point to fill the defect.

Indication

Rotational flaps are indicated for the repair of anterior lamellar deficiencies of the eyelid (typically the lower eyelid) in which there is inadequate tissue available for direct simple closure. These defects are most commonly secondary to cancer resection surgery, including Mohs surgery, and trauma. The rotational flap can redirect tension on the wound into the horizontal as opposed to the vertical plane, thereby minimizing the risk of eyelid malpositions, particularly ectropion.

Contraindications

In trauma patients, surgery should be deferred until the patient is stable and a suitable candidate for surgery. Also more serious injuries, such as a ruptured globe, take precedence and should be repaired prior to the eyelids. The donor tissue to be transposed must be healthy and viable.

Techniques and Principles

In planning the appropriate design and orientation of the rotational flap the surgeon carefully considers the degree of local skin mobility and the orientation of relaxed skin tension lines, which will result in the least conspicuous scar. In general tissue is transposed from an area of relative excess to an area with insufficient tissue to allow closure. The rotational flap, particularly when used in the lower eyelid, can also be utilized to redirect tension on the wound into the horizontal as opposed to the vertical plane, thereby minimizing the risk of eyelid malpositions, particularly ectropion. The incision is created and the tissue undermined until arcuate advancement can be achieved to fill the defect. Very large lower eyelid defects can be reconstructed with an extensive Mustarde rotational flap.

Outcome

Rotational flaps allow for recruitment of vascularized anterior lamellar tissues (skin and muscle) for reconstruction of eyelid defects. The desired result is a functional eyelid, which can provide adequate protection of the globe. The resultant scar is semicircular in shape.

Complications

Any excess tension on the flap can result in wound dehiscence or flap necrosis. Eyelid malpositions including ectropion or entropion are possible, particularly with tension on the wound closure or exuberant wound contraction and fibrosis.

Synonyms

Direct siderosis

Definition

The product of an immune reaction produced by an oxidized iron foreign body in the cornea. Typically formed within 3–4 h after the introduction of the ferrous body (Brock and Gurekas 2013). Clinically identified as a reddish brown circular opacity confined to Bowman's layer or anterior stroma. Necrotic corneal tissue can be removed with the use of a burr or small gauge needle (McGuinness and Knight-Jones 1968).

Etiology

Immune product from an oxidized iron foreign body in the cornea (Zuckerman and Lieberman 1960).

Occurrence

A corneal rust ring typically develops 3–4 h after the iron foreign body is introduced in the cornea (Fig. 1). Corneal foreign bodies are very common eye injuries in workers dealing with metallic objects and high speed drills and

Rust Ring, Iron Foreign Body Causing, Fig. 1 Iron foreign body

grinders. They are the most common industrial ocular accident. The majority of corneal foreign bodies are centrally located and can leave a residual scar in the patient's visual axis (Tasman and Jaeger 2001). The presence of iron particles within the cornea causes localized tissue necrosis which is typically removed in order to facilitate wound healing (Brown et al. 1975). Incomplete removal of necrotic tissue should be suspected when delayed epithelialization, chronic foreign body sensation, and extended light sensitivity follow the removal of a corneal metallic foreign body.

Classification

Immune-mediated reaction
Oxidation reaction to ferrous foreign body

Salzmann Nodular Degeneration

Aaron Wang
Wilmer Eye Institute, Johns Hopkins, Baltimore, MD, USA

Definition

Salzmann's nodular degeneration is a slowly progressive, degenerative condition of the cornea that is rare, noninflammatory, and characterized by bluish-white nodules on the corneal surface.

Etiology

The disease can be idiopathic, but often times, it is from chronic ocular surface irritation and associated with preexisting corneal diseases. It often presents in patients with a history of keratitis, most commonly trachomatous or phlyctenular, but also in vernal or other forms of keratitis caused by scarlet fever, measles, and uveitis (Das et al. 2005). Other associations include epithelial basement membrane dystrophy, Thygeson's punctate keratitis, postcorneal surgery, keratoconus, contact lens, and ocular trauma.

Clinical Presentation

Salzmann nodules are bluish-white-to-gray subepithelial nodules that tend to develop slowly (Das et al. 2005). They are usually round prominences, but can be conical or elongated, often less than 2 mm, but can be as large as 4 mm or more. They usually number between 1 and 8 and can be distributed on any part of the cornea. The nodules may or may not be vascularized. They may affect vision by direct obstruction of visual axis or by induced spherical or astigmatic error. They are associated with iron-containing line and negative fluoresce in staining or pooling at the base of the nodule.

Diagnosis

Diagnosis of Salzmann nodules is based on the clinical exam. Examination is primarily based on the slit-lamp biomicroscopy, but should also include keratometry and corneal topography to record surface irregularity. Histologically, the epithelium cells show degenerative change,

10.1007/978-3-540-69000-9_100703"

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

including epithelial cells that have flattened and basal cells that have lost their columnar shape and contain degenerative vacuoles and clumped nuclear chromatin. The bowman's layer could be absent and replaced by granular PAS-positive eosinophilic material (Das et al. 2005). Hyaline plaques have also been found between the corneal epithelium and Bowman's layer.

Differential Diagnosis

Bullous keratopathy
Climatic droplet keratopathy
Corneal amyloidosis
Corneal keloid
Hereditary hypertrophic scarring
Pterygoid corneal dystrophy

Therapy

Treatment is not necessary if the patient is asymptomatic. Asymptomatic patients are mostly those with nodules limited to the peripheral cornea. For mild irritation, lubrication is recommended. Surgical intervention should be considered in patients who have nodules that exhibit growth, decrease in surface regularity, and loss of visual acuity. In cases where the nodule is easily separated manually from the corneal surface and does not involve Bowman's layer, recurrence rates are low. If lesions involve Bowman's layer and superficial stroma, phototherapeutic keratectomy should be considered for surface irregularities. Manual removal methods have included using forceps to grasp and strip them from the surface of the cornea, using a Graefe's knife or no. 15 blade to perform a superficial excision, or a trephine to remove the base of the nodules and reach clear cornea. Cryotherapy has been used previously. Cauterization has also been used but may induce corneal opacification. Amniotic membrane transplantation may help with reducing inflammation, scarring, and vascularization after a superficial keratectomy. Recurrences may warrant superficial keratectomy or phototherapeutic keratectomy with application of mitomycin C. One study that looked at 30 eyes that underwent superficial keratectomy and mitomycin C found no recurrence during a mean follow-up of 28 months. Visual acuity and corneal clarity may improve in some patients after treatment. Lamellar or penetrating keratoplasty may be needed for lesions that extend to the mid-stroma. Though recurrences have been reported after penetrating keratoplasty, it is hardly ever needed (Bowers et al. 2003).

Prognosis

The disease is slowly progressive, with most patients not being aware of their disease beginning. In about 60% of eyes, the nodules are located in the paracentral and central areas. Surgical removal has been shown to be effective, and application of mitomycin C has helped reduce reoccurrences (see "Therapy" above). One study has reported up to almost three lines of visual acuity improvement after PTK (Maloney et al. 1996).

Epidemiology

Salzmann nodular degeneration has been reported more commonly in white, elderly, and female persons (Das et al. 2005). The disease is more often unilateral. However, it has been seen in patients of different ages, races, and gender and can be bilateral.

Sarcoid

► Sarcoidosis

Sarcoidosis

Atif Mohiuddin[1] and Faraaz Khan[2]
[1]Department of Ophthalmology, George Washington University, Washington, DC, USA
[2]Ophthalmology, Virginia Commonwealth University Health System, Richmond, VA, USA

Synonyms

Sarcoid

Definition

Sarcoidosis is a non-caseating granulomatous inflammatory disorder mediated by T-lymphocytes. Its exact cause has not been elucidated. Sarcoidosis can range from affecting a single organ to being a fatal multiple system disease. Most often, mediastinal lymph nodes, lungs, liver, parotid glands, spleen, skin, and the eye are affected.

Etiology

The cause of sarcoidosis is unknown. The disease process involves T-cell-mediated granulomatous inflammation.

Clinical Presentation

Sarcoidosis can have an acute or insidious onset. Two syndromes, Lofgren syndrome and Heerfordt syndrome, are known to present acutely in young patients. In Lofgren syndrome, patients present with erythema nodosum and bilateral hilar lymphadenopathy that is also associated with fever, arthralgia, and anorexia. In Heerfordt syndrome, also known as uveoparotid fever, patients present with uveitis, fever, parotitis, and cranial nerve palsy, usually involving the seventh cranial nerve.

In insidious onset sarcoidosis, the disease can present skin lesions, pulmonary disease, and other less common manifestations such as neurological disease, arthritis, bone cysts, renal disease, lymphadenopathy, splenomegaly, glaucomatous liver disease, and cardiac arrhythmias. Pulmonary disease can manifest as bilateral asymptomatic hilar lymphadenopathy, diffuse reticulonodular infiltrates, or even pulmonary fibrosis which may result in pulmonary hypertension and cor pulmonale. In 25% of patients, skin lesions may manifest as erythematic nodosum, glaucomatous scattered plaques or nodules, lupus pernio, or glaucomatous deposits in long-standing scars. In 5–10% of patients, sarcoidosis may result in a unilateral facial nerve palsy. More rare neurological manifestations include meningitis, seizures, peripheral neuropathy, and psychiatric symptoms. In chronic sarcoidosis, patients may experience arthritis of the large and small joints. This can be confused with juvenile idiopathic arthritis in children because in the young, sarcoidosis is more likely to present as an arthropathy than with pulmonary findings. Renal disease can manifest as nephrocalcinosis.

There are a myriad of ways that sarcoidosis presents affecting the eye. The most common is uveitis which can be anterior, intermediate, or posterior in nature. Other ocular manifestations include keratoconjunctivitis sicca, conjunctival nodules, and, very rarely, scleral or orbital lesions. Patients can have an acute anterior uveitis or a chronic granulomatous which typically affects older patients with pulmonary disease. These patients can also have nodules of the iris or even trabecular meshwork. Sarcoidosis patients with intermediate uveitis may present with snowballs. Other patients may have periphlebitis which would appear as yellowish or gray-white perivenous sheathing which can sometimes also involve the optic nerve. Severe periphlebitis will result in perivenous exudates called candlewax dripping nodules. Other manifestations include KCS, conjunctival nodules, and, rarely, orbital and scleral lesions. Although rare, choroidal infiltrates can present as many small, pale yellow "punched-

out" infiltrates, multiple large confluent lesions with amoeboid margins, or exceedingly rarely as solitary choroidal granulomas. When sarcoidosis present as multifocal choroiditis, visual prognosis is poor. This is because choroidal neovascularization may result in loss of central vision or a chorioretinal scar. Other ocular findings can include retinal granulomas, peripheral retinal neovascularization secondary to retinal capillary dropout, a nummular keratitis, and optic nerve involvement. Optic nerve involvement could include focal granulomas by the optic nerve, papilledema secondary to central nervous system involvement, or persistent disk edema associated with vitreous or retinal involvement.

Diagnosis

Without histologic confirmation, sarcoidosis is a diagnosis of exclusion. Enzyme assays of angiotensin-converting enzyme (ACE) and lysozyme levels in addition to biopsy are common methods used to assess for sarcoidosis. Lung biopsy is the highest yield (90%). This is so even in asymptomatic patients with a normal chest X-ray. In patients with conjunctivitis with conjunctival nodules, biopsies are positive 70% of the time. In enlarged lacrimal glands, biopsies are positive 75% of the time, but in un-enlarged lacrimal glands, biopsy yield can be as low as 25%. Pulmonary function tests would show a restrictive lung disease pattern. A strongly positive Mantoux test to a tuberculin unit would make a diagnosis of sarcoidosis less likely. Chest radiographs will be abnormal 90% of the time.

Differential Diagnosis

The differential diagnosis of posterior segment sarcoidosis is organized into small choroidal lesions, large choroidal infiltrates, and periphlebitis. Small choroidal lesions could also be tuberculosis, birdshot chorioretinopathy, or multifocal choroiditis with panuveitis. Findings of large choroidal infiltrates could also be large cell lymphoma, Harada disease, serpiginous choroidopathy, or metastatic tumor. Finally, other causes of periphlebitis could be Behcet syndrome, tuberculosis, or cytomegalovirus retinitis.

Prophylaxis

There is no prophylaxis for this disease.

Therapy

Therapy for anterior uveitis is topical and/or periocular steroids. On the other hand, posterior uveitis may require systemic steroids or immunosuppressive agents such as methotrexate, cyclosporine, or azathioprine. Cyclophosphamide has been shown to be useful in refractory disease as well as infliximab.

Prognosis

Prognosis is generally good if patient has timely diagnosis and treatment. However, in cases of multifocal choroiditis, visual prognosis is especially guarded as the patient may develop choroidal neovascularization resulting in loss of central vision or a chorioretinal scar.

Epidemiology

Sarcoidosis more commonly affects patients of African than Caucasian descent. It is also more frequently found in colder climates.

Definition

Sarcoidosis is a multisystem autoimmune disease with manifold features. The name sarcoid is derived from the Greek root *sarx* – meaning flesh – and sarcoidosis is so-named because the characteristic granulomas seen in sarcoidosis have a fleshy consistency.

Basic Characteristics

Clinical Features

Sarcoidosis is considered one of the "great imitators" in human disease and may present with protean features. The characteristic lesion in sarcoidosis is the noncaseating granuloma.

Any organ system can be affected, but the chest is most commonly involved and pulmonary nodules are seen in 90% of cases. Sarcoidosis may involve any part of the orbit and any part of the eye itself. Anterior uveitis is the most common ocular finding. Orbital involvement is present in 8–10% of patients with sarcoidosis (Demirci 2015). Within the orbit, the lacrimal gland is the most common orbital site, with up to 60–80% of patients demonstrating lacrimal gland involvement on gallium scanning. Other orbital tissues are rarely involved but may include the extraocular muscles and the optic nerve.

Presentation

Exam findings in orbital sarcoidosis include palpable mass or palpable lacrimal gland enlargement, proptosis, diplopia, pain, ptosis, limited ocular motility, and ocular irritation. Lacrimal gland inflammation may present symptoms of dry eye or with an enlarged lacrimal gland. Within the orbit, the lacrimal gland is the most commonly affected site, (42%) followed by orbital fat/soft tissue (39%), eyelids (12%), and lacrimal sac (8%) (Demirci 2015; Black and Smith 2012).

Epidemiology

While sarcoidosis may affect persons of all ages and races, most cases are diagnosed between the ages of 20 and 40. In the United States, sarcoidosis most commonly affects African-Americans, but high rates are also found in Ireland and in Scandinavia. In the United States, the incidence is 3–10 per 100,000 for Caucasians and 35–80 per 100,000 for African-Americans. In the ACCESS (A Case Control Etiologic Study of Sarcoidosis), which included 706 newly diagnosed patients, ocular involvement was more common in African-Americans than in Caucasians (Demirci 2015; Black and Smith 2012).

Diagnosis

Diagnostic testing for sarcoidosis may include chest radiographs or chest CT to evaluate for pulmonary nodules. Orbital imaging demonstrates diffuse homogenous or lobular enlargement and enhancement of the lacrimal gland. Serum assays include ACE and calcium levels, complete blood counts, and complete metabolic panel and a chest X-ray for hilar lymphadenopathy. Conjunctival biopsy may be helpful in the diagnosis of systemic sarcoidosis, but biopsies of clinically or radiographically significant nodules have a higher yield. The defining characteristic of sarcoidosis on histology is the noncaseating granuloma. Biopsy of affected tissues is diagnostic. Lacrimal gland biopsy is often diagnostic for orbital involvement, and lesions demonstrate the typical noncaseating granuloma.

Management

Potent anti-inflammatory or immunosuppressive medications are the mainstay of treatment for sarcoidosis. Corticosteroids are typically used in the acute phase, and steroid-sparing agents such as azathioprine, methotrexate, and plaquenil are used for chronic therapy. In localized orbital disease, periocular injections of triamcinolone may be used.

Malignant mesenchymal tumor of orbit

Definition

Sarcomas are malignant soft tissue tumors of mesenchymal origin. Derived from the Greek root word *sarx*, meaning "flesh," the term sarcoma refers to a variety of malignancies derived from soft tissues, including cartilage (chondrosarcoma), bone (osteosarcoma, Ewing sarcoma), connective tissue (fibrous histiocytoma, alveolar sarcoma), muscle (leiomyosarcoma), and fat (liposarcoma). Sarcomas are rare but aggressive tumors and may affect the orbit.

Etiology

A variety of sarcomas may affect the orbit, all of which are rare, accounting for less than 1% of all orbital malignant tumors. Orbital sarcomas include malignant tumors of bone (osteosarcoma, Ewing sarcoma), connective tissue (fibrous histiocytoma, alveolar sarcoma), muscle (leiomyosarcoma), and fat (liposarcoma).

Osteosarcoma is the most common malignant bone tumor overall, but orbital involvement is rare, and these comprise only 0.5–1% of orbital tumors. Osteosarcoma arises from mesenchymal bone precursor cells and can occur in any bone, usually the metaphyseal plates of the long bones. Typically orbital involvement occurs secondarily, as a result of invasion from the adjacent paranasal sinuses, although metastases from distant sites have also been reported. Most tumors arise de novo, but osteosarcoma may also arise in the setting of dysplastic bone growth, such as Paget's disease, fibrous dysplasia, or prior radiation therapy. Osteosarcoma is known to occur as a second malignancy in patients with familial retinoblastoma who have undergone orbital radiotherapy for retinoblastoma (Perry and Singh 2013). Approximately 10% of patients with osteosarcoma have a history of prior radiotherapy to the affected area, and similarly, retinoblastoma patients undergoing radiotherapy have approximately a 10% risk of developing osteosarcoma by age 25 (Black and Smith 2012).

Ewing sarcoma is a malignant tumor of bone that occurs most commonly in younger patients, with 75% aged 20 or younger and 90% aged 30 or younger at the time of presentation. Ewing sarcoma is classically a tumor of the long bones, and orbital involvement typically occurs secondarily as a result of metastatic spread (Esmaeli 2010).

Fibrous histiocytoma is the most common mesenchymal tumor in adults. Malignant fibrous histiocytoma or myxofibrosarcoma may arise de novo, as a primary malignancy or as a secondary malignancy following orbital radiation for retinoblastoma, especially in patients with germline mutations. Malignant fibrous histiocytomas are aggressive tumors and require orbital exenteration. Distant metastases are rare but local recurrence and local infiltrative disease are common (Perry and Singh 2013).

Leiomyosarcomas, malignant tumors of smooth muscle, are seen most often after orbital

radiotherapy in children, such as orbital radiation for retinoblastoma. Smooth muscle origins for these tumors include perivascular smooth muscle, Muller's muscle, and precursor cells (Perry and Singh 2013).

Liposarcoma is common in adults, but very rarely occurs within the orbit. Orbital involvement may occur in the setting of disseminated metastases (Perry and Singh 2013).

Clinical Presentation

Orbital sarcomas may present similarly to orbital inflammatory disease or orbital infection, with "orbital signs" including pain, proptosis, periocular edema, and limited extraocular movement and signs of optic nerve dysfunction such as decreased visual acuity, dyschromatopsia, or an afferent pupillary deficit. Depending on the location of the lesion, sensory nerve paresthesia may occur. Anteriorly located masses may be palpable on physical exam. Malignant lesions often progress insidiously over weeks or months, but may also present acutely with rapid development of pain, proptosis, and globe indentation or displacement. Overall, the most common presenting symptoms are proptosis, globe displacement, and diplopia.

Orbital involvement is typically secondary to systemic disease, and patients often have systemic symptoms of metastatic disease at the time of diagnosis, including fever, weight loss, and anorexia (Esmaeli 2010; Perry and Singh 2013; Black and Smith 2012).

Diagnosis

In addition to clinical history and physical examination, imaging is essential in the workup and diagnosis of orbital sarcomas. Dedicated CT or MRI of the orbit is indicated to assess mass location and extension and may help distinguish mass lesions from infectious disease. Orbital involvement is usually secondary to systemic malignancy or metastatic disease, and appropriate workup with an oncologist is indicated and may include PET-CT. A variety of orbital mass lesions may have a similar clinical presentation, and biopsy is required for definitive histopathologic diagnosis. Immunohistochemistry and flow cytometry techniques aid in diagnosis through the use of specific tumor markers. Characteristic imaging and histopathologic findings for several types of sarcoma are discussed below.

Osteosarcoma is visualized on CT imaging as a mixed lytic and sclerotic mass with irregular margins and tissue invasion and destruction. Lesion density may vary depending on the relative proportion of osseous, cartilaginous, and fibrous elements. Calcified areas and areas of dense osteoid appear bright on CT, but areas of fibrovascular proliferation appear darker than bone. There is marked enhancement with CT contrast. MRI is preferred for evaluation of soft tissue and demonstrates a lesion that is hyperintense on T1 and hypointense on T2 relative to muscle. Surrounding tissue edema may make the tumor appear larger on STIR sequences. There is heterogenous enhancement of the lesion with gadolinium.

The defining characteristic of osteosarcoma on histopathology is the production of malignant osteoid. Osteosarcoma arises from mesenchymal bone-forming precursors, and histopathology demonstrates osteoblastic, chrondroblastic, and fibroblastic malignant cells. On sectioning, islands of osteoid are surrounded by sheets of atypical osteoblasts. Areas of necrosis, calcification, and vascular proliferation may be seen (Black and Smith 2012).

Ewing sarcoma appears as an irregular, extraosseous mass on CT imaging with mottling and destruction of adjacent bone. There is variable enhancement with iodinated contrast, and necrotic or hemorrhagic areas appear hypodense. MRI similarly demonstrates an extraosseous mass with adjacent bony destruction. On T1 sequences, Ewing sarcoma is hypointense to muscle, whereas, on T2 sequences, the lesion appears hyperintense to muscle. Fat-suppressed sequences may be useful as the lesion appears isointense to fat on T2-weighted MRI. There is heterogenous enhancement with gadolinium with areas of necrosis appearing darker (Esmaeli 2010). Immunohistochemistry is an essential tool for diagnosis and can be used to detect expression of the EWS or MIC2 genes in Ewing sarcoma.

CT imaging of alveolar sarcoma demonstrates a well-defined mass most frequently involving the superior orbit. These lesions are highly vascularized, and consequently they demonstrate avid enhancement. Necrotic areas within the center of the tumor may appear dark. On histopathology, alveolar sarcoma appears with many large, polygonal cells with large nuclei and prominent nucleoli (Perry and Singh 2013).

Leiomyosarcoma: On CT, leiomyosarcoma appears as a well-defined, heterogenous, multilobed mass. The lesion may demonstrate molding to the contours of the globe and destruction of adjacent bone. Histopathology demonstrates multinucleated giant cells within the tumor (Perry and Singh 2013).

Liposarcoma may appear like a cyst, containing fat surrounded by a dense pseudocapsule. MRI will demonstrate hyperintense signal on T1 consistent with a fat-containing lesion (Perry and Singh 2013).

Differential Diagnosis

See Table 1.

Sarcoma, Orbital, Table 1 Differential diagnosis of orbital sarcoma

Infectious	Bacterial orbital cellulitis Fungi (aspergillosis, mucormycosis) Mycobacteria (tuberculosis) Parasites (i.e., hydatid cyst)
Noninfectious/ inflammatory	Idiopathic orbital inflammation (orbital pseudotumor) Thyroid eye disease Sarcoidosis Granulomatosis and polyangiitis Churg-Strauss Scleritis
Neoplastic	Metastatic disease Rhabdomyosarcoma Lymphoma Leukemia Extension of intraocular tumors (retinoblastoma, ocular melanoma) or periocular tumors (nasopharyngeal cancers, etc.)
Vascular	Cavernous sinus thrombosis Carotid-cavernous fistula Lymphangioma Cavernous hemangioma
Other	Trauma Ruptured dermoid Hematoma Orbital foreign body

Adapted from Black and Smith (2012), p. 936

Prophylaxis

Given the high rate of orbital osteosarcoma following orbital radiation, especially in children undergoing radiotherapy for retinoblastoma, surveillance with appropriate imaging should be performed in these patients.

Therapy

Surgical excision and radiotherapy are the standard treatment (Karcioglu 2014). Combination chemotherapy had been demonstrated to be effective for orbital sarcomas. Owing to the rarity and varied histology of orbital sarcomas, it is difficult to study treatment regimens prospectively, and there is limited evidence to support a particular treatment regimen. Combination chemotherapy has been used successfully and has been shown to be effective for the treatment of orbital sarcomas. Treatment of specific tumor types is described below.

Ewing sarcoma: Ewing sarcoma involving the orbit is considered a manifestation of systemic disease and is treated with systemic multi-agent chemotherapy. Chemotherapy regimens include combinations of vincristine, doxorubicin, cyclophosphamide, and dactinomycin. Following neo-adjuvant chemotherapy, definitive treatment is either surgical excision or radiation followed by adjuvant chemotherapy. Following treatment, patients are followed closely for recurrences (Esmaeli 2010).

Alveolar soft part sarcoma: For alveolar sarcoma, surgical resection with wide margins is required and may include orbital exenteration for recurrent or aggressive disease. The role of chemotherapy and radiation is unknown (Perry and Singh 2013).

Osteosarcoma: Osteosarcoma is managed surgically with preoperative and postoperative chemotherapy. Multi-agent regimens are utilized and may include methotrexate, dacarbazine, cyclophosphamide, doxorubicin, or cisplatin. Radiation is also used as an adjunctive treatment and is especially useful for patients with residual tumor or unresectable tumors (Black and Smith 2012).

Leiomyosarcoma: Leiomyosarcoma is an aggressive tumor with 60% recurrence within 3 years after local resection. Most cases require extended orbital exenteration with wide margins, including adjacent bones. Treatment may include systemic chemotherapy and adjunctive local radiotherapy (Perry and Singh 2013, p. 144).

Liposarcoma: Well-differentiated tumors may be treated with local resection and adjuvant radiation. Metastases from orbital disease are uncommon (Perry and Singh 2013).

Prognosis

Treatment outcomes for orbital sarcoma vary depending on tumor type and extent at the time of diagnosis. The prognosis for localized orbital tumors is generally more favorable than for patients with disseminated disease.

Ewing sarcoma treated with multimodal therapy has a 5-year survival of approximately 65% for patients with localized disease. Metastases portend a poor prognosis, with only a 25% 5-year survival rate (Esmaeli 2010).

Alveolar soft part sarcoma limited to the orbit carries a relatively good prognosis, with 10-year survival approaching 85%. Disease involving the lower extremities carries a worse prognosis (Perry and Singh 2013).

Orbital osteosarcoma carries a poor prognosis with a 5-year survival of approximately 10% (Perry and Singh 2013; Black and Smith 2012).

Epidemiology

Sarcomas are very rare malignancies of the orbit. The most common orbital sarcomas in adults are malignant fibrous histiocytoma, hemangiopericytoma, fibrosarcoma, malignant peripheral nerve sheath, chondrosarcoma, and liposarcoma, each of which accounts for less than 1% of all orbital tumors (Karcioglu 2014). Typical age at presentation varies depending on tumor type. Osteosarcoma is the most common mesenchymal tumor of the orbit in children, whereas fibrous histiocytoma is the most common in adults.

Osteosarcomas have been associated with fibrous dysplasia, Paget's disease, and prior radiotherapy. Approximately 10% of patients with orbital osteosarcoma have a history of prior radiation to the orbit. Familial retinoblastoma is also associated with orbital osteosarcoma, and patients with germline mutations carry a 10% risk of developing osteosarcoma by age 25. Ewing sarcoma primarily affects young patients with 90% of cases occurring before age 30 (Esmaeli 2010; Perry and Singh 2013).

Sattler's Veil (Central Epithelial Edema)

Rasha Ali
Department of Ophthalmology, Wohl Eye Center, University of Minnesota, Bloomingdale, IL, USA

Synonyms

Central corneal clouding; Central epithelial edema

Definition

Sattler's veil is defined as acute, central, intracellular microcystic epithelial edema. This edema often results in minor ensuing blurry vision caused by contact lens wear.

Etiology

Sattler's veil occurs secondary to acute hypoxic effects on the central corneal epithelium and is usually associated with tight-fitting rigid gas permeable or hydrogel contact lens wear. Vision is decreased when light is diffracted in the swollen epithelium. The central cornea presents with a distinct frosted glass appearance and is separated from the peripheral cornea with a clear zone. However, a diffuse haze may occur across the entire epithelium if the hypoxia is caused by tight-fitting hydrogel lenses.

Occurrence

The occurrence of Sattler's veil has decreased with the advent of better fitting hydrogel contact lenses.

Classification

Iatrogenic self-limiting disease (reversible upon cessation of contact lens wear).

Confocal microscope

Definition

The confocal microscope is an imaging instrument, first described by Minsky in 1957, designed to improve optical resolution up to 1–2 μm laterally by focusing both the light source and observation system on the same single point, hence the term confocal. Since the field of view is quite limited with a point source of light, a scanning confocal microscope was developed to rapidly scan the focal point over a larger area and create a real-time image (Jalbert et al. 2003; Guthoff et al. 2009). In vivo scanning confocal microscopy is the use of a scanning confocal microscope to view tissues in a living subject at high resolution without the need for tissue resection (Jalbert et al. 2003).

Purpose

The scanning confocal microscope is used in basic science research when high magnification is needed to view samples, since it has improved resolution when compared with light microscopes. Initially, confocal microscopes were used solely for basic science research, but have been transitioned for clinical usage. Using the same principle of confocality, high-resolution cellular-level images of living tissues can also

be taken in a clinic setting. This is called in vivo scanning confocal microscopy (IV SCM). In the field of ophthalmology, in vivo scanning confocal microscopy allows for noninvasive images with microns of resolution of eye structures, such as the cornea, conjunctiva, and lid margin (Guthoff et al. 2006).

Principle

The basic configuration of a confocal microscope consists of a pinpoint light source that is focused onto a point on the specimen (Guthoff et al. 2009). The type and shape of the light source are different depending on the type of confocal microscope. The light reflected from the specimen is collected by a lens and passed on to a beam splitter. The deflected light then enters a photodetection device though a conjugate pinhole, suppressing light originating from outside the focal point. The photodetection device converts the light signal into an electrical signal, which can be read and interpreted by software into an image. There are three main types of scanning confocal microscopes which are described below: tandem scanning confocal microscopes, slit scanning confocal microscopes, and laser scanning confocal microscopes. Newer generations of confocal microscopes are basically changing the light source to a less intense and more coherent light source (white light vs. single nanometer wavelength light) in order to attain cleaner images. With each successive generation of confocal microscope, the axial (z axis) resolution improves making the images much clearer. The scanning confocal microscope can also be used for contact or noncontact microscopy (Jalbert et al. 2003).

Tandem Scanning Confocal Microscope

The tandem scanning confocal microscope (TSCM) uses a spinning Nipkow disk, which is a metal plate with pinholes arranged in a spiral. The pinholes allow for multiple point illuminations at a single time, and the rapid rotation of the disk provides quick scanning of the specimen (Guthoff et al. 2009). The TSCM provides real-time images with true color; however, the image quality is marginal as the reflected light is low in intensity. Because the reflected light is low in intensity, the TSCM requires a very bright illuminating source such as a xenon or mercury arc lamp. Two companies developed a clinical version of this microscope, which is no longer in production. The lateral resolution (x-y axis) has been reported as 0.5–1.0 μm, and the axial resolution (z axis) has been reported as 9–11 μm using the TSCM (Jalbert et al. 2003).

Slit Scanning Confocal Microscope

The slit scanning confocal microscope (SSCM) uses thin optical slits for rapid scanning of the specimen. This allows for increased light output compared to SSCM and increases the speed at which an object can be scanned, as all points along the axis of the slit are scanned at the same time. Also the reflected light in the SSCM has greater intensity than the reflected light in a TSCM, so it requires a weaker illuminating source such as a 12V halogen lamp. One disadvantage is that the SSCM is truly confocal in only one axis. Clinical SSCMs are commercially available. The lateral resolution (x-y axis) has been reported as 0.8–1.4 μm, and the axial resolution (z axis) has been reported as 8–25 μm using the SSCM (Jalbert et al. 2003; Guthoff et al. 2009).

Laser Scanning Confocal Microscope

The laser scanning confocal microscope (LSCM) uses the basic configuration of a confocal microscope with a specific wavelength laser as the light source. Two oscillating mirrors are placed in the path of the beam of light in order to scan the specimen. LSCM can be used to view the anterior segment of the eye in vivo by placing a high-quality lens between the eye and the device, creating a laser focus less than 1 μm in diameter. This resolution provides the highest quality image and highest speed investigation of all layers of the cornea. LSCMs are commercially available. The

LSCM uses a single-wavelength laser, such as a 670 nm red laser, as its illumination source. This single-wavelength, coherent light source is less noisy than the nonuniform white light used in TSCM and SSCM, allowing for improved resolution, especially in the z axis. The lateral resolution (x-y axis) has been reported as approximately 2.0 μm, and the axial resolution (z axis) has been reported as approximately 4 μm using LSCM (Guthoff et al. 2006).

Contact Versus Noncontact In Vivo Scanning Confocal Microscopy

Contact in vivo scanning confocal microscopy is most frequently used to view the five layers of the cornea: the corneal epithelium, Bowman's layer, corneal stroma, Descemet's membrane, and corneal endothelium. In contact IV SCM, the objective tips of the TSCM and SSCM are optically coupled to the patient's cornea using a viscous gel. The LSCM uses a lens cap that forms a planar contact surface with the cornea using a coupling gel during contact IV SCM. The lens cap is able to keep the distance from the cornea to the microscope stable. Noncontact IV SCM can be used to image the tear film as well as the keratinocytes and endothelium of the cornea. Dynamic processes, such as breakup of tear film, can be viewed with noncontact LSCM due to its rapid imaging capabilities. For noncontact IV SCM, dry objectives are used with all three types of IV SCMs, and the lens cap of the LSCM is removed (Guthoff et al. 2006).

Indication

The full potential of in vivo scanning confocal microscopy has yet to be reached, and at this time it is commonly used for diagnosing infectious keratitis and for counting corneal nerves. The high resolution allows for in vivo visualization of fungal hyphae in keratomycosis and double-walled cysts in acanthamoeba keratitis. IV SCM has also been helpful when diagnosing Lyme borreliosis and herpetic and Thygeson's keratitis. Research is currently being done to explore possible future indications of IV SCM. Clinicians have successfully used it to diagnose other corneal diseases such as neurotrophic and toxic keratoconjunctivitis and characterize corneal dystrophies such as epithelial basement membrane and Reis-Bücklers', Meesmann's, lattice, fleck, granular, Schnyder crystalline, posterior polymorphous, and Fuchs dystrophies. Research has been done using IV SCM to study corneal wound healing after refractive surgeries and penetrating keratoplasties and also to study the effects of contact lenses on the cornea (Guthoff et al. 2009). More recently, IV SCM has been used to study both benign and malignant epithelial lesions of the conjunctiva, showing a high sensitivity and specificity for diagnosing melanocytic tumors (Guthoff et al. 2006).

Contraindication

Because in vivo scanning confocal microscopy is not an invasive diagnostic technique, few contraindications exist. Contact in vivo scanning microscopy should not be performed on any patient with an open globe, as the pressure created by the contact can further damage an open-globe injury. Patients with corneal epithelial disease can obtain a corneal abrasion after contact IV SCM imaging. Topical anesthetics, fluorescein sodium, and other dyes are often used during in vivo confocal microscopy (Guthoff et al. 2006). Before using any of those products, the operator should check for possible contraindications such as drug hypersensitivities.

Advantage/Disadvantage

The scanning confocal microscope allows for noninvasive high-resolution real-time imaging of eye structures at the cellular level and is specifically useful for viewing the cornea. Advantages include the ability to diagnose vision-threatening diseases that cannot be differentiated by slit-lamp

biomicroscopy, such as acanthamoeba and fungal keratitis, and to clearly define borders of conjunctival tumors to make sure there are clear margins during excision.

While the small focal area of IV SCM creates high resolution and shows incredible detail, its small field of view causes several disadvantages. Minute involuntary eye movements due to pulse, respiration, and ocular microsaccades can cause blurring of the image. The confocal microscope image can also defocus in multiple planes – not only in the transverse axis (x and y axes) but also in depth (z axis) – making clean images difficult to attain depending on patient cooperation. This is especially true with non-contact IV SCM, as it is difficult to keep the distance from the cornea to the microscope constant when the objective is not coupled to the cornea. The small field of view also makes it incredibly difficult to return to the same area of the cornea multiple times for sequential analysis. For contact in vivo scanning confocal microscopy, the image quality degrades over time and can leave compression artifacts as the coupling gel on the eye runs thin (Guthoff et al. 2009). Functional imaging using fluorescence microscopy or immunohistochemistry with IV SCM is limited due to the limited availability of dyes that are safe to use in the living eye. Current studies are using fluorescein and rose bengal staining (Guthoff et al. 2006).

Scanning Electron Microscopy

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

A scanning electron microscope (SEM) uses an electron beam which scans the object to generate a magnified image of the object from the interactions of the electrons with the object surface.

Structure

The electron beam is generated by an electron source which is usually an electron gun with a heated tungsten filament that thermionically emits the electron beam. To prevent interactions of the electrons with air, the sample is placed in a high vacuum chamber. The images of the sample are shown on a cathode ray tube.

Function

The beam with energy of 0.5–40 keV is focused to a spot of 0.4–5.0 nm in size. It is deflected to scan the specimen in a raster fashion over a rectangular area of the specimen surface. The interaction of the electrons with the surface causes scattering of electrons and emission of electromagnetic radiation. These are detected and amplified and shown on the cathode ray tube where they form a rastered magnified image of the specimen.

The magnification of a scanning electron microscope ranges from about 10 times to 500,000 times. It is not a function of the power of the objective lens but of the ratio between the raster size on the object and the raster size on the display.

All samples to be imaged by SRE must be electrically conductive. Therefore, metallic samples require little preparation except cleaning and mounting in the microscope chamber. Nonconductive samples like plastic materials or biological specimens require ultrathin coating of the surface (sputtering) with a conductive material, usually gold.

Clinical Relevance

SEM has been used extensively to show the ultrastructure of tissues and organs in biology, anatomy, and pathology. It is also extremely useful in assessing the surface quality of surgical instruments or intraocular implants (Versura and Maltarello 1988).

Schirmer Tests

Jessica Selter
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Schirmer lacrimation test; Schirmer's tear test

Definition

The Schirmer test is the most commonly used procedure to evaluate tear production. The Schirmer test examines tear production through placing a filter paper under the eyelid and determining the length that tears reach on the paper in a certain period of time (Kaštelan et al. 2013). Therefore, the longer the distance that the tears are measured on the filter paper signifies a greater amount of tear production (Cho and Yap 1993).

Purpose

The purpose of the Schirmer test is to evaluate insufficient tear production in patients, and it is an indirect test for lacrimal gland dysfunction (Asbell and Lemp 2006). The results of the Schirmer test can be used to provide evidence for the diagnosis of dry eye disease or Sjogren's disease. The criteria vary, but a result of less than 5 mm on the strip is considered abnormal (Asbell and Lemp 2006).

Principle

There are multiple versions of the Schirmer test described below:

Schirmer I Test

– Blotting paper strip 5 × 35 mm is placed in the inferior cul-de-sac at the junction between the middle and lateral thirds of the lower eyelid. Both eyes are tested at the same time. (Savini et al. 2008)

– The strip is kept in place for 5 min, while the patient either gently closes their eyes or blinks normally.
– The strip is removed and the millimeters of wetness are assessed.

Variations of Schirmer I test can include using topical anesthetic, placing the strip in slightly different locations along the lower lid margin, or having the patients close their eyes, while the strip is in place. The Schirmer I test measures both basal and reflex tearing.

Schirmer II Test

– A similar method to the Schirmer I test is used. However, the eye is anesthetized beforehand and a cotton tip applicator is used to irritate the nasal mucosa. The Schirmer II test is often performed if the Schirmer I test is abnormal. The Schirmer II test measures only reflex tearing (Savini et al. 2008).

One-Minute Schirmer Test (Savini et al. 2008)

A 1-min version of the Schirmer I test has been proposed to minimize discomfort and save time. The 1-min Schirmer test with anesthesia has been shown to correlate with the 5-min Schirmer I test with anesthesia.

Phenol Red Thread Test

In this test, a fine thread with phenol red dye is used instead of filter paper and is inserted into the conjunctival sac for 15 s (Savini et al. 2008). The pH of tears will turn the thread red, and then the wetness of the tears can be measured.

Indication

The Schirmer test is used to diagnose insufficient tear production and is part of the diagnostic workup of dry eye disease. Dry eye could be due to a variety of factors including age, climate changes, infections, prior eyelid surgery, Sjogren's syndrome, vitamin-A deficiency, etc. The Schirmer test can also be used to evaluate tolerance for contact lens use (Cho and Yap 1993).

Contraindication

There are no noted contraindications for the Schirmer tests.

Advantage/Disadvantage

Advantages (Cho and Yap 1993):

– Widely used
– Commercially available
– Easy to perform

Disadvantages (Cho and Yap 1993):

– Large discrepancies in repeatability of the Schirmer test.
  (a) Changes in light, temperature, and patient anxiety can change reflex tearing rates and modify results.
– Ocular discomfort from the filter paper.
– Potential injury to the cornea if the paper shifts out of place.
– The mean Schirmer test results in normal subjects can vary widely.

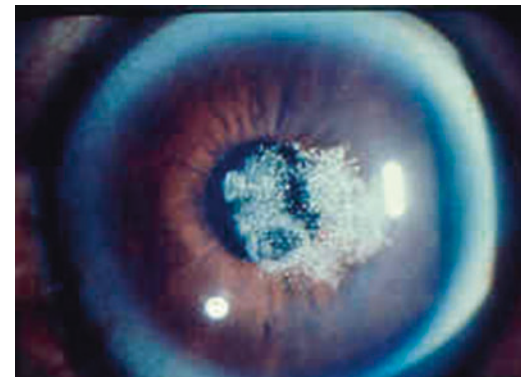
Definition

Schnyder corneal dystrophy is a progressive disease characterized by central corneal haze and crystals with lipid and cholesterol deposits in Bowman's layer and the anterior stroma (Figs. 1 and 2).

Etiology

Inheritance is autosomal dominant and there is an association with hypercholesterolemia and



Schnyder Crystalline Dystrophy Syndrome, Fig. 1 Central subepithelial crystalline deposition

Schnyder Crystalline Dystrophy Syndrome, Fig. 2 Advanced disease with crystalline deposits and arcus lipoides

genu valgum. The corneal deposits are possibly caused by a defect in cholesterol metabolism linked to a genetic mutation on chromosome 1 (Krachmer et al. 2011).

Clinical Presentation

Patients present in the second or third decade of life with central disciform corneal haze and polychromatic crystal deposits in Bowman's layer and the anterior stroma. Over the next decades, the haze becomes denser, the number of deposits increases, and presenile arcus lipoides develops. Eventually the entire cornea is hazy. Patients complain of glare and progressive vision deterioration. Decreased corneal sensation is found on examination (Weiss et al. 2008).

Diagnostics

Fasting blood level of cholesterol and lipoprotein electrophoresis can add in diagnosing hyperlipidemia. On histology, special stains such as oil red O and Sudan black highlight abnormal phospholipid and cholesterol deposits in the stroma, Bowman's layer, and basal epithelial cell layer. The crystals are birefringent. Sometimes the epithelial basement membrane is absent, and there is complete destruction of Bowman's layer from glycogen deposits. The stroma may reveal round empty spaces, signifying former fat deposits. Confocal microscopy demonstrates highly reflective intracellular and extracellular deposits (Weiss et al. 2008).

Differential Diagnosis

Differential diagnosis includes herpes simplex, acanthamoeba, Bietti's crystalline dystrophy, cystinosis, mucopolysaccharidoses, systemic disease with immunoglobulin deposition (lymphoma, benign monoclonal gammopathy, multiple myeloma, etc.), and haze from photorefractive keratectomy.

Prophylaxis

No prophylaxis is known.

Therapy

As the vision continues to decrease, superficial or phototherapeutic keratectomy may provide some benefit. However, keratoplasty, either lamellar or penetrating, is the treatment of choice when the vision has deteriorated significantly. The crystals frequently recur in the graft (Krachmer et al. 2011).

Prognosis

Progression is slow but most patients over 50 years old require keratoplasty for visual rehabilitation (Weiss et al. 2008).

Epidemiology

The disease is rare with the prevalence unknown.

Scleral Fixation of Intraocular Lens

Thomas Kohnen and Melanie Bödemann
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Transscleral fixation

Definition

Surgical technique for fixation of posterior chamber intraocular lenses (IOL) when capsular support is not effective. In contradiction to the surgical technique of iris fixation of posterior chamber lenses, scleral fixation is independent from the need of adequate iris tissue. Scleral fixation includes several different techniques as there are one-point, two-point, three-point, and four-point fixation. Some techniques for transscleral fixation include ab interno methods, in which the suture is passed from the inside of the eye to the external surface, and ab externo methods, in which the suture is initially passed from the external surface.

History

In 1986, two-site scleral fixation was first described by Malbran et al. Subsequently, in the following years, other techniques like one-site, three-site, and four-site fixation have been developed. Until today, there is a permanent employment and improvement of scleral fixation, for example, techniques with or without scleral flaps or techniques using suture retrieval through a scleral tunnel or sutureless intrascleral fixation of intraocular lenses which was first described by Maggi et al. in 1997. Sutureless scleral fixation was developed because disadvantages of suture scleral fixation were late exposure and breakage of sutures especially in patients with skin sclera or contraction following the use of diathermy.

Clinical Features

Generally posterior chamber intraocular lenses are implanted in the capsular bag of the crystalline lens. The capsular bag assures stability and adequate centration of the intraocular lens. In many cases, e.g., complicated cataract surgery, traumatic aphakia, or infantile eye deformities, the capsular of the crystalline lens can be damaged or absent. In these cases, other possibilities of

posterior chamber intraocular lens fixation are required such as scleral or iris fixation.

Tests

Postoperative checks for testing adequate intraocular position of the secondary intraocular lens should include best-uncorrected and best spectacle-corrected visual acuity, detailed slit-lamp examination in narrow and dilated pupil, and Scheimpflug imaging. Scleral suture should be controlled while slit-lamp examination.

Etiology

See "History" section above.

Treatment

As described in the history section, there exist many surgical techniques for secondary posterior chamber lens implantation by scleral fixation. In recent years, posterior chamber IOL implantation by means of intrascleral fixation without sutures has become more popular. The different surgical techniques are configured for different types of intraocular lenses and disbursed for different anatomical conditions. There exists, for example, a sutureless technique for sulcus fixation of a posterior chamber IOL using permanent incarceration of the haptics in a scleral tunnel parallel to the limbus which combines the control of a closed-eye system with the postoperative axial stability of the posterior chamber IOL. Other techniques are useful for situations in which adequate capsule and lens remain to support the second haptic. For more information please use current literature.

Synonyms

Sutureless scleral fixation

Definition

Surgical technique that is commonly used for sutureless fixation of posterior chamber intraocular lenses (IOLs) when capsular support is not effective. Scleral fixation can be performed under the protection of scleral flap. Techniques for transscleral fixation include ab interno methods, in which the suture is passed from inside of the eye to the external surface, and ab externo methods, in which the suture is initially passed from the external surface. Common to all the techniques is the necessity to bury, cover, or rotate the knot created for fixation so conjunctival erosion and endophthalmitis are less likely to develop. A variation of scleral flap technique is a nonperforating scleral tunnel which covers the knot created for scleral fixation.

Epidemiology

A scleral tunnel with hook retrieval of the suture ends can be used in any procedure requiring transscleral fixation including implantation of secondary IOL repair of dislocated IOLs, employment of adjunctive surgical devices such as Ahmed capsular tension segments and Cionni capsular tension rings, and repair of iridodialysis.

History

In 2006 Hoffmann et al. described the surgical technique of creating a scleral tunnel as a variation of posterior chamber intraocular lens fixation through transscleral fixation.

Clinical Features

Options for secondary intraocular lens implantation in an eye without capsular support include iris fixation and transscleral fixation through the ciliary sulcus or pars plana. Methods for scleral fixation of posterior chamber intraocular lenses are transscleral fixation or sutureless fixation through a scleral tunnel. The advantage of scleral tunnel fixation is that the construction of a scleral tunnel is easier than that of a triangular flap. Furthermore it affords a greater surface area for suture placement through ab externo or ab interno approach. The avoidance of rotation and cover of knots reduce the risk of complications such as conjunctival erosion or endophthalmitis.

Tests

Postoperative examinations for testing adequate intraocular position of the secondary intraocular lens should include best-uncorrected and best spectacle-corrected visual acuity, detailed slit-lamp examination in both narrow and dilated pupil, and Scheimpflug imaging.

Differential Diagnosis

Transscleral lens fixation.

Etiology

There are no datas available in this topic.

Treatment

In this technique a double-armed suture is passed through the roof of the scleral tunnel into the eye using an ab externo or ab interno approach. Retrieval of the suture ends through the external incision, and subsequently tying the knot allows the suture knot to pass under the roof of the tunnel, without the need for suture knot rotation.

Scleritis

Kathleen Jee
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

Scleritis is inflammation of the sclera that is generally immune mediated but can infrequently be of infectious etiology. There is an association with systemic autoimmune diseases, notably rheumatoid arthritis (RA) and Wegener granulomatosis (WG). Immune-mediated scleritis is classified as anterior or posterior, with respect to the insertion of the extraocular rectus muscles. Anterior scleritis can be further subdivided into diffuse (the most common form), nodular, necrotizing, and necrotizing without inflammation (sclero-malacia perforans).

Etiology

It is believed that an underlying disordered immune response results in tissue and blood vessel damage characteristic of scleritis. Damage is mediated by immune complex deposition within the episcleral and scleral perforating capillary and postcapillary venules and a subsequent chronic granulomatous response. Inflammatory cells (macrophages, T cells, and B cells) and mediators (tumor necrosis factor-α, interleukin-1, interleukin-2, interleukin-3, interleukin-6, interferon-γ, and matrix metalloproteinases) are elevated in the sclera and overlying conjunctiva in patients with scleritis. Previous viral infection or self-antigens to connective tissue within the sclera can also instigate an autoimmune response (Krachmer et al. 2011).

Immune-mediated scleritis is most commonly caused by systemic autoimmune diseases (i.e., connective tissue disease, vasculitis), which about half of patients with scleritis have prior to presentation. The most commonly associated diseases in descending order are RA, WG, and relapsing polychondritis (Krachmer et al. 2011). The more severe necrotizing forms of anterior scleritis have a particularly high association with systemic disease. It is important to realize that scleritis may be the first sign of an underlying vasculitis or connective tissue disease.

Infectious scleritis is rare (4–18% of cases in a tertiary-care setting). Exogenous infections are the most common and can be posttraumatic and postsurgical or spread from surrounding ocular infection (i.e., keratitis, choroiditis, endophthalmitis). Endogenous infections are associated with systemic infections and can often present like immune-mediated scleritis. Tuberculosis, syphilis, leprosy, and Lyme disease are included in this category.

Clinical Presentation

Patients with scleritis present with pain worse with eye movement that characteristically radiates to the forehead, eyebrow, or jaw and may awaken the patient at night. The pain can be exquisitely tender. Other symptoms include tearing, photophobia, and blurry vision. The most common sign of scleritis is a violet-blue scleral hue with edema. In about half of patients, the presentation is bilateral. Non-ocular signs in conjunction with systemic disease may be present as well. Each form of scleritis has typical manifestations.

Anterior Scleritis

- Diffuse – In the most common and least severe form of scleritis, onset is gradual, starting with ocular redness and progressing to pain over a

couple of days, including the face and temple. The sclera may be salmon, violet, or blue underneath inflamed episclera. Vascular congestion and dilatation with edema is present. As the inflammation resolves, the sclera appears translucent or gray-blue as a result of rearrangement of scleral fibers.

- Nodular – Patients present with gradual ocular pain, increasing redness and tenderness, and the development of one or more scleral nodules. The nodules are yellow-red, firm, tender, immobile, and frequently found in the interpalpebral zone adjacent to the limbus. The sclera becomes more translucent with resolution.
- Necrotizing – The most aggressive and visually compromising form presents with gradual onset of severe pain radiating to the temple, brow, or jaw that may awaken the patient from sleep. On examination, necrosis appears as a dark area surrounded by active inflammation. White, avascular areas of the sclera develop with adjacent swelling and congestion. As the sclera thins, uveal tissue can be seen underneath the conjunctiva.
- Necrotizing without inflammation – This form is typically seen in older women with RA. Patients are often asymptomatic but may have non-specific irritation. There are avascular necrotic scleral plaques adjacent to the limbus with thinning of the sclera and episclera and uveal exposure.

Posterior Scleritis

Patients present with decreased vision, diplopia, and pain. Signs include chemosis, proptosis, periorbital edema, and ophthalmoplegia. Posterior segment findings include choroidal folds, uveal effusion, exudative retinal detachment, subretinal mass, and disk edema. There can be concomitant anterior scleritis.

Infectious Scleritis

The presentation can be similar to immune-mediated scleritis. Patients may complain of pain and irritation. Clinical signs include conjunctival or episcleral hyperemia, mucopurulent discharge, scleral necrosis, subconjunctival nodule, subconjunctival abscess, subconjunctival hemorrhage, uveitis, uveal prolapse, scleral perforation, and conjunctival ulceration. Infection spreading from the peripheral cornea may manifest as limbal erythema, edema, and infiltrate.

Diagnosis

A proper scleral examination is essential for diagnosis. On slit-lamp examination, congestion can be seen most prominently in the deep scleral vessels, which cannot be moved with a cotton-tipped applicator. Edema of the sclera can also be visualized. Red-free light enhances the blood vessels, particularly areas of nonperfusion. Topical administration of a sympathomimetic dilating drop (2.5–10% phenylephrine) blanches the superficial but not the deep vessels.

If suspicious for a systemic disorder, laboratory tests should be ordered. Non-specific markers of inflammation include increased erythrocyte sedimentation rate or C-reactive protein, anemia, leukocytosis, decreased complement, and circulating immune complexes. Screening for autoimmune disease includes antinuclear antibodies, rheumatoid factor, anti-DNA antibodies, anti-neutrophil cytoplasmic antibodies, anti-phospholipid antibodies, and HLA-B27.

Imaging can further assist with the diagnosis. Chest X-ray is useful in diagnosing WG, sarcoidosis, and Churg-Strauss syndrome. Joint X-rays can demonstrate arthritis. Fluorescein angiography (FA) detects areas of vascular nonperfusion seen in necrotizing scleritis. Additionally, patients with WG can have neovascularization, transudation, and localized vasculitis on FA. In posterior scleritis, B-scan ultrasound is used to assess for scleral thickening, scleral nodules, sub-Tenon fluid, disk edema, choroidal folds, or retinal detachment. MRI and CT can show scleral thickening and proptosis. Scleral biopsy is not typically performed but can determine if there is systemic inflammation, vasculitis, or infection.

Infectious scleritis is often diagnosed by culturing infected tissues, typically from the cornea or vitreous. Blood cultures and serologies can also be drawn.

Differential Diagnosis

Episcleritis is benign inflammation of the more superficial episclera that causes mild discomfort and has a red-colored appearance. In contrast, scleritis presents with more severe, radiating pain, and globe tenderness, with a deeper violet-blue hue. Topical administration of phenylephrine blanches the superficial blood vessels affected in episcleritis but not the deeper vessels inflamed in scleritis.

The differential for posterior scleritis includes thyroid eye disease, orbital inflammatory disease, orbital cellulitis, orbital tumors, choroidal tumors, and central serous retinopathy.

Therapy

Immune-Mediated Scleritis

- Oral nonsteroidal anti-inflammatory drugs (NSAIDs): This is the first-line treatment for non-necrotizing scleritis to reduce inflammation and pain. One NSAID at a time should be tried and switched if not effective for the individual patient. Months or years of therapy may be required. Topical forms are usually not efficacious.
- Systemic corticosteroids: Corticosteroids are indicated for necrotizing scleritis and severe non-necrotizing scleritis unresponsive to oral NSAIDs. Prednisone is dosed starting at 1 mg/kg/day and tapered based on clinical response. Topical steroids are not commonly used.
- Immunosuppressive agents: This therapy is used when the disease is uncontrolled with corticosteroids or NSAIDs or as a steroid-sparing alternative for those requiring long-term therapy. Patients with RA can be treated with methotrexate (up to 20–25 mg/week). Patients with WG are given cyclophosphamide starting at 2.5 mg/kg/day. Other agents include azathioprine (starting dose of 2.5 mg/kg/day), mycophenolate mofetil (2–3 g/day), and cyclosporine (2.5–5.0 mg/kg/day).
- Biologic agents: Use of biologic agents may be considered in cases refractory to other treatments. Infliximab (5 mg/kg infusions every 2–8 weeks) and rituximab are promising new drugs.
- Periocular steroid injections: These are used for non-necrotizing and necrotizing.
- Surgery: Emergent repair of scleral perforation or scleral thinning at risk of rupture is required in necrotizing scleritis and scleromalacia perforans. Tectonic scleral and peripheral corneal patch grafting can be performed. Newer techniques include conjunctiva-Müller muscle pedicle flap and tarsoconjunctival pedicle flap (Krachmer et al. 2011).

Infectious Scleritis

- Appropriate antimicrobial therapy against the causative organism
- Topical or systemic steroids to reduce inflammation
- Removal of foreign bodies or associated materials contributing to the infection
- Surgical debridement of infected tissue can ameliorate antibiotic response, if indicated

Prognosis

Almost 60% of patients with scleritis develop an ocular complication, most commonly late in their course. Vision loss occurs in 16–37% of patients. Vision-threatening sequelae include keratitis, uveitis, and glaucoma. Keratitis presents in 14–37% of patients, with peripheral ulcerative keratitis being the most severe form. Uveitis manifests in over one-third of patients. Glaucoma occurs in about 13% of patients (Krachmer et al. 2011).

Overall prognosis is dependent on the severity or form of the scleritis. In the diffuse form, duration is an average of 6 years, with recurrences less frequent after the first 18 months and an overall good visual prognosis. Nodular scleritis has a comparable duration as the diffuse form. More than 10% of patients develop the necrotizing form, but this can be mitigated with early treatment. Necrotizing scleritis has the worst visual prognosis; up to 82% of patients have been found to lose vision (Krachmer et al. 2011). Inflammation may progress to affect the anterior globe and peripheral cornea if not treated. In the necrotizing form without inflammation, vision loss is not common, although areas of scleral thinning often do not heal. Posterior

scleritis is rare but severe and can lead to rapid blindness. In infectious scleritis, the prognosis is worse with bacterial keratoscleritis.

Prognosis of scleritis with systemic disease depends on the disease itself. Necrotizing scleritis in WG is severe and may cause permanent visual loss. In RA or relapsing polychondritis, severity is intermediate. In spondyloarthropathies or systemic lupus erythematosus, prognosis is good and self-limiting.

Epidemiology

Scleritis most commonly occurs in the fourth to sixth decades. In immune-mediated scleritis, women are more affected than men. There is no known racial predominance. There is a 25–50% chance that patients with scleritis have a systemic disease causing their condition. In terms of systemic disease, 14% of patients with relapsing polychondritis, 10% of those with WG or inflammatory bowel disease, and 6% of those with polyarteritis nodosa or RA develop scleritis (Krachmer et al. 2011).

Sclerocornea

Jessica Selter
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Severe anterior segment dysgenesis

Definition

Sclerocornea is a rare congenital malformation disorder characterized by bilateral, asymmetric scleral tissue extending anteriorly to the cornea (Gerstenblith et al. 2012). It can occur as a primary anomaly but can also be associated with other ocular defects (Elliott et al. 1985). Scleralization can occur in the peripheral cornea or can take over the entire cornea (Elliott et al. 1985). If the peripheral cornea is affected, it is vascularized with arcades of superficial scleral vessels (Elliott et al. 1985). In total sclerocornea, the entire cornea can become opaque and vascularized (Elliott et al. 1985).

The disease is nonprogressive and non-inflammatory (Harissi-Dagher and Colby 2008).

Etiology

Sclerocornea is due to a congenital abnormality of the anterior segment of the eye and is extremely rare (Elliott et al. 1985). It is thought that half of the cases of the disease are due to a sporadic mutation and half are inherited (Harissi-Dagher and Colby 2008). Of the cases that are inherited, the autosomal dominant forms of the disease are milder than the autosomal recessive forms (Harissi-Dagher and Colby 2008). In sclerocornea, there is a disruption in neural crest migration during embryogenesis and corneal development which leads to this anterior segment dysgenesis (Elliott et al. 1985). It is thought that the mesenchymal tissue that normally forms the cornea stroma does not form clear cornea but rather forms tissue that resembles the sclera instead (Garg et al. 2011).

Clinical Presentation

Patients with sclerocornea disease will present at birth. The degree of vision loss is dependent on the amount of scleralization of the cornea (Harissi-Dagher and Colby 2008). If the scleralization is only peripheral and has a relatively flat center, vision can be relatively normal (Harissi-Dagher and Colby 2008). If the scleralization extends to more areas of the cornea, it can prevent development of normal vision, and measures should be taken soon after birth to prevent irreversible deprivation amblyopia (Harissi-Dagher and Colby 2008).

Diagnosis

Sclerocornea is suspected when corneal opacity is detected at birth and the opacity is not associated with interstitial keratitis, ulceration, or an inflammatory disease of the cornea (Harissi-Dagher and Colby 2008). Other causes of congenital corneal opacity must be eliminated in order to diagnose sclerocornea (Harissi-Dagher and Colby 2008). Ultrasound biomicroscopy can also be used to help with diagnosis (Garg et al. 2011). Histologically, patients with sclerocornea have thickened collagen fibers in the superficial stroma of the cornea compared to the posterior stroma, which is a pattern that is normally seen in the sclera (Garg et al. 2011).

Differential Diagnosis

The differential diagnosis includes:

- Congenital glaucoma
- Peters anomaly
- Congenital hereditary endothelial dystrophy

Prophylaxis

None indicated for sclerocornea disease.

Therapy

Treatment of sclerocornea is often complex and depends on the severity of the disease (Binenbaum et al. 2008). Patients have to be monitored and treated for amblyopia, glaucoma, and other ocular abnormalities that may arise (Binenbaum et al. 2008). Keratoplasty is often considered if there is central opacification, but allografts have been shown to have a high rate of rejection (Binenbaum et al. 2008).

Prognosis

If the disease is limited to the periphery, vision may not be severely affected (Harissi-Dagher and Colby 2008). Keratoplasty is often indicated in more severe disease, and the rate of surgical success has increased in the past few decades (Harissi-Dagher and Colby 2008). However, the success rate for the procedure is still lower than that with other congenital corneal abnormalities (Harissi-Dagher and Colby 2008). Even after surgery, there is a risk for development of other

ocular abnormalities such as coloboma, glaucoma, and shallow anterior chambers that could lead to reduced vision (Harissi-Dagher and Colby 2008).

Epidemiology

Sclerocornea is usually bilateral and affects males and females with equal incidence (Garg et al. 2011).

Scleritis with keratitis

Definition

Scleritis is inflammation of the sclera and may occur with or without keratitis (inflammation of the cornea).

Disease

Sclerokeratitis is inflammation of the sclera with associated corneal inflammation. Patients with sclerokeratitis present with ocular redness, pain, and decreased vision. Any portion of the sclera may be inflamed. Keratitis, which can occur in association with scleritis, typically presents with peripheral corneal infiltrates, corneal thinning, and neovascularization.

Scleritis can be classified as anterior/posterior, diffuse, nodular, or necrotizing. Anterior scleritis is the most common presentation, accounting for 80–85% of all scleritis cases (Larson and Sen 2012). Diffuse anterior scleritis is the most common form of scleritis overall, occurring in approximately 60% of patients. Nodular scleritis is the second most common form and accounts for approximately 20% of cases. Patients with nodular scleritis typically exhibit a tender, firm, and immobile focal thickening of the sclera, often near the limbus (Galor and Thorne 2007). Necrotizing scleritis is the most severe and destructive form of scleritis and is most often associated with sight-threatening sequelae (Okhravi et al. 2005; Galor and Thorne 2007). Necrotizing scleritis usually occurs in older patients and is more likely to be associated with an underlying systemic disease (50–80%), especially rheumatoid arthritis and granulomatosis with polyangiitis. Patients with necrotizing scleritis typically present with features of anterior scleritis and areas of white sclera, which results from capillary closure of the episcleral vessels leading to necrosis of the underlying sclera. Corneal melting is uncommon but more likely to occur in the presence of anterior or necrotizing scleritis (Jabs et al. 2000; Galor and Thorne 2007). Scleromalacia perforans is a rare and severe form of necrotizing scleritis that tends to be bilateral and is unique in that patients do not present with pain, redness, or edema (Okhravi

et al. 2005; Galor and Thorne 2007; Larson and Sen 2012). There is often loss of the episclera and episcleral vasculature with localized areas of infarcted tissue, which may lead to thinning so severe that the underlying choroid is exposed. Classically, scleromalacia perforans develops in elderly women with a history of long-standing rheumatoid arthritis. It is unusual for a case of scleritis to evolve from one type to another (Galor and Thorne 2007).

Sclerokeratitis can occur in any age group but usually occurs between the ages of 30 and 50. Women are affected approximately twice as often as men. No geographic or racial predilections have been identified. The prevalence of scleritis is estimated to be six cases per 100,000 persons among the general population but may be as high as 0.2–6.3% and 7% among rheumatoid arthritis and granulomatosis with polyangiitis patients, respectively, making these the most commonly associated noninfectious systemic diseases in the setting of scleritis (Galor and Thorne 2007). Additional noninfectious systemic disease associations include connective tissue disease (juvenile rheumatoid arthritis, reactive arthritis, systemic lupus erythematosus, relapsing polychondritis, polymyositis, inflammatory bowel disease, and spondyloarthropathy), vasculitides (polyarteritis nodosa, allergic angiitis of Churg-Strauss, Cogan syndrome, Takayasu disease, Behcet disease, giant cell arteritis, and sarcoidosis), neoplastic processes such as lymphoma and metastases and gout (Okhravi et al. 2005; Larson and Sen 2012).

Infectious sclerokeratitis can be caused by viral, parasitic, fungal, and bacterial etiologies. Infections are more likely to occur in tissue compromised by disease, surgery, or trauma. Patients with a history of pterygium surgery, topical antimetabolite therapy, and retinal detachment repair may be at increased risk for developing infectious sclerokeratitis. Overall, the two most common causes of infectious sclerokeratitis are herpes zoster and syphilis. Other reported viral causes include Epstein-Barr and Coxsackie B5. Reported bacterial causes include tuberculosis, *Pseudomonas*, *Staphylococcus*, *Streptococcus*, *Mycobacterium*, *Haemophilus*, *Borrelia*, *Corynebacterium*, *Serratia*, *Nocardia*, leprosy, and *Listeria monocytogenes*. Fungal causes of scleritis include *Aspergillus*, *Scedosporium prolificans*, and *Sporothrix schenckii*. Acanthamoeba in association with keratitis and toxoplasmosis have also been reported as amoebic and parasitic etiologies, respectively (Okhravi et al. 2005).

Surgically induced necrotizing sclerokeratitis (SINS) occurs most commonly after cataract surgery when a corneal limbal incision is used. Interestingly, 75% of patients who develop SINS have undergone two or more surgical procedures prior to disease onset, and most who undergo systemic work-up are later diagnosed with systemic autoimmune disease. Patients tend to present anywhere from 2 weeks to 9 months postoperatively. Surgically induced diffuse scleritis has been reported, but is less well recognized (Okhravi et al. 2005).

Basic Science (Section Omitted: Combined with Pathology Section)

Pharmacotherapy

The therapeutic approach to sclerokeratitis varies based on the underlying etiology. Treatment with appropriate antimicrobials should be initiated immediately if there is suspicion for an infectious etiology. Most cases involve modulation of the inflammatory process to relieve symptoms and minimize further ocular injury. Sclerokeratitis associated with systemic disease generally requires more aggressive immunosuppressive therapy, as does the presence of posterior or necrotizing scleritis. Non-necrotizing scleritis may respond to systemic nonsteroidal anti-inflammatory drugs (NSAIDs), which include nonselective cyclooxygenase inhibitors (e.g., flurbiprofen and indomethacin). The most prominent side effects of these medications are gastrointestinal irritation and bleeding. Corticosteroids are typically used for patients with severe disease and those that have failed to respond to NSAIDs. Systemic corticosteroids can be administered orally or intravenously at high doses acutely to rapidly induce disease remission if an infectious etiology is not suspected. Oral prednisone is often

started at 1 mg/kg/day (maximum dose of 60 mg/day) and may be tapered based on clinical response. Intravenous methylprednisolone is useful when rapid control of inflammation is necessary, particularly in the setting of impending sclerocorneal perforation. Alternatively, local corticosteroid therapy, either with subconjunctival injections or topical difluprednate ophthalmic emulsion 0.05%, is occasionally used for cases of non-necrotizing anterior scleritis, particularly when patients are unable to tolerate systemic therapy. Although rare, cases of scleral melt after subconjunctival steroid injections have been reported (Jabs 2012). Other potential side effects of corticosteroid therapy are wide ranging and dependent on route of administration, dosage, and duration. Immunosuppressive therapy is typically considered for severe or recurrent ocular disease, particularly when chronic corticosteroid therapy in excess of 7.5–10 mg/day of prednisone is required for control of inflammation. Immunosuppressive therapy is particularly appropriate in patients with sclerokeratitis and an underlying systemic disease associated with increased mortality (Okhravi et al. 2005; Larson and Sen 2012).

Non-pharmacotherapy

Surgical intervention for sclerokeratitis may be necessary in clinical situations that require biopsy of the episclera, superficial sclera, and/or cornea to exclude potential infectious and neoplastic etiologies. Elective or emergent tectonic repair may also be indicated to prevent or treat globe perforation. Corneal perforations are more common than full-thickness scleral defects and may require emergent repair with lamellar or penetrating keratoplasty. In some instances, small corneal perforations may be glued and/or covered with a contact lens as temporizing measure while the inflammatory process is treated, or a more definitive surgical intervention is planned. Ultimately, control of the inflammatory process is essential for graft survival. Donor sclera is more robust than donor corneal tissue, and several other tissues may be used for scleral tectonic grafts, including fascia lata, pericardium, and dura. Cataracts and glaucoma may develop as a result of sclerokeratitis and/or corticosteroid therapy, but elective surgical interventions should ideally be delayed until disease quiescence is established. Trabeculectomy may be especially challenging as a result of scleral thinning, thereby necessitating tube-shunt placement (Okhravi et al. 2005).

Diagnostic Procedures

Patients with sclerokeratitis may present in the absence of any known associated systemic disease. The physician may elect to pursue a medical work-up, based on the patient's past medical history and review of systems. A targeted and cost-efficient approach to testing should be emphasized. Work-up may include testing for granulomatosis with polyangiitis, which generally consists of a chest x-ray or chest CT, cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA), and urinalysis with microscopy. Likewise, perinuclear antineutrophil cytoplasmic antibody (p-ANCA) may be ordered to assess for the possibility of polyarteritis nodosa and other vasculitides. Testing for rheumatoid arthritis (rheumatoid factor, anti-citrullinated cyclic protein) and systemic lupus erythematosus (antinuclear antibody, anti-dsDNA) may be ordered when clinically indicated. HLA-B27 testing and further work-up may be indicated for patients with findings or symptoms concerning for seronegative spondyloarthropathies or inflammatory bowel disease.

Serologic testing for syphilis includes treponemal-specific (fluorescent treponemal antibody absorption [FTA-Abs]) and nonspecific (rapid plasma regain [RPR] or venereal disease research laboratory [VDRL]) tests. When risk factors are present, evaluation for tuberculosis can be done with a purified protein derivative (PPD) skin test or interferon gamma release assay (QuantiFERON-TB Gold). Serologies for viral hepatitis and Lyme disease may be indicated. Orbital CT imaging may be considered in atypical cases. Cultures and/or corneoscleral biopsy may be necessary in cases of suspected infectious sclerokeratitis (Okhravi et al. 2005; Galor and Thorne 2007; Larson and Sen 2012).

Signs and Symptoms

Scleral inflammation may be unilateral or bilateral and typically produces prominent pain and redness, which may occur focally or diffusely. Vascular engorgement of the deep episcleral plexus produces a characteristic violaceous hue in sclerokeratitis, which is in contrast to the red hue produced by dilation of conjunctival vessels and superficial episcleral plexus that occurs in episcleritis. Examination performed in natural lighting can be very useful in making this discrimination, as these hue distinctions may be difficult to appreciate on slit lamp examination. Conjunctival and superficial episcleral vessels blanch with 2.5–10% phenylephrine and are mobile with a cotton-tipped applicator, while deeper vessels generally do not blanch and are not mobile. This is in contrast to the findings of episcleritis, in which the affected vessels are more superficial and, as a result, are noted to be freely mobile and responsive to topical phenylephrine (Okhravi et al. 2005; Larson and Sen 2012).

Interstitial keratitis, defined as stromal inflammation with an intact epithelium, may develop (Akpek et al. 2004). In these cases, examination may reveal stromal haze with or without the presence of active peripheral corneal neovascularization and associated intrastromal lipoprotein exudates. Peripheral ulcerative keratitis may also occur, with epithelial breakdown, corneal inflammation, and loss of stromal tissue. Rearrangement of scleral collagen fibers following diffuse anterior scleritis may result in the sclera taking on a blue-gray hue, which does not represent thinning. Alternatively, necrotizing scleritis can result in scleral thinning and translucency, which allows the underlying uveal tissue to be seen (Galor and Thorne 2007).

The characteristic symptom of sclerokeratitis is severe, "boring" pain in the eye and/or orbit, which may radiate to involve regions of the face. Patients with sclerokeratitis typically notice redness and tenderness of the globe and may experience associated tearing and photophobia. Sclerokeratitis generally has a subacute onset, worsening over the course of days to weeks. Pain is often exacerbated with eye movement, can limit the ability to perform normal daily activities, and may even awaken patients from sleep (Okhravi et al. 2005).

Major Studies and Classifications

In 2004, Akpek and colleagues reported a series of 243 patients with scleritis. Of these patients, 37% had an associated rheumatic disease, and an additional 7% had an underlying infectious cause. The most frequent infection was herpes zoster and the most frequent rheumatic disease was rheumatoid arthritis. Of the 107 patients with an underlying disease, 77.6% had a previously diagnosed disease, 14% were diagnosed as a result of their initial work-up, and 8.4% developed a systemic disease during follow-up. Keratitis was present in 18.2% of patients.

Pathology

Most eyes with sclerokeratitis are not biopsied or enucleated, and studies on the pathogenesis of scleritis are limited. Available data suggests that T cells play an important role in the inflammatory process. Evidence of vasculitis with fibrinoid necrosis and neutrophil invasion of the vessel wall, as well as antibody deposition, has been described. Plasma cells may also be involved through the production of metalloproteinases and TNF-alpha. However, additional studies displayed a lack of antibody or complement deposition, suggesting that T cells are the primary effector cell in scleritis (Okhravi et al. 2005; Galor and Thorne 2007).

Diagnosis and Treatment

The broad differential of sclerokeratitis includes episcleritis, conjunctivitis, blepharitis, keratoconjunctivitis sicca, anterior uveitis, acute angle closure glaucoma, carotid or dural sinus fistula, conjunctival mucosa-associated lymphoid tissue lymphoma, and sentinel vessels in the setting of uveal melanoma (Okhravi et al. 2005; Galor and Thorne 2007). The main goal of treatment in the

acute setting is rapid control of inflammation. The long-term goals of treatment are the prevention of recurrences, structural complications, and vision loss. Also of critical importance is the diagnosis and treatment of underlying systemic disease when present. Various treatment strategies may be employed based on the known or presumed underlying etiology and are discussed in the pharmacotherapy portion of this article.

Potential ocular complications associated with sclerokeratitis include scleral and corneal thinning/perforation, anterior segment ischemia, glaucoma, hypotony, uveitis, and cataract (Okhravi et al. 2005). Among patients with anterior or necrotizing scleritis, corneal complications were the most common ocular complications (Jabs et al. 2000). One study reported the incidence of cataract and glaucoma as 17% and 13%, respectively (Okhravi et al. 2005). In a retrospective chart review by Jabs and colleagues in 2000, ocular complications occurred in nearly 59% of patients with scleritis, while approximately 56% of patients with diffuse anterior scleritis and 21% of patients with nodular anterior scleritis were treated with oral corticosteroids or immunosuppressive drugs. In summary, disease prognosis varies widely based on the site of inflammation, type of scleritis, associated complications, the presence or absence of underlying systemic disease, response to therapy, and the risk of side effects resulting from treatment (Larson and Sen 2012).

Scleromalacia: Overview

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Necrotizing scleritis without inflammation

Definition

An aggressive form of scleritis presenting with necrosis but no signs of inflammation.

Etiology

Unknown

Clinical Presentation

Patients with scleromalacia perforans present with deep scleral ulcerations. These scleral ulcerations coalesce, and the thinned sclera shows a bluish color from the underlying uveal tissue. There is a lack of pain, inflammation, or vascular congestion, which distinguishes this condition from the closely related necrotizing scleritis (McCormick and Aquavella 2008; Kanski and Bowling 2011). Examination reveals yellow necrotic lesions near the limbus (McCormick and Aquavella 2008; Kanski and Bowling 2011). These will slough off and leave defects in the sclera.

Diagnosis

No lab diagnostics

Differential Diagnosis

Episcleritis

Necrotizing Scleritis
Conjunctivitis
Scleral hyaline plaque

Prophylaxis

Unclear

Therapy

When complications arise or the disease progresses, treatment is indicated. Immunomodulatory drugs have been effective despite the lack of clinically observable inflammation. Topical prednisolone and prednisone have been shown effective when combined with phenylbutazone or cyclophosphamide (McCormick and Aquavella 2008). After the eye has stabilized, the steroids should be tapered over several weeks. NSAIDs do not help in treating the disease. Eye protection during active disease is important because of the high risk of perforation secondary to trauma (Virasch et al. 2011). If the medical therapies fail, surgical methods must be used to reinforce the thinned sclera or repair perforations. This can include scleral autografts or grafts using preserved sclera or a variety of other tissues (McCormick and Aquavella 2008).

Prognosis

Perforation is an unlikely event for scleromalacia perforans (McCormick and Aquavella 2008). However, even minor trauma carries a high risk of perforation.

Epidemiology

While scleromalacia perforans can present in anyone, it classically presents in postmenopausal women who have long histories of rheumatoid arthritis (Goldstein and Tessler 2009).

▶ Blue Cone Monochromatism

Scoptopic Pupil Diameter

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Pupil diameter under low light conditions

Definition

Pupil size measured upon reduced illumination.

Purpose

To help estimate expectable postoperative visual symptoms such as glare and halos or photophobia prior to refractive surgery. In keratorefractive surgery, postoperative visual symptoms can be caused by disparity between scotopic pupil size and the effective optical zone. Complaints of patients having refractive lens surgery are associated with optical aberrations becoming more dominant when the pupil dilates (Kohnen and Kasper 2006).

Principle

Preoperative measurement of pupil size using a binocular pupillometer providing different lighting conditions.

Indication

Measurement of the scotopic pupil diameter is crucial in the preoperative evaluation of patients undergoing refractive surgery and is a key inclusion or exclusion criterion (Kohnen et al. 2004).

Advantage/Disadvantage

To help identify patients who are likely to experience visual symptoms such as glare and halo after refractive surgery.

Sealed Capsule Irrigation Device

Tanja M. Rabsilber and Gerd U. Auffarth
Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Synonyms

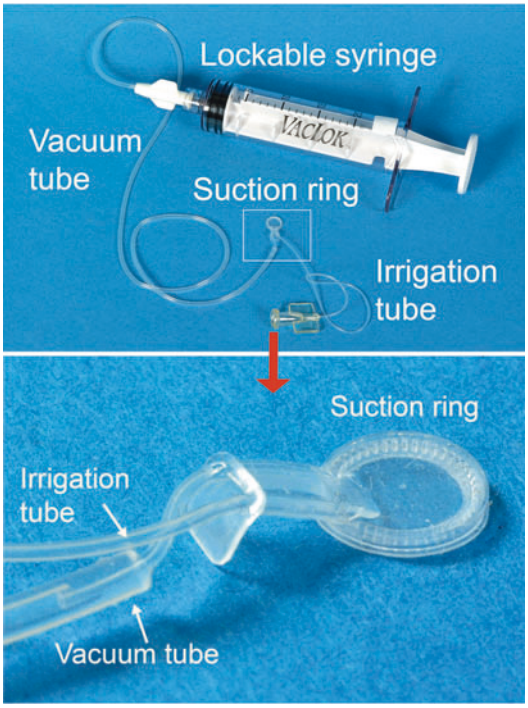
Perfect Capsule device

Definition

The sealed capsule irrigation device (Milvella Pty. Ltd., Sydney, Australia) allows selective targeting of lens epithelial cells by temporarily sealing the capsular bag. The device is made of silicone and consists of a foldable suction ring (overall diameter: 7.0 mm; inner diameter: 5.0 mm) and two separate lines (Fig. 1) (Rabsilber and Auffarth 2006).

History

The use of the device was first published in 2003 (Agarwal et al. 2003; Maloof et al. 2003). Compared to the first model, the system has been improved over time. A cogwheel pattern of the suction ring rim is supposed to provide an even stronger vacuum sealing. Furthermore, the irrigation process is facilitated by adding a second tube instead of the former channel.



Sealed Capsule Irrigation Device, Fig. 1 Perfect Capsule device for sealed capsule irrigation

Treatment

After cataract removal the device is inserted in the anterior chamber and positioned onto the anterior capsule covering the capsulorhexis completely. One tube is now used for vacuum application via the lockable syringe and the second one for irrigation of the internal capsular bag using pharmacological agents. The procedure is also known as sealed capsule irrigation (SCI).

Clinical Features

The device has been investigated in experimental as well as in clinical studies (Abdelwahab et al. 2006; Rabsilber et al. 2007). No complications occurred once the vacuum was built up and corneal endothelial cell count as well as pachymetry was stable postoperatively. The sealed capsule irrigation procedure was not feasible in eyes with deep anterior chambers, small pupils, or capsulorhexis diameters larger than five mm. Using distilled water, no statistically significant difference was found in terms of posterior capsule opacification prevention comparing treated eyes with corresponding control eyes two years after surgery (Rabsilber et al. 2007). Similar results were found in young rabbit eyes with highly proliferative cells. The vacuum to the anterior capsule was tight, and the system was sealed in all eyes. Distilled deionized water did not prevent capsular bag opacification but 5-fluorouracil reduced after cataract significantly (Abdelwahab et al. 2006).

In summary, it has been shown that the sealed capsule irrigation device and procedure are safe without causing any damage to surrounding tissues and effective in the experimental setup with regard to cytotoxic substances; however, it has not become a routine clinical treatment yet. Further developments have to be awaited.

Sebaceous Adenoma

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Definition

A benign tumor that is derived from sebaceous glands.

Etiology

Sebaceous adenoma is a rare benign tumor. Some are associated with Muir-Torre syndrome (autosomal dominant disease) (Albert and Jakobiec 2008; Shields and Shields 2008).

Clinical Presentation

It typically presents as a solitary, small, yellow papula or nodule which has a predilection for the face (particularly the eyelids) or for the scalp. It may be solitary or when numerous be associated with the Muir-Torre syndrome. Patients with the Muir-Torre syndrome develop multiple cutaneous sebaceous neoplasms and occasionally keratoacanthomas, as well as multiple adenocarcinomas of the colon, stomach, and duodenum (Albert and Jakobiec 2008; Shields and Shields 2008).

Diagnostics

Biopsy of this lesion with histopathology analysis.

Differential Diagnosis

Differential diagnosis includes apocrine hidradenoma, dermoid cyst, sebaceous hyperplasia, basal cell carcinoma, and sebaceous carcinoma.

Prophylaxis

Unknown.

Therapy

Solitary lesions are treated by complete surgical removal.

Prognosis

Good. Incomplete removal has occasionally resulted in local recurrence.

Epidemiology

Sebaceous adenoma is the most common benign neoplasm of the sebaceous glands.

Sebaceous Carcinoma/ Adenocarcinoma

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Meibomian gland carcinoma; Sebaceous cell carcinoma; Sebaceous gland carcinoma

Definition

Sebaceous carcinoma (SC) is an aggressive malignant neoplasm arising in the holocrine adnexal epithelium of sebaceous glands.

Etiology

The most common site of origin is the meibomian glands of tarsal plate. However, this neoplasm can occur in other sebaceous glands, such as in the caruncle, the glands of Zeis, and in the eyebrow. SCs are typically found in women, more often in the seventh decade of life, and they usually are on the upper eyelid margin since here are more meibomian glands in the upper lid than the lower lid (Fig. 1). Although sebaceous cell carcinomas are more common in elderly patients, they may be seen in younger patients with a history of radiation to the face, immunosuppressed, and can be associated with the Muir-Torre Syndrome (Shields et al. 2005; Albert and Jakobiec 2008; Shields and Shields 2008).

Sebaceous Carcinoma/Adenocarcinoma, Fig. 1 Sebaceous carcinoma presenting on the superior tarsal conjunctiva, seen with eyelid everted

Clinical Presentation

Highly variable. Classically, this lesion is a firm, painless nodule associated with the loss of cilia that in early stages is often misdiagnosed as a chalazion. The diffuse growth pattern presents as diffuse tarsal thickening that can mimic unilateral blepharoconjunctivitis (Fig. 2). Diffuse intraepithelial spread can extend in a pagetoid pattern across the tarsal and bulbar conjunctiva.

Diagnostics

Biopsy should be considered for recurrent chalazion or unilateral blepharitis resistant to usual treatment. Biopsy usually requires a full thickness lid section sent for histopathologic evaluation. Either fresh tissue or formalin-fixed tissue not exposed to alcohol can be frozen. Conjunctival map biopsies are very important in determining the extent of the lesion and detecting pagetoid

Sebaceous Carcinoma/Adenocarcinoma, Fig. 2 Sebaceous carcinoma on the lower eyelid mimicking unilateral blepharoconjunctivitis

spread (Shields et al. 2005; Albert and Jakobiec 2008; Shields and Shields 2008).

Differential Diagnosis

Differential diagnosis includes ▶ chalazion, ▶ blepharoconjunctivitis/keratoconjunctivitis, ▶ basal cell carcinoma ▶ squamous cell carcinoma, ▶ melanoma, Merkel cell carcinoma, and ▶ sweat gland neoplasms.

Prophylaxis

Unclear

Therapy

Wide surgical excision with frozen section or Mohs micrographic surgery is standard treatment for primary SC. Lymph node evaluation is necessary to evaluate metastasis. Treatment for pagetoid spread controversial (options include cryotherapy, topical mitomycin C, or exenteration when associated with anterior orbital tissue invasion). For metastatic disease, radiation and/or chemotherapy may be applicable (Shields et al. 2005; Albert and Jakobiec 2008; Shields and Shields 2008).

Prognosis

SC is characterized for masquerading as benign or malignant lesions, resulting in delays in diagnosis and relatively high morbidity and mortality. It invades locally and can metastasize to regional lymph nodes and distant organs. The sites of metastasis include lungs, liver, and bone. Mortality increases with increasing tumor size (diameter exceeding 10 mm) (Shields et al. 2005; Albert and Jakobiec 2008; Shields and Shields 2008).

Epidemiology

5–7% of malignant eyelid tumors.

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Pilar cyst; Trichilemmal cyst

Definition

A fluid cavity secondary to obstruction of the duct of a sebaceous gland.

Etiology

Occlusion of meibomian glands, Zeis gland, or sebaceous gland associated with hair follicles of the lid or brow region (Albert and Jakobiec 2008; Shields and Shields 2008).

Clinical Presentation

Sebaceous cyst can be solitary or multiple and appear as smooth, elevated, yellow subcutaneous lesions. It may have a waxy comedo plug in the center and is filled with epithelial cells, keratin, fats and cholesterol crystals. Calcification may be seen.

Diagnostics

Biopsy and histopathological examination. May be clinically indistinguishable from epidermal inclusion cysts.

Differential Diagnosis

Differential diagnosis includes ▶ fibroma, ▶ epidermal inclusion cyst, and ▶ xanthelasma.

Prophylaxis

Unknown

Therapy

Observation or surgical excision with removal of the cyst capsule.

Prognosis

Excellent

Epidemiology

Most lesions are found on the scalp (90%) and less common on the brow region and medial canthus of the eyelid (Albert and Jakobiec 2008; Shields and Shields 2008).

Rare, aggressive, malignant neoplasm arising from sebaceous glands of the skin adnexa.

Epidemiology

In the United States, SGC is the fourth most common eyelid tumor after basal cell carcinoma, squamous cell carcinoma, and melanoma, and it represents approximately 5% (2–7%) of eyelid malignancies. In Asian countries like India and China, where basal cell carcinoma is less common, SGC represents about a third to a half of all malignant eyelid neoplasms.

SGC typically occurs in the sixth or seventh decade of life, with a wide age range from early childhood through the 90s. There is a predilection for women – more than one half up to three-fourths of cases occurs in women without any clear explanation for the preponderance (Niederhuber et al. 2013; Shields and Shields 2008).

Etiology

The etiology is not entirely known. Though sebaceous gland carcinoma (SGC) is more common in elderly patients, it has been reported in patients who have undergone radiation therapy for hemangioma, facial acne, or eczema at any age or hereditary retinoblastoma patients who received external beam radiotherapy in their teenage years. There also appears to be a greater preponderance of SGC and Merkel cell carcinoma in younger age groups of immunocompromised patients with acquired immunodeficiency syndrome (AIDS) and organ transplantation (Niederhuber et al. 2013; Shields and Shields 2008).

Clinical Presentation

SGC presents as a solitary, tarsal nodule in approximately 40% of cases and as a diffuse thickening of the eyelids in about 60% of cases. In the solitary form, the firm tarsal nodule becomes yellow and causes overlying loss of cilia as it grows. Ulceration is uncommon but may occur in advanced cases. In the early stages, this form is frequently misdiagnosed as a chalazion. The diffuse growth pattern is responsible for SGC masquerading as chronic blepharoconjunctivitis. Other less common presentations include eyelid margin lesion from Zeis gland involvement, lacrimal gland mass from deeper invasion of subtle or subclinical eyelid lesion, pedunculated mass, and yellow enlargement of caruncle (Niederhuber et al. 2013; Shields and Shields 2008).

Approximately two-thirds of sebaceous carcinomas arise in the upper eyelid, reflecting the greater mass of meibomian gland tissue in the upper eyelid as compared to the lower eyelid. Though the meibomian gland is the most common site of origin, SGC may also arise from sebaceous glands of the cilia (Zeis glands), caruncle, or eyebrow (Niederhuber et al. 2013).

SGC may exhibit locally aggressive behavior and metastasize to regional lymph nodes and distant organs. SGC may spread by direct or perineural extension into the orbit, sinuses, and intracranially (Niederhuber et al. 2013; Shields and Shields 2008). SGC metastasizes via hematolymphoid channels to preauricular and cervical lymph nodes, the lungs, liver, brain, and

skull. The lung and the liver are the most common sites of distant metastasis (Patterson 2013).

SGC, like sebaceous adenoma, may be associated with Muir-Torre syndrome, an autosomal dominant, inherited syndrome caused by defects in mismatch repair genes, which predispose patients to gastrointestinal and genitourinary tract malignancies. Almost half of patients with SGC have been reported to have additional visceral neoplasms (Niederhuber et al. 2013; Shields and Shields 2008; Patterson 2013).

Diagnosis

The mean duration of signs or symptoms before diagnosis is 2 years. Historically, SGC has been notorious for masquerading as other benign and malignant lesions. Although ophthalmologists are more familiar with the clinical variability of periorbital SGC, there remain delays in diagnosis and misdirected therapy, which translate into increased morbidity and mortality. Given the aggressive, potentially lethal nature of SGC and variability of presentation, one must have a high index of suspicion and low threshold for biopsy. Any elderly patient with chronic, unilateral blepharoconjunctivitis or keratoconjunctivitis that does not respond to treatment should have a biopsy. Chronic and/or recurrent chalazia in the right clinical context should also be submitted for histopathologic examination.

Clinically, there are no pathognomonic features of SGC that differentiate it from other epidermal lesions. In contrast to most cases of blepharitis, SGC is unilateral and tends to cause more thickening and induration. In contrast to the typical chalazion, SGC tends to cause madarosis and destruction of meibomian gland orifices.

In patients who present with a chronic inflammatory condition, SGC frequently exhibits pagetoid spread or conjunctival intraepithelial invasion. In those with diffuse conjunctival involvement, the superior tarsus, conjunctiva, and fornix are involved in almost all cases. Direct orbital invasion occurs in about 10–15% of cases (Niederhuber et al. 2013; Shields and Shields 2008).

Pathology

Microscopically, sebaceous carcinoma is defined by cells with a characteristic lipid-rich and vacuolated cytoplasm. This is not to be confused with the cytoplasmic clearing seen in clear cell carcinomas, either primary in the skin or metastatic (e.g., metastatic clear cell renal cell carcinoma). Lipid stains such as Oil Red O or Sudan IV can be used to help confirm intracytoplasmic lipid but must be done on frozen section, as solvents used in standard tissue processing and paraffin embedding dissolve fat. Although there are several methods of classifying SGC, there are four recognized histopathologic patterns: lobular, comedocarcinoma (central necrosis), papillary, and mixed (any combination of the three patterns). It may be further grouped into well-, moderately, and poorly differentiated varieties. By immunohistochemistry, sebaceous carcinomas are immunopositive to epithelial membrane antigen (EMA), Ber-EP4, and others including cytokeratin 7, Cam5.2, and BRST-1. EMA is typically negative in basal cell carcinoma, and Ber-EP4 is typically negative in squamous cell carcinoma; this profile can be helpful when attempting to determine if a poorly differentiated tumor is of sebaceous, squamous, or basal cell origin. P16 readily highlights pagetoid cells within the epidermis and conjunctival epithelium (Niederhuber et al. 2013; Patterson 2013; Cummings 2012; Eagle 2011).

Differential Diagnosis

SGC must be differentiated from other malignant neoplasms such as basal cell carcinoma, squamous cell carcinoma, and Merkel cell carcinoma and from inflammatory conditions like chalazion and blepharoconjunctivitis (Niederhuber et al. 2013).

Prophylaxis

No clear method of prophylaxis exists. However, limiting or avoiding ionization radiation where possible may lower risk of developing SGC.

Therapy

Treatment must be tailored to the patient based on extent of disease and specific needs of the patient. In cases with diffuse conjunctival involvement, multiple mapping biopsy specimens should be obtained and submitted for histopathologic examination to guide surgical planning. The mainstay of treatment for SGC without orbital involvement is wide, local excision with monitoring of margins with both permanent and frozen sections. In the majority (~75%) of cases, initial management is surgical excision with or without cryotherapy. In cases with extension beyond the basement membrane and orbital involvement, exenteration is often warranted. In the 5–10% of cases with perineural invasion, there may be a role for postoperative adjuvant radiotherapy after primary excision. External beam radiotherapy (EBRT) is reported to be a safe, effective, curative treatment for eyelid SGC when a dose of greater than 55 Gy is used. In the appropriate setting, brachytherapy with ^{192}Ir or similar isotopes should be considered as an alternative to surgical excision. Complications of surgical procedures, cryotherapy, and radiation of the eyelids and conjunctiva include eyelid and conjunctival scarring, symblepharon, and eyelid malpositioning. Finally, there is a role for antimetabolites such as mitomycin C in treating superficial SGC with diffuse intraepithelial involvement (Niederhuber et al. 2013; Shields and Shields 2008).

Prognosis

Although SGC is a highly malignant neoplasm, the prognosis is improving, as clinicians and pathologists become more familiar with the condition, leading to earlier recognition and more efficient treatment (Shields and Shields 2008). Tumor mortality is estimated to about 15%. Factors associated with poor prognosis include upper eyelid origin, meibomian gland origin, diameter >10 mm, duration of symptoms before diagnosis >6 months, infiltrative growth pattern, poor sebaceous differentiation, extensive pagetoid invasion, and invasion of lymphatics, vessels, and the orbit (Eagle 2011). With wide excision and no evidence of metastasis, surgery results in cure. However, sebaceous lesions have a high incidence of recurrence and metastasis.

Sebaceous Glands of Eyelid, Tumors Arising in

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Chalazion; Sebaceous carcinoma; Sebaceous gland adenoma; Sebaceous gland hyperplasia

Definition

Sebaceous glands are holocrine glands that produce sebum, responsible for the outer portion of the tear film that prevents evaporation. Sebaceous glands in the periocular region include the meibomian glands of the tarsus, zeis glands of cilia, and the sebaceous glands of the caruncle. These glands can give rise to neoplastic transformation and infiltration. Specific lesions include sebaceous adenoma, sebaceous hyperplasia, chalazion, and sebaceous carcinoma (Shields and Shields 1999; Albert and Jakobiec 2008).

Characteristics

Rare outside the periocular region.

Sebaceous adenoma is a benign lesion with a yellow-fatty papillomatous appearance. Sebaceous gland lobules demonstrate incomplete differentiation on histopathology. Sebaceous adenoma has an association with Muir-Torre syndrome, an autosomal dominant condition associated with sebaceous tumors of the skin and visceral malignancies, often colon cancer.

Sebaceous gland hyperplasia is the enlargement of preexisting sebaceous lobules while maintaining the normal glandular architecture. There is no association with visceral tumors in sebaceous hyperplasia.

Sebaceous carcinoma is an aggressive tumor of the eyelid that causes loss of the normal eyelid architecture. Findings include madarosis, scarring or notching at the lid margin, and mass formation. It may mimic more benign conditions, such as blepharoconjunctivitis, cellulitis, and recurrent chalazions. It is has a tendency for recurrence and metastasis. Mortality has been reported around 30% over 5 years (Shields and Shields 1999; Albert and Jakobiec 2008).

Differential Diagnosis

Sebaceous gland adenoma
Sebaceous gland hyperplasia
Sebaceous carcinoma
Chalazion

Management

See individual entities for further information. Genetic testing may be indicated if Muir-Torre syndrome is suspected.

Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Pseudoadenomatous hyperplasia; Sebaceous gland hyperplasia; Sebaceous hyperplasia

Definition

A benign growth of sebaceous gland lobules.

Etiology

Hyperplasia of holocrine glands of the eyelid that include meibomian glands, Zeis glands, and sebaceous glands of the caruncle. Sebaceous glands are androgen sensitive and as levels of androgens decrease with age, a hamartomatous enlargement of the sebaceous gland and sebaceous hyperplasia occurs. The lesions tend to maintain normal appearing sebaceous gland architecture (Shields and Shields 1999; Deplewski and Rosenfield 2000; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Clinical Presentation

As multiple, small, white-yellow papules that may have central umbilication and telangiectasia. Lesions may be very similar to basal cell carcinoma in appearance; however, they tend to have a more yellowish color and be softer on palpation. It tends to present on the forehead and cheeks in middle age. Examples of sebaceous hyperplasia include rhinophyma of acne rosacea and the yellowish lobular masses sometimes seen on the caruncle (Shields and Shields 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Diagnostics

Excisional biopsy is not necessary; however, suspicious lesions should be excised to distinguish it from other lesions.

Differential Diagnosis

Acrochordon
Basal cell carcinoma
Milia
Molluscum contagiosum
Muir-Torre syndrome
Sebaceous adenoma
Sebaceous carcinoma
Syringoma
Trichoepithelioma
Trichofolliculoma

Prophylaxis

May recur if not completely excised.

Therapy

Benign therefore treatment is not mandatory. Suspicious lesions should be biopsied to distinguish it from other lesions. Options for excision include traditional excision, cryotherapy, photodynamic therapy, and laser and chemical treatments (Shields and Shields 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Prognosis

Excellent.

Epidemiology

Common finding, especially in adults, reported in approximately 1% of the population.

Seborrheic Blepharitis

Sonia Walia Rana
Lansing Ophthalmology in East Lansing, Michigan, MI, USA

Synonyms

Blepharitis; Posterior blepharitis

Definition

Inflammation of the anterior portion of the eyelid, centered around the eyelashes and follicles.

Etiology

Abnormal oily secretions causing irritation to the eyelids.

Clinical Presentation

Seborrheic blepharitis is a type of inflammation of the anterior portion of the eyelid, centered around the eyelashes and follicles. The disease is the result of chronic abnormal oily secretions that cause irritation to the eyelids (Asbell and Lemp 2011). The eyelids are characterized by oily or greasy residue without any ulceration or loss of the eyelashes. Seborrheic blepharitis is associated with rosacea up to 33% of the time (External Disease and Cornea 2011).

Differential Diagnosis

Rosacea, staphylococcal blepharitis, and sebaceous carcinoma.

Prophylaxis

Warm compresses and lid hygiene.

Therapy

Lid hygiene, antibiotics, steroid eye drops or ointments, and artificial tears treat the underlying condition.

Secondary Angle-Closure Glaucoma

Jörg Stürmer
Kantonsspital Winterthur, Brauerstrasse, Winterthur, Switzerland
Augenklinik Kantonsspital, Winterthur, Switzerland

Definition

Secondary angle-closure disorders are all forms of angle-closure glaucoma that occur in the presence of a second ocular disease such as with iris

neovascularization, uveitis, trauma, or lens disease-related conditions (Allingham et al. 2005).

Etiology

The angle-closure mechanisms include situations in which the peripheral iris is in apposition to the trabecular meshwork or peripheral cornea (Rauscher and Parrish 2008). The peripheral iris may either be "pulled" (anterior mechanism) or "pushed" (posterior mechanism) into this position. In the anterior mechanism of angle-closure glaucoma, an abnormal tissue bridges the anterior chamber angle and subsequently undergoes contraction, pulling the peripheral iris into the iridocorneal angle. Examples of the contracting tissue include a fibrovascular membrane, an endothelial layer with a Descemet-like membrane, and inflammatory precipitates. In the posterior mechanisms, pressure behind the iris, lens, or vitreous causes the iris to be pushed into the anterior chamber angle. This may occur with or without pupillary block. In primary pupillary block glaucoma, functional apposition between the peripupillary iris and the lens increases resistance of aqueous humor flow into the anterior chamber, resulting in a relative increase in posterior chamber pressure and forward bowing of the peripheral iris. The functional apposition in these patients is due to a genetically determined configuration of the anterior ocular segment. In other (secondary) conditions, the same functional apposition between the lens and iris results from a forward shift of the lens (e.g., intumescent cataract or subluxated lens). In still other cases, a pupillary block may be due to posterior synechia associated with inflammation of the anterior ocular segment. In each of these conditions, apposition between the iris and the lens, intraocular lens, and vitreous obstructs the flow of aqueous humor into the anterior chamber, resulting in increased pressure in the posterior chamber and forward bowing of the peripheral iris into the anterior chamber angle. In the posterior mechanism of angle closure without pupillary block, increased pressure in the posterior portion of the eye pushes the lens-iris or vitreous-iris diaphragm forward. Examples include malignant (ciliary block) glaucoma, plateau iris syndrome, intraocular tumors, cysts of the iris and ciliary body, and contracture of retrolenticular tissue.

Clinical Presentation

The anterior mechanisms of secondary angle closure are seen in the angle-closure stage of neovascular glaucoma, in the group of iridocorneal endothelial (ICE) syndromes, in posterior polymorphous corneal dystrophy, in penetrating or nonpenetrating ocular trauma, and in cases where inflammatory precipitates in the chamber angle contract. In addition, it may play a significant role in patients with congenital aniridia (which usually is not total) and in patients with secondary glaucoma due to surgery of congenital cataracts.

Posterior mechanisms with pupillary block are seen in secondary angle closure due to lens-induced mechanism (intumescent, subluxated, or mobile lens) and in eyes with posterior synechia formation, in patients with iris-intraocular lens block in pseudophakia, uveitis with posterior synechia, and iris-vitreous block in aphakia (Tarongoy et al. 2009).

Posterior mechanisms without pupillary block are seen as secondary angle-closure glaucoma in malignant glaucoma, in lens-induced mechanism (intumescent,subluxated, or mobile), following lens extraction (forward vitreous shift), following scleral buckling surgery for retinal detachment, following panretinal photocoagulation, and following central retinal vein occlusion, in the presence of intraocular tumors such as malignant melanoma or retinoblastoma, in patients with cysts of the iris or ciliary body, and in cases where retrolenticular tissue is contracting (i.e., retinopathy of prematurity (retrolental fibroplasia) or persistent hyperplastic primary vitreous).

Diagnostics

To differentiate between these forms, a careful clinical investigation including slit-lamp

biomicroscopy, indirect binocular funduscopy, and careful gonioscopy is mandatory. Together with the history (especially previous intraocular surgeries), diagnosis may be obvious. Additional investigations include standard A- and B-mode ultrasound echography (to exclude tumors and the measure axial length and lens thickness) and high-resolution ultrasound biomicroscopy (UBM) to determine the anatomical relationship between the structures of the anterior segment (the chamber angle, iris, ciliary body, and lens). Ultrasound biomicroscopy is extremely helpful to differentiate between primary iris en plateau syndrome and secondary angle closure due to iris or ciliary body cysts. Additional tests should be used according to the diagnosis (i.e., specular microscopy in patients with presumed ICE syndrome)

Differential Diagnosis

There is a wide variety of differential diagnosis according to the various forms. In the anterior mechanism, ICE syndromes may be difficult to differentiate from posterior polymorphous corneal dystrophy. In these cases, specular microscopy has been shown to be especially helpful. The Axenfeld-Rieger syndrome has striking clinical and histopathologic similarities to the ICE syndrome, but the congenital nature and bilaterality help to separate these conditions. Some advanced cases of progressive iris atrophy might resemble aniridia, but the bilaterality of the latter disorder is a helpful differential feature.

In the posterior mechanisms, diagnosis of pupillary block is important. This may either be done by clinical investigations including UBM or *ex juvantibus* by performing a laser iridotomy and observing the changes in iris configuration and in the chamber angle thereafter. Laser iridotomy in cases with extensive posterior synechia formation may close soon due to extensive inflammatory response, and a surgical iridectomy with or without synechiolysis is indicated.

An important differential diagnosis is nanophthalmos. This is a rare, bilateral, sporadic, or familial condition characterized by small eyes, with adult axial lengths of less than 20 mm, shallow anterior chambers with narrow angles and convex irides, small corneal diameters, high hyperopia, thick sclera and choroid, high lens/eye volume ratio, high corneal refractive power, absence of other congenital malformations, and the frequent occurrence of angle closure.

Another important differential diagnosis is capsular bag distension syndrome, which occurs when a liquified substance (retained hyaluronic acid) accumulates within a closed lenticular bag, which usually forms when the IOL occludes or adheres to the anterior capsulorrhexis. Clinical features, evident 1–14 days postoperatively, include anterior IOL and iris displacement, causing myopia and anterior chamber shallowing. A narrow slit-lamp beam will identify a thin strip of posterior capsule, confirming the diagnosis.

If none of the abovementioned causes are found, a careful medical history may reveal the use of drugs that induce angle-closure glaucoma (Razeghinejad et al. 2011). Usually this is the case in patients with preexisting occludable angles, but especially sulfa drugs (topiramate, hydrochlorothiazide, acetazolamide), quinine, and tetracycline may cause a secondary angle closure without pupillary block. The mechanism is a swelling of the choroid and the ciliary body.

Prophylaxis

Laser peripheral iridotomy eliminates the pressure differential between anterior and posterior chambers and is the current standard treatment to correct pupillary block in the initial approach to angle closure. It is also a safe and effective prophylaxis in suspect eyes with occludable angles secondary to pupillary block. It is also regarded as prophylaxis in young patients with lens subluxation and will prevent the occurrence of acute angle closure. As the lens plays a significant role in the development of angle closure in secondary angle-closure glaucoma, lensectomy may be a logical step in prophylaxis. Cataract surgery in eyes with angle closure, however, carries a significantly increased risk of complications. Using modern cataract surgical techniques, the potential risk is minimized, and when the surgery is performed by an experienced

cataract surgeon, the benefits outweigh the risks in a majority of cases. A protective effect of lensectomy is obvious in patients with phacomorphic angle closure but may also be successful in patients with nanophthalmos and patients with angle closure due to retinopathy of prematurity.

Therapy

The therapy of secondary angle closure should be primarily focused on the mechanism of the angle closure but should also take the underlying disease into account. In those cases with anterior mechanisms, the causing disease should be treated. In a case with neovascular glaucoma, the stimulus for neovascularization should be minimized, and in patients with inflammatory disease, the uveitis should be aggressively treated. In addition to IOP-lowering medications, topical steroids and cycloplegic agents may improve the situation. In the posterior mechanisms with pupillary block, a laser or surgical iridectomy is mandatory. If extensive posterior synechia is present, synechiolysis either medically or surgically will improve the situation. If the anterior hyaloid face is blocking the pupil, an anterior vitrectomy together with a surgical iridectomy will probably be required as a laser iridotomy may be blocked too easily. In posterior mechanism without pupillary block, maximal cycloplegia and hyperosmotic agents may be able to reverse the vicious circle. Using argon laser peripheral iridoplasty may be favorable in some of the above situations but may not be curative. Before any form of filtering glaucoma surgery is necessary, lensectomy should be performed, or a combined procedure may be preferred.

Prognosis

Prognosis is much dependent on the underlying disease, but as some of these secondary angle-closure glaucomas are rare, exact diagnosis may be missed and adequate treatment delayed. Early diagnosis and appropriate treatment may cure the majority of cases.

Epidemiology

Because there is such a variety in diagnoses and underlying diseases, no epidemiologic data are available.

Secondary Open-Angle Glaucoma

Jens Funk
Augenklinik, Zürich, Switzerland

Definition

A secondary open-angle glaucoma is a glaucoma caused by a separate ophthalmic or systemic disease and showing an open anterior chamber angle.

Etiology

Etiology depends on the subtype of secondary open-angle glaucoma.

Diagnosis

Diagnosis of a secondary open angle glaucoma should be based on slit-lamp biomicroscopy, ophthalmoscopy, gonioscopy, and perimetry.

Differential Diagnosis

Differential diagnosis includes primary open-angle glaucoma, secondary angle closure glaucoma, and congenital glaucoma.

Prophylaxis

Treatment of the underlying disease before glaucoma occurs.

Therapy

Whenever possible therapy should start with treatment of the underlying disease, followed by medical or surgical intraocular pressure reduction.

Prognosis

Prognosis strongly depends on successful intraocular pressure reduction.

Epidemiology

About 10% of all glaucomas are secondary open-angle glaucomas.

Semicircular Flap for Eyelid Repair

Ronald Mancini[1] and Nicole Khadavi Kohan[2]
[1]Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA
[2]Jules Stein Eye Institute, David Geffen School of Medicine at UCLA, University of California Los Angeles, Los Angeles, CA, USA

Synonyms

Local advancement flap; Semicircular advancement flap; Semicircular flap; Semicircular temporal advancement flap; Tenzel advancement flap

Definition

A semicircular local advancement flap is often utilized in the reconstruction of full thickness eyelid defects. It allows recruitment of tissues lateral to the lateral canthus and medial mobilization of the eyelid to allow direct wound closure.

Indication

Semicircular advancement flap is indicated in the reconstruction of upper or lower full thickness eyelid defects involving approximately 1/3 to 1/2 of the eyelid. The Tenzel advancement flap is most commonly employed in reconstruction following resection of a neoplasm at the eyelid margin, or in cases of trauma with full thickness tissue loss.

Contraindications

The defect size and laxity of the individual patient's tissues dictate which reconstructive options are available to the surgeon. Large defects, usually greater than 50% of full thickness eyelid, require reconstructive techniques other than a semicircular advancement flap to allow recruitment of adequate tissue for reconstruction.

Techniques and Principles

The eyelid defect is assessed and the appropriate reconstructive technique determined. Full thickness eyelid defects encompassing approximately 1/3 to 1/2 of the eyelid, and having intact eyelid structures at the lateral canthus which can be advanced medially, are generally good candidates for reconstruction with a Tenzel flap. A semicircular flap of appropriate size is marked beginning at the lateral canthus. The flap typically extends approximately 1/2 to 2/3 of the distance from the lateral canthus to the hairline depending on the extent of advancement required. The flap is created with a superior semicircular incision and rotated inferiorly or conversely and created with an inferior semicircular incision and rotated superiorly for lower and upper eyelid defects, respectively.

Lateral canthotomy in combination with cantholysis are performed to free the lateral eyelid and allow mobilization nasally. The wound margins are apposed by direct closure in a standard fashion for full thickness eyelid repair ensuring that excess tension on the wound has been relieved via mobilization of the lateral eyelid segment. Suturing the flap to the orbital rim periosteum forms the lateral lid contour. The lateral canthus is fixated and the conjunctiva is undermined and advanced to the flap edge if necessary.

Outcome

A semicircular incision extending temporally from the lateral canthus with reconstruction of the full thickness eyelid defect is the final result. The lateral most aspect of the reconstructed eyelid will be devoid of eyelashes secondary to the medial advancement of the eyelid tissues formerly residing at the lateral canthal region.

Complications

Excess tension on the newly reconstructed full thickness eyelid defect can result in wound dehiscence. Phimosis and rounding of the lateral canthus can occur with healing particularly if excess wound tension is present. Damage to the zygomatic branch of the facial nerve with resultant orbicularis occuli weakness secondary to deep dissection in the lateral canthal region.

[2]Departments of Ophthalmology, Neurology, and Neurosurgery, Weill Cornell Medical College, Houston, TX, USA
[3]Department of Ophthalmology, The University of Texas Medical Branch, Galveston, TX, USA
[4]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Downward Ocular Deviation; Sunset Eye Sign

Definition

The "setting sun" sign is an ophthalmologic phenomenon where the eyes appear driven downward bilaterally. The inferior border of the pupil is often covered by the lower eyelid, creating the "sunset" appearance. This finding is classically associated with hydrocephalus in infants and children.

Etiology

The pathogenesis of the setting sun sign is believed to be related to aqueductal distention in the dorsal midbrain on the vertical gaze innervation bilaterally. In children with hydrocephalus, up to 40% of cases will present with this sign. Of these patients, 13% harbor ventriculoperitoneal shunts that have failed. The sign is also associated with kernicterus and other features of the full Parinaud syndrome (i.e., dorsal midbrain syndrome). Interestingly, the setting sun sign may also transiently appear in healthy infants up to 7 months of age. This benign phenomenon is believed to be caused by immaturity of reflexes controlling eye movements.

Clinical Presentation

Patients with setting sun sign present with bilateral up-gaze paresis, with the eyes appearing to be driven downward. The superior sclera is largely exposed between the upper eyelid and the iris. The inferior iris and pupil may be partially covered by the inferior eyelid. This condition may be persistent or transient.

Diagnostics

The setting sun sign is often a marker of hydrocephalus. Thus, whether the condition is persistent or transient, patients must be assessed for ventricular obstruction, failed ventriculoperitoneal shunts, lesions and/or tumors of the midbrain and periaqueductal structures, or other causes of increased intracranial pressure via

ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), or intracranial pressure-monitoring techniques. Bilirubin levels could be performed in cases of suspected kernicterus.

Differential Diagnosis

Kernicterus
Hydrocephalus
Shunt failure
Transient benign finding in infants

Therapy

Treatment should be directed at the underlying etiology.

Prognosis

The prognosis of the setting sun sign in patients is dependent on the etiology. The most common cause, hydrocephalus, is a potentially life-threatening condition and even if successfully treated can result in permanent brain injury. However, the setting sun sign is often the earliest marker of elevated intracranial pressure in children, and with quick diagnosis and treatment, permanent neurological damage can be minimized.

Epidemiology

The sign is often seen in children especially those with shunted hydrocephalus.

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Bell palsy; Facial nerve palsy

Definition

Seventh nerve palsy is classified into two distinct categories, central lesions and peripheral lesions. Central lesions involve upper motor neurons, while peripheral lesions involve lower motor neurons and will present with slightly different symptoms and signs. Upper motor neurons extend from

the precentral gyrus of the cerebral cortex and descend through the brainstem via corticobulbar tracts to synapse at lower motor neuron cranial nerve seven (VII) nuclei in the pons. The musculature of facial expression above the eyebrow is innervated bilaterally, while the musculature of facial expression below the eyebrow is innervated contralaterally. Depending on the level of the lesion, symptoms can include weakness or paralysis of musculature of facial expression, loss of lacrimation and salivation, hyperacusis, and loss of taste from the anterior two-thirds of the tongue.

Clinical Features

Central lesions manifest as weakness or paralysis in the lower facial musculature below the eyebrow with the ability to close the upper eyelid and wrinkle the forehead intact. Peripheral lesions manifest as weakness or paralysis in the facial musculature above and below the eyebrow. In both categories, patients can present with flattened nasolabial folds, drooping of the corner of the mouth, paralytic ectropion, or lagophthalmos. Patients may also display decreased lacrimation and salivation, hyperacusis, and loss of taste from the anterior two-thirds of the tongue. Later in the course, patients may display cranial nerve VII aberrant regeneration and synkinesis.

Tests

After a complete history is taken, a thorough neurological exam to determine if the condition is a central or peripheral palsy and if it is complete or incomplete is necessary. Test for taste sensation to the anterior two-thirds of the tongue and assess functioning of other cranial nerves. A complete ocular exam is required for ocular motility and nystagmus. Otolaryngologic examination is required to assess the ear and oropharynx for lesions, to assess the parotid gland for possible lymphadenopathy, and to assess hearing. Computed tomography (CT) scans are required if there is a history of trauma, and CT and magnetic resonance imaging (MRI) scans may be required if there are any other localizing signs or a history of cancer. If sarcoidosis is suspected, a chest radiograph and angiotensin-converting enzyme levels could be performed. If collagen vascular disease is suspected, rheumatoid factor, erythrocyte sedimentation rate, antinuclear antibody, and antineutrophil cytoplasmic antibody tests could be performed. Depending on the clinical presentation, Lyme titer, Epstein-Barr virus titer, RPR, HIV test, and CBC with differential may be performed.

Differential Diagnosis

- Myasthenia gravis
- Lyme disease
- Sarcoid

Etiology

Central lesions can be cortical, extrapyramidal, and in the brainstem. Cortical lesions often occur because of stroke or tumor. Extrapyramidal lesions of the basal ganglia often occur from parkinsonism, a vascular lesion, or tumor. Brainstem lesions can occur from multiple sclerosis, stroke, or tumor. Peripheral lesions involving lower motor neurons can be found in the cerebellopontine angle from masses such as acoustic neuromas, facial neuromas, meningiomas, cholesteatomas, and metastasis. Trauma and otitis can also be causes for peripheral seventh nerve palsy. Other conditions that may cause symptoms of peripheral seventh nerve palsy include Ramsay Hunt syndrome, Guillain-Barre syndrome, Lyme disease, sarcoidosis, parotid neoplasm, metastasis, diabetes mellitus, botulism, human immunodeficiency virus, syphilis, Epstein-Barr virus, acute porphyrias, nasopharyngeal carcinoma, and collagen-vascular disease.

Treatment

Treatment should be directed at the underlying etiology. Exposure keratopathy management might include artificial tears and lubricating ointment and, in extreme cases, eyelid gold weight or spring implants to aid in eyelid closure.

Shack-Hartmann Aberrometry

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Hartmann-Shack wave front sensing

Definition

Non-interferometric wave front aberrometer.

Purpose

Measuring the optical path of light rays through the eye to detect all aberrations at all points in the optical system of the human eye.

Principle

The Hartmann-Shack wave front sensor is used to measure the wave aberrations of the human eye by sensing the wave front emerging from the eye produced by the retinal reflection of a focused light spot on the fovea. It comprises a microlenslet array subdividing the reflected wave of light into multiple focused beams. The incident plane wave results in a square grid of spots captured by an image detector in the focal plane of the lenslet array. The distorted wave front causes lateral displacements of the spots on the CCD array. Thus, from the spot pattern, the shape of the incident wave front can be reconstructed (Bille 2000; Bille et al. 2004).

Indication

Measurement of the aberrations of the eye, correlation with visual symptoms, wave front sensing for preoperative evaluation of refractive surgical procedures.

Contraindication

None.

Advantage/Disadvantage

Shack-Hartmann aberrometry employs the fastest technique compared to other wave front sensing devices. Yet, if the grid of image spots is too distorted, indexing problems may be experienced (i.e., the boundary between adjacent spots is not clear). The use of a laser light source can produce an undesirable speckle effect in a Shack-Hartmann sensor. This speckle noise can affect the precision and accuracy of the wave front sensor measurement and limited number of pixels.

As a fixed monolithic microlenslet array is used, the sampling configuration cannot be modified unless different microlens arrays are used. Shack-Hartmann aberrometers rely on a good retinal reflection, which can be a problem in retinal pathologies (Moreno-Barriuso et al. 2001; Wang et al. 2003).

Shagreen, Crocodile

Farhan I. Merali
Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Valerio's mosaic degeneration; Vogt's crocodile shagreen dystrophy

Definition

Initially described in 1927 by Weizenblatt and named by Vogt in 1930, crocodile shagreen is an opacification of the cornea characterized by a mosaic-like arrangement of polygonal, gray opacities separated by clear zones, resembling cobblestone or crocodile skin. There are anterior and posterior forms of the degeneration, which will be discussed in greater detail below.

Etiology

The anterior form of crocodile shagreen is most often due to senile change, but has also been associated with hypotony, trauma, band keratopathy, pseudoxanthoma elasticum, glaucoma, polymorphic amyloid degeneration, and juvenile X-linked megalocornea. Similar changes have also been described in patients with keratoconus who wear hard contact lenses, as well as with fluorescein staining of the cornea after pressure is patched. The posterior form, however, has been described solely as an age-related degeneration.

Occurrence

The anterior form of the degeneration usually occurs bilaterally and centrally, whereas the posterior form may occur peripherally, occasionally resembling corneal arcus. The opacities are usually visually insignificant and require no treatment.

Classification

As stated above, both anterior and posterior forms of crocodile shagreen exist. Anterior crocodile shagreen is generally a central corneal opacity at the level of Bowman layer. Histologically, the Bowman layer is thrown into ridges, and calcium may be deposited at the peaks of the folds. Posterior crocodile shagreen shows similar sawtooth folds in the deep stroma near Descemet's

membrane. The posterior variety of crocodile shagreen is clinically identical to central cloudy dystrophy of François, though the latter occurs in an autosomal dominant pattern and does not typically extend to the periphery.

Shave Biopsy

B. Ranjodh Singh[1], Allison J. Chen[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

Shave biopsy is the removal of a superficial skin lesion for diagnostic or therapeutic reasons.

Purpose

A shave biopsy serves to diagnose and at times provide definitive treatment for superficial skin conditions.

Principle

Choosing the appropriate site for biopsy is key in yielding diagnostic potential (Alguire and Mathes 1998). For inflammatory lesions, it is generally recommended to biopsy lesions in the advanced stages of inflammation. On the other hand, for blistering lesions, the earlier the lesion, the better for biopsy. For lesions 1–4 mm in diameter, biopsy the middle or excise the whole lesion. For larger lesions, biopsy the thickest part, the edge, or the area with most abnormal color. Vesicles and bullae should be biopsied with the lesion edge intact.

To perform the procedure, first obtain informed consent from the patient (Pickett and O'Callaghan 2011). Next clean the area using povidone-iodine or chlorhexidine. Next anesthetize the skin using lidocaine. For macular or raised non-suspicious lesions, carefully remove a shallow, thin disk of lesion or the entire lesion itself by meticulously holding the blade parallel to the skin. For suspicious, pigmented, raised lesions, saucerization may be performed. This entails anesthetizing the lesion to create a wheal and pinching the area to facilitate the biopsy. Rather than holding the blade parallel like in a classic shave biopsy, in saucerization, the blade is held at a 45° angle to the skin; the blade is bent or bowed depending on the lesion size, and a disk of tissue is removed. If pigment still remains after saucerization, a punch biopsy may be performed to remove and examine the remaining pigment.

Indication

Cutaneous lymphoma, deep tissue infection, dysplastic nevi, erythema multiforme, erythema nodosum, Kaposi sarcoma, lupus erythematosus, malignant melanoma, panniculitis, pemphigoid, pemphigus, and vasculitis.

Contraindication

If the lesion is located on challenging areas, e.g., the eyelids and nose, the patient should be referred

to an oculoplastic surgeon or dermatologist to prevent an aesthetically undesired scar. Usually biopsies should not be done at an infection site, unless the infection of the lesion is the indication for the procedure. Since the shave biopsy procedure involves the use of topical anesthetics, any adverse medical reactions to the topical agents used may be a contraindication. Lastly, if a patient has a bleeding disorder or is taking warfarin or another anticoagulant, the patient should be referred to an oculoplastic surgeon or dermatologist for the procedure.

Advantages/Disadvantages

Shave biopsies can be performed in the urgent care or clinic setting with appropriate equipment. When performed properly, shave biopsies can yield clinically useful information and provide definitive therapy for superficial, small lesions.

Shave biopsies are ideally not performed in areas with poor healing. These include cosmetic areas, e.g., eyelids and the nose, or deltoid and chest area, where hypertrophic scarring occurs. Biopsies over the tibia can be an issue for patients with poor wound healing, e.g., diabetics and patients with arterial or venous insufficiency. Lastly, biopsies in the groin or axilla are prone to secondary infections.

Sickle Cell Retinopathy

Siegfried Wagner and Susan Downes
The Oxford Eye Hospital, Oxford, UK
Nuffield Laboratory of Ophthalmology, University of Oxford, Oxford, UK

Definition

Sickle cell retinopathy describes the progressive retinal changes of both a nonproliferative and proliferative nature, which occur secondary to sickle cell disease.

Etiology

Sickle cell anemia is a hemoglobinopathy characterized by the production of abnormal erythrocytes, which become rigid and take up a sickle shape exacerbated by hypoxia or acidosis. This leads to red cell membrane damage and hemolysis. Normal hemoglobin comprises a central heme ring with tertiary conformation by two surrounding

pairs of globin polypeptides chains. Hemoglobinopathies and thalassemias occur as a consequence of alterations in the amino acid composition of globin chains or the rate of their production. The most prevalent sickle genotype is HbS and is caused by a single nonconservative missense mutation in the β -globin chain (glutamic acid > valine). Inheriting this mutation from both parents results in homozyosity for Hb S, designated as Hb SS. A number of hemoglobin variants exist, e.g., Hb C, E, D, O, and G. Inheriting different mutations from parents can result in a compound heterozygous state as seen in Hb SC, where the Hb S variant is inherited from one parent and Hb C from the other parent. The Hb SC genotype is the commonest compound heterozygous state. Carriers of Hb S with one normal allele are known as Hb AS (Tibbets and Ho 2013).

Sickle cell retinopathy results from repeated vaso-occlusion and adhesion of the sickled erythrocytes to the vascular endothelium, particularly in locations where both arterial PaO_2 and pH are lower, as in the small capillaries of the peripheral retina. Sickle cell carriers generally have limited systemic disease and minimal evidence of retinopathy unless they have co-morbidity such as diabetes. However, Hb SS or the compound heterozygous state, e.g., Hb SC, or Hb AS together with β thalassemia, or Hb SS with α thalassemia, will usually lead to ocular disease manifestations, and the compound heterozygotes state is associated with earlier onset of retinal neovascularization and visual complications, whereas patients with homozygous sickle cell disease, e.g., Hb SS, tend to have more severe systemic disease but milder retinal disease (Emerson et al. 2006).

Clinical Presentation

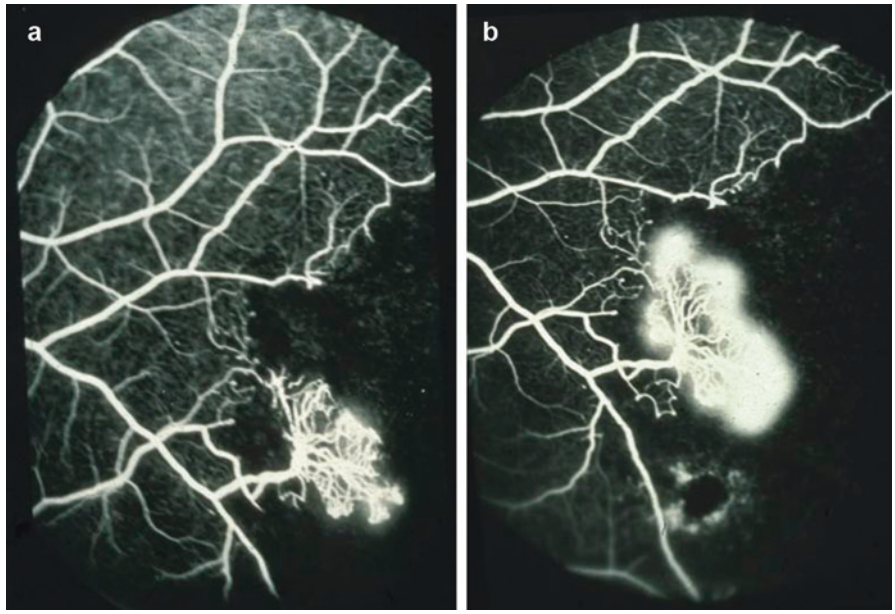
Most patients will be referred for ophthalmology screening after receiving a diagnosis of sickle cell disease. Due to the early changes occurring in the far periphery of the retina, patients will rarely notice any visual disturbance unless proliferative sickle retinopathy develops. Nonproliferative findings, which may be seen in the retina of a patient with sickle cell disease, can include:

1. Increased vessel tortuosity and vascular remodeling caused by peripheral vascular obstructions and reperfusions. Over the years, the centripetal band of ischemia progresses posteriorly, and "silver wiring" of vessels can be seen in areas of non perfusion.
2. Central retinal arterial obstruction.
3. Macular depression sign representing atrophy and thinning of the neural retina. Macular infarctions can occur.
4. Choroidal vascular occlusions, posterior ciliary arterial obstructions.
5. Epiretinal membranes and macular holes – more commonly in patients with previous or current neovascularization and/or laser treatment.
6. Salmon patches: retinal hemorrhages – traditionally called salmon patches due to their characteristic orange-red color after the acute phase, hemorrhages typically result from obstruction and subsequent rupture of intermediate-sized retinal arterioles.
7. Schitic cavities which occur after reabsorption of salmon patches.
8. Black sunbursts – these pigmented round lesions represent migration and hyperplasia of the underlying retinal pigment epithelium and may represent reactive proliferation after hemorrhage.
9. Iridescent spots – glistening copper-colored granules, which are the breakdown products of intraretinal blood.
10. Angioid streaks.

Goldberg classified sickle cell retinopathy in five stages:

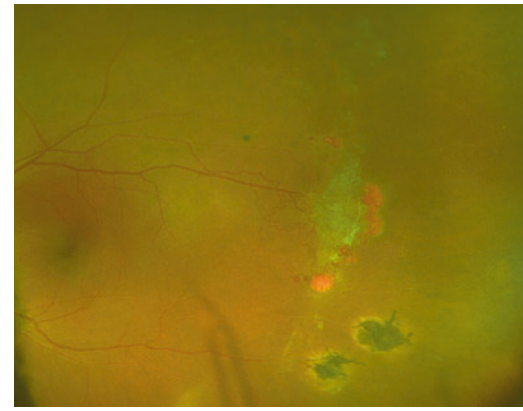
Stage I: Peripheral arteriolar obstructions
Stage II: Peripheral arteriolar-venular anastomoses
Stage III: Preretinal neovascularization – sea-fan neovascularization (Fig. 1)
Stage IV: Vitreous hemorrhage
Stage V: Retinal detachment (either rhegmatogenous, tractional, or combined) (van Meurs et al. 2007)

Signs of sickle cell retinopathy have been reported as early as 8 years of age, but the natural history of proliferative sickle retinopathy (PSR) is



Sickle Cell Retinopathy, Fig. 1 (**a**) and (**b**) Images of a sea fan developing over the interval of a year (Courtesy of Bird/Sarjent Sickle cell unit Jamaica)

that it peaks from 20s to early 40s then seems to plateau and is uncommon before teenage years. PSR is characterized by the growth of seafans, which develop in the ischemic peripheral retina in a circumferential distribution. A proportion of these will autoinfarct. This is a dynamic process and seafans may take years to close with new areas becoming active. A major cause of visual loss in PSR is vitreous hemorrhage, which may be recurrent and can spontaneously reabsorb, but in some cases, membranes may persist. Other than arterial obstructions and macular infarctions, the main cause of permanent visual loss is due to retinal detachments either untreated or with a poor outcome. Combined tractional and rhegmatogenous retinal detachments can occur in the thin non perfused retina adjacent to, or affected by, fibrosing seafans (Downes et al. 2005) (Figs. 2 and 3).



Sickle Cell Retinopathy, Fig. 2 Showing fibrosing seafan with active tips and bleeding and two *black* sunburst patches inferiorly with silver wiring of occluded vessels in the peripheral retina

Diagnosis

Sickled erythrocytes can be seen on blood smear microscopy and confirmed through hemoglobin electrophoresis. DNA analysis can identify the causative mutation. Diagnosis and assessment of proliferative sickle retinopathy is best visualized using fluorescein angiography.

Differential Diagnosis

Retinopathy of prematurity
Familial exudative vitreoretinopathy

Proliferative diabetic retinopathy
Eales' disease

Prophylaxis

Laser treatment has been used aiming at reducing the frequency of vitreous hemorrhages and inducing regression of PSR. As seafans can autoinfarct, and laser treatment is aimed at PSR closure, the evidence that laser prevents development of retinal detachments is not clear, but it can prevent vitreous hemorrhages. Targeted retinal photocoagulation can be used to treat retinal ischemia anterior to the seafans and has been shown to induce regression of PSR. Alternatively, a 360 laser to the anterior circumferential ischemic zone can be applied to prevent further neovascularization. Direct feeder vessel photocoagulation, where high-power laser is administered to the feeding arteriole, is not recommended and can be associated with significant complications including chorioretinal or choriovitreal anastamoses. Careful assessment of the peripheral retina on a regular basis, when PSR is present, is important for early detection and management of a retinal detachment. Patients should also be educated regarding retinal detachment symptoms, so that if they occur they need to be seen on an urgent basis (Elagouz et al. 2010).

Therapy

Surgery should generally be reserved for those with recurrent vitreous hemorrhage (>6 months), retinal detachment, and significant epiretinal membranes and macular holes. Modern vitrectomy techniques and even buckling procedures have been associated with positive visual outcomes. Good control of intraocular pressure, good hydration, oxygenation, and maintenance of body temperature during any procedure is imperative (Chen et al. 2014).

Prognosis

Visual prognosis is dependent on the variant of sickle cell disease. Compound heterozygous disease SC is associated with the most frequent and severe ocular manifestations, and severe visual loss is commoner in this group. Visual loss is most commonly due to recurrent vitreous hemorrhage and retinal detachment.

Epidemiology

Prevalence of sickle cell trait reaches approximately 20% in some regions of Africa and 8% in African-Americans. Men and women are equally affected. The development of PSR is dependent on genotype and age, with the highest risk period from 20 to 34 years in SC and the 40–50 years age group in SS.

Siderosis: Signs and Symptoms

David Loring Nash and Mark M. Fernandez
Eastern Virginia Medical School, Norfolk, VA, USA

Synonyms

Ocular siderosis; Siderosis; Siderosis bulbi

Definition

Siderosis is a degeneration of specific ocular tissues as a result of intraocular trivalent iron ion deposits (Davidson 1933). Signs of siderosis include dilated pupil (early), constricted visual field (late), cataract, glaucoma, iris heterochromia, and anisocoria due to a mydriatic and poorly reactive pupil in the affected eye (Yamaguchi and Tamai 1989). Symptoms may include decreased night vision, decreased color vision, and decreased visual acuity.

The classical clinical description of siderosis includes a rusty brown discoloration of the iris and a yellow-brown discoloration of the lens with deep brown opacities in the peripheral subcortical area (Spalton et al. 1994). Patients may recall a history of trauma to the eye or an occupation involving metal work (Ballantyne 1954).

Etiology

Siderosis is primarily caused by retained intraocular foreign bodies containing iron. Iron deposits in ocular tissues include the iris and its musculature, retina, anterior lens capsule, cornea, optic nerve, and trabecular meshwork (Ballantyne 1954). Electron microscopy of enucleated eyes with siderosis has shown ferritin particles deposited within the cytoplasm, in intracellular vacuoles (siderosomes) and within cell nuclei (Tawara 1986). There have been reports of retained iron-containing intraocular foreign bodies that did not cause siderosis (Lim et al. 2011). Characteristically, electroretinogram (ERG) shows an initial increase in the a-wave followed by flattening of the b-wave providing an objective way of following retina function over time (Mester and Kuhn 2002). Vitreous hemorrhage has also been known to cause changes consistent with siderosis (Ballantyne 1954). Additionally, a rare autosomal recessive disease called aceruloplasminemia results in iron overload in certain tissues including the retina leading to a clinical picture similar to siderosis (Dunaief et al. 2005).

Occurrence

Siderosis is rare. In a report of 40 patients with intraocular foreign bodies from two orbital surgery departments, only one had an iron-containing foreign body and follow-up indicated no signs of siderosis (Fulcher et al. 2002).

Classification

Siderosis, a type of metallosis, is a degenerative process secondary to iron exposure, most frequently traumatic in nature.

Silicone Intraocular Lens

Daniel Kook[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Silicone IOL

Definition

An intraocular lens that is made of silicone (polysiloxane).

Epidemiology

Of all implanted IOLs, silicone material accounts for about 5%.

History

After the first experimental studies by A. D. Ruedemann in the 1970s, silicone has been used as an IOL material since the early 1980s with Food and Drug Administration (FDA) approval obtained in 1990. The first silicone IOL had a refractive index of 1.41.

Clinical Features

Advantages of IOLs made of silicone are that they are heat resistant, autoclavable, moldable, compressible, highly transparent to visual light, and very flexible and provide good tensile and tear strength. Their disadvantages are that they are slippery, which makes them more difficult to manipulate, can be pitted, have a lower refractive index than acrylic lenses which refers to a higher thickness, and show high adherence to silicone oil after vitreoretinal surgery (Findl et al. 2010; Kohnen et al. 1995). Silicone's angle of water contact is 99°, which makes it more hydrophobic compared to hydrophobic acrylic IOLs that show an angle of water contact of 73°. Latest generations of silicone IOLs have a higher refractive index (1.41–1.46) and thus, thinner optics.

Tests

Good biocompatibility of silicone IOLs has been shown in numerous studies (Werner 2008).

Differential Diagnosis

Other IOL materials are polymethylmethacrylate (PMMA) or hydrophilic/hydrophobic acrylic.

Etiology

The term "silicone" refers to "silicon ketone" and was coined by F. S. Kipping to describe polydiphenylsiloxane by analogy of its formula Ph_2SiO.

Treatment

Silicone IOLs come as one-piece or three-piece IOLs and as monofocal, multifocal, and toric IOLs.

Silicone Intubation

Kira L. Segal, Benjamin Levine and Gary Joseph Lelli
Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Bicanalicular intubation; Lacrimal stents; Lacrimal tubes

Definition

Silicone intubation is performed by placing a tube through the lacrimal system. Placement of a silicone tube as part of various procedures of the tear drainage system is thought to increase success rate by maintaining patency of surgical created passages (Table 1).

Indications

The duration that the silicone tubes left in place varies based on surgeon preference and surgery type. Tubes are typically left in place for 3 months and then removed either in the office setting or under sedation.

Silicone Intubation, Table 1 Surgical indications for silicone stenting by anatomic location in the nasolacrimal system

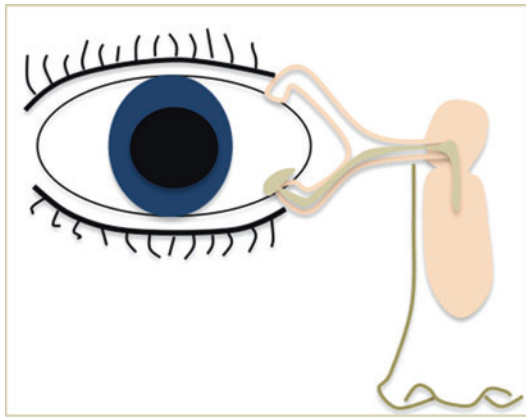
Punctum	Canaliculus	Nasolacrimal duct
Punctoplasty	Canalicular trauma repair	External dacryocystorhinostomy (DCR)
Punctal reconstruction	Canalicular recanalization	Endoscopic dacryocystorhinostomy (eDCR)
	Canaliculotomy	Balloon catheter dacryoplasty
		Nasolacrimal duct probing
		Turbinate infracture
		Silicone intubation (for functional NLDO)

Debate in the literate exists as to the benefit of using intubation devices for routine endoscopic and external DCR. Chong et al. conducted a randomized clinical study in patients undergoing endoscopic DCR and found no difference in success rates when silicone stent was utilized (Chong et al. 2013). Two meta-analyses also demonstrated no benefit when silicone stenting is added in traditional or external DCR surgeries (Feng et al. 2011; Gu and Cao 2011). The use of silicone stenting varies by surgeon preference and clinical scenario.

Intubation Devices

Silicone is currently the material of choice for intubation devices as silicone has proved to be inert, flexible, well tolerated, and extremely durable.

Intubation devices can be divided broadly into monocanalicular or bicanalicular categories. Monocanalicular tubes traverse either the upper or lower canaliculus, whereas bicanalicular tubes enter into both the upper and lower canaliculi. Bicanalicular tubes form a continuous loop in the medial palpebral fissure with both ends of the tube in the nasolacrimal system. Monocanalicular tubes have one end at the



Silicone Intubation, Fig. 1 Cartoon depicting Mini-Monoka monocanalicular intubation device (*gray*) traversing the lower canaliculus

punctum – usually a blunted or bulbed end – and the other end in the nasolacrimal system.

The Mini-Monoka silicone stent is an example of a commonly used monocanalicular intubation device (Fig. 1). The Mini-Monoka is advanced through the punctum into the canaliculus and terminates in the nasolacrimal system. At the proximal end of the tube, a plug is available in different sizes to prevent the tube from dislocating further into the nasolacrimal system. The tube can be easily removed by grasping the bulb end in the puncta and pulling the tube out through the lid.

The Crawford tube is an example of a bicanalicular intubation device utilizing metal probes with round- or olive-shaped tips. The metal probes are used to thread through the lacrimal system both in the upper and lower canaliculi and are then retrieved in the nose using a Crawford hook. The probes are removed, and the silicone tubes are tied, sutured to the nasal sidewall, or left free to hang in the nose.

Complications

Intraoperative complications of silicone stents include false passage and tube breakage during intubation. Lacrimal probing is essentially a blind procedure guided entirely by feel and mastery of nasolacrimal anatomy. Creation of false passage may lead to scarring and/or further stenosis of the lacrimal passage (Schaefer 2014).

Tube prolapse is probably the most common complication reported in the use of silicone tubes. Lower lid laxity, low knot position, and younger or less compliant patient all increase risk for tube prolapse. Corneal and conjunctival irritation, punctal erosion, and generalized patient discomfort may all result from tube prolapse. Artificial tears and ointment can alleviate some discomfort. Prolapse often results in earlier tube removal, though multiple studies have suggested that the duration the tube remains in place does not correlate with outcome. Occasionally, on postoperative exam, tubes are no longer present on visual inspection of the punctum. Nasal endoscopy should be performed with tube loss given potential for foreign body retained in the nasolacrimal system.

Additional postoperative complications of silicone intubation include erosion or cheese wiring of the tube and granuloma formation. Chronic rubbing and irritation or tubes inserted with inappropriate distribution of tension are hypothesized to cause erosion. Tubes should be removed when persistent erosion is observed though this must be balanced with potential for canalicular stenosis (Korn and Kikkawa 2016). Pyogenic granulomas are initially treated with topical steroids. With failure of topical therapy, granulomas can be removed surgically.

Silicone Oil

Michael R. Martinez
Department of Ophthalmology, Tel Aviv Medical Center, Tel Aviv, Israel

Definition

Silicone oil in ophthalmology is used in vitreoretinal surgery where a long tamponade is needed to maintain the adhesion between retina and retinal pigment epithelium for a long period. It is a sterile, highly purified long-chain polydimethylsiloxane.

Its viscosity is measured in centistokes (cs). It ranges from 1,000 to 5,000 cs.

Surgeons prefer silicone oil tamponade due to its extended effect that can remain in the eye for months or years. In addition, it is the best option for eyes with multiple breaks or large retinotomies. There are no restrictions on air travel. Furthermore, it provides a better tamponade in eyes with hypotony.

Indication

The indication for use of silicone oil is related to the factors around the retinal surgery, like complicated retinal detachment, trauma, giant retinal tear, retinal detachment related to viral retinitis, patients with severe proliferative diabetic retinopathy, and tractional retinal detachment. Also, it is indicated in patients that have to fly or that are not cooperative for head positioning like children.

Contraindication

Use of silicone oil is contraindicated in pseudophakic patients with a silicone intraocular lens, due to chemical interaction of silicon oil and lens creating a thick coating with droplet formation on the lens surface.

Techniques and Principles

Silicone oil injection: After completing vitrectomy for retinal detachment repair and immediately after completing fluid-air exchange, the silicone oil is injected into the vitreous cavity through one of the vitrectomy surgery ports; it can be injected through a 23G port but often the sclerotomy is enlarged to 20G. The silicone oil is injected under direct visualization with the wide-angle view system. The air infusion pressure is lowered to 10 mmHg. When the silicone oil reaches the level of the infusion cannula, it is disconnected from the system to prevent sudden elevation of intraocular pressure, thus permitting the remaining air to exit trough the infusion cannula. At this point, the aim is to achieve a full vitreous cavity with a normal intraocular pressure. After completing the silicone oil injection, careful closure or suturing of sclerotomies is performed.

Silicone oil removal: A standard three-port vitrectomy is commonly used to remove silicone oil, with active suction from a 23G or 25G port using 10 ml syringe with a silicone cannula. In case of heavy fluorinated silicone, a larger silicone tube connected to the aspiration system is used to aspire above the optic nerve head. A common practice is to perform one or two fluid-air

exchanges to wash out every remaining bubble of silicone. At the end of the procedure, air or balanced salt solution can be left in the vitreous cavity.

Outcome

After removal of silicone oil, eyes with attached retinas generally showed improvement in visual acuity.

Complications

Cataract formation is one of the most common complications after silicone oil tamponade of the retina. This complication usually is detected within 4–8 months.

Elevation of intraocular pressure is common due to different types of mechanisms. After migration of emulsified silicon bubbles into the anterior chamber, damage can occur to the trabecular meshwork. Also elevation of IOP occurs in several instances. Elevation can be secondary to overfill of silicone oil. It can be due to pupillary block in aphakic eyes blocking the passage of aqueous humor to anterior chamber with aqueous misdirection, shallow anterior chamber, and closed angle.

Band keratopathy is another complication of the use of silicone oil. It can be present after migration of silicone oil to anterior chamber but not necessary always.

Macular pucker is observed within 6 months and occurs in 4–11% of eyes after successful conventional surgery for retinal detachment without PVR. Using data from the Silicone Study, we found in our center, that the 6-month point prevalence rate of postoperative macular pucker was 15%.

Recurrent retinal detachment and missed retinal breaks give raise to recurrent retina detachment.

Silicone Oil Tamponade

Armin Wolf
Department of Ophthalmology, Ludwig-Maximilians Universität München, München, Germany

Synonyms

Polydimethylsiloxane

Definition

Fluid of lower density than water which is used in vitreoretinal surgery for various indications as vitreous tamponade

Epidemiology

Silicone oil as vitreous tamponade is used worldwide, especially for retinal detachment with proliferative vitreoretinopathy (PVR), severe diabetic retinopathy, giant tears, or severe trauma.

History

Silicone oil as vitreoretinal tamponade was introduced by Cibis in 1962, before pars plana vitrectomy was established. By injection of silicone oil into the vitreous cavity along with transscleral drainage of subretinal fluid, the hydraulic forced allowed reattachment of the retina (Cibis et al. 1962).

When pars plana vitrectomy was introduced in 1971 and further developed, Haut established the combination of pars plana vitrectomy and silicone oil endotamponade.

There was a discussion on possible toxicity of silicone oil that led to temporary withdrawal of FDA admission in 1966. This possible toxic effect was mainly due to short-chained silicone oils (Capone and Aaberg 1995).

Nowadays, purified long-chained silicone oil (>2,4 kDa) shows no toxicity, and there are various reports on long-term tamponade by silicone oil.

Clinical Features

There are several types of different silicone oil used for endotamponade. The most common are 1000 cst and 5000 cst silicone oil, with Stoke being the unit for kinetic viscosity (cst = 1 mm^2/s)

Additionally, heavy silicone oil with a higher-than-water-density is becoming more popular to treat inferior retinal detachment with PVR.

As silicone oil is not absorbed, it has to be removed during a second surgery.

Complications of silicone oil used as endotamponade are emulsifications which occur during long-term tamponade and cause secondary glaucoma. These emulsifications may also be found in optic nerve structures in some cases.

Additionally, silicone oil may induce endothelial cell loss of the cornea when in contact with corneal endothelium. Therefore, displacement of silicone oil into the anterior chamber has to be avoided; otherwise, corneal edema and secondary corneal ulceration may occur.

Tests

Biocompatibility of silicone oil has been shown in numerous studies. One study mentioned vacuoles of silicone oil in retinal tissue. These vacuoles are nowadays believed to be preparation artifacts.

Differential Diagnosis

"Silicone" must not be confused with "silicon," which is the chemical element with the symbol Si.

Etiology

The term "silicone oil" refers to polydimethylsiloxane. There are short-chained oils that may induce phagocytosis and inflammation. Therefore, nowadays only purified long-chained silicone oil is used.

Treatment

In ophthalmology, there are several indications for endotamponade with silicone oil, the most prominent being retinal detachment with PVR, severe diabetic retinopathy, rubeosis iridis, and severe trauma.

Synonyms

Polyorganosiloxane; Polysiloxane

Definition

A broad family of synthetic organosiloxane polymers containing a repeating silicon-oxygen backbone with organic side groups attached via carbon-silicon bonds. Depending on their structure, silicons are classified as liquids, gels, and elastomers.

Epidemiology

Soft contact lenses, intraocular lenses, and oil tamponades made of silicone are produced and used throughout the world.

History

At the beginning of the twentieth century, chemist F. S. Kipping experimented with the element silicon and its compounds. Thereby, he discovered substances similar to resin and named them "silicon ketones." In 1940, E. G. Rochow and R. Mueller found a way for industrial fabrication of methylchlorosilanes. Quickly after commercial availability of silicone materials in 1946, methylchlorosilanes were described to treat glassware to prevent blood from clotting. At the same time, F. Lahey implanted a silicone elastomer tube for duct repair in biliary surgery. Since these pioneers, interest for silicones in medical applications has remained because of their recognized biocompatibility. In 1962, silicone oil was introduced into vitreoretinal surgery as an endotamponade by P. A. Cibis (Cibis et al. 1962). As an intraocular lenses material, silicone has been used since the early 1980s with Food and Drug Administration (FDA) approval obtained in 1990. The first silicone-hydrogel soft contact lens was launched in 1999 onto the market. This new material encapsulated the benefits of silicone with the extremely high oxygen permeability with the comfort and clinical performance of the conventional hydrogels which had been used for soft contact lenses the previous 30 years.

Clinical Features

Silicones show good electrical insulation; thermal stability; excellent resistance to oxygen, ozone, and UV light; low chemical reactivity; low toxicity; and high gas permeability and do not stick. In medical devices and pharmaceutical applications, silicones are used because of their biocompatibility in a wide variety of physical forms. These forms range from volatile and low oligomers to high molecular weight polymers with viscosities from 0.65 to 20 $\times$ 106 cSt to viscoelastic compounds and cross-linked elastomers.

Tests

Biocompatibility of silicone materials has been shown in numerous studies.

Differential Diagnosis

"Silicone" must not be confused with "silicon," which is the chemical element with the symbol Si.

Etiology

The term "silicone" refers to "silicon ketone" and was coined by F. S. Kipping to describe polydiphenylsiloxane by analogy of its formula Ph_2SiO.

Treatment

In ophthalmology, most important silicon products are soft contact lenses, intraocular lenses, endotamponades for vitreoretinal surgery, and punctum plugs.

Definition

Clinical single-photon emission computed tomography (SPECT) is the use of gamma ray-emitting radiopharmaceuticals to produce functional imaging of an organ or tissue of the human body. In SPECT, the selected injectable radioisotope emits a single photon of gamma radiation as it decays. These emitted rays travel outside of the body and are received by the

surrounding detectors which translate the signal into a 2D horizontal, cross-section image. Many of these images are compiled and reconstructed to make a functional 3D image. In SPECT imaging, disease or aberrant structures can be seen as abnormally bright or dark regions within an image (focal deficit of the radiotracer).

In contrast to conventional structural imaging like CT or MR scans, SPECT allows for functional imaging which reveals characteristics such as glucose metabolism, blood flow, and receptor concentrations at different points in the body. However, unlike structural imaging, SPECT alone does not provide sufficient spatial resolution for accurate topographical localization like x-ray-based computed tomography (CT) scanning. Therefore, a SPECT study is typically combined with a matching CT scan (referred to as SPECT/CT) for the purpose of combining functional and anatomical imaging. The result is a combined image with identification of a functional abnormality on SPECT that is correlated with a structural localization on CT.

History

The first gamma-ray scanning device using a calcium tungstate scintillator was developed in 1949 by Cassen et al. Two years later, clinical usage of a commercial-based scanner, based on Cassen's design, was developed by Reed-Curtis. These early gamma scanning devices used only a single detector; however, multi-detector devices started to emerge after the development of the first computer-controlled dual-detector scanner from Kuhl and Edwards at the University of Pennsylvania in 1964. In the following years, commercial industries began to build multi-detector scanners in attempt to improve image quality and resolution in the following years.

Basic Mechanism

A selected radiopharmaceutical is injected into the patient. As the radioisotopes decay, gamma rays are emitted and are first passed through a collimator to filter out indirect rays which, if unfiltered, would result in excess noise in the computed image. The filtered rays deposit their energy into a scintillation crystal that converts the emitted gamma rays into multiple visible light photons which move through the crystal to an arrangement of high-sensitivity photomultiplier tubes (PMTs). After receiving these visible photons, each of the PMTs produces an electrical current proportional to the amount of photons it detects. Computational software collects the inferred points of emission of each photon and translates each to a specific location in a 2D image. Multiple 2D image cross sections are reconstructed to produce a functional 3D image.

Clinical Uses

SPECT may be used for bone analysis studies, brain studies, and myocardial perfusion. In bone SPECT, uniform distribution of the radioisotopes indicates a normal result, while focal uptake might be indicative of an abnormality (e.g., neoplasm). In brain SPECT, abnormalities can be seen as hypoactivity (e.g., hypoperfusion) or hyperactivity in various regions. Myocardial perfusion SPECT utilizes two different radioisotopes, Thallium-201-TiCl and Technetium-99m-sestamibi, and images the heart at rest and at stress, respectively. Abnormalities can be identified by comparing the two studies. Many SPECT studies use various forms of the radioisotope Technetium-99m.

Comparison with PET

The radioisotopes emitting single photons used in SPECT differ from those used in the related nuclear imaging process of positron emission tomography (PET) where positrons emitted from radioisotopes undergo annihilation to produce two gamma photons. Using only a single gamma photon per decay event, SPECT has a lower image resolution than PET. However, SPECT imaging is more widely available and less expensive than PET systems.

Radiopharmaceuticals for SPECT imaging are likewise more affordable, are longer-lived isotopes, and can involve a large variety of isotopes and tracer compounds. However, PET is usually the preferred imaging method in research applications due to its higher resolution (See "► Positron Emission Tomography").

Paranasal sinuses

Definition

The paranasal sinuses comprise of the ethmoid sinus, frontal sinus, maxillary sinus, and sphenoid sinus.

Structure

The nasal sinuses are lined with pseudostratified ciliated columnar respiratory epithelium with many goblet cells. They arise from and drain into the nasal cavity. The drainage is facilitated by cilia hairs.

The paranasal sinuses surround the nasal cavity and drain into the nasal cavity. The nasal wall is composed of the superior, middle, and inferior turbinates that appear as bulbous projections into the central space. The turbinates divide the nasal cavity into three air passages: the superior, middle, and inferior meati. These are inferior to each respective turbinate.

The frontal sinus is not seen radiographically until the sixth year of life, and pneumatization is not complete until early adulthood. The frontal sinus empties into the middle meatus. The right and left frontal sinuses are separated by the intersinus septum.

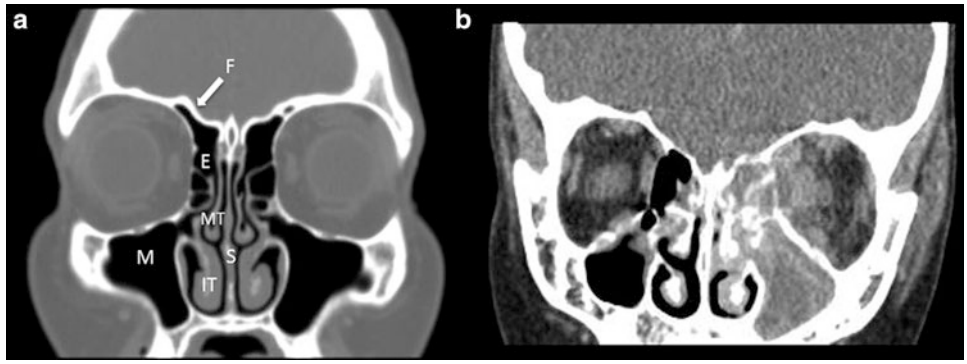
The ethmoid sinus is located between the orbit and the nose. It consists of ethmoid air cells that lie between the medial orbital wall and lateral wall of the nose. They expand in the early years of childhood and can extend into the frontal, lacrimal, and maxillary bones. The anterior and middle air cells drain into the middle meatus; the posterior air cells train in the superior meatus. It is often from the ethmoid sinuses that orbital cellulitis develops.

The sphenoid sinus is the most posterior sinus and is located immediately inferior and medial to the optic canal and internal carotid artery. It is embedded into the clivus. The sinus develops through childhood reaching its full size at puberty. It drains into the sphenoethmoidal recess of each nasal fossa, which lies just lateral to the nasal septum.

The maxillary sinus is the largest of the paranasal sinuses and forms the floor of each orbit. The infraorbital nerve and artery travel along the roof of the sinus and floor of the orbit from the inferior orbital fissure. The sinus drains into the middle meatus of the nose through the maxillary ostium (Fig. 1).

Function

The sinuses function to warm and humidify the air, trap irritants, lighten the weight of the skull, act as a resonating chamber for the voice, and



Sinuses, Fig. 1 (**a**) CT Sinus demonstrating sinus anatomy. *M* maxillary sinus, *F* frontal sinus, *E* ethmoid sinus, *S* septum, *IT* inferior turbinate, *MT* middle turbinate. (**b**) CT Sinus of a 12-year-old male with severe sinusitis demonstrating dense opacification of the anterior and posterior ethmoid air cells, left greater than right, and complete opacification of the left maxillary sinus. In addition, there is also a medially based small subperiosteal abscess that ultimately required surgical drainage

provide protection for the brain in the case of trauma.

Clinical Relevance

Understanding the anatomy of the sinuses is relevant in ophthalmology as it is through the sinuses that orbital tumors or orbital infections often spread. Pathophysiologic processes of the sinuses that secondarily affect the orbit include sinonasal carcinomas, inverted papillomas, zygomycoses, Wegener granulomatosis, mucoceles, and sinusitis which may cause orbital cellulitis or abscesses. Orbital fractures also usually prolapse into the sinuses.

Bacterial orbital cellulitis is most commonly caused by spread of infection in the ethmoid sinus either into the orbit directly through the lamina papyracea or via the anterior or posterior ethmoidal vessels. The frontal, sphenoid, and maxillary sinuses are less often the culprit. Orbital complications of paranasal sinusitis can include superior ophthalmic vein thrombosis, cavernous sinus thrombosis, and blindness, although these are rare.

Mucoceles can develop in the frontal sinus when there is obstruction of the sinus drainage. This can lead to displacement of the orbital contents inferiorly and laterally over time.

Inferior orbital floor fractures, or blowout fractures, cause prolapse of orbital tissues into the maxillary sinus. This is why it is recommended not to blow one's nose if there is an inferior floor fracture to avoid causing orbital emphysema. The infraorbital nerve can also be injured in these fractures causing hypesthesia of the cheek and upper gingiva.

Given how close the sphenoid sinus is to the optic nerve, sphenoid sinusitis may cause damage to the optic nerve.

Sipple Syndrome

▶ Sipple-Gorlin Syndrome, Enlarged Corneal Nerves

Sipple-Gorlin Syndrome, Enlarged Corneal Nerves

Hyunjoo Jean Lee
Department of Ophthalmology, School of Medicine, Boston University, Boston, MA, USA

Synonyms

Multiple endocrine neoplasia (MEN) 2B; Sipple syndrome

Definition

Enlarged corneal nerves are stromal corneal nerves visible at the slit lamp that appear thickened, beaded, or to have perineural inflammation. Sipple-Gorlin syndrome (MEN 2B) is an autosomal dominant disease characterized by medullary carcinoma of the thyroid gland, pheochromocytoma, and mucosal neuromas. Ophthalmic findings in MEN 2B syndrome can include enlarged corneal nerves, conjunctival and eyelid neuromas, thickened upper eyelids with mild ptosis and eversion of the eyelid margins, and keratoconjunctivitis sicca. Other typical features of MEN 2B include marfanoid habitus and a long history of diarrhea and/or constipation (Eter et al. 2001; Kim and Dohlman 2001; Parker et al. 2004).

Etiology

Enlarged corneal nerves are most importantly associated with MEN 2B (Sipple-Gorlin syndrome). MEN 2B is inherited in an autosomal dominant pattern and is associated with high mortality from metastatic thyroid carcinoma, with reported 5-year survival rates of 35%. Up to 60% of cases of MEN 2B are associated with de novo mutations (Eter et al. 2001). Mutations in the *RET* proto-oncogene on chromosome 10 are associated with MEN 2B. Familial medullary thyroid cancer patients, who have medullary thyroid cancer but do not have pheochromocytomas, also often have enlarged corneal nerves. Patients with MEN 2A have occasionally also been noted to exhibit mildly enlarged corneal nerves (Kim and Dohlman 2001).

The prominent corneal nerves in MEN 2B have been found to consist of an increased number of nonmyelinated axons in close association with Schwann cells (Spector et al. 1981).

Other diseases associated with enlarged corneal nerves include Refsum syndrome (phytanic acid storage disease), leprosy (Hansen disease), familial dysautonomia (Riley-Day syndrome), neurofibromatosis type 1, and *Acanthamoeba* keratitis (Kim and Dohlman 2001). Corneal nerves may be more visible but not necessarily enlarged in keratoconus, ichthyosis, Fuchs endothelial dystrophy, posterior polymorphous corneal dystrophy, corneal edema, herpes simplex, herpes zoster, and congenital glaucoma (Eter et al. 2001).

Occurrence

Enlarged corneal nerves are a ubiquitous manifestation of MEN 2B. All patients described in the literature with MEN 2B have displayed enlarged corneal nerves. In MEN 2B, the enlarged corneal nerves are usually present in the first decade and have been detected as early as 2 years of age. Seven of 11 members of a family with familial medullary thyroid cancer, without the other manifestations of MEN 2B, were found to have enlarged corneal nerves. Enlarged corneal nerves are less often a manifestation of other conditions in an otherwise normal-looking cornea.

Classification

In MEN 2A medullary thyroid cancer occurs with pheochromocytoma and hyperparathyroidism. In MEN 2B medullary thyroid cancer occurs with pheochromocytoma and hyperparathyroidism and in addition, mucosal neuromas, marfanoid body habitus, gastrointestinal ganglioneuromatosis, and ophthalmic abnormalities.

Synonyms

Abducens nerve palsy; Cranial sixth nerve palsy; Lateral rectus palsy; Sixth nerve palsy

Definition

Abducens nerve palsy is dysfunction of the sixth cranial nerve which provides the motor innervations to the ipsilateral lateral rectus muscle. It has a long subarachnoid course and is thus susceptible to dysfunction from increased intracranial pressure. The sixth nerve nucleus is located ventral to the floor of the fourth ventricle and lateral to the medial longitudinal fasciculus (MLF) at the level of the pons. The nucleus provides innervation via the MLF to the contralateral third nerve nucleus and medial rectus muscle to coordinate horizontal gaze. The fascicle of the sixth nerve travels ventrally and exits the pons into the subarachnoid space then proceeds rostrally along the clivus and turns to enter the substance of the cavernous sinus lateral to the internal carotid artery but medial to the dural wall of the cavernous sinus. From the cavernous sinus, the sixth nerve enters the orbit via the superior orbital fissure to innervate its target extraocular muscle, the lateral rectus muscle.

Etiology

The most common cause of an isolated sixth nerve palsy in adults over age 50 years is ischemic. In one population-based study, the causes of sixth nerve palsy were as follows: hypertension alone (19%), concomitant hypertension and diabetes (12%), trauma (12%), multiple sclerosis (7%), neoplasm (5%), diabetes alone (4%), cerebrovascular accident (4%), post-neurosurgery (3%), aneurysm (2%), and other miscellaneous causes (8%). Sixth nerve palsy was the presenting sign in only one case of neoplasm and in three aneurysms. In contrast to adults, neoplasm is one of the leading causes of sixth nerve palsy in children.

Given the anatomical position of the sixth cranial nerve within the substance of the cavernous sinus, it is believed to be more vulnerable than other cranial nerves which are relatively more protected in the dural wall of the cavernous sinus. In addition, intracavernous pathology (e.g., carotid aneurysm, meningioma, carotid-cavernous fistula) can present with sixth nerve palsy with or without concurrent Horner's syndrome or other ocular motor cranial neuropathies or trigeminal neuropathy. As noted previously, a unilateral or bilateral sixth nerve palsy can also present as a non-localizing sign of increased intracranial pressure (e.g., idiopathic intracranial hypertension). In addition, an isolated sixth

nerve palsy can also occur due to clivus lesions (e.g., chordoma, meningioma). Thus, an isolated and especially chronic or progressive sixth nerve palsy can be a harbinger of underlying neoplasm without other neurologic signs or symptoms. Despite modern neuroimaging techniques, however, up to 25% of cases remain of undetermined etiology. Serial imaging might still be necessary in progressive or chronic cases with special attention to the cavernous sinus or clivus.

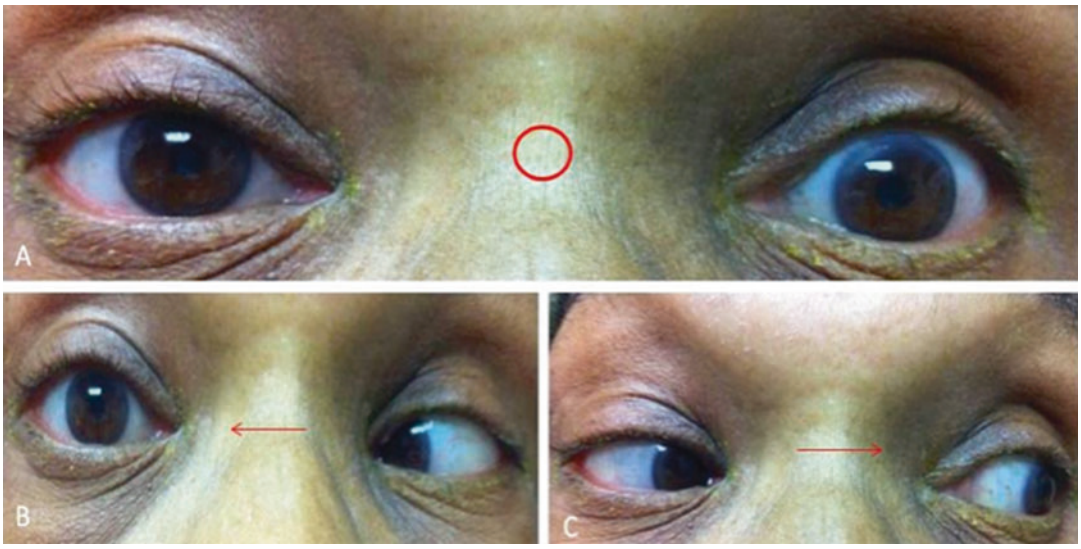
Clinical Presentation

Patient with a sixth nerve palsy usually present with binocular, horizontal diplopia that is worse with gaze in the direction of action of the impaired lateral rectus muscle (see Fig. 1). Extraocular muscle examination usually shows an esotropia (ET) in the primary position that worsens (laterally incomitant ET) with gaze in the direction of the affected lateral rectus muscle. Thus, the patient may present with an anomalous face turn to minimize the diplopia by looking away from the affected lateral rectus muscle. In addition to the diplopia, the patient may have other symptoms (e.g., headache, facial numbness) or signs (e.g., ptosis, facial nerve palsy, trigeminal numbness, anisocoria) depending on the localization of the sixth cranial nerve lesion. Thus, one of the critical components of the evaluation of a sixth nerve palsy is to insure that it is truly neurologically isolated or conversely to anatomically localize the lesion based on the accompanying symptoms or signs.

Diagnostics

The evaluation for an isolated and presumed vasculopathic sixth nerve palsy is controversial but many sources suggest that watchful waiting for improvement is appropriate for up to 2–3 months when vasculopathic risk factors are present. However neuroimaging (preferably contrast-enhanced MRI of the brain following the course of the sixth nerve) is indicated if the sixth nerve palsy is not neurologically isolated and is progressive or if the presumed vasculopathic sixth nerve palsy fails to improve or worsens after the initial observation. Atrophy of the lateral rectus muscle is seen in denervation atrophy and can be a radiographic sign of chronic and long-standing sixth nerve palsy.

An emergent head CT may be preferred over MRI in some settings especially when there is a history of trauma or if evaluation of orbital disease, sinus, bone, acute bleeding, or foreign body



Sixth Nerve Palsies, Fig. 1 Patient with left sixth nerve palsy with esotropia in the primary position that worsens in the direction of affected lateral rectus muscle.

is required. However, typically in nontraumatic cases, if there is no contraindication to MRI, then a cranial MRI with contrast is the imaging modality of choice for sixth nerve palsy.

Other diagnostic testing obviously could be considered depending on the suspected etiology. For example, an MRV may be necessary if increased intracranial pressure due to possible cortical venous sinus thrombosis is suspected (e.g., sixth nerve palsy with papilledema). A lumbar puncture might also be indicated if the neuroimaging is negative or suggestive of increased intracranial pressure or meningeal disease. Laboratory studies may be considered depending on the clinical presentation including complete blood cell (CBC) count, erythrocyte sedimentation rate, and/or C-reactive protein (in elderly patients suspected of having giant cell arteritis), rapid plasma reagin (RPR) test or fluorescent treponemal antibody-absorption test (FTA-ABS) for syphilis, or Lyme titer. Because thyroid eye disease could mimic the abduction deficit and esotropia of sixth nerve palsy, thyroid function tests and orbital imaging (e.g., orbital ultrasound or CT of the orbit) might be useful. Myasthenia gravis (MG) can mimic any painless, pupil-spared ophthalmoplegia including sixth nerve palsy, and evaluation for MG might include anti-acetylcholine receptor antibodies, edrophonium (Tensilon) or ice testing, neurologic consultation, etc (Patel et al. 2004; Lee et al. 2009; Gonçalves et al. 2002).

Differential Diagnosis

1. Thyroid eye disease (restrictive involvement of the medial rectus muscle)
2. Idiopathic intracranial hypertension (non-localizing sixth nerve palsy)
3. Giant cell arteritis (myogenic or neurogenic ischemic)
4. Myasthenia gravis
5. Duane syndrome
6. Convergence spasm (papillary miosis, variable deviation)

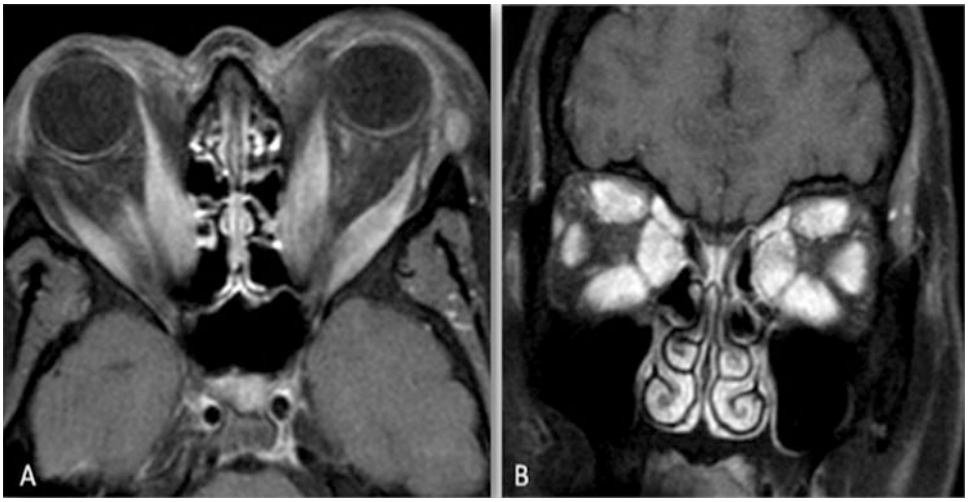
Thyroid Eye Disease (TED)

A restrictive myopathy of the medial rectus muscle (rather than a paretic sixth nerve process) can produce an incomitant esotropia, an abduction deficit, and a deviation worse in the direction of the presumed paretic lateral rectus muscle that can mimic a sixth nerve palsy. TED is an autoimmune disorder that causes an inflammatory enlargement and secondary fibrotic contraction of the extraocular muscles. Although the inferior rectus is the most commonly affected muscle (resulting in restriction on upgaze and hypotropia), the medial rectus is the second most affected muscle in TED and thus can present with abduction deficit resembling a sixth nerve palsy. Restrictive myopathy (TED) can be differentiated from an acute isolated paretic sixth nerve palsy with forced duction testing or saccadic testing (restrictive saccade versus slowed, paretic saccade). Patients with a presumed sixth nerve palsy especially with a history of autoimmune thyroid disease should be evaluated for the presence or absence of other signs of TED (e.g., lid retraction, lid lag, chemosis, conjunctival injection, proptosis, compressive optic neuropathy, etc.)

TED usually results in bilateral symmetric enlargement of multiple extraocular muscles with sparing of the tendon that can be seen radiographically on CT, MR, or ultrasound (see Fig. 2) of the orbits. Although cranial MRI with contrast is the imaging study of choice for unexplained sixth nerve palsy, an orbital study could be added to the MR scan if there is some doubt about potential TED mimicking sixth nerve palsy.

Idiopathic Intracranial Hypertension (IIH), Also Known as Pseudotumor Cerebri (PTC)

An isolated unilateral or bilateral sixth nerve palsy can be a non-localizing sign of increased intracranial pressure (ICP) and occurs in approximately one fourth of cases of IIH. Other associated signs and symptoms of increased ICP may include headache, transient visual obscurations, or tinnitus. Patients with suspected increased ICP should be evaluated for papilledema, rarely choroidal folds, and nerve fiber visual field defects on formal visual field testing. Radiographic signs of increased ICP might include an empty sella, flatting of the posterior globe, and visible cerebrospinal fluid within the optic nerve sheath. An elevated opening pressure with normal cerebrospinal fluid content in the setting of normal neuroimaging (except for signs of



Sixth Nerve Palsies, Fig. 2 Thyroid eye disease with bilateral enlargement of multiple extraocular muscles.

elevated ICP) is diagnostic of IIH and is a common cause of sixth nerve palsy in adults with papilledema (Quattrone et al. 2006).

Giant Cell Arteritis (GCA)

Although sixth nerve palsy is a rare presentation of GCA, other signs and symptoms of GCA (e.g., headache, jaw pain, visual loss) should be sought in elderly patients with a sixth nerve palsy. Stat serum ESR and CRP, empiric steroid therapy, and a temporal artery biopsy may be necessary.

Myasthenia Gravis (MG)

MG is an autoimmune neuromuscular junction disorder that can produce any pattern of pupil-spared, nonproptotic ophthalmoplegia and can mimic a sixth nerve palsy. Variability and fatigability are the key differentiating symptoms of myasthenia gravis. Other common symptoms (e.g., ptosis, generalized weakness, difficult breathing) and signs (variable ptosis, orbicularis weakness, the Cogan lid twitch sign, enhancement of ptosis) of MG should be evaluated. Patients with suspected MG might require laboratory or other testing for MG.

Therapy

The vasculopathic, isolated sixth nerve palsy in adults typically resolves over time, and recovery is often completed within 3–6 months. Other sixth nerve palsies may improve over time depending on etiology (e.g., postviral, posttraumatic, demyelinating, or idiopathic often improve). For vasculopathic patients, control of the underlying vasculopathic risk factors (e.g., hypertension, diabetes, hyperlipidemia), lifestyle modifications (e.g., weight loss, exercise, smoking cessation), and perhaps a daily aspirin (if no contraindication) are recommended. Prism and patching therapy are the first-line conservative treatments for symptomatic diplopia. *Botulinum* toxin injection could be considered as temporizing measure especially for traumatic sixth nerve palsy as relaxing the medial rectus may allow the lateral rectus time to better recover function. Strabismus surgery is generally reserved for patients who fail, are intolerant to, or noncompliance with patching or initial prism therapy and who have stable ocular deviations.

Prognosis

The majority of idiopathic sixth cranial nerve palsies resolve within 3 months, with vasculopathic sixth nerve palsy more likely to resolve (up to 86%). Sixth nerve palsy however depending on etiology may recur in up to 1/3 of patients, and these patients may require repeat diagnostic evaluations. Patients with progression, bilateral involvement, or lack of recovery should undergo further evaluation including

neuroimaging. Spontaneous recovery within days would be atypical but can be seen in myasthenia gravis or in some mimickers of sixth nerve palsy (e.g., convergence spasm). Recurrent isolated vasculopathic sixth nerve palsy is uncommon but has been reported, and in diabetics recurrent sequential ocular motor cranial mononeuropathies are not uncommon. Multiple simultaneous or rapidly sequential cranial neuropathies however are atypical and should prompt further evaluation for additional diagnoses (Sanders et al. 2002).

Epidemiology

Sixth nerve palsy is the most common ocular motor palsy (representing up to 40–50% of ocular motor neuropathy). The annual incidence of sixth nerve palsy may be up to 11.3 per 100,000 and can affect all age groups, either gender, and any race. The etiology will vary in part depending on the age with ischemic etiologies being more common in older populations and congenital and postviral causes more prevalent in children.

Synonyms

Hertwig-Magendie sign

Definition

Skew deviation is a vertical deviation that is caused by a lesion to the brainstem, cerebellum, or vestibular system (Wong 2010). The injury can be uni- or bilateral in nature and will result in a misalignment of the vertical axis. There may also be a compensatory head tilt (i.e., the ocular tilt reaction) and torsion (typically bilateral and toward the hypotropic eye) (Brodsky et al. 2006).

Etiology

Skew deviation is primarily seen in older patients who have suffered a stroke that affects the brainstem, but other lesions in the posterior fossa may produce skew (e.g., multiple sclerosis, tumor, trauma, abscess, hemorrhage, or surgical complications) (Brodsky et al. 2006). Rarely, the skew deviation can also come from an acute unilateral vestibular lesion (Brodsky et al. 2006).

Clinical Presentation

Skew deviation often presents as part of the clinical triad including the vertical deviation (typically not localizing to any one extraocular muscle or ocular motor cranial nerve distribution), ocular torsion, and head tilt (Wong 2010). These hallmark signs can be accompanied by torticollis and subjective visual vertical (Brodsky et al. 2006).

Diagnostics

Skew deviation shares many common features with other conditions, and so it is necessary to conduct thorough testing to make the proper diagnosis. Using the double Maddox rod test, a point source of light appears as two red or white (depending on the color of the rod) horizontal streaks (Parulekar et al. 2008). If one or both horizontal streaks were perceived as slanted, the subject is then instructed to rotate the orientation of the rods until the streak(s) becomes parallel horizontally (Parulekar et al. 2008). Ocular torsion and vertical misalignment that decrease from the upright position to the supine position may also indicate skew deviation, whereas torsion and vertical misalignment that do not change significantly between positions are more consistent with trochlear nerve palsy (Parulekar et al. 2008).

Next, the magnitude of vertical strabismus can be measured using the prism and alternate cover test. To properly conduct this test, the patient must not adopt their usual tilted head posture and must sit straight up with their chin parallel to the ground. Prisms of increasing power are then placed over the deviated eye while the cover alternates between the eyes (Parulekar et al. 2008). The highest prism strength when no refixation movement occurred is then recorded.

Differential Diagnosis

(a) Superior oblique palsy
(b) Inferior oblique palsy
(c) Superior division third nerve palsy
(d) Third nerve palsy
(e) Trochlear nerve palsy

Prophylaxis

Therapy

The treatment of skew deviation is directed against the etiology (Brodsky et al. 2006). Some effective treatments for symptomatic diplopia include patching, prisms, botulinum toxin, and vertical rectus muscle recession (Brodsky et al. 2006).

Prognosis

Prognosis for recovery is viable for patients with skew deviation. Seventy percent of patients will recover with a median time of 7.5 months depending on the underlying etiology (Borruat et al. 1998). Surgery should be postponed at least 12 months (Borruat et al. 1998).

Epidemiology

The prevalence of skew deviation depends on the etiology and may occur in any age, or either gender, and may affect any race.

Snap test

Definition

The snapback test is a diagnostic procedure utilized in the assessment of eyelid tone and severity of horizontal eyelid laxity.

Purpose

The snapback test is an important part of the preoperative evaluation of involutional eyelid malposition. The ability to identify the severity of eyelid malposition aids in the selection of a surgical repair procedure suitable for each individual. The snapback test may also help in the differentiation of various causes of eyelid malposition (Bartley 1995). Involutional entropion is usually associated with eyelid laxity, while eyelid malposition secondary to cicatricial changes occurs due to eyelid rotation from inflammatory scarring of the eyelid. Fibrous scar tissue increases resistance to traction, which correspondingly increases the difficulty with pulling the eyelid away from the globe in the snapback test, compared to increased ease in cases of involutional entropion.

Principle

The underlying principle of the snapback test is based upon the intrinsic elastic properties of normal tissue. The lower eyelid spans the medial and lateral canthi, and apposition to the globe is normally conferred through the normal tone and elasticity of the eyelid. A decrease in elastic fibers with ultrastructural abnormalities and an overexpression of elastin-degrading enzymes with age results in loss of eyelid tone, and elasticity in involutional ectropion and entropion results in eyelid malposition (Nagi et al. 2011).

Procedure

1. Pull the lower eyelid down and away from the globe for 2–3 s before releasing the eyelid.
2. Assess the time it takes for the eyelid to return to its original position, or the new resting position if the eyelid does not return to its original position. This should be completed without the patient blinking.

Grades

0. Returns to original position immediately
1. Returns to original position in 2–3 s
2. Returns to original position in 4–5 s
3. Returns to original position in >5 s
4. Does not return to original position, remains in a position of ectropion

Indication

Clinical and preoperative evaluation of eyelid laxity and eyelid tone in involutional eyelid malposition.

Contraindication

The snapback test is a simple, noninvasive, and low-risk diagnostic test that is easily incorporated into the clinical examination of the patient with involutional eyelid malposition. Nevertheless, the test should only be performed in patients who have indicated consent to the procedure. The test is contraindicated in cases when pressure around the periocular area should be avoided or when the integrity of the eyelid tissue is compromised. Non-exhaustive examples of such situations include eyelid or periocular trauma and suspicion for globe rupture.

Advantage/Disadvantage

Advantage

The snapback test is simple, easy to learn, and cost-effective and provides a quick and relatively reliable clinical assessment of eyelid malposition that helps with the clinical evaluation and preoperative assessment of patients who are suitable surgical candidates.

Disadvantage

The snapback test grossly evaluates for the presence of eyelid laxity but does not specifically localize the region in which laxity is greatest,

which may alter the surgical plan for repair of eyelid malposition. Additional tests such as lateral and medial traction of the eyelid with observation of punctal displacement may aid with localization of eyelid laxity.

Snellen Acuity

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Snellen ratio

Definition

For a long time, the visual acuity (VA) chart designed by Herman Snellen in 1862 was the reference chart for VA testing. The basis for the construction of the Snellen chart was an angular subtense of 5 arcmin (5′) of letter height and width (which equals an angle of resolution of 1′ because the stroke width of the letter is one fifth of the height). Snellen considered the angle of 1′ as reference, although many healthy subjects are able to recognize smaller angles. Snellen visual acuity is defined by the equation

$$\mathrm{VA} = d/d_s$$

where d is the distance under which the subject the letter and d_S is the distance under which letter height subtends an angle of 5′ (► MAR 1′). For example, if a subject reads a letter row the letters subtend an angle of 5′ at a testing distance of 6 m, the ratio reads 6/6. If another subject just recognizes the letter row where the angles subtend 5′ at a distance of 12 m (or 10′ at 6 m), the ratio would read 6/12. Another form of expressing Snellen acuity is a fraction of $20/d_S$, based on the testing distance of 20 ft. The decimal form of visual acuity (1/MAR) is equal to the result of the Snellen fraction, because Snellen chose 1′ as reference.

Solid-State Lasers

Rahul Yadav
Department of Ophthalmology, Center for Visual Sciences, University of Rochester, Rochester, NY, USA

Definition

Solid-state laser is the term used for lasers, which have a solid gain medium, instead of liquid or gaseous gain medium. Although laser diodes also have a solid semiconductor-based gain medium, they are not classified as solid-state laser as the mode of operation of these lasers is different from solid-state lasers.

Overview

The very first laser demonstrated by Maiman was a solid-state laser, which used ruby crystal (Cr^{3+}:Al_2O_3) as the gain medium. Soon afterward neodymium-doped yttrium aluminum garnet, Nd:$Y_3Al_5O_{12}$ (Nd:YAG)-based laser was developed which has become one of the most popular solid-state laser. In the past three decades, new gain mediums based on rare earth ions (Er^{3+}, Tm^{3+}, Ho^{3+}, and Yb^{3+}) and transition metal ions (Cr^{3+} and Ti^{3+}) in a variety of host crystals have been discovered. The emission wavelength of the laser depends on the interaction of the electrons in the metal ion with the electrostatic field in the host crystal. A variety of doping ions and host crystals has enabled solid-state lasers, which emit in UV, visible and NIR wavelengths. To further diversify the emission wavelengths many times, the solid-state lasers are used with nonlinear wavelength conversion techniques such as generation of higher harmonics, sum and difference frequency generation, and optical parametric processes. Tunable solid-state lasers have also been developed using intra-cavity techniques such as using gratings or etalons inside the cavity. Titanium-doped sapphire (Ti-sapphire) laser is a widely used tunable solid-state laser with a tuning range from 660 to 986 nm. Most of the tunable solid-state lasers use gain medium with transition metal ions.

Pumping

Traditionally solid-state lasers were pumped using arc or flash lamps; however, this pumping technique leads to low-power efficiency. Also flash lamps have low lifetime and produce a lot of heat. Recently pumping using laser diodes has gained popularity. Such lasers are called diode-pumped solid-state lasers (DPSS) and offer various advantages over traditionally pumped solid-state lasers, which includes compact design, higher lifetime, and very good beam quality.

Operation

Solid-state lasers can operate in pulsed or continuous wave (CW) or quasi-CW mode. Pulsed lasers generally use Xenon flash lamps for pumping. The high peak power intensity in the pulsed lasers is obtained by Q-switching. In Q-switching, the laser resonator is initially disabled, until the population inversion in the gain medium is complete. The cavity is then allowed to resonate for a short interval of time, during which high intensity pulse is emitted by the laser. The output of the pulsed laser is specified in joules of energy per pulse. To calculate the output power, the energy per pulse is to be multiplied by pulse repetition rate per second. It should be noted that although high peak intensity can be achieved in pulsed solid-state lasers, the average power output for these lasers is quite low.

CW solid-state lasers provide higher average power output as they use diode lasers for pumping, which is very efficient. Arc lamps may also be used for pumping, but this approach is now becoming obsolete as the output power is

low. Quasi-CW lasers are pulsed lasers with very high pulse repetition rate (10–100 KHz) such that the laser appears to be CW. Such high repetition rates are achieved by Q-switching though electro-optics in the laser cavity.

Applications in Ophthalmology

Solid-state lasers have been widely used in ophthalmology to precisely cut soft tissue or break it into smaller pieces. Many of the ophthalmic surgeries are now carried out using solid-state lasers. These surgeries include:

- Femtosecond pulsed solid-state lasers in cutting the flap for LASIK surgery, providing a more precise flap creation, thus reducing complications in the surgery. Corneal ablation for refractive correction however is still carried out using excimer laser, which is not a solid-state laser.
- Laser trabeculoplasty, where solid-state laser is used to burn the trabecular meshwork to increase fluid flow. Increased fluid flow leads to a reduction in intraocular pressure in Glaucoma
- Solid-state lasers are widely used in removing the posterior capsule opacification after cataract surgery by performing YAG capsulotomy.
- In the recent times, laser-assisted cataract surgery procedure has been developed where solid-state laser is used to break the cataract. This has made the surgery more predictable and precise.
- Retinal laser photocoagulation procedure is used in diabetic retinopathy patients. A pulsed solid-state laser beam is made incident on the retina. The resulting heat generated from the incident laser light seals or destroys the leaking blood vessels.

Solid-state lasers have revolutionized the way ophthalmic surgeries are carried out, making these surgeries more precise and controlled. Although solid-state lasers have been replaced by the more robust and compact diode lasers in many industrial CW applications, their superior performance in pulsed laser arena still makes them more suitable for medical applications. Many new areas of application have been explored with these lasers for ophthalmic surgeries, and it is expected that these laser will continue to play a crucial role improving the success rate of ophthalmic surgeries.

[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Definition

Spasmus nutans is usually a benign disorder, unaccompanied by neurologic abnormalities, defined by a triad of signs occurring in the first year of life that consists of pendular nystagmus and head nodding, and torticollis (Quiros and Yee 2014). However, the complete triad is not present in all patients (Quiros and Yee 2014).

Clinical Presentation

The nystagmus of spasmus nutans can be vertical, horizontal, or torsional with a frequency of 3–11 Hz and variable amplitude while varying from conjugated, monocular, and dissociated (eyes beat independent of each other) within a few minutes (Tamhankar and Liu 2008). The nystagmus is converted to a larger amplitude, slower, binocularly symmetrical, pendular oscillations with improved vision due to head nodding inducing vestibulo-ocular responses (Tamhankar and Liu 2008). However, the head bobbing occurs less frequently than the nystagmus, and is thus not considered a compensatory action (Lavin 2012).

Diagnostics

The diagnosis is one of exclusion. Diagnostics include careful clinical examination and electronic recordings of eye and head movements to differentiate spasmus nutans from congenital nystagmus (Tamhankar and Liu 2008). The nystagmus frequency is higher and the amplitude more variable in spasmus nutans (Tamhankar and Liu 2008). MRI studies may be warranted to differentiate spasmus nutans from CNS tumors in patients with accompanying visual loss, relative afferent papillary defect, optic atrophy, abnormal growth and development, or older age of onset (Tamhankar and Liu 2008).

Differential Diagnosis

Visual loss in children, intracranial tumors, congenital nystagmus, retinal disorders, spinocerebellar degeneration.

Prognosis

The syndrome typically resolves by age 1–2 years, but electronic eye movement recordings show small-amplitude, intermittent, dissociated pendular nystagmus that may be present until age 5–12 years (Tamhankar and Liu 2008).

Sphenoid Bone

Elizabeth Marlow[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Structure

The sphenoid bone is a compound bone that forms the base of the cranium and contributes to all walls of the orbit except the floor. It resembles a butterfly and consists of a central median portion, known as the body, which is flanked by a set of two greater and two lesser winglike projections that extend out laterally on either side. The lesser wing of the sphenoid contributes to the orbital roof along with the frontal bone, as well as to the medial wall along with the lacrimal, ethmoid, and maxillary bones. The greater wing of the sphenoid joins the zygomatic bone in forming in the orbit's lateral wall.

At the anterior surface of the sphenoid is the sphenoidal crest, which contributes to the nasal septum and is flanked by the openings of the two sphenoidal air sinuses that comprise the body of the sphenoid. On the most anterior extent of the superior surface of the body is the ethmoidal spine, which articulates with the cribriform plate of the ethmoid. Moving posteriorly on the superior surface, the ethmoidal spine is followed by a smooth surface with a slightly raised midline that creates a groove into which the olfactory bulbs rest. Directly posterior to the olfactory grooves is a transverse ridge that forms the anterior boundary of the chiasmatic groove (optic groove), which ends on either side in the optic foramen. The optic chiasm rests on the chiasmatic groove, and the optic nerve and ophthalmic artery are carried through the optic foramen into the orbital cavity. The optic foramen is the opening to the optic canal, which transmits the optic nerve, ophthalmic artery, and sympathetic fibers into the orbital cavity. The left and right optic canals are oriented 25 mm apart posteriorly and 30 mm apart anteriorly (Black et al. 2012).

Dorsal to the chiasmatic groove is a deep saddle-shaped depression known as the sella turcica that houses the pituitary gland (hypophysis). The anterior boundary of the sella turcica is formed by the two middle clinoid processes; the posterior boundary is formed by the dorsum sellae with two projecting tubercles known as the posterior clinoid processes. On the surface of the dorsum sellae is a notch along which the abducens nerve passes. Directly behind the dorsum sellae is the clivus, which articulates with the occipital bone and supports the pons. The posterior surface of the sphenoid body joins to the occipital bone by a plate of cartilage that becomes ossified by early adulthood (Mancall and Brock 2011).

The lesser wings of the sphenoid attach to the body anterior to the greater wings. Their superior surface supports the frontal lobe of the brain, while the inferior surface contributes to the posterior portion of the orbital roof and the superior orbital fissure. The levator palpebrae originates from the lesser wing of the sphenoid above the annulus of Zinn.

The greater wings of the sphenoid connect to either side of the lateral surface of the body. The carotid groove is at the anterior extent of this connection and lodges the internal carotid artery and the cavernous sinus. The superior surface of the greater wings contributes to the middle cranial fossa and contains the foramen rotundum and foramen ovale for the transmission of the maxillary (V2) and mandibular (V3) divisions of the

trigeminal nerve, respectively. The foramen spinosum at the posterolateral tip of the greater wing transmits the middle meningeal vessels and a recurrent branch of the mandibular nerve.

Along the inferior surface of sphenoid bone's greater wing is the orbital surface that forms the posterior aspect of the orbit's lateral wall, contributing the posterolateral boundary of the inferior orbital fissure, while its medial margin forms the lower boundary of the superior orbital fissure. Beneath the superior orbital fissure is a grooved surface forming the posterior wall of the pterygopalatine fossa. The pterygoid processes project from the posterior end of the greater wings.

Function

The sphenoid bone contributes to the base and sides of the skull as well as the floor and walls of the orbits. It is the site of attachment for most muscles of mastication. In addition, it contains fissures and foramen that are traversed by nerves and blood vessels supplying the head and neck.

Clinical Relevance

The optic canal, which is situated within the lesser wing of the sphenoid, serves to carry the optic nerve, ophthalmic artery, and sympathetic fibers into the orbital cavity. The optic nerve dura is continuous with the intracanalicular orbital periosteum, making it susceptible to transmitted force from blunt head trauma that can lead to traumatic optic neuropathy. The injury may be caused by shearing action or by swelling of the optic nerve within the optic canal that disrupts blood supply to the nerve. Orbital hemorrhage and optic nerve sheath hematomas can also precipitate traumatic optic neuropathy by direct compression (Levin et al. 2004).

The sella turcica houses a protrusion off the hypothalamus known as the pituitary gland. The optic chiasm lies on top of the pituitary gland and envelopes the pituitary stalk. Since the sella turcica forms a boney caudal border for the pituitary gland, pituitary tumors often extend upward into the suprasellar region where it can compress the optic chiasm leading to a bitemporal hemianopia, which is pathognomonic for a pituitary tumor in the absence of trauma. Empty sella syndrome is the condition of an underdeveloped pituitary gland.

Spheric Intraocular Lens

▶ Spherical Intraocular Lens

Spherical Equivalent

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

Synonyms

Best spherical lens

Definition

Spherical equivalent is the characteristic value of a spherocylindrical spectacle or contact lens which shows the astigmatic eyes ametropia, whether it's myopic or hyperopic. Spherical equivalent can be calculated from the prescription given by the spectacle lens. It is the arithmetic numeric value between the two principal meridians of an astigmatic lens.

Spherical Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Spheric intraocular lens; Spherical IOL

Definition

Spherical means having the morphological form of a sphere, globular. A spherical intraocular lens is an IOL that has a spherical shape (Auffahrt 2008).

Epidemiology

The number of implanted spherical IOLs is constantly decreasing since aspheric IOL designs are increasing and their superior optical quality especially in contrast sensitivity under mesopic conditions compared to spherical IOLs has been proven in various studies.

History

Since it has been known that the cornea with its prolate surface has a lower refractive index in its periphery in the 1970s and that the human cornea has a positive asphericity, aspheric lenses started to be developed with no or negative spherical aberration. In 2002 the Tecnis IOL (Advanced Medical Optics, AMO) was the first aspheric lens to receive Food and Drug Administration (FDA) approval in the USA. Since the advent of the original Tecnis IOL, two other aspheric monofocal lenses have joined the mix and received FDA clearance: the LI60 AO (Bausch and Lomb), which corrects a smaller amount of spherical aberration than the Tecnis, and the AcrySof IQ IOL (Alcon), which is designed to reduce spherical aberration that is induced by the IOL.

Clinical Features

Upon the optical aberrations of the eye, spherical aberration is the most important (el-Hage and Berny 1973). Regarding IOL design four different types of IOL must be differentiated:

- Spherical IOLs that induce spherical aberration (traditional IOLs)
- IOLs inducing no spherical aberration (aspherical neutral)
- IOLs with negative spherical aberration (aspherical correcting)
- IOLs reducing spherical aberration of the eye in a customized fashion (aspherical optimized)

Tests

Any spherical IOL contributes to the positive spherical aberration of the pseudophakic eye. The amount of spherical aberration induced by the IOL can be determined by subtracting the aberration of the corneal surface from that of the entire eye (Kohnen and Koch 2009).

Differential Diagnosis

Aspherical IOL design is provided with monofocal IOLs, multifocal IOLs, accommodative IOLs, toric IOLs, and blue-light filter IOLs today.

Etiology

The term spherical refers to the Latin word "sphericus" meaning round, globular, or orbicular.

Treatment

Aspherical IOLs are implanted like spherical IOLs into the eye. See also entries "▶ Cataract Surgery" and "▶ Intraocular Lens."

Spherocylindrical Lenses

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

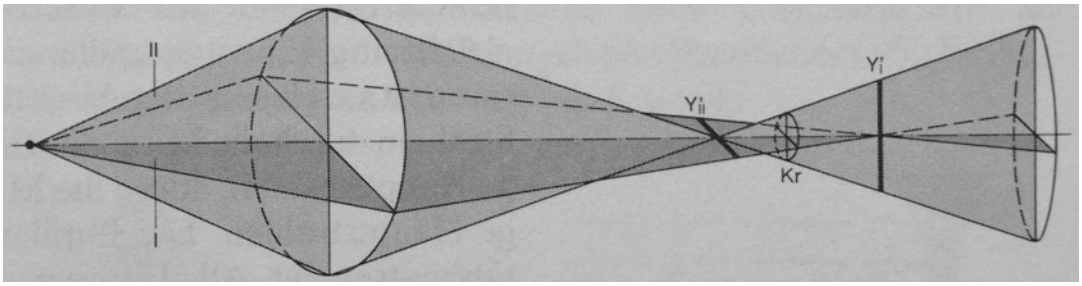
Synonyms

Astigmatic lens; Spherotoric lens; Spherotoroidal lens

Definition

Lenses with spherocylindrical power image a real object point not as an image point, but as two image lines with different image distances. The image lines of an axial object point are perpendicular to the optical axis and lie in the principal meridians lying perpendicularly to each other. The ray bundle of an object point which has a circular cross section at any point prior to refraction exhibits an elliptical cross section subsequent to refraction. The size and shape of the ellipse vary depending on its position. The two image lines are the extremes of the cross section. Between them lies the only point where the cross section of the bundle is circular (instead of a point). The cross section formation (Sturm's conoid) shows this circle of least confusion.

The principal meridian with the mathematically smaller (i.e., weaker positive or stronger negative) refractive power F_β is called the first



Spherocylindrical Lenses, Fig. 1 Sturm's conoid, to demonstrate the nature of astigmatic imagery

S

principal meridian β, while the other is known as the second principal meridian α and has the mathematically larger refractive power F_{α}.

Application: For the correction of astigmatic ametropia.

Duke University Eye Center, Durham, NC, USA

Synonyms

Several previously reported clinical entities describe globular deposits of the cornea that may represent the same condition, with geographic variations or subtypes:

Band-shaped nodular dystrophy of the cornea; Bietti corneal degeneration; Chronic actinic keratopathy; Climatic droplet keratopathy; Colloid degeneration of the cornea; Degeneratio hyaloidea grannuliformis corneae; Elastoid degeneration; Elastotic degeneration; Eskimo corneal degeneration; Fisherman's keratopathy; Hyaline corneal degeneration; Keratinoid corneal degeneration; Keratoid corneal degeneration; Labrador keratopathy; Nodular corneal dystrophy in tropical arid countries; Proteinaceous corneal degeneration; Sphaerularis elaiodes; Spheroid degeneration; Spheroidal keratopathy; Superficial central primary degeneration oleogutta; The blindness of Dahalach

Definition

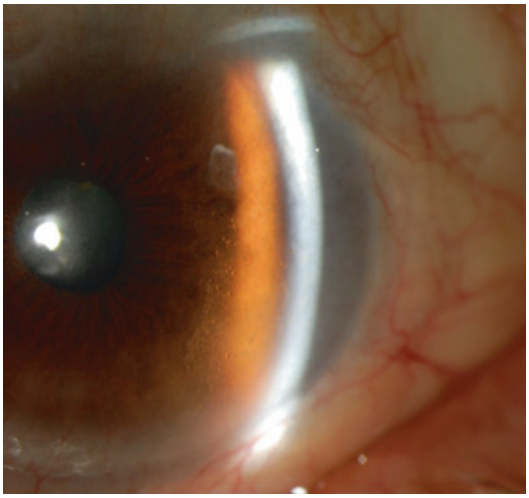
A degeneration of the cornea and/or conjunctiva characterized by the appearance of golden yellow spherules or globules of varying size at or beneath the epithelium.

Etiology

The exact source of the protein material forming the spherules is unknown. It has been postulated that the material may result from the actions of ultraviolet light on serum proteins that diffuse into the cornea from limbal vessels (Farjo and Sugar 2009). Increasing age and exposure to ultraviolet light are the most common associated factors. Other proposed risk factors include dry eyes, malnutrition, corneal trauma or microtrauma (wind, sand, ice), low humidity, and extremes of temperature. Associated ocular diseases include keratitis, lattice corneal dystrophy, and glaucoma (Fraunfelder and Hanna 1973).

Clinical Presentation

Spheroidal degeneration is characterized by the presence of yellow or golden spherules at or beneath the corneal or conjunctival epithelium (Fig. 1). The spherules, or globules, are generally clear but may become more opaque over time and range in size from approximately 0.1 to 0.6 mm in diameter. These lesions are located in the superficial corneal stroma, bowman membrane, subepithelium, and occasionally in the epithelium in advanced degeneration (Magovern et al. 2004).



Spheroidal Degeneration, Fig. 1 Numerous golden spherules are seen in the mid-peripheral, superficial cornea within the palpebral fissure

The clinical presentation has been described as either a primary corneal type associated with age, a secondary corneal type associated with other ocular pathology, and a conjunctival form that may or may not be associated with either type of corneal degeneration (Fraunfelder and Hanna 1973). In the primary form, the lesions are typically seen at the horizontal limbus within the palpebral fissure, and with progression, the spherules enlarge and spread toward the central cornea. In the secondary corneal form, the lesions are less likely to assume a band-shaped configuration and may be concentrated around areas of prior scarring, neovascularization, or inflammation. The lesions are generally bilateral except in secondary cases where there is associated unilateral pathology such as scars, trauma, or keratitis. In the conjunctival form, lesions occur interpalpebrally at the 3 and 9 o'clock positions and are frequently found in association with pinguecula.

Diagnosis

Diagnosis is made clinically based on the characteristic appearance. Biopsy with histologic examination can support or confirm the diagnosis but is not typically required. Histologically, deposits appear as extracellular amorphous globules, which may coalesce to form larger masses in Bowman's membrane (Farjo and Sugar 2009).

Differential Diagnosis

Similar appearing clinical entities include corneal amyloid degeneration, gelatinous drop-like corneal dystrophy (familial subepithelial amyloidosis), band keratopathy, climatic proteoglycan stromal keratopathy, primary lipoidal degeneration of the cornea, Salzmann nodular degeneration, and limbal girdle of Vogt (type II).

Prophylaxis

Unknown. Based on the recognized association with sunlight exposure, it is plausible that methods to reduce sunlight exposure could potentially reduce the development or progression of spheroidal degeneration.

Therapy

Treatment is rarely required since the majority of individuals are asymptomatic. In patients with loss of vision from central corneal lesions, treatment can be considered. Possible treatment options include superficial keratectomy, phototherapeutic keratectomy, lamellar keratoplasty, or penetrating keratoplasty depending on the depth and density of the lesions.

Prognosis

The majority of individuals do not develop any symptoms and progression is slow in the primary form. However, progression may result in loss of vision, particularly in areas of the world where climatic exposure is severe. Visual acuity may be affected due to involvement of the visual axis of the cornea or from irregular astigmatism. In advanced disease, accumulation of globular masses or plaques may cause heaping up of the

corneal surface, epithelial defects, and recurrent corneal erosions. Corneal sensation may be reduced, and sterile ulceration may rapidly progress to microbial keratitis or perforation.

Epidemiology

The prevalence varies based on geographic location with rates of 6% in England and over 60% in males in Labrador (Farjo and Sugar 2009). It is approximately three times more common in males and increases with age, being found in roughly 50% of patients over 70 years of age (Fraunfelder and Hanna 1973). It is most frequently seen in areas with high sunlight exposure. While the primary form is generally considered a degeneration, there are rare reported cases describing a more dystrophic form that may be familial and occur in relatively young patients without a history of other ocular disease or environmental exposure (Santo et al. 1993).

Spiradenoma

- ▶ Spiradenoma, Eccrine

Spiradenoma, Eccrine

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Eccrine spiradenoma; Spiradenoma

Definition

A rare, benign tumor of eccrine sweat gland origin.

Etiology

Histopathologically, the tumor involves basophilic cells arranged in rosettes with differentiation towards eccrine secretory cells. A tumor suppressor gene has been suggested in the development of eccrine spiradenomas (American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Clinical Presentation

Typically, as 1 cm solitary nodules on the head and neck that are covered by intact skin. Lesions may be intermittently painful. They commonly arise between the ages of 15 and 35 years. Multiple eccrine spiradenomas have been reported in zosteriform and linear patterns. Malignant transformations have been reported in long standing cases and are typically large ulcerated lesions of the trunk and extremities (Beekley et al. 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Diagnostics

Excisional biopsy is necessary to provide definitive diagnosis.

Differential Diagnosis

Adenoid cystic carcinoma
Dermatofibroma
Leiomyoma
Neurolemoma
Poroma

Prophylaxis

Lesions tend not to recur after surgical excision.

Therapy

Surgical excision provides definitive diagnosis. Solitary eccrine spiradenomas are typically benign. Multiple large eccrine spiradenomas may be treated with carbon dioxide laser. Malignant eccrine spiradenoma requires metastatic work-up and consultation with oncologists and radiation oncologists (American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Prognosis

Most eccrine spiradenomas are benign and prognosis is excellent. Malignant spiradenomas have been reported to metastasize in 50% of cases and can be fatal (Beekley et al. 1999).

Epidemiology

Eccrine spiradenomas are the rarest of the eyelid adnexal lesions (Fig. 1).

Spiral Computed Tomography, in Orbital Evaluation

Paul Petrakos[1], Apostolos J. Tsiouris[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Helical computed tomography

Definition

An imaging technique used to distinguish different tissues by measurement of their different densities using their absorption values after exposure to X-rays.

Purpose

Spiral computed tomography is a useful imaging modality in evaluating patients with orbital disease.

Principle

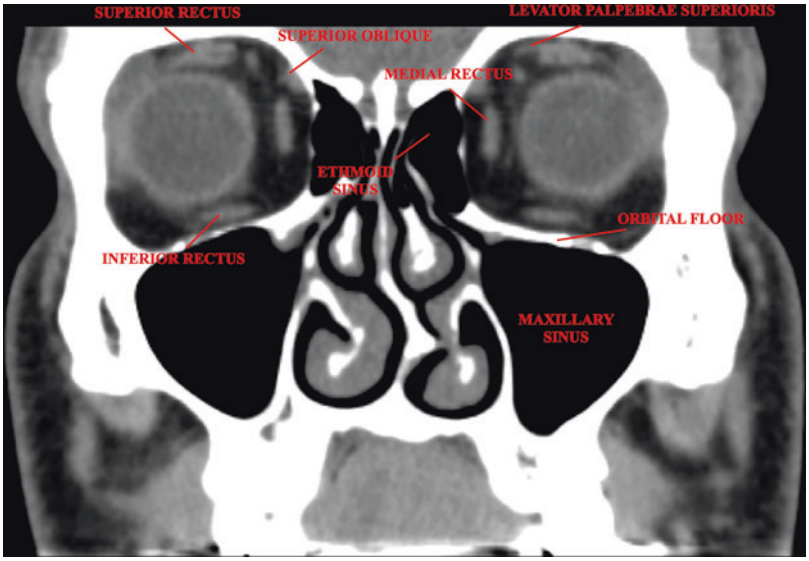
Computed tomography works by using X-ray radiation beams. In comparison to earlier CT units, a spiral CT has multiple detector ports with the scanner and collecting tube moving in a spiral fashion around the patient. This generates a continuous data set that allows for highly detailed reconstructions in all imaging planes. Resolution and tissue-contrast capabilities allow the imaging of soft tissues, bones, foreign bodies, and contrast containing blood vessels (Figs. 1 and 2). This is accomplished using the different absorption values of tissues after the exposure to the X-ray. The final image depends on the tissue attenuation of X-ray, which is denoted by Hounsfield units.

Indication

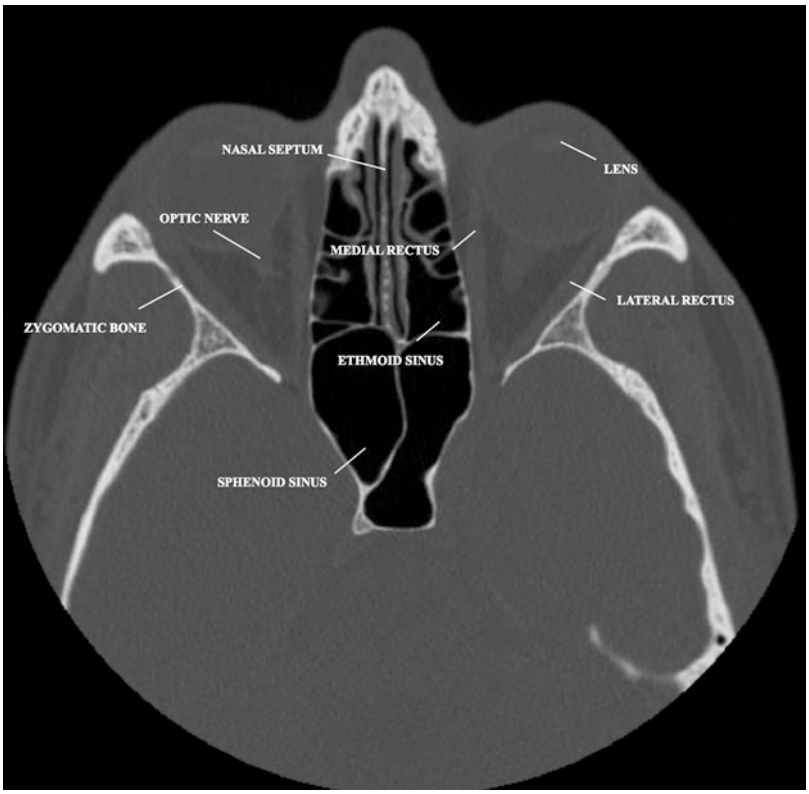
Orbital trauma
Orbital infection
Orbital tumors
Thyroid eye disease
Inflammatory lesions
Proptosis or globe malposition
Preoperative planning

Contraindication

The use of iodine or contrast dye is contraindicated in patients with iodine or contrast allergies and/or renal impairment.



Spiral Computed Tomography, in Orbital Evaluation, Fig. 1 Coronal spiral CT imaging demonstrating orbital and sinonasal anatomy



Spiral Computed Tomography, in Orbital Evaluation, Fig. 2 Axial spiral CT imaging demonstrating orbital and sinonasal anatomy

Advantage/Disadvantage

A spiral CT is a more effective technique for evaluating orbital fractures than traditional plain film X-rays. The short duration of the procedure makes it the preferred technique for orbital evaluation in an emergent situation. The shorter scanning time allows for less motion artifact and patient tolerance. Furthermore, it is safe to use in patients who are

being evaluated for potential metallic foreign bodies.

Disadvantages include exposure to radiation and beam hardening artifacts from metallic objects, including dental fillings. Orbital CTs are also limited in evaluating orbital soft tissue and provides poor definition of the orbital apex in comparison to an MRI.

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Epidermoid carcinoma; Squamous cell cancer (SCC)

Definition

Malignant skin tumor of squamous (keratinized) epithelium (epithelium that contain squamous cells – thin, flat cells that appear as fish scales microscopically) (Dailey et al. 1994; Albert and Jakobiec 2008; Shields and Shields 2008).

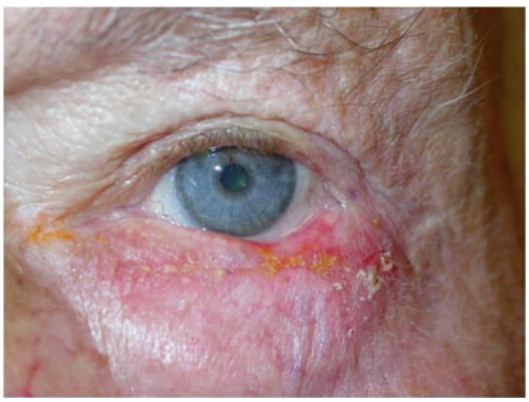
Etiology

SCC arises from the keratin-producing cells of the epidermis (keratinocytes). In the early stages, they

are referred to as squamous cell carcinoma in situ (Bowen's disease). Invasive SCC exhibits extension beyond the basement membrane of the epidermis into the dermis. These tumors can develop spontaneously or in areas of previous actinic keratoses, burns, scars, or chronic ulcers. It is most often encountered in elderly, fair-skinned individuals who have a history of chronic sun exposure. Other risk factors include radiation therapy, exposure to carcinogens, chronic skin irritation or inflammation, genetic diseases (xeroderma pigmetosum, albinism), and presence of premalignant lesions. Squamous cell cancer can also occur after organ transplantation (immunocompromised hosts) (Dailey et al. 1994; Albert and Jakobiec 2008; Shields and Shields 2008).

Clinical Presentation

SCC, although much less common than basal cell carcinoma (BCC), behaves more aggressively. Usually they appear as painless elevations or nodules, often with a pearly appearance, with either loss or distortion of the eyelashes. There may be ulceration of the involved area, with bleeding, crusting, redness, and/or distortion of the normal skin appearance (Fig. 1). Palpation of preauricular and submandibular lymph nodes is important to detect potential metastatic spread (Dailey et al. 1994; Albert and Jakobiec 2008; Shields and Shields 2008).



Squamous Cell Carcinoma of Eyelid, Fig. 1 Squamous cell carcinoma of the left lower eyelid, demonstrating diffuse infiltrative tumor with crusting and ectropion of the eyelid

Diagnostics

Diagnosis is established by biopsy and histopathological confirmation. In some instances, SCCs may be found at the base of a cutaneous horn; therefore it is imperative to examine the base of these types of tumors histologically.

Differential Diagnosis

Differential diagnosis includes basal cell carcinoma, ▶ actinic keratosis, ▶ seborrheic keratosis, ▶ sebaceous carcinoma, ▶ keratoacanthoma, ▶ melanocytic nevus, ▶ melanoma, ▶ trichoepithelioma, and ▶ inverted follicular keratoses.

Prophylaxis

Avoidance of sun exposure; use of sunscreens, sunglasses, and hats.

Therapy

SCC is treated best by early intervention with complete excision (frozen-section control of the margins or with the Moh's technique). Other treatments include radiation, cryotherapy, photodynamic therapy, and systemic chemotherapy but are perhaps not as efficacious as surgical intervention. Extension into the orbit and sinuses may require more extensive surgical intervention (e.g., exenteration, sinusectomy) with subsequent radiation therapy (Dailey et al. 1994; Albert and Jakobiec 2008; Shields and Shields 2008).

Prognosis

The prognosis is excellent if the lesion is detected early and completely excised. Prognostic factors

Squamous Cell Carcinoma of Eyelid, Fig. 2 Extensive SCC with massive diffuse involvement of eyelid and orbit invasion

include the degree of differentiation, the etiology, tumor size, and the immune status of the patient. Unlike BCC, SCC has the ability to invade local tissues (orbital invasion) and metastasize to lymph nodes and distant sites (Fig. 2). Perineural spread is another adverse prognostic sign (Dailey et al. 1994; Albert and Jakobiec 2008; Shields and Shields 2008).

Epidemiology

SCC represents approximately 5–10% of all eyelid malignancies. It is the second most common form of skin cancer after BCC (Dailey et al. 1994; Albert and Jakobiec 2008; Shields and Shields 2008).

Squamous Cell Carcinoma, of the Conjunctiva

Tin Yan Alvin Liu
Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Conjunctival squamous cell carcinoma

Definition

An abnormal proliferation of dysplastic cells arising within the epithelial layer of the conjunctiva. Various histopathological abnormalities including but not limited to cellular pleomorphism, increase in mitotic figures, suprabasal mitotic figures, and a decrease in desmosomal/hemidesmosomal attachments can be seen. When the dysplastic cells penetrate the epithelial basement membrane and invade the subepithelial connective tissue, the lesion becomes an invasive squamous cell carcinoma.

Etiology

It is caused by disordered maturation of the epithelium. Ultraviolet B radiation, which can cause point mutation in the p53 tumor suppressor gene, human papillomavirus (types 16 and 18), and

immunosuppression (often due to HIV) have been implicated in the pathogenesis of this disease (Tunc et al. 1999).

Clinical Presentation

Some common presenting symptoms include eye redness, foreign body sensation, pain and tearing. Conjunctival squamous cell carcinoma usually arises in the interpalpebral, perilimbal conjunctiva as a slightly elevated, well-demarcated lesion, accompanied by feeding blood vessels. The lesion can also be nodular, gelatinous, pigmented, or diffuse. It can sometimes mimic benign conjunctival degeneration or chronic conjunctivitis (Hamam et al. 2009).

Diagnosis

It is generally diagnosed by excisional biopsy, although cytologic analysis is sometimes used. Microscopic analysis shows dysplastic changes involving most or all of the epithelial thickness, often with sharp demarcation from normal conjunctiva at the peripheral borders. Extension through the epithelial basement membrane and involvement of the subepithelial tissue distinguish invasive carcinoma from in situ tumors. Immunohistochemical staining can show expression of the oncogene p63 and mutant tumor suppressor gene p53, although these are not specific (Hamam et al. 2009). It is staged according to the tumor-node-metastasis (TNM) staging system developed by the American Joint Committee on Cancer (AJCC) and Union for International Cancer Control (UICC).

Differential Diagnosis

Dermoid, dyskeratosis, conjunctival intraepithelial neoplasia, intraepithelial sebaceous neoplasia, lymphoproliferative process, papilloma, pingueculum, scar tissue, conjunctival melanoma, and chronic conjunctivitis.

Prophylaxis

There are no proven prophylaxes.

Therapy

Therapy consists of surgical excision, usually accompanied by adjuvant cryotherapy and/or adjuvant topical therapy with mitomycin (MMC), 5-fluorouracil (5FU), or interferon alpha 2b. For nonresponsive carcinomas, palliative treatment with subconjunctival ranibizumab and external beam radiation therapy (photons, electrons, or protons) have also been used (Yousef and Finger 2012).

Prognosis

Reported local recurrence rate varies widely and can be as high as 50% (Zaki and Farid 2009) when there is residual tumor in the surgical margins. Risk factors for tumor recurrence include tumor size larger than 5 mm, larger than 2 mm extension onto the cornea, and tumor local invasiveness (Yousef and Finger 2012). Intraocular invasion has been reported to happen in 2–8% (Tunc et al. 1999) of the cases. Metastases are rare. The first sites of metastasis are the preauricular and submandibular regional lymph nodes, but more distant metastases to the parotid gland, lungs, and bone have also been reported (Yousef and Finger 2012). Surgical excision with adjuvant therapy carries a higher rate of cure, compared to surgical excision alone. Surgical excision with adjuvant cryotherapy, topical MMC, topical 5FU, or topical interferon alpha 2b has a cure rate of at least 80% (Hamam et al. 2009).

Epidemiology

The disease affects all racial groups of all ages. However, it has a slight male predominance, with an average age of onset in the 50s. Fair-skinned populations at latitudes closer to the equator may be at a higher risk, and xeroderma pigmentosum is associated with an increased risk of earlier

development of this condition. The average annual incidence of conjunctival squamous cell carcinoma has been estimated to be 17–20 cases per million persons per year (Hamam et al. 2009).

Squamous Cell Papillomas of Eyelid

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Acrochordon; Papilloma; Skin tag; Squamous papilloma

Definition

Benign hyperplasia of squamous epithelium of the skin (Albert and Jakobiec 2008; Shields and Shields 2008).

Etiology

Due to UV, other cell damage, but most often arise de novo. Papillomas represent benign overgrowths of normal epithelium, with varying levels of keratinization and pigmentation.

Clinical Presentation

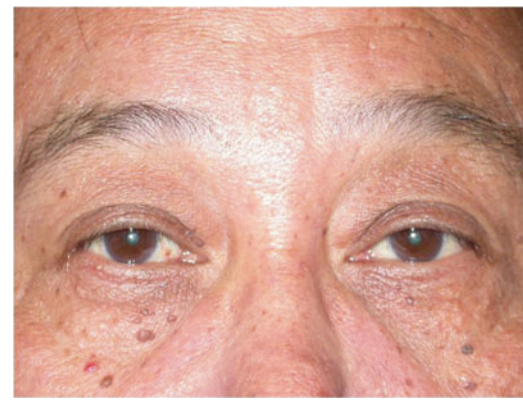
Squamous cell papilloma (SCP) may be pedunculated, sessile, solitary, multiple, pigmented, or same color of the skin. Sessile papilloma often has a broad base and a smooth surface (Fig. 1). Unlike pedunculated papilloma, it has a rough and cerebriform convoluted surface (Fig. 2). The onset is gradual and with slow growth. Much more common in middle age or elderly individuals. In rare instances, they represent precancerous lesions, so malignant conversion remains a consideration (Albert and Jakobiec 2008; Shields and Shields 2008).

Diagnostics

Biopsy and histopathologic interpretation.

Differential Diagnosis

Differential diagnosis includes ▶ melanocytic nevus, ▶ basal cell carcinoma ▶ seborrheic keratosis, ▶ fibroma, ▶ Verruca Vulgaris, and ▶ actinitic keratosis.



Squamous Cell Papillomas of Eyelid, Fig. 1 Woman with squamous papillomas on upper and lower eyelids

Squamous Cell Papillomas of Eyelid, Fig. 2 Pedunculated papilloma arising on upper eyelid

Prophylaxis

Avoidance of sun and UV exposure (use of sunscreens, sunglasses, umbrellas, and hats).

Therapy

Usually serial observation or surgical excision of the lesion. If any signs of malignancy develop, biopsy and removal are essential. Treatment is complete surgical resection. When surgery is not appropriate or possible, radiotherapy, cryotherapy, or pharmacotherapy can be considered.

Prognosis

Excellent with little risk of malignant transformation.

Epidemiology

Common; perhaps the most common eyelid benign lesion.

Squamous Dysplasia of Conjunctiva

Saeed Alwadani
Department of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Synonyms

Conjunctival intraepithelial neoplasia (CIN); Conjunctival squamous dysplasia

Definition

Conjunctival intraepithelial neoplasia (CIN), or dysplasia, is analogous to actinic keratosis of the eyelid skin. In CIN, the dysplastic process does not invade the underlying basement membrane and is classified in mild, moderate, or severe,

according to the degree of the extension and amount of atypical cells involving the epithelium.

Etiology

The conjunctiva is a mucus membrane as many others in the body but is different because it is partially exposed to the sun. The relative contributions to this condition such as HPV infection, chronic sunlight exposure, and host factors have not been determined yet. Exposure to tobacco, petroleum products, and history of HIV infection may be predisposing factors for rapidly progressive and aggressive diseases.

Clinical Presentation

Individuals with CIN clinically present with symptoms ranging from foreign body sensation, redness, and irritation to an evident growth on the ocular surface that may be a potential cause of visual loss.

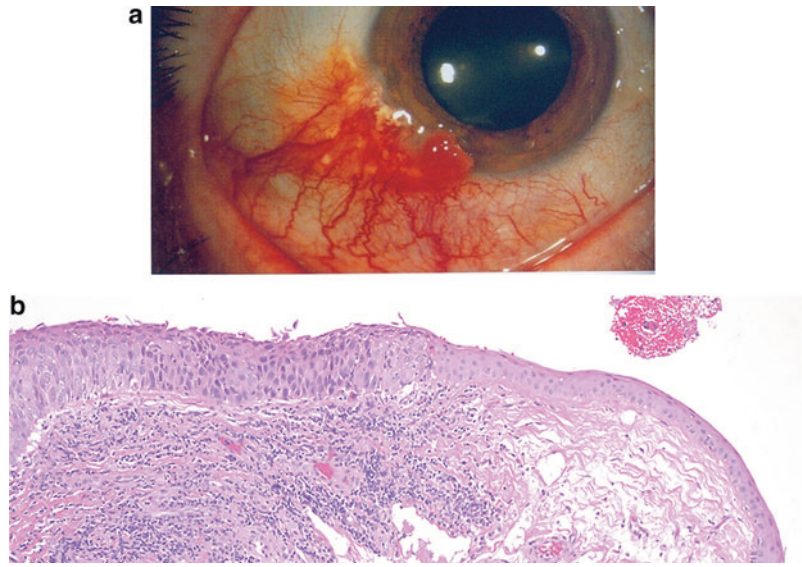
CIN is usually found at the limbus in the interpalpebral zone (Fig. 1a). There are three principal clinical variants:

1. Papilliform, in which a sessile papilloma harbors dysplastic cells
2. Gelatinous, as a result of acanthosis and dysplasia
3. Leukoplakic, caused by hyperkeratosis, parakeratosis, and dyskeratosis

Mild inflammation and various degrees of abnormal vascularization may accompany CIN lesions, but large feeder blood vessels indicate a higher probability of invasion beneath the epithelial basement membrane. CIN lesions are slow-growing tumors, nearly always centered at the limbus but with the potential to spread to other areas of the ocular surface, including the cornea.

Diagnosis

Histologically, CIN typically shows an abrupt transition between normal conjunctival epithelium and the dysplastic epithelium, which are characterized by hyperplasia, loss of normal cell polarity, nuclear hyperchromasia, pleomorphism, mitotic figures, and in some cases, goblet cell loss (Fig. 1b). There is often surface keratinization, correlating with the leukoplakia observed clinically. Dyskeratosis (non-surface cells producing keratin) may also be seen. A chronic inflammatory response is often present in the substantia propria.



Squamous Dysplasia of Conjunctiva, Fig. 1 (**a**) Clinical presentation. (**b**) Histopathology finding

It is important to perform an adequate histological evaluation in order to classify the degree of epithelial dysplasia, and whether or not, the lesion is contained by the basement membrane. The epithelial dysplasia may be graded as mild, moderate, or severe, according to the degree of cellular atypia.

Differential Diagnosis

- Squamous cell carcinoma
- Limbal stem cell deficiency
- Squamous papilloma
- Pterygium
- Pinguecula

Therapy

Surgical excision of OSSN with or without cryotherapy or brachytherapy is still commonly performed; however, in the last decade, topical chemotherapy using mitomycin C, 5-FU, and interferon alfa-2b has become popular in the treatment of CIN.

Prognosis

Although the histopathologic grading and evaluation play an important role, distinguishing in between the extent of disease does not necessarily have clinical utility in terms of prognosis.

In cases with the most severe atypia, full-thickness involvement of the epithelium is seen, often with squamous eddies or keratin whorls/pearls. For these more advanced lesions, the term squamous carcinoma in situ may be used. If, however, the neoplastic cells have invaded the stroma, then the diagnosis is invasive squamous cell carcinoma. Clinically, the term CIN has fallen out of favor in preference to the more general term OSSN, because it is not possible to determine on clinical examination whether stromal invasion has occurred. CIN should be regarded as a histologic term, reserved for noninvasive lesions. Invasion through the sclera or cornea and intraocular spread are uncommon complications of invasive squamous carcinoma.

Epidemiology

CIN affects men more than women; it is associated to chronic sun exposure and tobacco.

Staphylomas, Congenital, Anterior

Charline Boente
Ophthalmology, University Hospitals Eye Institute, Case Western Reserve University, Cleveland, OH, USA

Synonyms

Congenital corneal ectasia; Keratectasia

Definition

Congenital anterior staphyloma refers to severe thinning and bulging of the cornea or sclera which is present at birth.

Etiology

Although no single theory exists on its etiology, congenital anterior staphyloma is generally thought to occur as a result of abnormal embryologic migration of mesenchymal tissues. Other theories proposed include in utero exposure of infectious or inflammatory conditions resulting in corneal thinning (Sugar and Wadia 2009).

Clinical Presentation

The infant typically presents at birth with corneal opacity and bulging of the anterior segment through the palpebral fissure beyond the eyelid plane, resulting in a "flask-shaped" eye. Exposure keratopathy can occur, which can lead to epithelial metaplasia and keratinization. The anterior sclera may be very thin and transparent but is typically of normal thickness starting posterior to the rectus muscle insertion (Watson et al. 2012). Because of the disorganization of anterior segment structures, glaucoma is a common sequela of this disease from anterior synechiae leading to secondary angle closure. This condition may be unilateral or bilateral (Leff et al. 1986).

Acquired anterior staphylomas may occur in the setting of scleral inflammation with constant and prolonged increased intraocular pressure >40 mmHg, such as in chronic anterior uveitis or rheumatoid scleritis combined with secondary glaucoma. This results in the protrusion of uvea through an inflammatory scleral defect. Acquired anterior scleral staphylomas may also occur in the setting of trauma, surgery, or overlying masses (Watson et al. 2012).

Diagnostics (Lab Diagnostics)

Laboratory markers are not utilized in the diagnosis of congenital anterior staphylomas, but histopathological studies have helped to identify this condition. Corneal specimens have shown an irregular epithelium, attenuated Bowman's layer, stromal thickening with vascularity, and absent Descemet's membrane and endothelium corresponding with the area of posterior uveal lining (Zein and Mokhtarzadeh 2013). A detailed fundus exam should also be performed to assess the viability of posterior segment structures.

Differential Diagnosis

The differential diagnosis for congenital anterior staphylomas includes Peters anomaly, anterior segment dysgenesis, keratoglobus, buphthalmos, pigmented conjunctival tumor, extraocular extension of a ciliary body melanoma, or foreign body (Shields et al. 2003; Watson et al. 2012).

Prophylaxis

No known prophylactic measures to prevent congenital anterior staphylomas have been noted to date.

Therapy

Congenital anterior staphylomas may be managed with penetrating keratoplasty, not only for visual rehabilitation but also for cosmetic appearance. The success of penetrating keratoplasty is not well studied in these patients and is highly variable based on disease severity.

Prognosis

Visual prognosis is poor for infants born with this condition. Enucleation is often necessary if the eye becomes blind and painful.

Steatoblepharon

Gary Joseph Lelli[1] and Matthew Nguyen[2]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Weill Cornell Medical College, New York, NY, USA

Definition

The word steatoblepharon comes from steato, which means fat, and blepharon, which means eyelid. It refers to the herniation of orbital fat from the eyelids. "Eyelid bags" is a more general term used to encompass all the factors, including steatoblepharon, that cause outpouching of the eyelids.

Etiology

Orbital fat is contained by the orbital septum and protrudes causing steatoblepharon. It has been observed that steatoblepharon occurs from aging with several studies describing volume loss and gravitational effects on the orbital septum as contributing factors. Over time, the orbital septum may become more lax, and fat can prolapse forward resulting in steatoblepharon. Volume loss of the overlying skin may also contribute to the prominence of the fat.

Clinical Presentation

Steatoblepharon presents as outpouching of the overlying eyelid skin with fullness of the eyelids. It is often found along with ptosis, dermatochalasis, and other effects of aging.

Diagnostics

Diagnosis is made clinically by observation.

Differential Diagnosis

Steatoblepharon from aging should be differentiated from other causes of masses or edema around the eyes including malignancy, thyroid eye disease, or trauma. Other factors that can cause eyelid bags include eyelid fluid and loss of the elasticity of the skin.

Therapy

The treatment for steatoblepharon is surgery, usually as a part of blepharoplasty to remove the excess protruding skin and prolapsed fat. During blepharoplasty the orbital septum and periorbital fat can be shaped or removed by cautery to improve the steatoblepharon.

Steep Central Islands

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Central island

Basic Characteristics

Result of an incomplete excimer laser ablation with a broad beam laser. Plumes of the ablation gathered over the central cornea lead to an incomplete ablation at the corneal center. Topography shows a marked central area of increased curvature, often with local irregularities. Central steep islands are associated with reduced visual acuity (Krueger et al. 1996).

Other corneal conditions that result in a central corneal steepening such as central keratoconus, local iatrogenic keratectasia, corneal laser refractive surgery for hyperopia or presbyopia, and central scars may mimic a central steep island. Particularly, the creation of a hyperprolate cornea with presbyopia excimer treatments results in a central steep island.

The treatment of central steep islands is difficult. A rigid gas-permeable contact lens may improve image quality by correcting corneal higher-order aberrations. The surgical treatment with topography-guided laser refractive surgery turned out to be difficult and rarely satisfying.

Stem Cells, Limbal, Corneal Epithelium Maintenance

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Definition

Adult corneal stem cells are undifferentiated progenitor cells capable of rapid proliferation and self-renewal. Stem cells are capable of producing large numbers of differentiated progeny, which help maintain the corneal surface epithelium. They play an important role in wound healing through continued replacement and regeneration of the tissue.

Structure

There are several features that help to distinguish between the limbus and the central cornea. The limbal epithelial stem cells display a slower turnover cycle and consist of a thicker cell layer (eight to ten cells) than the corneal epithelium (five cells). The heavier pigment in the limbus may help protect these cells from sun damage that could lead to the development of malignant lesions. The limbal stroma's vascularity and innervation provide the ideal environment for stem cell growth and proliferation. Limbal blood vessels provide nutrients to the limbal epithelium and may contribute to the higher concentrations of Na^+/K^+ ATPase and carbonic anhydrase in the basal cells of the limbal epithelium. It is not clear yet whether these proteins are involved in cellular regulatory functions. Within the palisades of Vogt, the epithelial and stromal cells have a stronger physical connection making the stem cells less susceptible to trauma. The most common cause of limbal stem cell deficiency is destruction of those cells by chemical, thermal, or cryo-injuries, Stevens-Johnson syndrome, pemphigoid, radiation, and surgical trauma. Another less common cause is aniridia

Function

Under normal circumstances stem cells remain dormant and do not replicate frequently. This dormant state minimizes errors during cell division. In the presence of an epithelial injury, unique environmental and cellular characteristics allow stem cells to respond quickly. To do so stem cells give rise to amplifying cells. These amplifying cells have a shorter replication cycle and increased cell division. This translates into increased efficiency by increasing stem cell

division without increasing proliferation. Limbal basal cells express higher concentrations of epidermal growth factor receptor, $Na^{-}K^{-}$ATPase, cytochrome oxidase, and carbonic anhydrase. They also express intermediate fibers accounting for the stronger cellular adhesions in that area.

Clinical Relevance

The main function of the corneal epithelium is to provide a barrier against pathogens and to minimize trauma to the underlying stroma. Limbal stem cells help maintain an intact corneal epithelium by dispatching new basal cells into the central cornea. In the presence of an epithelial defect, surgically induced or as a result of other trauma, limbal basal stem cells rapidly proliferate to repopulate the surface defect.

Patients with stem cell deficiency may present with pain, decreased visual acuity, photophobia, redness, or tearing. In a cornea with limbal stem cell deficiency, an irregular dull corneal reflex can be demonstrated by slit lamp biomicroscopy. It may also present with chronic or recurrent epithelial defects. Limbal stem cell deficiency can ultimately lead to corneal scarring, vascularization, or perforation. Mildly symptomatic patients can be treated with artificial tears or lubricating ophthalmic ointments. Those with partial stem cell deficiency that present with visual impairment or chronic epithelial defects may benefit from surgical interventions such as epithelial debridement with close follow-up to monitor surface healing. Debridement can also be combined with amniotic membrane transplantation. Extensive stem cell deficiency may require limbal stem cell transplantation. The tissue used in this procedure can be an autograft from the fellow eye or allograft from a living relative or cadaver donor. Stem cell transplantation can be combined with amniotic membrane transplantation in patients with chemical burns, Stevens-Johnson syndrome, or cicatricial pemphigoid.

Patients receiving a limbal allograft are at high risk of an immunologic reaction to the transplanted cells. Immunosuppression can be achieved with cyclosporine-A or FK-506. The duration of treatment may be indefinite. The risk of rejection may be reduced by using HLA-matched cells.

Erythema multiforme major

Definition

Stevens-Johnson syndrome (SJS) is a severe autoimmune disease of the skin and mucous membranes with potentially devastating ocular consequences, and is part of a spectrum of similar disorders including erythema multiforme, and toxic epidermal necrolysis (TEN).

The term *Erythema multiforme major* is used interchangeably with SJS; erythema multiforme minor primarily involves the skin and at most one mucosal surface. In contrast, SJS by definition involves skin lesions and two or more mucosal surfaces, along with other systemic and ocular manifestations (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Etiology

SJS is commonly triggered by a drug reaction (i.e., sulfonamides, penicillin, salicylate, barbiturates, isoniazid, or phenytoin) or infection (HSV, adenovirus, *Mycoplasma*, and *Streptococcus* species). Drug toxicity is responsible for 50–60% of SJS cases. Sulfonamides are the most common drugs associated with SJS in healthy patients and those with HIV. Frequently used ophthalmic drops such as scopolamine, sulfonamide, dorzolamide, or tropicamide have all been associated with SJS.

SJS is considered to be a cell-mediated immune response to certain drugs and infectious agents, although exact mechanisms of disease have yet to be fully elucidated. The cause of skin and mucosal lesions involves Fas-Fas ligand interaction and cytotoxic T-lymphocyte activation resulting in keratinocyte apoptosis. Certain HLA markers have been associated with SJS; patients with the ocular lesions of SJS have a significantly raised incidence of HLA-B12, HLA-B44, HLA-Aw33, and HLA-DRw53.

In the eye, SJS triggers a nonspecific inflammatory response in the acute phase affecting subepithelial layers of conjunctiva. Collagen associated with arterioles and venules undergoes fibrinoid necrosis. In the chronic phase, the most prominent finding is cicatrization of the cornea, conjunctiva, and eyelids. In turn, conjunctival mucus-producing goblet cells decrease in number. A subsequent increase in basal epithelial cells and conjunctival cells correlates with disease severity (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Clinical Presentation

After 1–3 weeks of initial exposure or hours after re-exposure to the inciting agent, a characteristic systemic prodrome of fever, headache, malaise, arthralgia, and upper respiratory infection precedes dermatologic and ocular features. Days later, skin eruptions and ocular involvement causing decreased vision, pain, redness, and swelling occur. Skin lesions begin as erythematous macules and target lesions which progress to vesicular lesions and necrosis. In severe disease, Nikolsky's sign may be present, in which the outer epidermis undergoes exfoliation with light rubbing. Any mucosal surface can also be affected and show ulceration and strictures; lesions are commonest on the lips and oral mucosa.

Ocular manifestations of SJS and TEN can be severe, involving the bulbar and palpebral conjunctiva, eyelids, and cornea. Acute ocular complications, especially initial nonspecific conjunctivitis, may occur concurrently with the skin disease or precede it by several days. The bilateral conjunctivitis may be catarrhal or pseudomembranous. It may occur in 15–75% of patients with SJS. It is characterized by decreased visual acuity, conjunctival injection, mucous discharge, membranes, symblepharon, and trichiasis. Corneal ulceration, scarring, vascularization, and keratinization may also appear as a result of conjunctival scarring involving the lid margin, tarsus, and loss of the fornix.

The initial eye findings may resolve in 2–4 weeks. Late complications arise due to damage to the limbal epithelial stem cells and chronic inflammation or infection causing corneal opacity and neovascularization. Patients may develop chronic irritation of the cornea as a result of entropion, trichiasis, and lid margin keratinization. This may occur due to lacrimal duct cicatrization with destruction of the conjunctival goblet cells.

The level of corneal scarring is proportional to the severity of eyelid margin and tarsal pathology (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Diagnosis

A comprehensive history may reveal a causative agent in patients with suspected SJS. The diagnostic criteria for SJS are as follows:

- Less than 20% of body area involved in first 48 h
- Greater than 10% body area involvement
- Target (iris) lesions (typical or atypical)
- Individual lesions less than 3 cm in diameter (lesions may coalesce)
- Mucous membrane involvement (at least two areas)
- Fever
- Biopsy specimen compatible with erythema multiforme major

The eye exam should evaluate the lids for trichiasis, conjunctiva for injection, symblepharon, and ulceration, and the cornea for staining, ulceration, and scarring. During the acute phase of the disease, inspection of the skin and oral mucosa should be conducted which may reveal characteristic lesions (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Differential Diagnosis

Cicatricial pemphigoid may present with similar findings as chronic ocular manifestations of SJS. Symblepharon presents with more severity in cicatricial pemphigoid. Other disorders in the differential diagnosis include squamous cell carcinoma, scleroderma, sarcoidosis, ocular rosacea, and severe chronic keratoconjunctivitis caused by bacteria, viruses, medications, allergies, chemical burns, avitaminosis A, and trachoma. A useful diagnostic tool is the comprehensive history which may reveal a drug reaction with the typical skin and mucosal lesions of SJS (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Prophylaxis

Prophylactic use of IVIG in on-going trials has shown benefits in patients with previous SJS episodes. Agents most commonly associated with SJS should be avoided (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Therapy

During the acute stage of SJS, frequent conjunctival irrigation and prophylactic antibiotics may be used to prevent secondary infection. Corneal and conjunctival epithelium should be lubricated with artificial tear supplements. Cycloplegics may be used for presence of anterior uveitis. Careful use of topical steroids may decrease inflammation but increase risk for secondary infection. Symblepharon may be treated with daily lysis, clear plastic wrap, or a symblepharon ring. The treatment goal of ocular surface stability and termination of inflammatory process may necessitate amniotic membrane application over the conjunctiva and cornea.

Management goals of the chronic stages are to restore eyelid and forniceal anatomy and function, supply tear function, and restore the ocular surface. Artificial tear use may treat keratoconjunctivitis sicca that develops due to scarring of the conjunctiva and lacrimal ducts. Abnormal mucous discharge can be managed by administration of mucolytic agents such as 10% *N*-acetylcysteine. Management of epithelial defects may require use of bandage soft or gas-permeable contact lenses.

Surgical intervention includes tarsorrhaphy which can be used to improve the status of the ocular surface. Keratolimbal allograft may be used in select cases for the treatment of persistent epithelial dysfunction. Penetrating keratoplasty can be performed to improve vision once the epithelium has been stabilized; however, severe

cases unable to support a penetrating keratoplasty graft may benefit from keratoprosthesis. Topical transretinoic acid can also be applied to reverse conjunctival transdifferentiation following ocular surface injury (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Prognosis

The mortality rate of SJS is approximately 1–5%. The disease is usually self-limiting, but mucous membrane damage is permanent and chronic ocular complications may portend a devastating prognosis. In fact, it is the eye disease in SJS that causes substantial long-term morbidity (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Epidemiology

The annual incidence in all ages is approximately 1.9 in 1,000,000 individuals, higher among HIV positive patients. Approximately, 80% of patients hospitalized for treatment of SJS develop eye disease and 35% experience chronic ocular changes (Friedman and Kaiser 2007; Krachmer et al. 2011; Hoyt and Taylor 2012).

Stickler Syndrome (Hereditary Progressive Arthro-Ophthalmopathy)

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Synonyms

Hereditary progressive arthro-ophthalmopathy; Stickler syndrome membranous vitreous type; Stickler syndrome vitreous type I

Definition

Stickler syndrome type I is an autosomal-dominant progressive chondrodysplasia associated with vitreoretinal degeneration. It produces a variety of ocular, orofacial, and skeletal abnormalities.

Etiology

Stickler syndrome (type I) is due to an abnormality in the structural gene for type II collagen (COL2A1) on chromosome 12q13.11-q13.2. Most commonly, the abnormality is a premature stop codon mutation which produces COL2AI haploinsufficiency. Missense mutations can also occur. Stickler syndrome type I is different from Stickler syndrome type II, which involves an abnormality of the COL11A1 gene. Stickler syndrome type I is also different from Stickler syndrome type III, which displays no ocular abnormalities (Carr and Noble 1999; Edwards and Robertson 2006).

Clinical Presentation

Patients with Stickler syndrome (type I) present with early-onset cataract, open-angle glaucoma, myopia, degeneration of the vitreous, radial paravascular degeneration, lattice degeneration, retinal tear, and rhegmatogenous retinal detachment (Fig. 1). The classic findings on vitreous examination include an optically empty central vitreous with abnormal membranes posterior to the lens, in the peripheral vitreous, and over the pars plana. (Stickler syndrome type II can be clinically distinguished from type I by the presence of fibrillar or beaded vitreous.) Non-ocular findings of Stickler syndrome type I are variable and include midface hypoplasia, cleft palate, bifid uvula, hearing loss, and skeletal abnormalities/marfanoid habitus with early-onset arthritis (Fig. 2). Interestingly, patients with a premature stop codon located in exon 2 of COL2A1 have predominately the ocular phenotypes and lack many of the systemic findings typically seen with Stickler syndrome type I.

Diagnostics

Diagnosis of type I Stickler syndrome involves documenting the spectrum of ocular and non-ocular clinical findings associated with this systemic disorder. Genetic studies can help confirm a specific mutation but are not required to establish the diagnosis. All patients with a family history of Stickler syndrome should receive proper screening with slit lamp examination and dilated ophthalmoscopy with scleral depression.

Differential Diagnosis

The differential diagnosis of Stickler syndrome (type I) includes other chondrodysplasias that can produce vitreoretinal abnormalities including type II Stickler syndrome, Marshall syndrome, Kniest dysplasia, Knobloch syndrome, and Weissenbacher-Zweymuller syndrome. Differentiating between these conditions is based on spectrum of systemic abnormalities and modes of inheritance.

Prophylaxis

Although no prevention exists for Stickler syndrome, prophylactic laser retinopexy can be considered for all areas of retinal breaks and lattice retinal degeneration in patients with Stickler syndrome to help reduce the risk for retinal detachment. Although the value of this treatment remains unclear, such intervention is not unreasonable given the 50% lifetime risk of retinal detachment in these patients.

Stickler Syndrome (Hereditary Progressive Arthro-Ophthalmopathy), Fig. 2 (Stickler syndrome bifid uvula) Color photograph demonstrating bifid uvula

Therapy

No cure is currently available for Stickler syndrome. Management involves preventing amblyopia, optically correcting for myopia, managing open-angle glaucoma, and treating retinal breaks and detachments.

Prognosis

The visual prognosis for Stickler syndrome is predominantly determined by the extent of vitreoretinal abnormalities and the subsequent risk of retinal detachment. Although visual prognosis with retinal detachments has improved following recent advances in surgical techniques, permanent vision loss is still possible in many cases due to recurrent retinal detachment. Other factors that influence visual prognosis include amblyopia, cataract formation, and development of open-angle glaucoma.

Epidemiology

Stickler syndrome (type I) occurs in approximately 1 in 7,500–9,000 neonates.

Synonyms

Striate keratitis

Definition

Focal intraoperative insult to the corneal endothelium results in posterior corneal edema and linear folds in Descemet membrane. Lines radiate to an incision and may be secondary to direct trauma from the phacoemulsification probe, bending of the cornea in intracapsular cataract surgery, or especially contact with lens substance in extracapsular cataract extraction, and is seen in almost half of such cases. Striate keratopathy generally resolves within 1 week.

Striate Melanokeratosis

Kelly N. Ma[1] and Wuqaas M. Munir[2]
[1]Ophthalmology, Glaucoma Service Clackamas Medical Office NW Permanente, PC, USA
[2]Department of Ophthalmology, Boston Medical Center, Boston University School of Medicine, Boston, MA, USA

Synonyms

Corneal pigmentary lines; Corneal verticillata; Pigmented epithelial lines

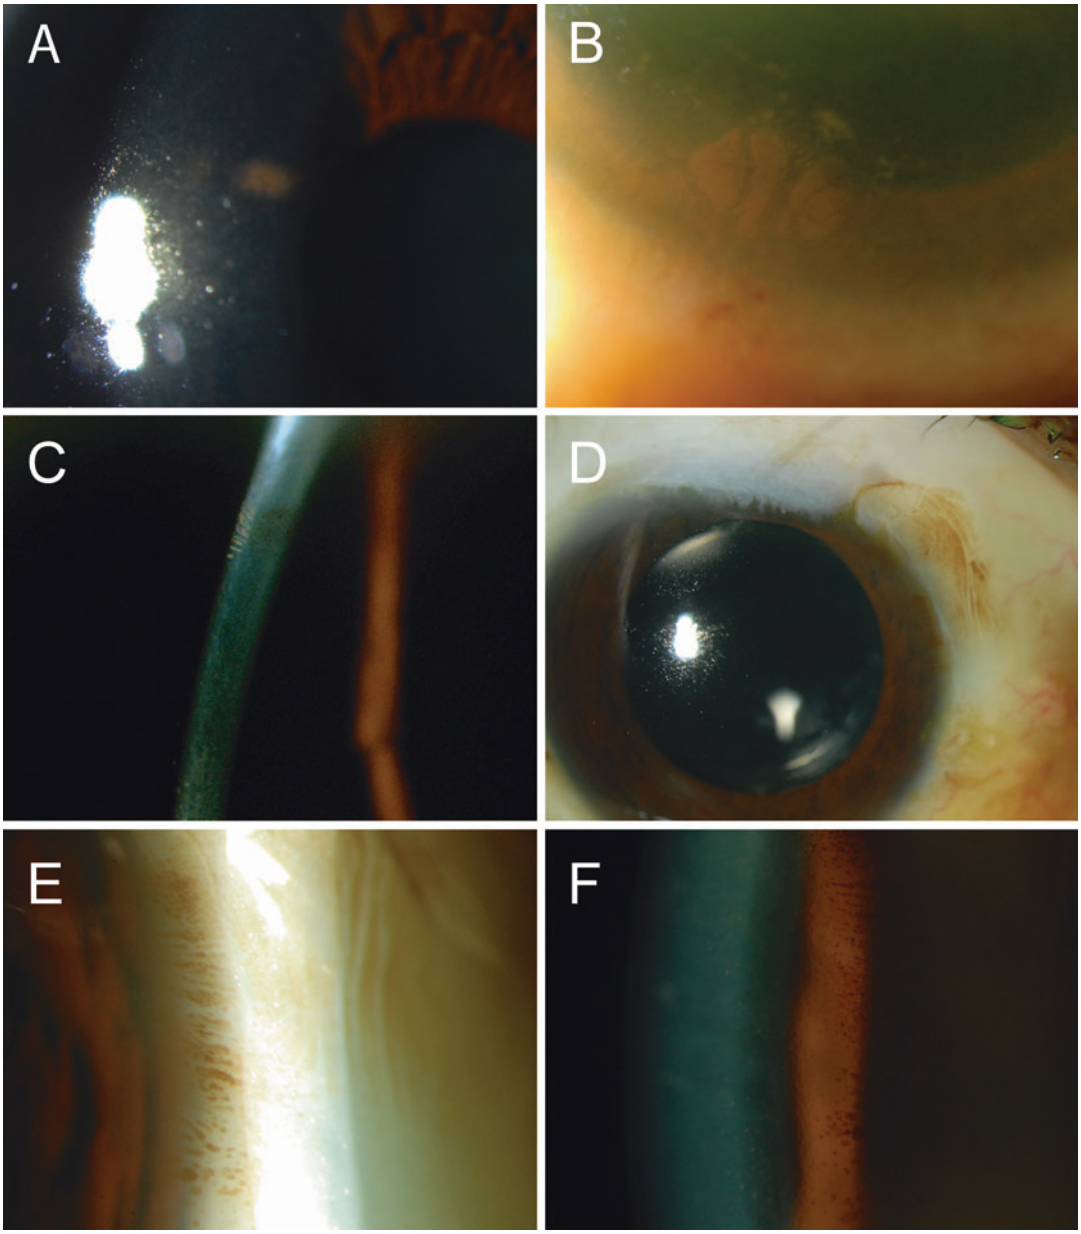
Definition

Striate melanokeratosis is a condition in which melanin-containing cells migrate centripetally along the subepithelial cornea, particularly in heavily pigmented individuals (Fig. 1a–c) (Boto-de-los-bueis et al. 2009). The corneal limbus contains a strip of melanoblasts containing pigment of varying density, depending on race. Individuals with dense perilimbal pigment will often demonstrate a benign migration under intact corneal epithelium, leading to a permanent local opacity. However, striate melanokeratosis may also be secondary to insult or chronic inflammation of the corneal epithelium. It has been postulated that melanin from local melanocytes transfers onto adjacent limbal epithelial cells, or the melanocytes themselves migrate centrally. This forms pigmented subepithelial lines, in some instances as part of a natural healing process in response to disruption of the corneal epithelium.

Histopathologic studies demonstrate melanin granules in the basal epithelium with occasional superficial scattering; the epithelium overlying remains intact and does not stain with fluorescein (Cowan 1964). The cornea, normally devoid of pigmented cells, assumes a vortex-shaped pattern of radiating lines extending from the limbus toward the apex 3–5 weeks after the inciting injury and may remain permanent or gradually fade. If substantial, cellular migration may even render the limbus unpigmented (Krachmer et al. 2010). While this process is typically benign and asymptomatic, the lesion may rarely be accompanied with impaired visual acuity (temporary or permanent), vascularization, and burning pain, the latter secondary to stimulation of corneal nerve endings by cell migration (Cowan 1964).

Etiology

Striate melanokeratosis typically manifests in dark-skinned individuals with markedly pigmented limbi in the abscess of corneal injury, but has been shown to occur secondary to disruption of corneal epithelium (especially within 4 mm of the limbus) such as diffuse superficial keratopathy, abrasion, recurrent corneal erosion, ulcerative keratitis, herpetic keratitis, neurotrophic keratitis, cataract surgery, and penetrating keratoplasty (Cowan 1964; Lemp 1991; Michaelson 1952; Stank



Striate Melanokeratosis, Fig. 1 Various presentations of striate melanokeratosis. (**a**) Striate melanokeratosis in heavily pigmented individual in paracentral cornea. (**b**) Peri-limbal pigment migration within peripheral cornea. (**c**) Pigment collection seen at the subepithelial cornea extending to corneal stroma. (**d**) Striate melanokeratosis in a post-trabeculectomy patient, low magnification. (**e**) Striate melanokeratosis in a post-trabeculectomy patient, high magnification. (**f**) Striate melanokeratosis in a post-trabeculectomy patient seen via retroillumination, high magnification

et al. 1990). In addition, 5-fluorouracil used during trabeculectomy has been observed to trigger pigmentary line formation in the cornea (Fig. 1d–f) (Krachmer et al. 2010; Peterson et al. 1990). This should not be surprising given that 5-fluorouracil has been demonstrated to stimulate pigment

formation in the skin with topical administration and in veins when used intravenously. Minor infiltration of pigmented cells (less than two millimeters) may also be seen with limbal nevus and melanoma (Cowan 1964).

Occurrence

Striate melanokeratosis is prevalent in heavily pigmented individuals with or without prior corneal epithelial injury. However, it has also been noted in Caucasians in cases of conjunctival melanosis, limbal nevus, and limbal melanoma.

Stromal Bed

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Residual stromal bed (after ablation)

Basic Characteristics

The stromal bed is the part of the corneal stroma which is ablated with an excimer laser. In PRK, the stromal bed is exposed after Bowman's layer is ablated. In LASIK, the stromal bed is exposed after the flap is created and folded back. For a regular excimer laser ablation, it should be avoided to touch or hydrate the stromal bed prior to ablation. The remaining stroma after the ablation is referred to as the residual stromal bed (RSB). Only the RSB but not the flap stroma does contribute to the biomechanical strength of the cornea. Therefore, RSB thickness is an important parameter. The RSB thickness can be estimated by subtracting nominal flap thickness and ablation depth from total corneal thickness. More accurate is an intraoperative measurement by ultrasonic or OCT pachymetry (Wirbelauer and Pham 2004).

An intraoperative monitoring technique of stromal bed surface has been described but is not commercially available yet (Schruender et al. 2002).

Stromal Degenerations

Omar Shakir
University of Florida – Jacksonville, Jacksonville, FL, USA

Synonyms

Keratoconus; Keratoglobus; Pellucid marginal degeneration (PMD)

Definition

Stromal degenerations of the cornea are characterized by bilateral, progressive thinning of the cornea.

1. Paracentral areas of the cornea in keratoconus
2. Peripheral thinning spherically in keratoglobus
3. Inferior and peripheral regions of the cornea in pellucid marginal degeneration

Epidemiology

Keratoconus is the most common corneal dystrophy/degeneration, while keratoglobus is rare. These degenerations are typically diagnosed in the second decade of life and progress into the third and fourth decades. Pellucid marginal degeneration is very rare.

Male and female distribution is roughly equal.

History

Patients with stromal degenerations can present both with stable and decreasing vision. Rarely, these patients may present with acute onset of pain and blurry vision in the setting of acute hydrops resulting from a break in Descemet's membrane.

Patients also sometimes complain of "ghost" images, or monocular polyopia. Often these visual aberrations cannot be corrected with spectacles. Patients may present after worsening irregular astigmatism having unsuccessfully tried spectacles and contact lenses.

Clinical Features

"Scissoring reflex" is evident on streak retinoscopy. Rizzuti's sign can be seen as a conical reflection of the nasal cornea when a penlight is shone from the temporal side. Munson's sign is seen as indentation of the lower eyelid when the patient looks down.

Slit-lamp exam demonstrates protrusion of the cornea paracentrally, inferiorly, or peripherally. Vogt's striae may be seen as vertical striations in the deep stroma or Descemet's membrane. The striae will disappear as pressure is applied to the cornea. A Fleischer ring may be seen in the epithelium as an iron deposit lines adjacent to areas of thinning.

Corneal topography exam will show thinning of the cornea with associated steepening also paracentrally, inferiorly, or peripherally.

Tests

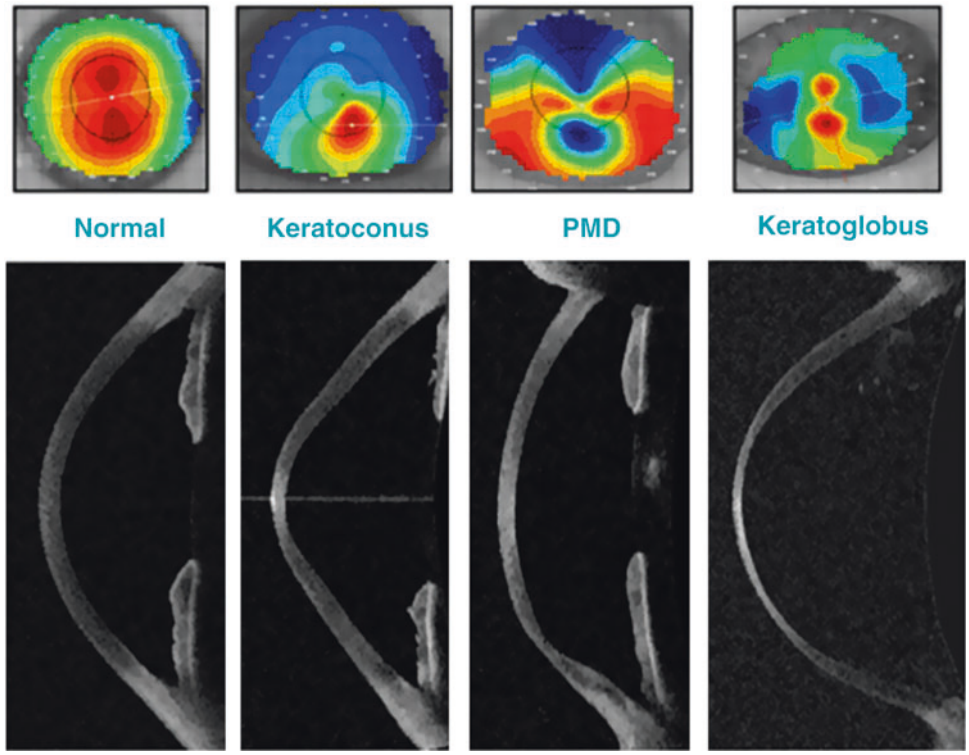
Corneal topography, manual keratometry, anterior segment optical coherence tomography (OCT), and pachymetry.

Differential Diagnosis

Contact lens induced corneal changes and corneal ectasia following refractive surgery.

Etiology

Etiology is unknown but they can be associated with collagen vascular disease, atopy, and Leber congenital amaurosis.



Stromal Degenerations, Fig. 1 Corneal tomography and corresponding anterior segment OCT in keratoconus, PMD, and keratoglobus

Treatment

Spectacles and contact lens may achieve suitable vision for the patient. Commonly, the patient will need a rigid gas permeable lens, or some type of hybrid contact lens to produce a hard central corneal surface.

Surgically, corneal collagen cross-linking with riboflavin and UV-A light has produced good results. Cross-linking restores mechanical strength to the corneal stroma and inhibits progression of the disease process.

Other surgical treatments include intrastromal corneal ring segments and radial keratotomy to flatten the corneal curvature in certain areas. End-stage surgical treatments include penetrating keratoplasty and deep anterior lamellar keratoplasty (Fig. 1).

Stromal Dystrophies

Saeed Alwadani
Department of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Synonyms

Amyloidosis V and familial amyloid polyneuropathy type IV (FAP-IV); Classic lattice

corneal dystrophy, LCD type 1 and Biber-Haab-Dimmer; Granular corneal dystrophy type 1 (GCD1), Groenouw corneal dystrophy type I; Granular corneal dystrophy type 2 (granular-lattice) (GCD2), Combined granular-lattice corneal dystrophy or Avellino corneal dystrophy; Lattice corneal dystrophy (LCD), gelsolin type (LCD2) Familial amyloidosis, Finnish type (FAF); Macular corneal dystrophy (MCD), Groenouw corneal dystrophy type II or Fehr spotted dystrophy; Meretoja syndrome

Definition

Corneal stromal dystrophies are a group of inherited disorders of the cornea that are caused by progressive accumulation of deposits within the stroma. These deposits are not caused by inflammation, infection, or trauma but by genetic mutations that lead to abnormal accumulation of insoluble material within the stroma. The disorders may or may not affect vision and can be symmetric or not. They usually present in the second to third decades of life. The major corneal stromal dystrophies include lattice, granular, and macular dystrophy.

Etiology

Stromal corneal dystrophies can be classified according to the presence or absence of the mutation in the transforming growth factor beta 1 (TGFB1) gene, located on chromosome 5q31. This gene encodes for keratoepithelin, a protein that is secreted by the corneal epithelium.

The TGFB1 dystrophies are granular, lattice, and Avellino. On the other hand, the non-TGFB1 dystrophies include macular dystrophy, Schnyder corneal dystrophy, congenital stromal corneal dystrophy, Fleck corneal dystrophy, central cloudy dystrophy of François, and pre-Descemet corneal dystrophy.

We will discuss here the most common three stromal dystrophies:

Lattice Stromal Dystrophy

Lattice corneal dystrophy (LCD) is the most common type of the corneal stromal dystrophies, and pattern of inheritance is autosomal dominant. There are five subtypes. LCD type 1 is the most frequent, which has been referred to as Biber-Haab-Dimmer corneal dystrophy. LCD type 2 is part of the systemic disorder familial amyloid polyneuropathy type 4 (Finnish type), also known as Meretoja's syndrome, and it is unrelated to the mutation of TGFBI protein. LCD types III and IIIA present later in life with thicker linear opacities in the mid-corneal stroma. LCD type III is an autosomal recessive condition presenting in the seventh to eight decade of life.

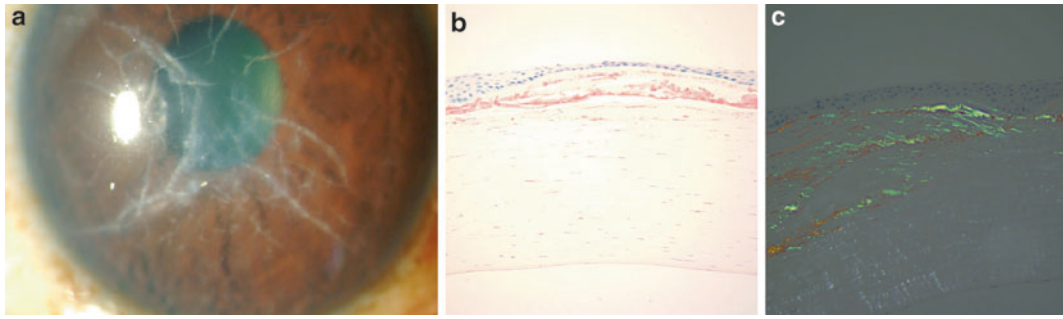
Clinically begins in the first decade and PK is indicated during the fourth or fifth decade. Recurrent epithelial erosions often occur. Stromal haze and epithelial surface irregularity may decrease vision.

On slit lamp, the opacities usually are most dense anterior and centrally, with a clear zone in the corneal periphery, characterized by lattice form of branching relucent lines in the corneal stroma (Fig. 1a). Histologically, corresponds to eosinophilic stromal deposits of amyloid that stain positive with Congo red (Fig. 1b) and show apple green birefringence with polarized light (Fig. 1c).

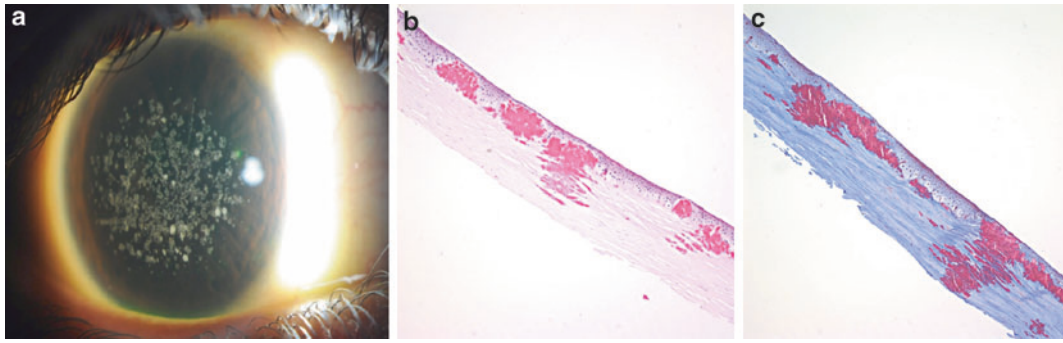
Granular Stromal Dystrophy

Granular corneal dystrophy (GCD) is an autosomal dominant condition also caused by mutations in the BIGH3 granular gene. There are two types of GCD including corneal dystrophy type I and granular corneal dystrophy type II (granular-lattice, Avellino corneal dystrophy).

GCD type I is the most common and benign entity of CSD. Clinically, most of patients are asymptomatic, whereas some others may develop recurrent erosions. Visual acuity remains stable because these opacities are separated by intervals of clear corneal stroma. Visual loss develops in the fifth decade of life or later. Slit-lamp examination is remarkable for the presence of well-demarcated opacities in the central stroma and intervening clear stroma (Fig. 2a).



Stromal Dystrophies, Fig. 1 (**a**) Clinical presentation. (**b**) Congo red. (**c**) Apple green birefringence



Stromal Dystrophies, Fig. 2 (**a**) Clinical presentation. (**b**) H&E. (**c**) Masson trichrome

Histopathologic findings with GCD type I show abnormal hyaline granular extracellular deposits within the stroma (Fig. 2b) that is highlighted by MT stains as chalky red stromal deposits (Fig. 2c).

GCD type II or Avellino dystrophy is a rare condition in which granular and lattice dystrophy components are present. The majority of patients with this condition are from Avellino region, in Italy.

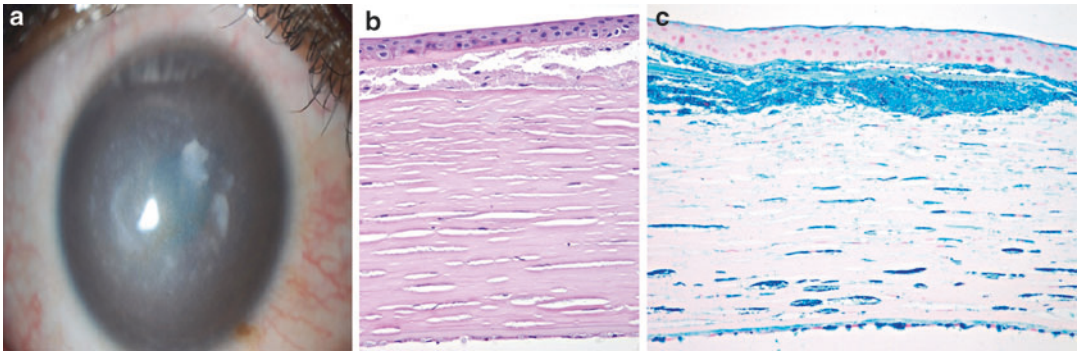
Histopathologically, stromal amyloid and hyaline deposits stain positive with Congo red and MT stains.

Macular Corneal Dystrophy

Macular corneal dystrophy (MCD) is an autosomal recessive condition caused by a mutation on chromosome 16, leading to a defect in the synthesis of keratan sulfate, the major glycosaminoglycan of the cornea. Although it is much less common than other main corneal stromal dystrophies, it is the most severe inherited disorder. MCD is relatively rare in the United States, but it is the most common stromal dystrophy in Iceland, due to its small gene pool, and in Saudi Arabia, due to frequency of consanguinity. There are three subtypes of MCD that have been described based on the presence or absence of immunoreactive keratan sulfate within various tissues.

Clinically, most of the patients develop severe visual loss by age 20–40 years and usually require corneal transplantation. On slit-lamp examination, the presence of a diffuse grayish indistinct stromal haze that extends from limbus to limbus, affecting all cornea layers, is noted (Fig. 3a).

Histopathologically, subepithelial extracellular deposits are highlighted by alcian blue stains (Fig. 3b) and colloidal iron stains (Fig. 3c), as well as intracellular abnormal mucopolysaccharide deposits in keratocytes and endothelial cells that demonstrate glycosaminoglycans.



Stromal Dystrophies, Fig. 3 (**a**) Clinical presentation. (**b**) Alcian *blue stain*. (**c**) Colloidal iron stain

Differential Diagnosis

Differential diagnoses for stromal dystrophies include:

- Epithelial and subepithelial dystrophies including epithelial basement membrane dystrophy, Meesmann corneal dystrophy, Lisch epithelial corneal dystrophy, and gelatinous drop-like corneal dystrophy
- Bowman's corneal dystrophies including Reis-Bücklers corneal dystrophy or Thiel-Behnke corneal dystrophy
- Endothelial corneal dystrophies including posterior polymorphous corneal dystrophy

Therapy

The treatment of corneal stromal dystrophies depends on the manifestation; if early in the disease process, no treatment is needed. Recurrent erosions can be treated with therapeutic contact lenses, superficial keratectomy, or PTK. When visual acuity is decreased, the phototherapeutic keratectomy, lamellar keratoplasty, or penetrating keratoplasty may be useful, depending on the depth of the corneal deposits.

In general, recurrence of any of these stromal dystrophies may occur also in the corneal graft. It is thought that lattice dystrophy recurs more often followed by granular and macular dystrophies.

Stromal Graft Rejection

Kathleen Jee
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

Stromal graft rejection is a host immunologic response to donor corneal tissue characterized by inflammatory cells infiltrating the stroma. Rejection typically occurs months to years following a corneal transplant, but at minimum, the graft must be previously clear for 2 weeks after keratoplasty for the diagnosis to be made. Of the types of corneal graft rejection, isolated stromal rejection is less frequent than endothelial and epithelial rejection

and has fewer long-term consequences. It can be seen in conjunction with endothelial rejection.

Characteristic signs include peripheral haze or infiltrate that progresses toward the center of the graft. Stromal neovascularization may also be observed. In more severe cases of graft rejection, the stroma can become necrotic. Patients may complain of pain, redness, decreased visual acuity, irritation, or photophobia, but can often present asymptomatically.

In most cases, a good visual outcome is attained with prompt, aggressive treatment with corticosteroids to maintain integrity of the graft and minimize progression to the more severe endothelial rejection and graft failure.

Stromal Keratitis (Herpetic)

Rabia Karani
Johns Hopkins School of Medicine, John Hopkins University, Baltimore, MD, USA

Synonyms

Endothelial keratitis; Herpes simplex stromal keratitis (Yanoff et al. 2009)

Definition

Primary inflammatory condition of the corneal stroma caused by herpes simplex virus (Rapuano 2011).

Etiology

The most common cause of stromal keratitis is herpes simplex virus (HSV). HSV-1 typically infects areas above the waist such as the face, lips, and eyes. HSV-2 mainly affects the genital area but can be transmitted to eyes during birth or intercourse. Most cases of childhood stromal keratitis are caused by HSV-2 virus transmitted during birth (Kanski and Bowling 2003). In children, stromal keratitis is more frequently bilateral than in adults. It has also shown greater recurrence in children and greater visual loss (Finch 2010). Recurrence in HSV virus in adults is mediated by environmental factors such as fever, menstruation, sunlight, irradiation, and emotional stress (Yanoff et al. 2009).

Stromal keratitis is primarily an immune-mediated disease and can be but is not necessarily caused by active, replicating virus (Yanoff et al. 2009). Corneal antigens and HSV antigens cause a cell-mediated destruction process of the corneal stroma. Alterations of the antigenicity of the stromal keratocytes in which the virus lives can cause recurrent cycles of an immune-mediated or autoimmune inflammatory response. These antigens are expressed on means of antigen processing (MHC) molecules in corneal stromal cells and become the target of lymphocytes, CD4+ T cells, antiviral antibodies, serum complement, polymorphonuclear leukocytes (PMNs), and macrophages. The host immune response is necessary to destroy the virus that is present in the eye, but the detrimental effects of the immune response include inflammation and tissue destruction (Krachmer et al. 2010).

Clinical Presentation

There are two major types of stromal keratitis caused by HSV: necrotizing stromal keratitis and non-necrotizing stromal keratitis, also known as ► disciform keratitis or immune stromal keratitis.

Necrotizing Stromal Keratitis

This disease is usually a hypersensitivity reaction to live viral particles in the corneal stroma. It is characterized by necrotic, cheesy, stromal infiltration with stromal melting, accompanied by severe corneal opacification. Epithelial defects may be present; anterior uveitis with keratic precipitates may underlie the area of stromal infiltration, and intraocular pressure is usually elevated even with

minimal anterior chamber involvement. In its most severe form, the disease may cause scarring, vascularization, perforation, and lipid deposition. Common symptoms include redness, tearing, irritation, blurred vision, and photophobia (Kanski and Bowling 2003; Rapuano 2011). This condition can sometimes lead to glaucoma (Yanoff et al. 2009).

Non-necrotizing Stromal Keratitis

Non-necrotizing stromal keratitis typically manifests as diffuse or focal stromal opacities accompanied by a Wessely Ring (Yanoff et al. 2009). The epithelium and endothelium are usually spared. Common symptoms include redness, tearing, irritation, blurred vision, and photophobia. Anterior uveitis, elevated intraocular pressure, limbitis, folds in Descemet's membrane, and decrease in corneal sensation are also associated with stromal keratitis (Rapuano 2011).

Diagnostics

Clinical observation mediated by the use of a slit lamp can be used to make a diagnosis. Diagnosis can be confirmed by the use of polymerase chain reaction (PCR) to detect viral antigens. Examination of corneal scrapings can be used to identify the immune response against the corneal stroma (Krachmer et al. 2010).

Differential Diagnosis

Non-necrotizing Stromal Keratitis

Differential diagnoses of non-necrotizing stromal keratitis include herpes zoster disciform keratitis, ▶ Fuchs' dystrophy, acute corneal hydrops of ▶ keratoconus, or contact lens overwear (Rapuano 2011).

Necrotizing Stromal Keratitis

Differential diagnoses include primary or secondary bacterial or fungal keratitis and diseases that also present with an overlying epithelial defect. These conditions should be considered if there is a little response to antiviral medications (Rapuano 2011).

Prophylaxis

Long-term daily oral acyclovir reduces the rate of recurrence of stromal keratitis by about 50% and is usually well tolerated. This therapy should be considered in patients with recurrence only (Kanski and Bowling 2003).

Therapy

Treatment for both forms of stromal keratitis is generally the same, with a few additional measures for necrotizing stromal keratitis. Non-necrotizing stromal keratitis may resolve itself if the inflammation is mild, but in more severe cases, treatment is needed. Topical steroids such as prednisolone 1% in conjunction with antiviral prophylaxis are common treatment measures. Recommended dosing is four times per day at the start of therapy, then gradually tapered to once a week. Any epithelial lesions should be treated before beginning treatment with corticosteroids. In cases of necrotizing stromal keratitis, systemic antiviral medication (acyclovir 400 mg) five times a day for many weeks is indicated, especially to treat anterior uveitis. Corneal transplant is not recommended for cases of necrotizing stromal keratitis (Rapuano 2011).

Prognosis

Prognosis of non-necrotizing stromal keratitis is usually good, although some stromal scarring may occur and cause a reduction in vision. Prognosis of necrotizing stromal keratitis is somewhat poor since significant stromal scarring that can severely affect the vision remains. There is also a threat of recurrence of the disease (Rapuano 2011).

Epidemiology

Herpes simplex stromal keratitis is the most common cause for corneal opacification in the developed world. Around 500,000 patients in the United States are afflicted, with 50,000 episodes every year, and 20,000 new cases appearing every

year. Approximately 60% of corneal ulcers in developing countries are caused by herpes simplex virus, and as many as ten million people may have herpetic eye disease worldwide (Kanski and Bowling 2003). HSV establishes latency and can thus cause recurrent cases of stromal keratitis (Finch 2010; Krachmer et al. 2010).

Stromal Micropuncture, for Recurrent Corneal Erosions

Eli B. Moses
Department of Ophthalmology, University of Texas – Southwestern Medical Center, Dallas, USA
Corneal Associates of New Jersey, Fairfield, NJ, USA

Synonyms

Corneal micropuncture; Epithelial reinforcement technique

Definition

An operative procedure where superficial puncture wounds are made in the cornea for treatment of recurrent erosion, map-dot-fingerprint dystrophy, and other superficial dystrophic or degenerative disorders of the cornea.

Indication

Patients with recurrent corneal erosions or epithelial basement membrane dystrophy (EBMD) that failed conservative medical management including lubricants, hypertonic saline solutions, topical corticosteroids, systemic tetracyclines, and therapeutic bandage contact lenses.

Contraindications

Patients with severe basement membrane dystrophy and numerous spontaneous, multifocal erosions are better candidates for superficial keratectomy than anterior stromal puncture. Patients with recurrent erosions or epithelial defects that are secondary to deeper corneal dystrophies or degenerations would not be good stromal puncture candidates. In these patients, the surgical management can vary from epithelial debridement for superficial disease to phototherapeutic keratectomy and anterior lamellar keratoplasty for stromal corneal pathology.

Techniques and Principles

Anterior stromal puncture is an in-office procedure generally done at the slit lamp after a careful exam for epithelial defects. Erosions and defects are best seen at the slit lamp using angled broad-beam illumination and retroillumination. Gentle pressure on the cornea may cause wrinkling indicative of loose epithelium.

Topical anesthetic and nonsteroidal drops are instilled preoperatively. A broad-spectrum antibiotic drop can be used preoperatively to reduce the chance of infection. Fluorescein can help aid in visualization of the erosions and puncture marks. A lid speculum can be used in a concerned patient.

The procedure can be performed using a specially designed 25-gauge needle with a bent top (preventing the patient from visualizing the tip and shaft) or a standard short 25-gauge needle attached to a tuberculin syringe. In the latter scenario, care must be taken to ensure that the punctures are made superficially. The clinician makes numerous superficial puncture wounds in the involved area. The punctures should not be confluent and should include 1–2 mm of normal epithelium outside the area of the defects. Treatment should be used with caution in the visual axis. Postoperatively, broad-spectrum antibiotic, nonsteroidal, and cycloplegic drops should be instilled. Some advocate for the use of a bandage contact lens after the procedure. Oral tablets for pain control can be useful. After the epithelium has healed, hypertonic drops should be used during the day and hypertonic ointments at night to promote epithelial integrity (Rubinfeld 1995).

While efficacious, the mechanism of action for anterior stromal puncture is not fully understood. The punctures are thought to produce a firm adhesion between the epithelium and the underlying stroma. This occurs through the epithelium filling the puncture sites forming a temporary adhesion, while normal attachment complexes can form (Hsu et al. 1993). Others postulate that the punctures induce a fibrotic reaction and a new basement membrane is formed. Histological studies have shown that the lesions produced by this procedure can indeed create subepithelial scars (Katsev et al. 1990).

Outcome

Reports of success after a single stromal puncture session for recurrent erosions are in the range of 80% (Reidy et al. 2000). The treatment may need to be repeated, usually because the initial area of treatment was inadequate. Significant scars are rarely visible for more than a few months after the procedure.

Complications

After anterior stromal puncture, patients can experience foreign body sensation as well as discomfort upon awakening. As with any corneal procedure, there is a rare chance of infection.

Sub-brow Fat Pads

Allison J. Chen[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Preseptal fat; Septal fat pannus; Submuscular fibroadipose tissue (SMFAT); Suborbicularis fibroadipose tissue

Definition

The sub-brow fat pad is a superficial fat layer existing between the orbicularis oculi muscle and orbital septum. It is a thin fat layer that is vastly spread in the upper eyelid just inferior to the orbital rim.

Structure

The sub-brow fat pad is a distinct layer of fibroadipose tissue that lies posterior to the orbicularis oculi and anterior to the orbital septum. Inferiorly, the sub-brow fat pad continues to the point where the orbital septum joins the levator aponeurosis, approximately 2–5 mm above the superior tarsal border (Meyer 1991; Kakizaki 2009). Superiorly and superolaterally, the sub-brow fat pad extends into the eyebrow region, where it is termed the "retro-orbicularis oculus fat" (ROOF).

The sub-brow fat pad contains more fiber components than the orbital fat pads. Histologic sections, gross dissections, and radiologic imaging have demonstrated that the fibrous septa within the fibroadipose tissue become contiguous with more compact lamellae of the orbital septum, giving the orbital septum a multilayered quality (Meyer 1991). The sub-brow fat pad is firmly attached to the orbital septum and cannot be completely dissected with blunt dissection.

Function

The physiologic significance of the sub-brow fat pad is to enhance eyelid and brow motility and to support the orbital septum.

Clinical Relevance

Over time, the sub-brow fat pad undergoes gravitational descent. Clinically, the displaced sub-brow fat pad can sometimes be confused with a prominent prolapsed preaponeurotic fat pad or a coexisting redundant eyelid fold. During blepharoplasty, the descended sub-brow fat pad must be addressed in addition to the skin/eyelid fat adjustment.

The anatomic relationship of the sub-brow fat pad and the eyelid must be remembered when operating on the eyelid, as the sub-brow fat pad can often be mistaken for the preaponeurotic fat of the eyelid and may lead to surgical error (Meyer 1991; Tan 2011).

In the Asian eyelid, there is often a more substantial sub-brow fat pad. Therefore, although ROOF resection alone is often efficacious in improving the thickness and heaviness of the upper eyelid in whites (Kakizaki 2009), it is often necessary to additionally resect the sub-brow fat pad in Asians to produce an aesthetic "double eyelid" (Ichinose 2008; Kakizaki 2009; Tan 2011).

In upper blepharoplasty procedures, volumizing the brow may result in a more aesthetically pleasing contour of the upper eyelid. If there is dermatochalasis due to deflation of the sub-brow fat pad, fat can be suctioned from a donor region (e.g., abdomen) and injected via cannula into the sub-brow fat pad region through the open blepharoplasty incision (Hoenig 2010).

Subconjunctival Hemorrhage

Maria J. Suarez
Ocular Pathology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Conjunctival hemorrhage; Hyposphagma

Definition

Subconjunctival hemorrhage (SCH) is a benign common clinical condition characterized by painless accumulation of blood underneath the conjunctiva or hemorrhage between conjunctiva and episclera in the absence of an obvious cause (Yanoff and Fine 2002; Tarlan and Kiratli 2013).

Etiology

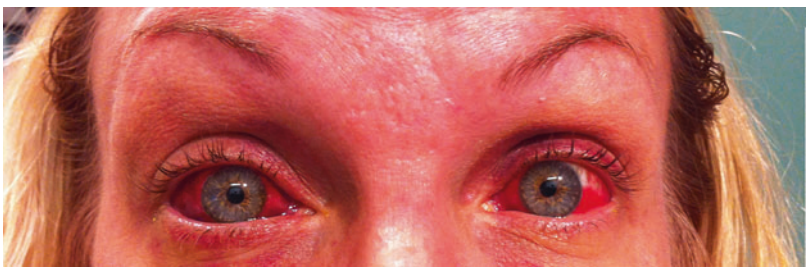
Most cases present suddenly without a clear cause. Contributing factors such as local trauma, acute hemorrhagic conjunctivitis, prolonged coughing, vomiting, or any other forceful Valsalva maneuvers have been previously described.

When SCH recurs, careful evaluation needs to be performed in order to assess association with systemic diseases such as diabetes mellitus, uncontrolled hypertension, and arteriosclerosis, any bleeding disorders including chronic therapy with anticoagulants, and, less commonly, ocular amyloidosis (Tarlan and Kiratli 2013).

There are ocular conditions that may also predispose to SCH. Besides any sort of globe rupture or orbital injury, conjunctivochalasis, contact lens wear, ocular surgery, and adnexal tumors can also be associated with SCH (Yanoff and Fine 2002; American Academy of Ophthalmology 2012; Sahinoglu-Keskek et al. 2013; Tarlan and Kiratli 2013).

Occurrence

SCH represents a relatively frequent eye entity and also a common emergency room diagnosis since its appearance can be dramatic and alarming to the patient (Fig. 1).



Subconjunctival Hemorrhage, Fig. 1 Bilateral subconjunctival hemorrhage

Classification

No classification has been documented for SCH.

Subepithelial Corneal Degenerations

Mingjuan Lisa Zhang
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Peripheral hypertrophic subepithelial corneal degeneration

Definition

Peripheral hypertrophic subepithelial corneal degeneration (PHSCD) is an idiopathic disorder that consists of peripheral, bilateral, elevated subepithelial corneal opacities, and adjacent abnormal limbal vasculature.

Etiology

The cause of PHSCD is unknown, though the lack of coexisting systemic or local ocular disease suggests that it is a primary condition. Similarities to familial pterygoid corneal dystrophy suggest that PHSCD may have a genetic component.

Clinical Presentation

PHSCD presents with peripheral, usually bilateral, symmetric elevated circumferential peripheral subepithelial corneal opacities (often sausage-roll shaped) and adjacent abnormal limbal vasculature. In most cases, the opacifications deform the normal shape of the cornea, leading to pronounced astigmatism. Some present with pseudopterygia. There is no chronic ocular surface inflammation. Symptoms include ocular surface discomfort (pain, itching, etc.) and reduced/blurred vision, though it can be asymptomatic (Maust and Raber 2003).

Diagnosis

PHSCD patients often present with decreased visual acuity due to astigmatism and ocular surface irritation caused by the irregular corneal surface and unstable tear film. Selected findings for the diagnosis of PHSD are (i) gray-colored continuous subepithelial fibrosis causing regular and irregular astigmatism, (ii) flattening of the cornea based on topography, and (iii) typical revascularization in the peripheral part of the fibrous tissue.

Differential Diagnosis

Idiopathic PHSCD, Salzmann nodular degeneration, familial pterygoid corneal dystrophy, corneal intraepithelial neoplasia, keratopathies, corneal amyloidosis, corneal keloid, hereditary hypertrophic scarring, and corneal trauma

Therapy

Asymptomatic patients do not require any treatment. Topical lubricants and superficial keratectomy can be used to relieve symptoms of ocular discomfort (Järventausta et al. 2014). Short-term recurrences after surgery are infrequent.

Prognosis

In the largest case study thus far (Gore et al. 2013), one-fourth of patients were asymptomatic and did not require any treatment. Conservative management with lubricants was sufficient for one-third of patients, and surgery was conducted in another one-third of patients who experienced significant ocular discomfort, progressive astigmatism, visual acuity changes, or neoplastic concerns.

Epidemiology

PHSCD was first described in 2003 and is a relatively new disease. It is uncommon and disproportionately affects white females, especially those with light-colored eyes.

Subepithelial Graft Rejection

Alireza Eslampoor
Eye Research Center, Khatam-al-anbia Eye Hospital, Mashhad, Razavi Khorasan, Iran

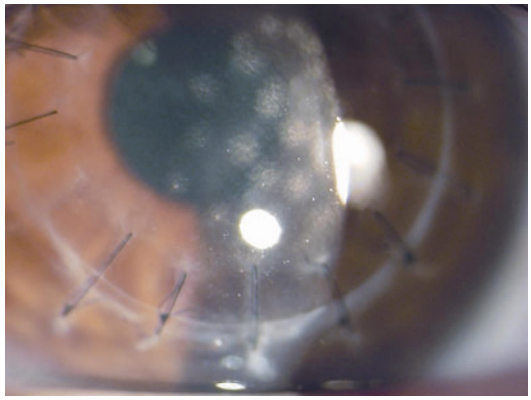
Synonyms

Allograft rejection; Subepithelial infiltrate

Definition

Subepithelial graft rejection refers to cellular infiltration of the cornea as discrete subepithelial infiltrates during allograft corneal graft rejection. These infiltrates are reminiscent of those seen in epidemic keratoconjunctivitis. They are small in size (0.2–0.5 mm) and hazy in color (white to grayish) and are usually scattered in the central cornea and occur exclusively in the donor tissue but not the peripheral recipient cornea. It could occur alone or in concert with attacks of epithelial or endothelial rejection (Copeland and Afshari 2013).

This phenomenon was first described by Krachmer and Alldredge in 1978 (Krachmer et al. 2011). These lesions are an early sign of acute allograft rejection and are considered to be harbinger of more intense reaction. They usually respond rapidly to topical steroid therapy and usually leave no residual infiltrate or scar. These infiltrates are usually seen early in the postoperative period (1–13 months). It seems that replacement of the epithelium with recipients' cells obviates its rejection in patients with older grafts. Symptoms include redness of the eye, decreased vision, light sensitivity, or discomfort in the eye that lasts longer than a few hours (Fig. 1).



Subepithelial Graft Rejection, Fig. 1 Subepithelial corneal graft rejection (Courtesy of Charles S. Bouchard, MD. American Academy of Ophthalmology, ONE Network Image Collection)

Etiology

Immunologic response of recipient cornea to antigens of donor cornea that occurred at the subepithelial layer of donor cornea.

Occurrence

Subepithelial graft rejection has occurred in 10–15% of cases of corneal graft rejection.

Classification

On the basis of anatomic location, corneal graft rejection could be classified as:

1. Epithelial
2. Subepithelial
3. Stromal
4. Endothelial

On the basis of locations for subepithelial infiltrates, they could be classified as:

Central and paracentral infiltrates. Where cellular infiltrates following subepithelial corneal graft rejection, acute adenoviral keratoconjunctivitis, protein-coated, extended-wear soft contact lenses and also after herpes simplex or zoster epithelial keratitis are classified in the central location (Krachmer et al. 2011).

Subepithelial infiltrates following marginal staphylococcal (catarrhal) keratitis and peripheral ulcerative keratitis (PUK) are located in paracentral or paralimbal zone (Copeland and Afshari 2013).

Subretinal Exudation

► Subretinal Fluid

Subretinal Fluid

João Pedro Marques and Rufino Silva
Department of Ophthalmology, Centro Hospitalar e Universitário de Coimbra (CHUC), Faculty of Medicine, University of Coimbra (FMUC), Coimbra, Portugal

Synonyms

Neurosensory retinal detachment; Serous detachment of the sensory retina; Subretinal exudation

Definition

Subretinal fluid corresponds to the accumulation of a clear or lipid-rich exudate (serous fluid) in the subretinal space, i.e., between the neurosensory retina (NSR) and the underlying retinal pigment epithelium (RPE), in the absence of retinal breaks, tears, or traction (Kanski et al. 2011). It represents a breakdown of the normal anatomical arrangement of the retina and its supporting tissues, i.e., the RPE, Bruch's membrane, and the choroid.

Etiology and Classification

Changes in choroidal flow, poor scleral outflow, breakdown of the RPE, and leakage/breakdown of normal or abnormal retinal vessels are the pathophysiological mechanisms that are isolated or in combination associated with subretinal fluid accumulation (Wolfensberger and Tufail 2000). There are some defining features, however, that are common to all cases of subretinal fluid: (1) serous fluid accumulation between the NSR and the RPE in the absence of a rhegmatogenous or tractional component; (2) a characteristic shifting of this fluid with postural changes; (3) a smooth, dome-shaped appearance of the detached retina lacking corrugations or fixed folds; and (4) the presence of associated local (ocular) or systemic conditions (Yanoff and Duker 2014). Identifying a precise etiology can be challenging since the causes of subretinal fluid accumulation are broad and heterogeneous, encompassing several ocular and systemic pathologies. For matters of systematization, an etiologic-based classification is portrayed here:

1. *Inflammatory and autoimmune diseases*: posterior scleritis, systemic lupus erythematosus, Wegener's granulomatosis, polyarteritis nodosa, relapsing polychondritis, dermatomyositis, Goodpasture's disease, rheumatoid arthritis, sarcoidosis, sympathetic ophthalmia, Vogt-Koyanagi-Harada disease, inflammatory bowel disease, pancreatitis
2. *Infectious diseases*: syphilis, toxoplasmosis, tuberculosis, Lyme disease, cat-scratch disease, cytomegalovirus infection, histoplasmosis, coccidiomycosis, cryptococcus, HIV infection
3. *Neoplastic disorders*: choroidal melanomas and nevi, retinal or choroidal hemangiomas, metastatic choroidal lesions, retinoblastoma, leukemia, multiple myeloma
4. *Vascular diseases*: diabetic retinopathy, retinal vein occlusions, retinal macroaneurysms,

hypertensive retinopathy, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, renal failure, eclampsia/preeclampsia

5. *Congenital abnormalities*: coat's disease, familial exudative vitreoretinopathy, retinal angiomatosis, optic pit, optic disk and/or retinal colobomas, morning glory syndrome, nanophthalmos
6. *Miscellaneous*: central serous chorioretinopathy, pathologic posterior vitreous detachment producing vitreomacular traction, epiretinal membrane, exudative age-related macular degeneration (AMD) (including neovascular phenotypes of AMD such as polypoid choroidal vasculopathy or retinal angiomatous proliferation), uveal effusion syndrome, iatrogenic (interferon or ribavirin treatment-related, among other dugs), bilateral diffuse uveal melanocytic proliferation (BDUMP)

Occurrence and Diagnosis

Unless precluded by hazy ocular media, the presence of subretinal fluid can generally be established during a thorough clinical examination using indirect ophthalmoscopy (Kanski et al. 2011). Even though the location, extent, and area occupied by the subretinal fluid can vary according to the etiology, the NSR detachment characteristically assumes a convex, dome-shaped configuration with a smooth, fold-free surface. Shifting of fluid to dependent positions with postural changes is a distinctive finding that should be sought during examination. Although the condition may be asymptomatic, decreased visual acuity can be manifest at presentation whenever the fluid accumulates under the macular area (e.g., central serous chorioretinopathy). Metamorphopsia, reduced color vision, and reduced contrast sensitivity are also commonly reported symptoms. The advent of leopard spots, consisting of scattered areas of subretinal clumping, may be seen after a prolonged NSR detachment has flattened (Yanoff and Duker 2014).

Subretinal fluid can be uni- or bilateral and may be observed as an isolate finding or occur in combination with other ocular findings such as lipidic exudation, retinal hemorrhages, serous and/or hemorrhagic retinal pigment epithelium detachments (PED), intraretinal fluid and/or cysts, choroidal neovascularization, choroidal effusion, cotton wool spots, or even optic nerve swelling. A detailed personal history along with a meticulous ophthalmologic examination in order to identify associated features is critical to establish a correct diagnosis. Sometimes the cause is readily apparent during fundus examination (e.g., choroidal tumor) but additional testing may be necessary depending on the clinical scenario (e.g., blood testing or even cerebrospinal fluid sampling when infectious or autoimmune etiologies are suspected).

Ancillary imaging like B-scan ultrasonography, computerized tomography, or magnetic resonance may be helpful in cases of hazy ocular media or retrobulbar pathology, whereas multimodal retinal imaging may assist in challenging cases (Kanski et al. 2011). With the advent of optical coherence tomography (OCT), the diagnosis of clinically asymptomatic serous elevations of the neurosensory retina has become more frequent. An optically empty space, filled with serous fluid, can be seen between the detached NSR and the RPE. OCT can be extremely valuable both in the differential diagnosis of subretinal fluid and in the monitoring of retinal changes during treatment (Yanoff and Duker 2014). Recently, advances in this imaging technique through enhanced depth imaging OCT (EDI-OCT) and swept-source OCT (SS-OCT) have been used to better evaluate choroidal changes in various diseases, such as central serous chorioretinopathy and Vogt-Koyanagi-Harada disease, thus enhancing our knowledge of the pathophysiological mechanisms involved. Fluorescein angiography (FA) and indocyanine green angiography (ICGA) can help differentiate various diseases, identify specific areas of leakage, and guide focal laser treatment and photodynamic therapy, when appropriate.

Differential Diagnosis

The differential diagnosis of subretinal fluid includes (1) serous or hemorrhagic PED, (2) tractional retinal detachment, (3) rhegmatogenous retinal detachment, (4) retinoschisis and/or foveoschisis, (5) intraretinal fluid accumulation (including cystoid macular edema), and (6) choroidal detachment (Wolfensberger and Tufail 2000). When a thorough fundoscopic examination is insufficient to establish the presence of a serous detachment of the sensory retina with a high degree of certainty, ancillary tests should be used to complement the clinical evaluation. This is especially significant in situations where treatment depends on the presence/absence of retinal/subretinal fluid (e.g., photodynamic therapy for chronic central serous retinopathy or focal laser treatment for focal diabetic macular edema). From all the available instruments, OCT is definitely the most widely used. It is a noninvasive diagnostic tool that provides insight into the retinal morphology through high-resolution, cross-sectional images of the retina. It can easily identify the precise location of fluid accumulation (intraretinal/subretinal/sub-RPE/choroid), thus being used both for diagnosis and follow-up.

Subtenon's Anesthesia

Armin Wolf
Department of Ophthalmology, Ludwig-Maximilians Universität München, München, Germany

Synonyms

Episcleral anesthesia

Definition

Percutaneous application of anesthetics into the subtenon space between the globe and tendon capsule.

Epidemiology

Subtenon's anethesia (STA) is mainly used as an alternative to retrobulbar anethesia in less invasive ocular surgery. Usually it causes anesthesia but ineffective motorblock. Some surgeons use STA before intravitreal injection. It is also used in cataract surgery.

History

Subtenon's anesthesia has been used for a long time.

Clinical Features

STA does usually not produce sufficient motorblock. Therefore, the advantages over topical anesthesia are mainly the full anesthesia of the whole globe (Davison et al. 2007). For STA, there is mainly two techniques (Nouvellon et al. 2010). The first technique is the blunt technique, in which a small conjunctival incision is performed creating a conjunctival "button hole." Thereafter,

anesthetic is delivered into the subtenon space using a blunt needle. The second technique is performed using a small gauge sharp needle: After the plica semilunaris is punctured by a sharp needle, the needle is then pushed forward subconjunctivally towards the canthus into the subtenon space. Thereafter, the needle is pushed posterior forcing adduction of the globe and anesthetic is applied.

In both techniques, the anesthetic distributes in the subtenon space providing sufficient anesthesia of the whole globe. Using higher volumes, motorblock can be reached; however, at higher volumes, conjunctival edema is frequent.

Tests

Conjunctival edema has been shown to occur in 6–60%, and subconjunctival hemorrhage is found in 7–100%.

Differential Diagnosis

Topical anesthesia (TA), peribulbar anesthesia (PBA)

Etiology

The term "subtenon's anesthesia" is describing the location of the anesthetic in the subtenon space.

Treatment

See also "▶ Clinical Features."

Superficial Keratectomy

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Superficial epithelial keratectomy

Definition

Operative procedure for treatment of recurrent erosion, map-dot-fingerprint dystrophy, and other superficial dystrophic or degenerative disorders of the cornea.

Epidemiology

No epidemiologic data available for this topic.

History

Superficial keratectomy has been performed since the early 1980s. Buxton et al. were among the first who performed this procedure to treat epithelial basement membrane dystrophy.

Clinical Features

See Treatment section below.

Tests

Thorough examination of the anterior segment with the slit lamp and corneal topography, pachymetry, and measurement of uncorrected and best spectacle-corrected visual acuity are mandatory to maintain best possible postoperative results.

Differential Diagnosis

Other types of incisional keratotomy:

- Phototherapeutic keratectomy
- Surface cautery
- Debridement
- Anterior stromal puncture

Etiology

See ► History section above.

Treatment

After topical anesthesia, the treated area is identified with fluorescein staining. The epithelium is then gently removed by scraping with a dry surgical sponge or a disposable blade. After the defined area is removed, the surface can be polished to receive best postoperative results. Finally, pressure patching is performed or the patient receives a therapeutic soft contact lens to assure appropriate wound healing and visual improvement.

Superior Limbic Keratoconjunctivitis

Lojain M. AlBat'hi and Majed Alkharashi
Department of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Synonyms

SLK; Theodore's superior limbic keratoconjunctivitis

Definition

SLK is a chronic noninfectious inflammatory disorder characterized by inflammation of the upper tarsal and bulbar conjunctiva. It was described by Frederick Theodore in 1963 as inflammation of tarsal and bulbar conjunctiva, punctate staining of the cornea and its adjacent conjunctiva, limbic proliferation, and presence of filaments limited to the superior limbus or upper fourth of the cornea.

Epidemiology

Superior limbic keratoconjunctivitis typically affects women with a female-to-male ratio of 3:1, usually affecting ages 20–60 years with a mean age of 50. There are no reported familial cases but it did affect identical twins. SLK affects people of different ethnic backgrounds and geographical distributions and not related to specific climates.

Etiology

The etiology of SLK is still to be determined as many studies were conducted and the causes are still unknown. Theories suspected a viral etiology but never have been proven. Whereas a bacterial cause has been excluded with negative cultures, no immunological-specific defect was found.

However, a number of associations were linked to SLK including dry eye disease, contact lens abuse, lid anomalies, and autoimmune diseases such as thyroid disease. Understanding the primary abnormality of the disease helps to explain many of these associations. In SLK there is continuous rubbing of the superior palpebral conjunctiva against the superior bulbar conjunctiva due to tight eyelids. This eventually leads to chronic inflammation and subsequently the clinical picture of SLK. Studies suggested that a mechanical factor was supported by the fact that there is upregulation of TGF-β2 and tenascin which are induced by mechanical trauma.

Based on this theory, several studies proved the association of SLK with thyroid dysfunction, particularly thyrotoxicosis, in which exophthalmos causes tightening of the eyelids which increases the friction between the palpebral and bulbar conjunctivae.

Furthermore, keratoconjunctivitis sicca (dry eye disease) is also associated with SLK. It occurs due to a deficiency in the tear film or tear component leading to a drying effect that causes friction between the upper lid and the bulbar conjunctiva, this causes inflammation of the palpebral conjunctival surface that prevents the normal healing process.

To summarize, there is no specific cause for SLK but a number of predisposing factors were proven, such as associated thyroid dysfunction (20–65%), autoimmune disease (3.5%), or contact

lens wear (10%). However, approximately 31.6% of cases are idiopathic or related to aging.

Clinical Presentation

SLK is a chronic disorder with flares and remissions. Typical symptoms may be unilateral or bilateral and include red eyes, foreign body sensation, pain, and tearing due to ocular irritation, mild photophobia, and frequent blinking. Some patients present with blepharospasm and mucoid discharge if filaments are present.

On examination, classical signs are (1) corneal hypoesthesia, (2) hyperemia and inflammation of the upper palpebral and bulbar conjunctivae, (3) fine papillary reaction, (4) sectoral injection, (5) thickening and redundancy of the superior bulbar and limbal conjunctiva (this is observed by having the patient look down and lifting the upper lid), (6) keratinization of the affected conjunctiva, (7) superior punctate epithelial keratitis, (9) and finally superior corneal and limbic filaments and thickening are frequently seen. In advanced cases, some patients present with ptosis and mucoid discharge.

Diagnosis

Diagnosis of SLK is mainly based on history and careful examination of the lid surface with lid eversion. Certain bedside tests can support the clinical diagnosis of SLK. With the use of topical anesthesia, sliding the superior bulbar conjunctiva over the superior cornea with a cotton-tip applicator, this shows the redundancy of the superior bulbar conjunctiva, as it is not seen in normal healthy eyes. In addition, the use of rose bengal or lissamine green stains will show coarse punctate staining of the superior bulbar and limbal conjunctiva, and the use of fluorescein dye clearly stains corneal epithelial defects such as punctate keratopathy. Cultures have no role, as no significant bacterial pathogen has been isolated. Histopathologically, the superior bulbar conjunctiva shows keratinized epithelium and polymorphonuclear leukocytes with an unusual pattern and aggregation of nuclear chromatin (pyknosis).

Differential Diagnosis

Using the clinical criteria in diagnosis, there are minimal differentials to SLK. Contact lens-induced keratoconjunctivitis mimics SLK in presentation and cytological characteristics but with lens intolerance and irritation. The use of thimerosal-preserved solution and superior riding of soft contact lens are suggested etiologies. The possible etiology of mechanical trauma behind the two could be the reason of similarity in presentation.

Contact lens-induced keratoconjunctivitis can be distinguished from SLK clinically as it occurs in younger patients, with no gender preference; could be unilateral, with greater corneal involvement and decreased vision, not associated with thyroid disease; and usually resolves upon discontinuation of use of contact lenses. Histopathologically, keratinization and filaments characterize SLK but are not as prominent in contact lens-induced keratoconjunctivitis. Therefore, the terminology contact lens-superior limbic keratoconjunctivitis (CL-SLK) is not precise to describe contact lens-induced keratoconjunctivitis and SLK cannot be used with contact lens consumers.

Other unlikely differentials are vernal and atopic keratoconjunctivitis which present with diffuse signs that are not confined to the superior limbus and tarsal conjunctiva as SLK. Also they are associated with seasonal recurrences and a history of atopy.

Prophylaxis

There are no definitive prophylactic therapies or recommendations to prevent the occurrence or relapse of SLK. However, some studies proved that after the combination use of 1% prednisolone acetate drops and 0.5% topical silver nitrate with the addition of 0.5% topical cyclosporine A four

times a day can give long-term (6 months–3 years) relief and improvement of signs and symptoms.

Therapy

Most patients will respond to lubricant eye drops, short course of topical corticosteroids eye drops, and mast cell stabilizers. Resistant cases may require additional treatment with autologous serum, bandage soft contact lenses, silver nitrate, thermocauterization, or others.

SLK is caused by mechanical trauma and dryness of the conjunctiva due to a defect in the tear volume and quality. Therefore, initial management of SLK includes the use of preservative-free artificial tears and lubricating ointments. Also application of mast cell stabilizers, such as lodoxamide tromethamine, cromolyn sodium, and ketotifen fumarate, has been proven to improve the symptoms of SLK.

Another treatment option is local application of 0.5–1% silver nitrate solution. It is applied to the palpebral or both the palpebral and affected superior bulbar conjunctiva. This causes chemical debridement which improves the symptoms for up to months. The use of solid nitrate should be avoided as it can cause serious chemical burn.

Different treatment modalities aim to reduce the mechanical interference between palpebral and bulbar conjunctiva. Patients who did not respond to silver nitrate and have normal Schirmer tear test and resection or recession of the conjunctiva serve best at improving symptoms. In cases with filaments, pressure patching or soft therapeutic contact lens could be used.

Permanent punctual occlusion can also be used in coexisting keratitis sicca with resolution of symptoms and findings including reversal of squamous metaplasia and increase in goblet cell number.

Several topical medications can help in the management of SLK. Topical steroids have significant effect in certain patients while vasoconstrictors only minimal. Vitamin A (retinol palmitate) eye drops are effective in 83% of users with no recurrence on continuation of use.

Cyclosporine A 0.5% can be used as primary or adjunctive therapy as immunosuppressant and immunomodulator that inhibits CD4, T-lymphocyte infiltration into lacrimal ducts, fibroblast proliferation, and collagen formation. It improves SLK symptoms by decreasing the inflammatory response and increasing tear production and may be effective in the management of SLK when treatment fails with topical corticosteroids.

Prognosis

Even though SLK is a chronic disease with remissions and relapses, with accurate diagnosis and management, it can be controlled. In general the prognosis of SLK is excellent because this disease is limited to the superior fourth of the cornea.

Definition

The superior orbital fissure is a foramen at the back of the orbit that separates the orbital roof from the lateral wall of the orbit and connects the orbit to the cavernous sinus in the brain.

Structure

The superior orbital fissure divides the lesser and greater wing of the sphenoid bone and is closed laterally by the frontal bone. It is wider at the medial end and is therefore often described as comma shaped. It is roughly 22 mm long and the largest communication between the orbit and middle cranial fossa. The tip of the fissure is roughly 30–40 mm from the fronto-zygomatic suture. There are a number of very important structures that run through the superior orbital fissure. These include the superior and inferior divisions of the oculomotor nerve (III); trochlear nerve (IV); lacrimal, frontal, and nasociliary branches of the ophthalmic division of the trigeminal nerve (V1), the abducents nerve (VI), the superior and inferior divisions of the ophthalmic vein, and sympathetic fibers from the cavernous plexus. The optic foramen, through which the optic nerve and ophthalmic artery run, lies just superior and medial to the superior orbital fissure in the lesser wing of the sphenoid. It is separated by the optic strut. There is a common tendinous ring, also known as the annulus of Zinn, that spans the superior orbital fissure between the wide medial and narrow lateral parts and is comprised of the origins of the rectus muscles and the superior tendon of Lonckwood. The frontal nerve, lacrimal nerve, trochlear nerve, and superior ophthalmic vein pass above the annulus of Zinn; all other structures run through the annulus of Zinn. In general, nothing passes below the annulus, except rarely the inferior ophthalmic vein.

Function

The superior orbital fissure functions as a bony aperture through which many important structures pass from the brain into the orbit.

Clinical Relevance

Given the number of important cranial nerves and vasculature that passes through the superior orbital fissure, compromise in this area can present as diplopia, exophthalmos, and ptosis. Known as superior orbital fissure syndrome, this can occur in cases of infiltrative, inflammatory, or ischemic processes. A complete superior orbital fissure syndrome is defined as when all neurovascular components are damaged producing a total ophthalmoplegia, ptosis, and corneal hypoesthesia. The pupil may be dilated, miotic, or unreactive depending on the balance of parasympathetic and sympathetic damage. The superior ophthalmic vein may be dilated if obstructed giving rise to increase intraocular pressure, fullness of the upper eyelid, hyperemia of the deep Tenon's vessels, and retinal vein dilation. Differentiating between a lesion of the superior orbital fissure and anterior cavernous sinus cannot be done clinically and must be seen through imaging. Posterior cavernous sinus pathology can be differentiated by the presence of hypoesthesia in the cranial nerve V2 distribution. Superior orbital fissure syndrome and orbital apex syndrome can be distinguished by the presence of visual loss in orbital apex syndrome indicating compromise that includes the optic canal (Fig. 1).

Synonyms

Whitnall's ligament

Definition

The primary suspensory support for the upper lid found at the intersection of the muscular and aponeurotic portions of the levator.

Structure

The superior transverse ligament (STL) is the transition point or fulcrum between the posterior muscular levator palpebrae superioris (LPS) and its anterior extension the levator aponeurosis (LA). The LPS originates in the orbital apex on the small wing of the sphenoid bone. It extends anteriorly to the orbital aperture where it is suspended from the STL. At this transition point to aponeurosis, it becomes thinner and fans out inferiorly in a sheet-like fashion. It extends horizontally forming the medial and lateral horns which attach to their respective canthi. Inferiorly, the LA attaches to the lower one third of the tarsal plate. The muscular portion of the levator is approximately 40 mm long, while the aponeurotic portion is approximately 14–20 mm in length.

Müller's muscle lies posterior to the levator aponeurosis. It extends from the superior border of Whitnall's ligament to where it inserts approximately 12 mm above the tarsal margin. The peripheral arcade runs along the surface of the muscle allowing for easier intraoperative identification.

The fibrous bands of the STL provide a hammock of support horizontally across the superior orbital aperture. Medially the STL attaches around the superior oblique tendon and trochlea. It extends laterally passing between the orbital and palpebral portions of the lacrimal gland to its lateral attachment approximately 10 mm above the lateral orbital tubercle (Whitnall's tubercle). The lateral orbital tubercle is adjacent to the superior oblique tendon. A few fibers also insert inferiorly at the lateral retinaculum.

Function

The superior transverse ligament (STL) was originally described by Whitnall in 1911. It is the

primary suspensory mechanism for the levator, upper eyelid, larcimal gland, and superior orbit. The STL is also the anatomic superior border of the upper eyelid and helps form the superior conjunctival fornix.

Given its location, the STL is responsible for the transition of the vector forces of the levator from anterior/posterior to the superior/inferior direction. Lockwood's ligament, found in the lower eyelid, is an analog to the STL (see "Retractors" and "Lower Eyelid").

Clinical Relevance

The levator and Müller's muscle are the two retractors of the upper eyelid. Disinsertion, dehiscence, abnormalities of the muscle, or lesions affecting these muscles can cause blepharoptosis or lid retraction. Blepharoptosis surgery is one of the most common oculoplastic procedures thus making identification in the operating room crucial.

The STL's location adjacent to the LPS and function as the primary suspensory mechanism of the upper lid make it an important landmark in surgery. Anatomically, it is often easily identified as white fibrous bands surrounding the levator (Lim et al. 2009). Structural differences in the STL of individuals may affect the eyelid structure and appearance which can impact the success of surgical results.

Weakening of the STL with aging or trauma has also been shown to decrease the ability to elevate the eyelid thus contributing to ptosis.

Surgical Approaches

Ronald L. Fellman and Davinder S. Grover
Attending Surgeon and Clinician, Glaucoma Associates of Texas, Dallas, TX, USA

Introduction

The most significant improvement in glaucoma surgery over the past 10 years is the transition to safer, more physiologic outflow procedures. These

newer blebless procedures lower IOP by reducing resistance to flow through natural trabecular or uveoscleral pathways and are easily combined with phacoemulsification. From a canal-based perspective, procedures such as iStent (Glaukos Corp, Laguna Hills, CA, USA), trabectome (NeoMedix Corporation, Tustin, CA, USA), canaloplasty (iScience Ellex, Menlo Park, CA), gonioscopy-assisted transluminal trabeculotomy (GATT), Kahook Dual Blade (KDB) (New World Medical, Rancho Cucamonga, California, USA), and Hydrus Microstent (Ivantis, Inc., Irvine, CA) likely provide the most long-term benefit to patients with early open-angle glaucoma before their natural collector channels undergo severe atrophy and develop a diminished ability to drain aqueous adequately (Nesterov et al. 1974; Fellman et al. 2015).

This may also be true for the newly approved supraciliary devices (Vold et al. 2016) aimed at reducing IOP by enhancing uveoscleral outflow. In addition, FDA trials involving less-invasive filtration procedures are promising as these newer techniques attempt to standardize filtration and offer safer methods to achieve external filtration (Sheybani et al. 2015; Batlle et al. 2016).

Although we are unable to visualize the improvement in aqueous flow into the collector channels postoperatively (Fellman 2014), one may be able to assess flow into the collector channels intraoperatively following canal-based surgeries (Fellman and Grover 2012). This inability to assess the surgical success postoperatively (aside from intraocular pressure) is very different than our experience with a filtering surgery. With a trabeculectomy, the bleb morphology can often help confirm a successful or failed surgery. When a canal-based surgery fails, we have a limited ability to determine why or how failure occurred.

Fortunately, over the past several decades, refinements in wound healing for trabeculectomy have improved filtration surgery (i.e., mitomycin C and 5-FU). To date, the authors know of no research or information on modulating wound healing within the anterior chamber angle following canal-based surgeries. Once wound healing in the canal can be modulated, the authors postulate that canal-based surgery will be even more successful and popular.

When one cannot maximize the patient's inherent trabecular or uveoscleral drainage system, a new drainage system must be created. The two most common glaucoma surgeries in which a new artificial drain is created are trabeculectomy and glaucoma drainage implants. Successful trabeculectomy creates a filtering bleb, which represents drainage of aqueous through a partial-thickness scleral flap into the subconjunctival and sub-tenon's space. Drainage implants use a tube to shunt aqueous from within the eye to a reservoir sutured to the sclera, beneath Tenon's capsule and conjunctiva. This chapter will further discuss these two main glaucoma surgeries as well as provide an overview of other less-invasive surgical procedures and their indications.

Philosophical Considerations on the Approach to a Surgical Glaucoma Patient

The decision for glaucoma surgery must always be made in conjunction with an understanding of what long-range IOP is necessary to prevent glaucomatous visual loss. This requires considerable experience. The more likely the patient is to lose vision during their lifetime due to uncontrolled glaucoma, the more likely the patient should have aggressive IOP control. Both the physician and patient should be cognizant of the important role incisional glaucoma surgery plays in reducing vision loss from glaucoma. Progressive VF loss is more likely to occur in advanced disease, especially without a significant reduction in IOP (Musch et al. 2009). Under these circumstances, the risks associated with significant IOP reduction are warranted. The physician must clearly explain the potential benefits and complications of the anticipated surgery with the full expectation of what needs to be accomplished and what to do if the surgery fails. To paraphrase George Spaeth MD "there must be a certainty when considering glaucoma surgery, that the person will become significantly worse in the absence of surgery." This is because glaucoma surgery, especially in patients with multiple risk factors for complications and or failure, is not

Surgical Approaches, Table 1 Factors in determining canal-based versus subconjunctival drainage of aqueous

Deciding factors	Canal-based (iStent, trabectome, canaloplasty, trabeculotomy, KDB) GATT	Subconjunctival surgery Filtration or tube shunt
Gonioscopy and angle	Angle must be open with clear landmarks, scleral spur delineated	Angle may be open or closed
Disk damage	Mild to moderate disk damage	Any level of disk damage, typically advanced
Risk	Lower risk surgery	Higher risk surgery (short and long term)
Age	Younger patients are better candidates because the collector system is less atrophic	Any age
Medication tolerability	Postoperative patients more likely to still require medications	Best for patients intolerant to medical therapy
Prior ALT	ALT may cause scarring in canal	Subconjunctival filtration not dependent on prior ALT
Ocular discomfort	Rare	More common with dysesthesia, tearing, potential diplopia, tube exposure, etc.

always successful, and a significant complication may further reduce vision. It is incumbent upon the physician to minimize surgical risk by choosing the best procedure for the unique circumstances for the patient (Table 1).

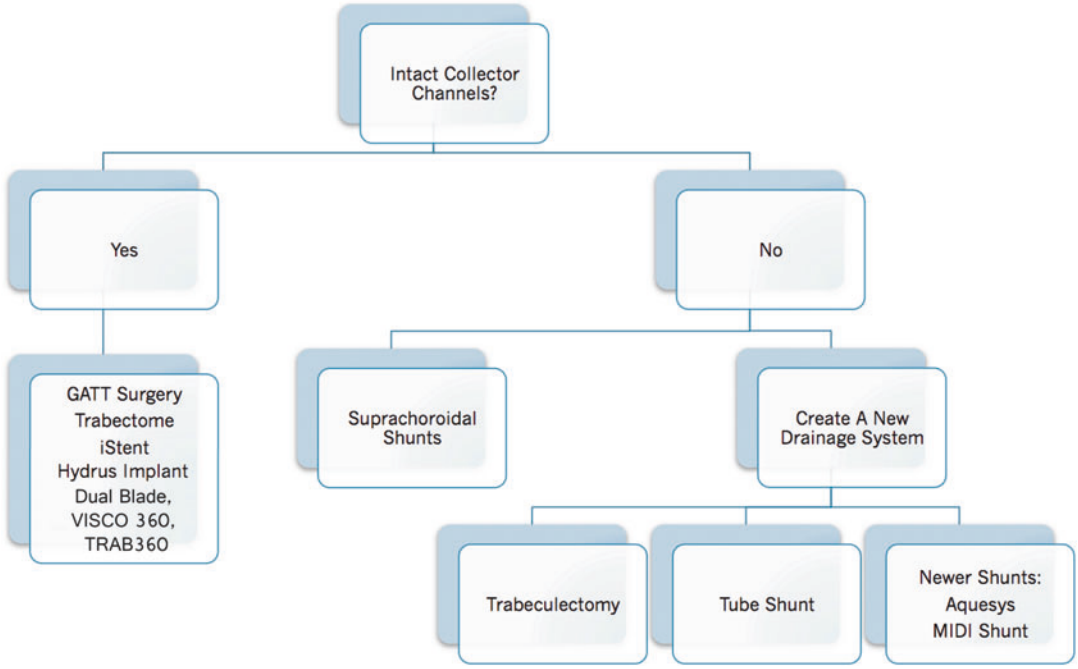
Glaucoma patients must understand that elevated IOP leads to visual loss and that in spite of our best efforts, glaucomatous visual loss may occur during their lifetime (Malihi et al. 2014) and that preventing blindness from glaucoma is an uphill battle. Communication between physician, patient, and family is crucial when dealing with the highly variable outcomes of glaucoma surgery that are mainly due to unpredictable wound healing and the intricacies of this unrelenting disease. The authors stress that the key to the surgical approach is to tailor the procedure to the patient's unique needs and disease state, not simply fall back, as in years past, on filtration or tube-shunt surgery for every patient. As we learn more about uveoscleral outflow, preserving collector channels and modulating wound healing in the canal, outcomes for improving natural channel outflow will improve, much like it has for filtration surgery over the past decades.

Preliminary Assessment of the Glaucoma Patient

Decades ago, most patients with uncontrolled primary open-angle glaucoma (POAG) or primary angle-closure glaucoma (PACG) underwent filtration surgery. Today, many surgeons prefer drainage implants over filters because no limbal bleb is present, but these devices still share many problems of external filtration including hypotony, scarring, and other unique problems such as diplopia and tube and plate erosion. Both of these time-honored procedures divert the aqueous underneath the conjunctiva creating an artificial drainage space. Today, patients now have a choice between improving flow into their natural drain and creating a new one (Fig. 1). A great deal of clinical experience is necessary in order to decide on the best surgical procedure for the glaucoma patient. The preliminary clinical assessment is the key to deciding what is best; the mnemonic A, B, C, D, and E is useful in the decision-making process.

(A) **Angle and age**

- Angle. It is imperative to assess the angle gonioscopically in order to diagnose the type of glaucoma and view the potential structures for canal-based surgery. If the surgeon is unable to locate the scleral spur, then the angle anatomy may not be favorable for a stent or canal procedure. If the angle structures are easy to identify, consider a canal procedure, especially if the desired IOP is in the mid-teens and the optic disk has mild to moderate damage. Explain to the patient that if flow



Surgical Approaches, Fig. 1 Decision tree for micro-invasive glaucoma surgery versus subconjunctival artificial drainage. Once the technology to visualize the native collector system is available, this decision tree will prove most useful to either enhance resident flow or create a new drainage system

does not improve through their natural collectors, they will need a more invasive procedure to create a new drainage system.

- Age. A also stands for age because younger patients likely have a more intact resident outflow collector system that can be revived compared to a patient who has been on topical glaucoma medications for 30 years with a more atrophic downstream collector system.

(B) **Blood aqueous barrier.** The condition of the aqueous should be evaluated prior to glaucoma surgery. Preoperative flare and cell are signs of a damaged blood aqueous barrier (BAB). A damaged BAB may result in an abnormally high amount of inflammation postoperatively and therefore must be detected preoperatively as this will affect the surgical decision process. For example, the success rates for trabeculectomy and many angle-based surgeries are highly dependent on a pristine blood aqueous barrier. Consider a drainage implant or possibly a trabeculotomy in patients with a permanently altered BAB.

(C) **Conjunctiva.** The condition of the conjunctiva is critical to the success of filtration surgery. If the patient has scarring of the conjunctiva or terrible ocular surface disease, consider a different procedure such as a drainage implant. Often, the health of the conjunctiva can also provide insight into the downstream collector system. If the conjunctiva is severely scarred, or scleral staphyloma is widespread, it is likely that the inherent collector system is dysfunctional.

(D) **Disk**. The stage of glaucoma exemplified by disk and field damage is critical in deciding on an appropriate glaucoma procedure. For example, if the patient has advanced disk damage, or is unable to tolerate drops, a trabeculectomy is ideal to blunt an IOP spike postoperatively and achieve long-term IOP reduction with minimal drug therapy. Under these circumstances, the risk of

blebitis and a lifetime of bleb vigilance are worth the risk of bleb-related visual loss.

(E) **Expertise.** When deciding on a new procedure, it is critical to find the optimal initial procedure. Consider the ABCDEs as a method to determine the best initial procedure for your patient. The overall most important decision is what is best for the patient in the hands of their surgeon. Many of these new minimally invasive surgeries have a steep learning curve and are not without risks.

In general, trabeculectomy lowers IOP more than a canal procedure and is mainly reserved for patients with advanced disease who require very low IOPs in order to maintain their vision. The newer MIGS procedures are finding their place in patients that require combined cataract-glaucoma procedures who have mild to moderate disk damage who may fare well with an IOP in the mid-teens. Typically, MIGS will not get the IOP below episcleral-venous pressure, which is usually close to 10 mm Hg.

This chapter will discuss incisional glaucoma surgery using an outline based on Fig. 1. First, we will discuss surgical procedures that are designed to enhance a patient's inherent drainage system. We will then proceed to discuss more invasive surgical procedures that are designed to create a new drainage system. Lastly, we will discuss surgical procedures designed to decrease aqueous production.

Overview of Incisional Glaucoma Surgeries That Enhance Drainage Through the Resident Venous Collector System (Trabecular Schlemm's Canal Episcleral Network)

Procedures

Trabeculotomy,

- 360° circumferential trabeculectomy, *ab externo*
- 360° circumferential trabeculotomy, *ab interno*, gonioscopy-assisted transluminal trabeculotomy (GATT)
- Trabectome, partial circumference *ab interno* trabeculotomy
- Kahook Dual Blade (KDB)

Mechanism of Action

Trabeculotomy cleaves open the trabecular meshwork and thereby improves flow into Schlemm's canal and resident collector channels. Following this surgery, aqueous no longer needs to travel through the trabecular meshwork juxtacanalicular tissue in order to gain access to the collector channels. *Ab externo* implies a limbal incision with scleral dissection to find the canal, while *ab interno* means that the canal is approached through the anterior chamber without conjunctival or scleral incisions, a major benefit if filtration surgery is ever needed.

Indications/Contraindications

Indications Open-angle glaucomas that are classified as mild to moderate. This surgery works best in glaucoma where the trabecular meshwork is likely the site of pathology, such as pseudoexfoliation glaucoma, developmental glaucoma, POAG, and steroid-induced glaucoma. Surprisingly, circumferential trabeculotomy is also effective in patients with failed filtration and tube-shunt surgery with open angles. Patients who have undergone several anti-VEGF intravitreal injections and develop subsequent glaucoma also do well with this surgery.

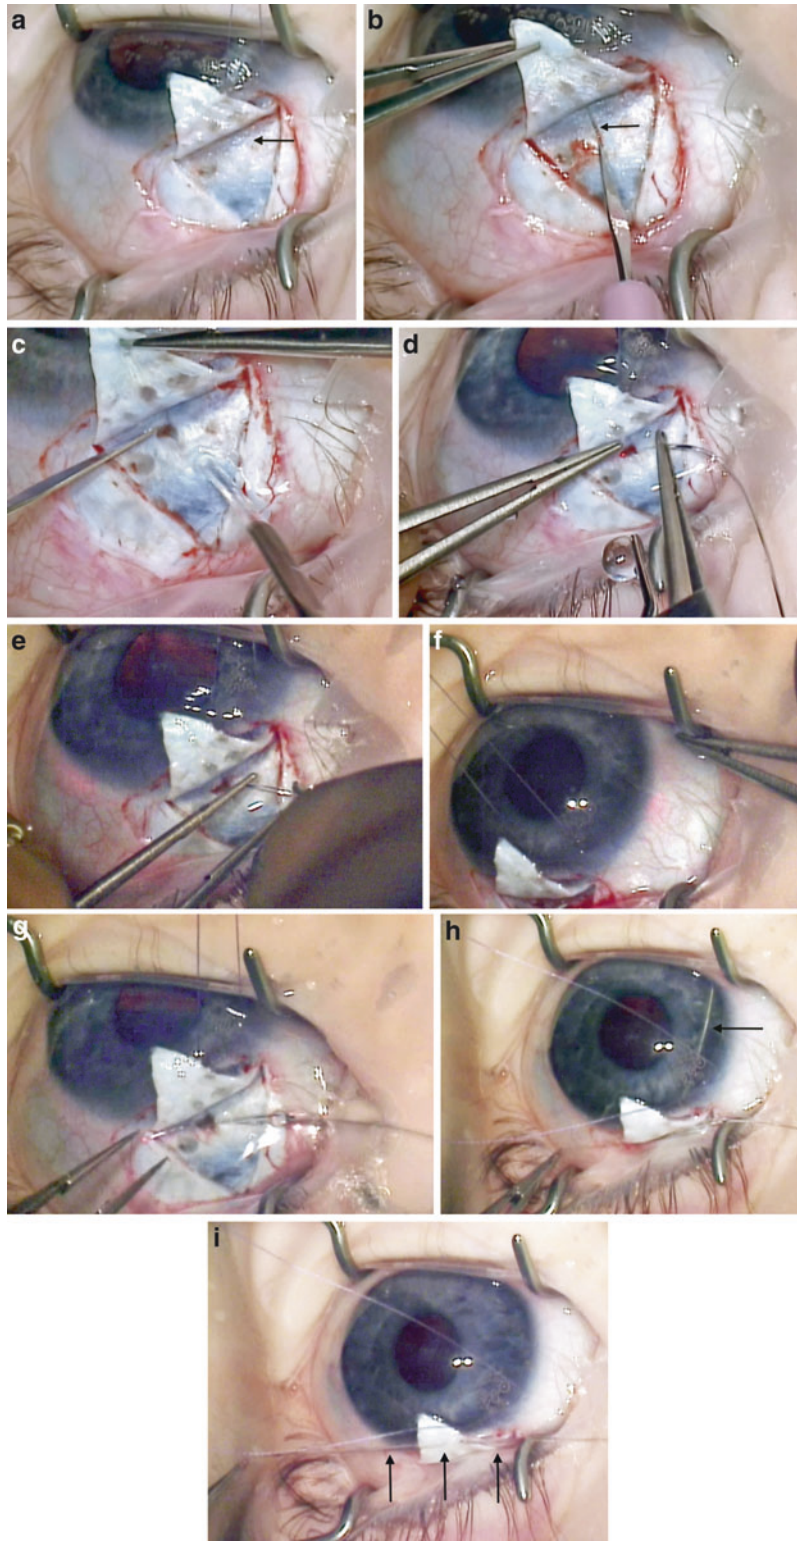
Contraindications Advanced glaucoma, closed-angle glaucoma, an inability to view the anterior chamber angle (except with external approach), a patient at high risk for snuff out if there were an IOP spike in the postoperative period, pseudophakia with advanced disease, and/or an unstable intraocular lens.

S

Key Procedural Components

360° Circumferential Trabeculotomy: *Ab Externo* (Fig. 2)

- Create a large scleral flap, and dissect it anteriorly into the cornea so that one can identify the scleral spur, a white circumferential band in the scleral bed (Fellman 2003).



Surgical Approaches, Fig. 2 (continued)

- Make a radial incision across the spur dissecting into the sclera, fiber by fiber, until the roof of the canal is penetrated, while avoiding entering the anterior chamber. Then make a T-shaped incision along the canal.
- Externally cannulate Schlemm's canal with either a 6.0 blunted Prolene suture or a micro-catheter and pass for 360°. If using a lighted micro-catheter, one can watch the beacon of light tip progress circumferentially along the canal. If using a suture, be sure to premeasure the suture so one knows when to expect to see the distal end. Keep in mind that the average circumference of Schlemm's canal is slightly under 4 cm.
- After retrieving the distal end, tension is placed on both sides of the suture and the 360° trabeculotomy is created. After washing out the hyphema, close the scleral flap and the conjunctiva in a watertight fashion.

GATT Procedure: 360° Circumferential Trabeculotomy: Ab Interno (Fig. 3)

- A cohesive viscoelastic is used to inflate the anterior chamber.
- A goniotomy is created in the nasal quadrant through a temporal corneal paracentesis. A suture (5-0 prolene suture with a small blunted tip) or lighted micro-catheter is passed through a superior or inferior paracentesis. Within the eye, the catheter/suture is used to cannulate Schlemm's canal and pass it around the canal 360°.
- The distal aspect of the catheter/suture is retrieved and externalized, thus creating a 360° trabeculotomy without limbal dissection.
- The viscoelastic is washed from the anterior chamber along with the resulting hyphema.

Trabectome (Fig. 4)

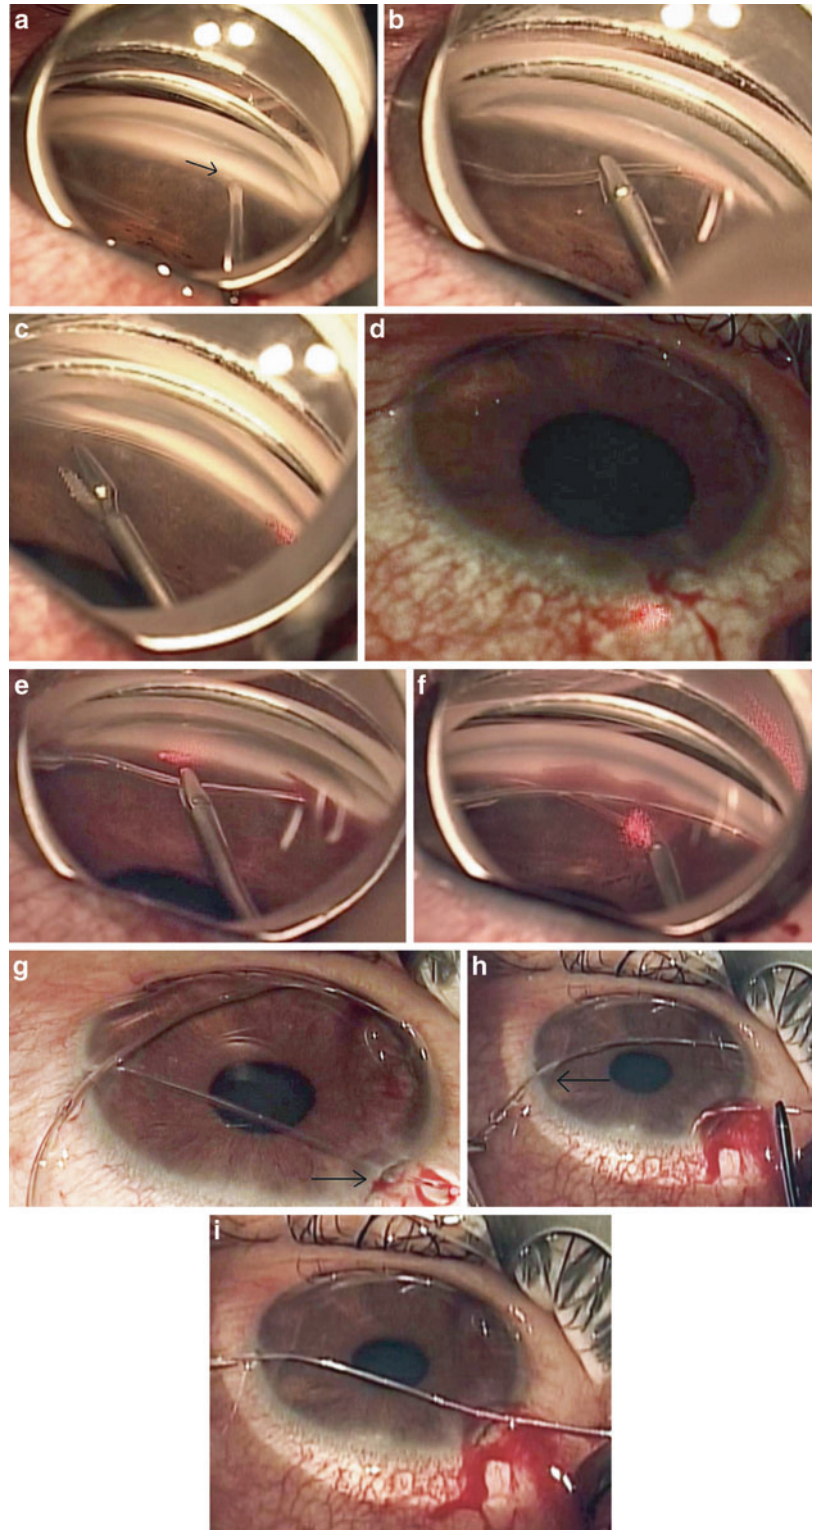
- A temporal clear corneal incision is created.
- The head is tilted away from the surgeon, and microscope tilted toward the surgeon.
- The trabectome handpiece is inserted into the anterior chamber after the irrigation is activated.
- A goniolens is placed on the eye, and the handpiece is directed into the nasal quadrant.
- The trabecular meshwork is incised with the tip of the handpiece. Electrosurgery is foot pedal activated which ablates the trabecular meshwork and inner wall of Schlemm's canal for typically a 4–5 clock hour arc.

Kahook Dual Blade

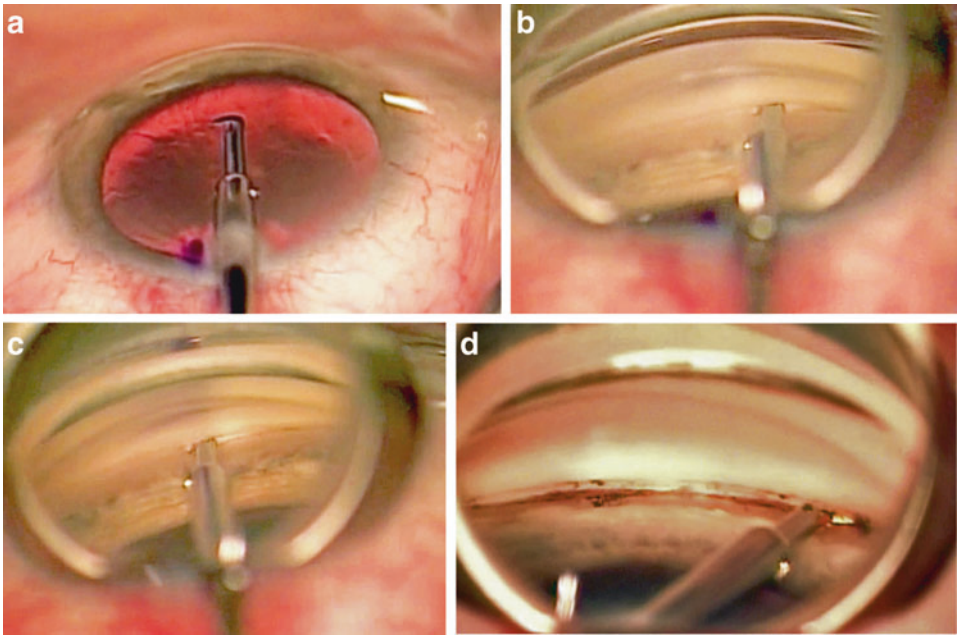
- Similar approach as the trabectome with the exception that the KDB manually incises the trabecular tissue, whereas the trabectome surgery uses electrosurgery.
- KDB requires only a blade and does not require the irrigating setup that is required by trabectome. However, the KDB is performed with the aid of an intracameral viscoelastic which is washed out at the end of the procedure.

S

Surgical Approaches, Fig. 2 Trabeculotomy *ab externo*. (**a**) Following a large conjunctival peritomy and the creation of a 70% thickness scleral flap, one can appreciate the scleral spur (*black arrow*). (**b**) A 15° blade is used to make a cut down perpendicular to Schlemm's canal. Once the canal has been entered, one can usually appreciate a "gush" of fluid or blood. The arrow is denoting the location of the canal. Sometimes, the canal is not where one would think it should be, especially in dysgenic angles. As such, one should make a large perpendicular cut down to ensure proper identification of the canal. (**c**) Once Schlemm's canal has been identified, a cut is made over the canal in a parallel fashion to allow for exposure to the canal and proper access with a suture or a micro-catheter. (**d**) The lighted micro-catheter is used to cannulate Schlemm's canal and ensure the catheter is in the correct location. (**e**) One can appreciate that the light is traveling along the circumference of Schlemm's canal. It has been passed nearly 90° at this point. (**f**) The lighted tip demonstrates the catheter has passed nearly 330°. One should be sure to watch the lighted tip as the catheter can occasionally go down a collector or in to the suprachoroidal space. (**g**) The distal catheter tip has been retrieved, after having passed 360° around the canal. (**h**) Applying traction on the proximal and distal ends of the catheter allows for creation of the trabeculotomy. The catheter can now be seen in the anterior chamber after having broken through the trabecular membrane. (**i**) A 360 circumferential trabeculotomy has been created with the catheter now externalized (*arrows*)



Surgical Approaches, Fig. 3 Gonioscopy-assisted transluminal trabeculotomy (GATT), trabeculotomy *ab interno*. (**a**) Initially, a goniotomy is created with a microvitreoretinal (MVR) blade. (**b**) Schlemm's canal is then cannulated with a micro-catheter, using microsurgical forceps. (**c**) One can appreciate that the catheter has already been passed 2–3 clock hours around Schlemm's canal. (**d**) Given the blinking red light on the distal end of the tip, one can follow the path of the catheter as it travels circumferentially around the canal. The catheter has passed 180° around the canal. (**e**) One can now appreciate that the micro-catheter has come full circle around the canal. (**f**) The distal tip of the catheter is retrieved within the anterior chamber using microsurgical forceps. (**g**) The distal tip of the catheter is then externalized through a paracentesis, and nearly 180° of the trabeculotomy has been completed. (**h**) Tension is placed on the proximal end of the catheter, thus completing the remaining 180° trabeculotomy. (**i**) A full circumferential trabeculotomy has been completed without violating the conjunctiva or sclera



Surgical Approaches, Fig. 4 Trabectome (**a**) Initially, the trabectome handpiece is inserted into the anterior chamber with the infusion in the "on" position. (**b**) The sharp tip of the probe is inserted through the trabecular meshwork. Care is taken to avoid damaging the back wall of Schlemm's canal. (**c**) Once treatment has been initiated, one can appreciate the white stripe representing the back wall of Schlemm's canal. Also note the bubbles near the leading tip of the probe. (**d**) Once treatment of the trabecular meshwork has completed, one is able to appreciate the trabecular groove and an open-angle drainage free of trabecular tissue. Anterior chamber aqueous now has direct access to the downstream collector system

Complications Common to Trabeculotomy

- A postoperative hyphema (most common).
  - Postoperative bleeding is most likely when the IOP drops below episcleral venous pressure (EVP). An intraoperative hyphema is usually a good prognostic indicator that the downstream collectors are intact. Observing an episcleral venous fluid wave is also a good sign.
  - To limit the amount of the postoperative hyphema, one can leave a 10–20% viscoelastic fill in the anterior chamber.
- An IOP spike (transient).
- Steroid-induced IOP elevation.
- A descemet's detachment or a hemorrhagic descemet's detachment can occur (rarely).

Outcomes

- Depending on the specific type of trabeculotomy performed, the success rates range anywhere from 50 to 90% (Grover et al. 2014).
- Developmental glaucomas and secondary open-angle glaucomas tend to do better than other advanced open-angle types of glaucoma.
- If the surgery goes without complication and the trabecular meshwork is removed as a source of resistance to outflow, then the IOP should fall into the mid to upper teens.
- Although direct comparisons between trabectome and circumferential trabeculotomy are not available, one can possibly conclude that treating more of the angle will result in better IOP lowering. This observation has been documented when comparing 360 circumferential filamentary trabeculotomy with segmental trabeculotomies created by a metal trabeculotome (Chin et al. 2012).

Keys to Success
- Understand angle anatomy from an internal and external perspective.
- Feel comfortable performing gonioscopy-assisted glaucoma surgery.
- A patient must have an intact inherent collector system in order for a trabeculotomy to be successful (therefore earlier disease likely will do better).

Procedure

Non-Penetrating Glaucoma Surgery (NPGS)

- **Canaloplasty** (Fig. 5)

Mechanism of Action

Circumferential viscodilation and tensioning of the inner wall of Schlemm's canal is believed to enhance flow into the natural collector channels.

Indications/Contraindications

Indications Open-angle glaucomas that are classified as mild to moderate. Eyes with moderate ocular surface disease where a bleb is not desirable are also candidates and works well in conjunction with cataract surgery.

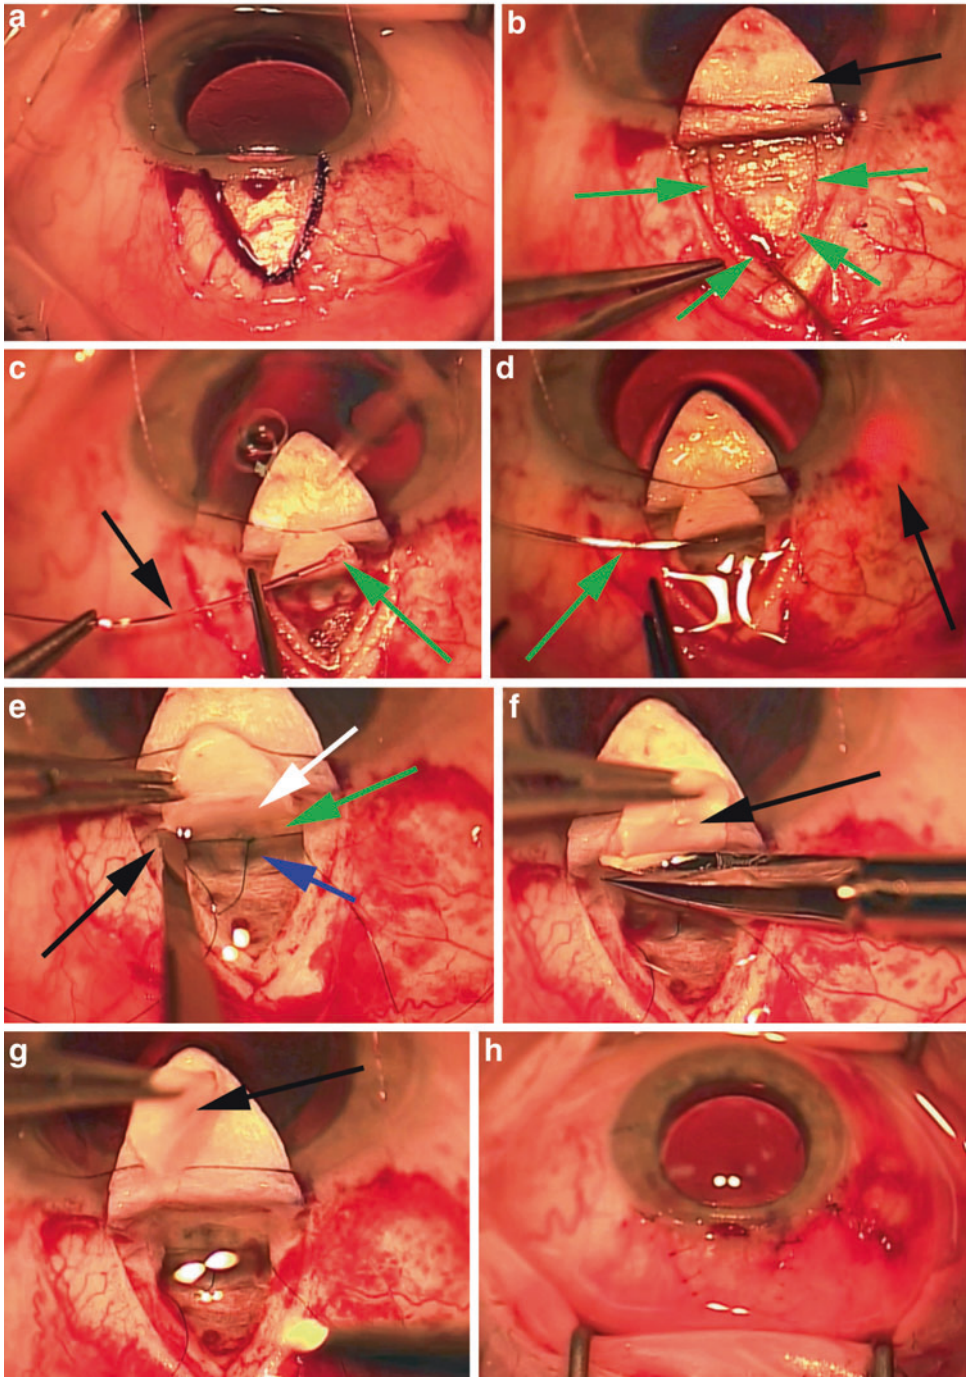
Contraindications Advanced glaucoma, closed-angle glaucoma, severe conjunctival scarring superiorly, uveitic glaucoma, and eyes that require a surgical peripheral iridectomy (PI) for PI is not carried out with canaloplasty.

Key Procedural Components
- Fornix-based conjunctival flap is easiest for complex limbal anatomic dissections.
- Create a superficial parabolic scleral flap (300–400 μm) followed by a second deep flap (600 μm) within the borders of the scleral bed.
- Some surgeons prefer to use mitomycin C to inhibit fibrosis at this stage.
- Unroof Schlemm's canal and fully visualize the canal.
- Some surgeons prefer to peel off the inner layer of Schlemm's canal, leaving the trabecular meshwork and trabeculodescemetic membrane (TDM).
- Viscodilate the cut ends of Schlemm's canal.
- Cannulate Schlemm's canal with a microcatheter (EllexiScience, Fremont, CA), and after 360°, tie on a 10-0 Prolene suture and retrieve iTrack for 360°. Inject viscoelastic every two clock hours during the retrieval. Trim and isolate the suture and tighten in the canal.
- Remove the deep flap, creating the deep sclerectomy, and secure the superficial flap.
- Close the conjunctiva in a watertight fashion.

Complications
- Postoperative hyphema common due to canal exposure
- Transient IOP elevation
- Anterior chamber perforation
- Descemet's detachment, rarely hemorrhagic
- Postoperative iris incarceration into TDM
- Hypotony possible but uncommon
- Dysesthetic bleb, not common
- Suture extrusion into anterior chamber

Outcomes
- A US-based prospective nonrandomized multicenter clinical trial demonstrated that at 3 years, all study eyes that underwent canaloplasty (n = 157) had a mean IOP of 15.2 mmHg 0±3.5 (standard deviation [SD]) and mean glaucoma medication use of 0.8 ± 0.9 compared to a baseline IOP of 23.8 ± 5.0 mmHg on 1.8 ± 0.9 medications (Lewis et al. 2011).
- A European-based prospective nonrandomized multicenter clinical trial demonstrated that at 3 years, all study eyes that underwent canaloplasty (n = 109) had a mean IOP of 15.1 ± 3.1 mmHg (SD) and mean glaucoma medication use of 0.9 ± 0.9 compared to a baseline IOP of 23.0 ± 4.3 mmHg on 1.9 ± 0.7 medications (Bull et al. 2011).

Keys to Success
- One must be able to construct two scleral flaps of adequate size and depth.



Surgical Approaches, Fig. 5 Canaloplasty (**a**) Outline of superficial scleral flap. The first flap is approximately 300–400 μm in thickness and fashioned into the clear cornea. (**b**) Formation of superficial flap and outline of deep flap. The *black arrow* designates the already fashioned superficial uniform flap, which is conveniently tacked down with the traction suture. The *green arrows* show the outline of the deep flap, which is all the way to the level of the suprachoroidal scleral fibers. (**c**) Completion of deep scleral flap and iTrack micro-catheter in position for canal entry. The *black arrow* delineates the illuminated flexible micro-catheter (200 μm), and the *green arrow*

- One must be able to create an ideal TDW and understand the required amount of tension that must be placed with the suture without breaking through the trabecular meshwork.

Procedure

iStent® (Fig. 6)

Mechanism of Action

A metallic microdevice that is aimed at bypassing the trabecular meshwork and creating a direct route from the anterior chamber to Schlemm's canal.

Indications/Contraindications

Indications Open-angle glaucomas that are classified as mild to moderate. In the US, this device must be placed in combination with cataract surgery and intraocular lens implantation.

Contraindications Advanced glaucoma, closed-angle glaucoma, uveitic glaucoma (relative), unmedicated IOP greater than 36 mmHg, and/or prior complicated glaucoma surgery.

Key Procedural Components

- Following an uncomplicated clear cornea cataract surgery, the same temporal wound is used.
- The stent on the tip of the injector is inserted through the clear corneal incision.
- The tip of the stent is inserted into Schlemm's canal with the aide of gonioscopy. The stent is inserted through the nasal trabecular meshwork and advanced slightly until the stent is secured into place and stable.
- Viscoelastic is removed, and wound management is similar to the conclusion of a typical cataract surgery.

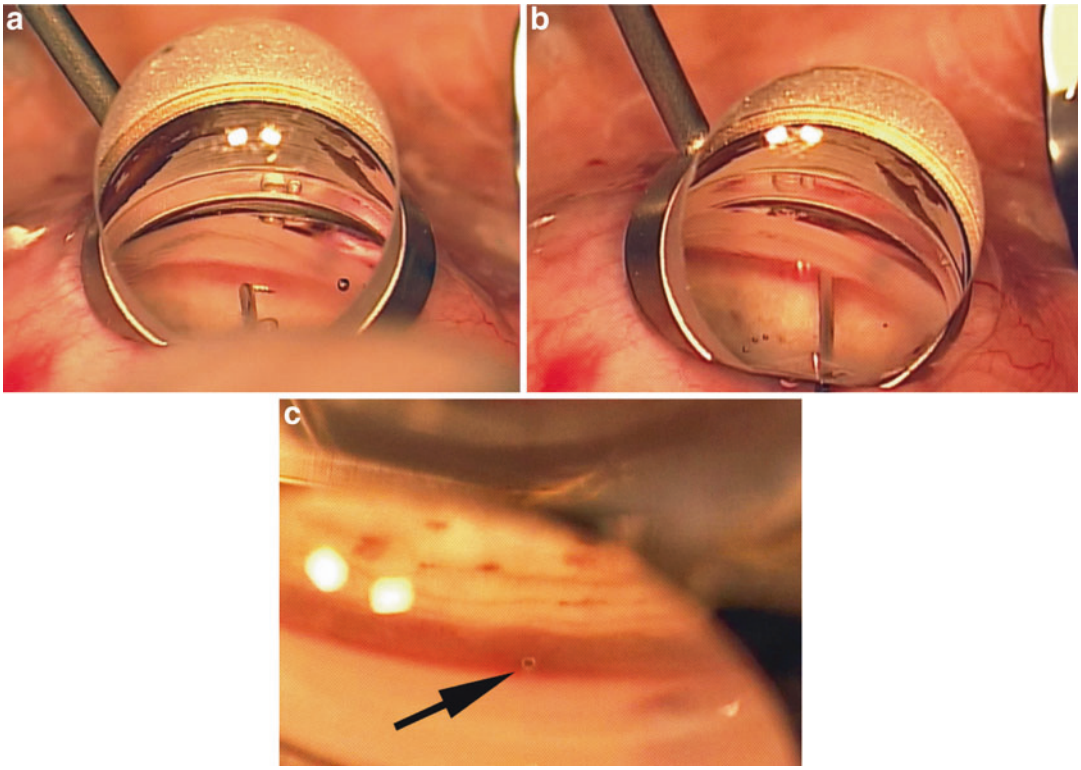
Complications

- Intraoperative
  - Iris touch of stent
  - Endothelial touch of stent
  - Stent malpositioning
- Postoperative
  - Inflammation
  - Stent malpositioning
  - Stent obstruction with the iris
  - IOP elevation
  - Hyphema

Outcomes

- A US-based prospective randomized controlled multicenter clinical trial demonstrated that at 2 years, the mean IOP in the stent group was 17.1 ± 2.9 mm Hg on a mean of 0.3 ± 0.6 medications. The mean IOP in the control group had increased to 17.8 ± 3.3 mm Hg on a mean of 0.5 ± 0.7 medications. At 24 months, the IOP in the stent group was 8.4 mmHg lower than the baseline medication washout IOP. In comparison, the IOP in the control group was

Surgical Approaches, Fig. 5 (continued) points to its tip, which is slightly larger in diameter (250 μm). (**d**) iTrack catheter in position in Schlemm's canal. The *black arrow* points to the illuminated tip of the iTrack, indicating its variable position in the canal. The illumination is very helpful to know the extent of canal traversed or if the device comes out of the canal. The proximal portion of the micro-catheter (*green arrow*) is kept in proper alignment to keep the catheter from coming out of the canal. (**e**) Suture in place in Schlemm's canal. With the suture in good position and tightened as necessary, the deep flap is further dissected (*black arrow*) to create the trabeculodescemetic membrane (TDM, *green arrow*). The TDM is the site of percolation of aqueous from the anterior chamber to the intrascleral lake which is created by removing the deep flap. As the deep flap is dissected, note the smooth area, *white arrow*, which is the roof of Schlemm's canal. The *blue arrow* is the floor of Schlemm's canal. (**f**) Deep sclerectomy. The deep flap (*black arrow*) is excised with Vannas scissors at its base. This is done in a very gentle fashion in order to avoid perforation into the anterior chamber. (**g**) Excised deep flap. The *black arrow* denotes the excised deep flap. The leftover space creates an intrascleral cavern for the enhanced egress of aqueous humor. (**h**). Closure of deep flap and conjunctiva. The superficial scleral flap and conjunctiva are closed in a watertight fashion. The authors close the flap to prevent any flow of aqueous that could form a bleb. Some surgeons close the flap so that a shallow bleb will form



Surgical Approaches, Fig. 6 iStent trabecular microbypass. (**a**) At the completion of phacoemulsification with PCIOL, the iStent inserter is visualized in the mid anterior chamber through a Swan-Jacob gonioprism. (**b**) The device is inserted into Schlemm's canal, slightly angled initially, then following the curve of the canal. The device is released once properly positioned in the canal. It takes considerable experience to complete this delicate maneuver. (**c**) Goniophotograph of properly positioned iStent

7.5 mm Hg lower than the baseline medication washout IOP (Craven et al. 2012).

Keys to Success

- One must be able to properly identify angle structure during intraoperative gonioscopy (specifically the scleral spur and trabecular meshwork).
- One must be comfortable with angle surgery.
- The stent must be confirmed, intraoperatively, to be in the correct place.

Incisional Glaucoma Surgeries that Create a New Artificial Drainage System

Procedure

Filtration Surgery (Fig. 7)

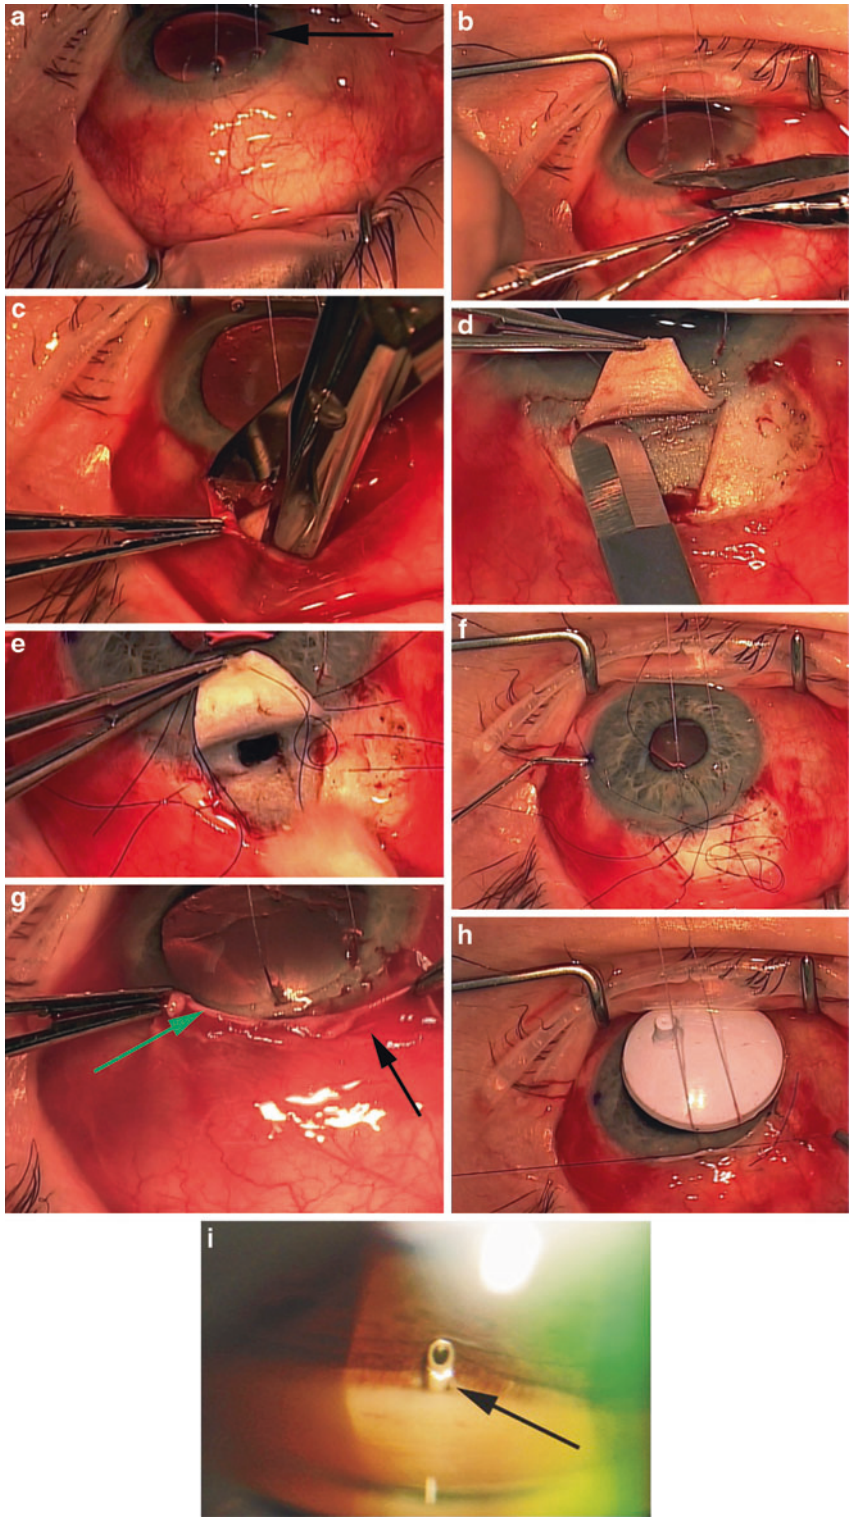
- Trabeculectomy
- EX-PRESS shunt

Mechanism of Action

Lowers IOP by diverting aqueous from the anterior chamber to the perilimbal subconjunctival region, producing a fluid-filled bleb cavity. Both procedures divert aqueous through the limbus, trabeculectomy by sclerectomy (removal of a block of tissue), and EX-PRESS through a miniature shunt.

Indications/Contraindications

Indications Most uncontrolled glaucomas, especially primary glaucomas (POAG, CACG), and combined phacotrabeculectomy for cataract glaucoma.



Surgical Approaches, Fig. 7 (continued)

Contraindications Severe conjunctival scarring; inflammation with altered blood aqueous barrier; limbal scleral scarring; moderate to advanced ocular surface disease such as rosacea, blepharitis, and pemphigoid; neovascular, inflammatory glaucoma; and epithelial downgrowth.

Key Procedural Components

- Decide on fornix versus limbal-based conjunctival flap. The authors prefer fornix-based approach.
- Obtain adequate exposure of the operative site.
- Fashion perilimbal flap, sclerostomy, and peripheral iridectomy.
- Closure of scleral and conjunctival flap.

Complications

- Choroidal effusion 14%
- Wound leak 12%
- Shallow or flat AC 10%
- Persistent corneal edema 9%
- Dysesthesia 8%
- Hyphema 8%
- Encapsulated bleb 6%
- Persistent diplopia 2%
- Hypotony maculopathy 5%
- Endophthalmitis/blebitis 5%

Outcomes

- TVT study (Gedde et al. 2012a): In the trabeculectomy arm of this study (4 mg/ml of Mitomycin C for 4 min in eyes with prior cataract or filtration surgery), 41 of 105 eyes failed due to uncontrolled IOP (17), reoperation for glaucoma (11), and persistent hypotony (13). At 5 years, IOP was 14.4 ± 6.9 mm Hg in the tube group and 12.6 ± 5.9 mm Hg in the trabeculectomy group, and the corresponding number of glaucoma medications was 1.4 ± 1.3 and 1.2 ± 1.5. The cumulative probability of failure was 29.8% in the tube group and 46.9% in the trabeculectomy group, and the rate of reoperation for glaucoma was higher in the trabeculectomy group.
- Hopkins review (Jampel et al. 2012): Target IOP was achieved at 4 years in 70% of eyes and was associated with progressive cataract and small risks of bleb-related complications. Approximately 14% of eyes had reoperation for glaucoma. Fornix-based procedures had a lower incidence of serious bleb-related problems.
- XVT study (Netland et al. 2013) EX-PRESS results: Mean intraocular pressure at 2 years after surgery was 14.7 ± 4.6 mm Hg and 14.6 ± 7.1 mm Hg in the EX-PRESS and trabeculectomy groups, with a respective success rate of 83 and 79% (MMC .25 mg/ml for 1–2 min for both groups). The vision was not significantly different compared with baseline at 1 month and after 3 months. The total number of postoperative complications was higher after trabeculectomy than after EX-PRESS implantation with a more rapid return to baseline vision in the EX-PRESS group.

Keys to Success

- Control inflammation before and immediately after surgery.
- Precise flap and sclerostomy construction with intraoperative flow through the scleral flap.
- Watertight closure of conjunctival flap to prevent wound leak.

S

Surgical Approaches, Fig. 7 Trabeculectomy. (**a**) The first surgical step is proper exposure of the operative site achieved with a corneal traction suture (*black arrow*). (**b**) A fornix-based conjunctival flap is useful for virgin eyes as well as eyes with prior conjunctival scarring. (**c**) Include Tenon's capsule in the dissection from the check ligaments at the limbus all the way posteriorly to create a sufficient subconjunctival space for a broad antimetabolite application. (**d**) Dissect a 2/3 thick uniform scleral flap to guard the sclerostomy. (**e**) A block of corneoscleral tissue is removed followed by peripheral iridectomy. (**f**) Titrate the flow through the scleral flap. (**g**) Inspect the edge of the conjunctiva (*black arrow*) and Tenon's capsule (*green arrow*) for closure and incorporate both into the limbal closure. (**h**) Close the conjunctiva and Tenon's capsule in a watertight fashion. (**i**) Goniophotograph of an EX-PRESS shunt used in place of making a sclerostomy

Procedure

Drainage Implant Surgery (Fig. 8)

- Baerveldt
- Ahmed
- Molteno

Mechanism of Action

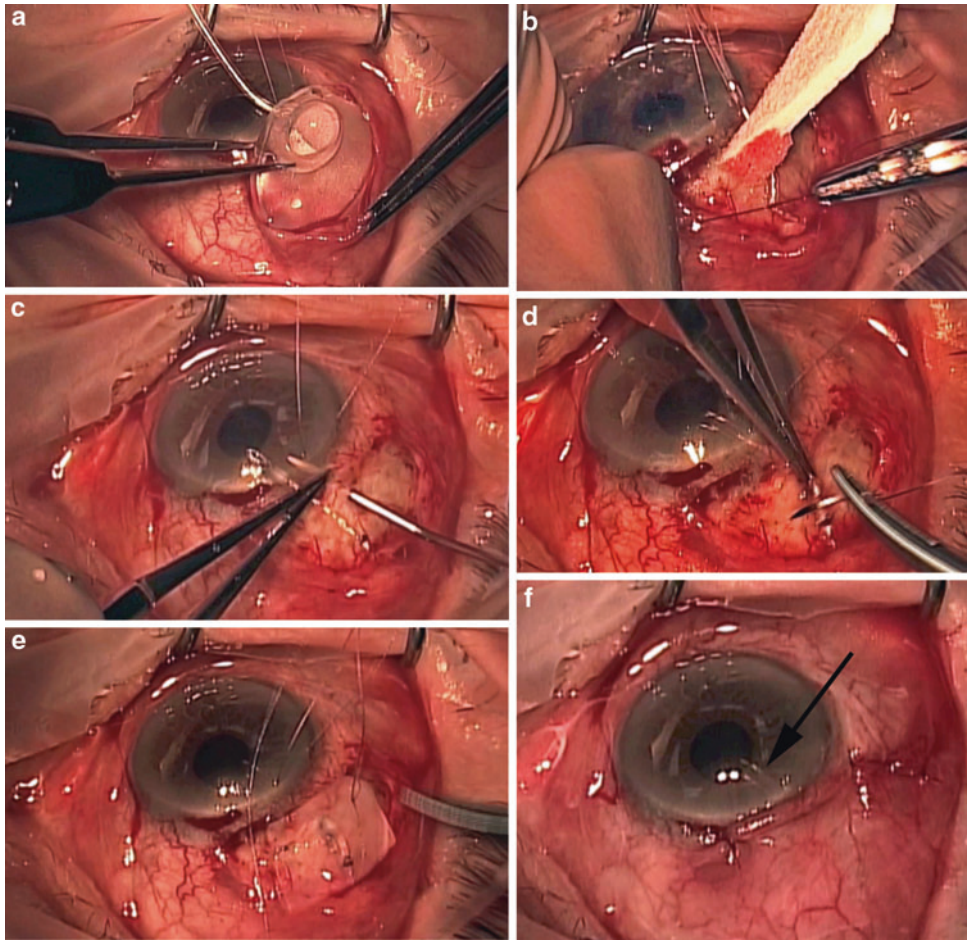
Lowers IOP by shunting aqueous from the anterior chamber to an equatorial bleb-promoting device

Indications

Uncontrolled primary or secondary glaucoma, phakic, aphakic, or pseudophakic. In high-risk eyes for hypotony or choroidal hemorrhage-related events, consider a two-stage approach or single-stage approach with controlled ligature release.

Contraindications

Insufficient conjunctiva to cover the device and difficulties in patients with encircling bands.



Surgical Approaches, Fig. 8 Glaucoma drainage implant surgery. (**a**) The device is inserted through a fornix-based incision and positioned and sutured to the sclera at the equator of the eye. (**b**) The tube is tied off with an 8–0 Vicryl absorbable suture in order to prevent immediate postoperative hypotony. The suture dissolves at 1 month and then aqueous flows to the plate. (**c**) A paracentesis is made with a 23-gauge needle in order to insert the trimmed tube. No viscoelastic is used at any time except for valved tubes such as an Ahmed. (**d**) The tube is vented with a needle to try and produce flow through the side of the tube in the immediate postoperative period. (**e**) A corneal patch graft is sutured over the tube to prevent erosion. (**f**) The conjunctiva is hooded over the device and secured to the limbus. The tube is easily seen in the anterior chamber (*black arrow*) in good position

Key Procedural Components
- Decide on fornix or limbal-based conjunctival approach.
- Decide on type of device, valved or non-valved.
- Affix device to equator of the sclera and place tube through a 23-gauge needle site.
- Ligate and vent the tube if non-valved.
- Cover the tube with corneal tissue.
- Complications.
- Persistent corneal edema 17%.
- Choroidal effusion 15%.
- Shallow or flat AC 11%.
- Persistent diplopia 6%.
- CME 5%.
- Tube erosion 5%.
- Tube obstruction 3%.
- Aqueous misdirection 3%.
- Suprachoroidal hemorrhage 2%.
- Endophthalmitis 1%.

Outcomes
- TVT study (Gedde et al. 2012b): The drainage implant arm of this study used the 350 sq. mm Baerveldt device. At 5 years, the cumulative probability of failure was 29.8%, 9% required further glaucoma surgery and 22% required reoperations for complications.
- AVB study (Christakis et al. 2013): At 3 years, the cumulative probability of failure was 51% in the Ahmed group and 34% in the Baerveldt group. Mean IOP was 15.7 ± 4.8 mmHg in the Ahmed group and 14.4 ± 5.1 mmHg in the Baerveldt group, and respective medications were 1.8 ± 1.4 and 1.1 ± 1.3. Postoperative interventions were 38% in the Ahmed and 50% in the Baerveldt. The Baerveldt group had a slightly higher rate of hypotony-related vision-threatening complications. Eleven percent of eyes required further glaucoma surgery. At 3 years, 25% of the Ahmed group and 50% of the Baerveldt group required no topical medications.
- ABC study (Budenz et al. 2011): At 1 year, postoperative IOP was 15.4 ± 5.5 in the AGV group and 13.2 ± 6.8 in the BGI group requiring 1.8 ± 1.3 and 1.5 ± 1.4 postoperative medications, respectively. Significant postoperative complications were noted in 20% of AGV and 34% in the BGI group, and cumulative probability of failure was 16.4% and 14%, respectively.

Keys to Success
- Adequately secure device to equator of the eye.
- Proper tube placement avoids iritis and corneal decompensation.
- Adequate coverage of tube with corneal tissue to prevent erosion.
- Adequate cover of tube and plate with conjunctiva may require extensive conjunctival dissection in some cases.

Procedure

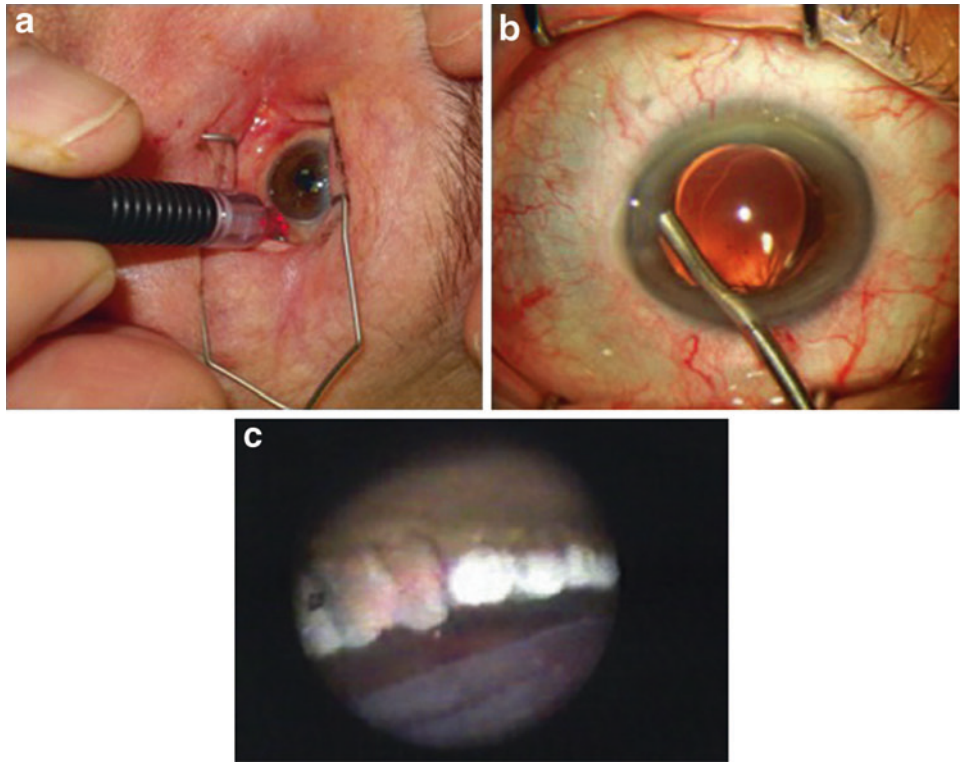
Cyclophotocoagulation (Fig. 9)

- Transscleral cyclophotocoagulation (TSCPC)
- Endocyclophotocoagulation (ECP)

Mechanism of Action
- A wavelength of 810 nm is used to directly laser the ciliary body processes (ECP) or indirectly through the sclera (TSCPC), and both methods lower IOP by reducing the formation of aqueous humor.

Indications
- Glaucoma and visually significant cataract.
- Plateau iris syndrome.
- Eyes with severe conjunctival scarring.
- High-risk eyes for choroidal events such as high myopia and bleeding tendencies.
- Aphakic or pseudophakic glaucoma.
- Refractory pediatric glaucoma.
- Uncontrolled glaucoma post-filtration surgery.
- TSCPC is an alternative for patients in poor health unable to tolerate intraocular surgery.

Contraindications
- Avoid ECP in phakic eyes due to lens damage.
- TSCPC may lead to long-term zonular damage in phakic eyes making future lens extraction more difficult.
- Pseudoexfoliation glaucoma.



Surgical Approaches, Fig. 9 Cyclophotocoagulation. (**a**) TSCPC. The G-probe (IRIDEX, Mountain View, CA) is applied to the limbus, directly over the ciliary body. Typically, 1200 mW for 4 sec duration is applied to three quadrants, sparing one of the quadrants in order to prevent hypotony. (**b**) The ECP 20-gauge microendoscope has a Xenon light source, 810 nm laser, and camera (Endo Optiks, Little Silver, NJ). (**c**) The ciliary body processes are visualized and targeted with the oval red aiming beam. The processes turn white and shrink the end point of the ablation

- Uncontrolled uveitis.
- Patients with altered anatomy preventing a view of the ciliary processes such as a Soemmering ring.

Key Procedural Components

- The most common use of ECP is to combine it with phacoemulsification; this is especially useful in narrow-angled eyes or eyes with plateau iris configuration.
- Upon completion of phacoemulsification, the anterior chamber is reformed with viscoelastic (Healon GV), making sure to elevate the iris away from the PCIOL.
- Insert the ECP probe through the cataract incision, visualize the ciliary body processes, and start the laser at .2 W. Increase the power until the ciliary body processes turn white and shrink.
- A second incision may be made for a 360° treatment.
- ECP requires approximately 200–400 mW of energy, while TSCPC energy settings are higher, at 1200 mW for 4 sec.

Complications

- IOP spike on day one
- Iritis (mild unless overtreated)
- Fibrin formation (rare)
- Cystoid macular edema (rare)

Outcomes

- ECP is effective after failed outflow procedures. In a prospective case series of 25 patients with uncontrolled IOP after drainage implant

surgery, IOP was reduced from 24–15 mm Hg, and medications were significantly reduced (Francis et al. 2011).
- A prospective study compared ECP to Ahmed implantation in refractory glaucomas post-failed filter and found a probability of success at 24 months of 70.59 and 73.5% for the Ahmed and ECP groups, respectively (Kima et al. 2004).
- Two-site phaco-ECP is more effective than one-site phaco-ECP with a mean IOP of 13 mm Hg versus 16 mm Hg without a higher incidence of complications (Kahook et al. 2007).
- A large retrospective study found TSCPC successful in 48% of eyes at a mean of 6 years (Lin et al. 2004).

Keys to Success
- Adequate treatment of ciliary processes, usually 360°.
- Avoid overtreatment which creates excessive inflammation.
- Avoid treating the posterior iris which leads to iritis.

Summary

The option to enhance flow through the patient's natural drainage system with canal-based or supraciliary surgery or rely on time-honored subconjunctival drainage with a filter or tube is now a critical preoperative question. As new surgical techniques evolve and preoperative assessment of the aqueous collector channels becomes available, surgeons will be able to predict the best possible procedure to serve their patient. When preoperative or intraoperative future testing reveals a collector system that appears salvageable, a canal-based procedure is reasonable. If the trabecular collector system appears atrophic, then potentially a supraciliary device may be useful. If the natural trabecular or uveoscleral channels are not salvageable, then either subconjunctival drainage with a filter or tube is necessary or potentially a procedure to reduce aqueous production. The key is the surgeon, and patients have the ability to tailor the surgery to the lifestyle and stage of disease. Patients with mild to moderate disease (with a presumably intact collector system), where an IOP in the mid- to high-teens is acceptable, may do well with a less-invasive canal-based surgery. The best place for a supraciliary device will likely be similar for canal-based procedures. Until our ability to assess the status of the trabecular and uveoscleral outflow system improves, patients with advanced disease who require lower IOP remain excellent candidates for more invasive filtration or tube-shunt surgery. Fortunately, outcomes with filtration surgery will continue to improve due to less-invasive filtration techniques as well as a better understanding of wound healing. The frequency of drainage implant surgery continues to rise as surgeons try to avoid limbal blebs and manage refractory glaucomas. However, complications from both filtration and tube surgeries are still problematic with blebitis, hypotony maculopathy, bleb failure, tube erosions, and double vision to name a few. Despite the numerous risks of trabeculectomy and glaucoma drainage implants, they are still the gold standard when a low IOP is critical to prevent further vision loss from glaucoma.

Surgical approaches to the orbit

Definition

Surgical spaces, orbital

Structure

The bony orbit is comprised of seven bones (frontal, sphenoid, zygoma, maxilla, palantine, ethmoid, lacrimal) and may be roughly divided

into a lateral wall, medial wall, roof, and floor. Its anterior limit is the orbital septum. The boney orbit is configured in a cone shape with its apex posteriorly, and although it contains only roughly 30 cc of volume, it harbors an intricate network of nerves, vessels, and muscles all serving the function of the globe. Several fissures and foramina allow for the entrance and exit of nerves and vessels supplying the soft tissues of the orbit.

The orbital bones are lined with periosteum, also referred to as periorbita, which serves as a fibrous sling surrounding the orbital contents but also creates a potential space between the bone and periosteum. This *subperiosteal* space can sometimes harbor pathology (e.g., subperiosteal abscesses), but more frequently is utilized during surgical dissection.

The *extraocular muscles* constitute another surgical space. The four rectus muscles arise from the annulus of Zinn, which surrounds the opening of the optic canal. As the four rectus muscles travel anteriorly as the muscle cone, they become interconnected by an intermuscular septum; this anatomy is often referenced in surgical consideration of orbital lesions that are either "*intraconal*" or "*extraconal*." Notable structures in the extraconal space include the lacrimal gland and superior oblique.

Orbital fat fills and envelops any orbital space not occupied by other soft tissue structures and often obscures seemingly obvious (radiologically) lesions. Proximal to the globe itself, the fat is held back by Tenon's capsule, which fuses with the optic nerve sheath posteriorly. *Tenon's space* provides another point of surgical access to the orbit.

Finally, adjacent structures to the orbit may play a role in orbital pathology or surgical access and are referred to as the *extraorbital space*. These structures include the nose, sinuses, brain, skin, and conjunctiva.

Due to the complex nature of the orbit and the important functions it serves, a detailed understanding of orbital anatomy and its surgical spaces is required to safely operate within the tight confines of this boney cavity.

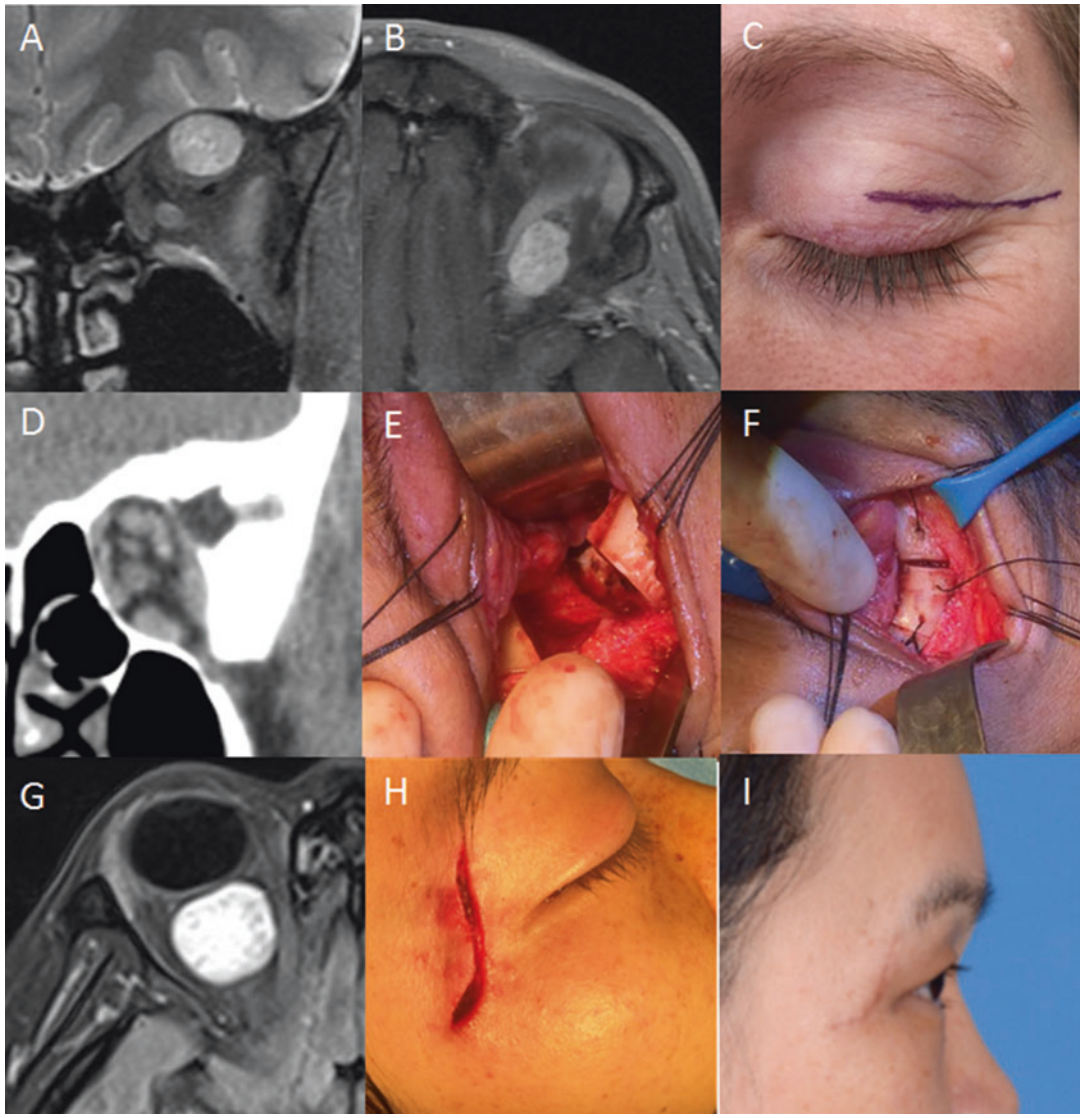
Clinical Relevance

When approaching the orbit surgically, one must consider many factors including the size, location, and nature of the lesion as well as the surrounding orbital anatomy and structures that would be encountered via each approach. In particular, one should note the position of the lesion relative to the optic nerve, so that the optic nerve will not be crossed during the approach. Surgical exposure and visualization are inherent challenges of operating within the deep, tight, confines of the orbit, and modification of those boney confines as described below may be considered depending on the size and location of the lesion. Surgical approaches can be roughly divided into lateral, medial, superior, and inferior approaches.

Lateral Approaches

To access lesions located laterally within the orbit, one often will utilize the natural crease of the upper eyelid as a point of access. This incision may be carried out laterally in an "extended lid crease" allowing for access to the lateral orbital rim and wall (Fig. 1a–c). The periosteum is incised along the lateral rim and a subperiosteal dissection carried out posteriorly where the zygomaticotemporal and zygomaticofacial neurovascular bundles may be encountered and often sacrificed. The periosteum may then be incised over the approximate depth of the lesion, and blunt dissection is carried out until the lesion is identified. Tagging the lateral, superior, or medial rectus anteriorly prior to surgery may facilitate identification of these muscles more posteriorly, either for direct biopsy or simply for orientation purposes. These muscles may then be retracted to provide further access to the intraconal space. This approach may be used to access the subperiosteal, extraconal, or intraconal spaces.

A similar surgical space may be accessed via simple lateral canthotomy and cantholysis followed by subperiosteal dissection posteriorly. While this provides reasonably good access to the lateral wall, it is somewhat more limited than the extended lid crease incision and therefore is



Surgical Spaces, Orbital, Fig. 1 Lateral approaches to the orbit: extended lid crease (without bone flap) to access a recurrent schwannoma (**a**–**c**), extended lid crease with bone flap used to approach posterior boney tunnel of orbital dermoid (**d**–**f**), and Kronlein approach with bone flap used to approach large cavernous hemangioma (**g**–**i**)

reserved for smaller or more anteriorly located lateral orbital lesions.

Conversely, particularly large lesions or lesions located more posteriorly in the lateral orbit may require more exposure, visualization, and space than a simple extended lid crease incision can provide. In these instances, a lateral bone flap should be considered. The approach is the same as an extended lid crease, except that prior to opening the periosteum, a segment of the lateral wall usually extends from the frontozygomatic suture line superiorly to the inferior curvature of the zygoma inferiorly and broken off at the zygomaticosphenoid suture line posteriorly (Fig. 1d–f).

Historically, this lateral orbitotomy with bone flap was performed with a Kronlein approach. This approach is similar to that of an extended lid crease, except the point of access is a "lazy S"-shaped incision directly over the lateral

rim and extending from the lateral brow to the zygoma (Fig. 1g–i). While providing excellent access, most have now come to adopt the extended lid crease incision as its incision is more cosmetically hidden without compromising exposure.

Lateral bone flaps may also be used in conjunction with other approaches for the sole purposes of providing additional space to improve visibility.

Medial Approaches

Accessing medially located lesions can sometimes be more challenging due to anatomic constraints; the location of the nose makes the medial orbit more confined via anterior approaches, and several medially based structures must be considered during dissection, including the ethmoidal arteries and supraorbital and supratrochlear neurovascular bundles.

One long-standing approach to the orbit is a Lynch or modified Lynch incision, which is a curvilinear incision in the shadow at the base of the bridge of the nose. It provides direct access to the periosteum, which can be incised and elevated laterally to expose the medial subperiosteal space. This incision remains a valuable approach to the orbit when the subperiosteal space is targeted (e.g., subperiosteal abscesses) and/or when a cutaneous drain is going to be left postoperatively.

However, there are several more cosmetically pleasing alternatives to the Lynch incision, which should be considered first. Much like the lateral extended lid crease incision, the medial lid crease can also be utilized as a well-guised access point to the medial orbit. The septum can either be directly incised or followed superiorly to the periosteum to access the subperiosteal space. Care must be taken around the trochlea and supratrochlear and supraorbital neurovascular bundles. A medial lid crease incision is commonly used for optic nerve sheath fenestrations, but may be used for any superomedial orbital lesion in the anterior half of the orbit (Fig. 2a).

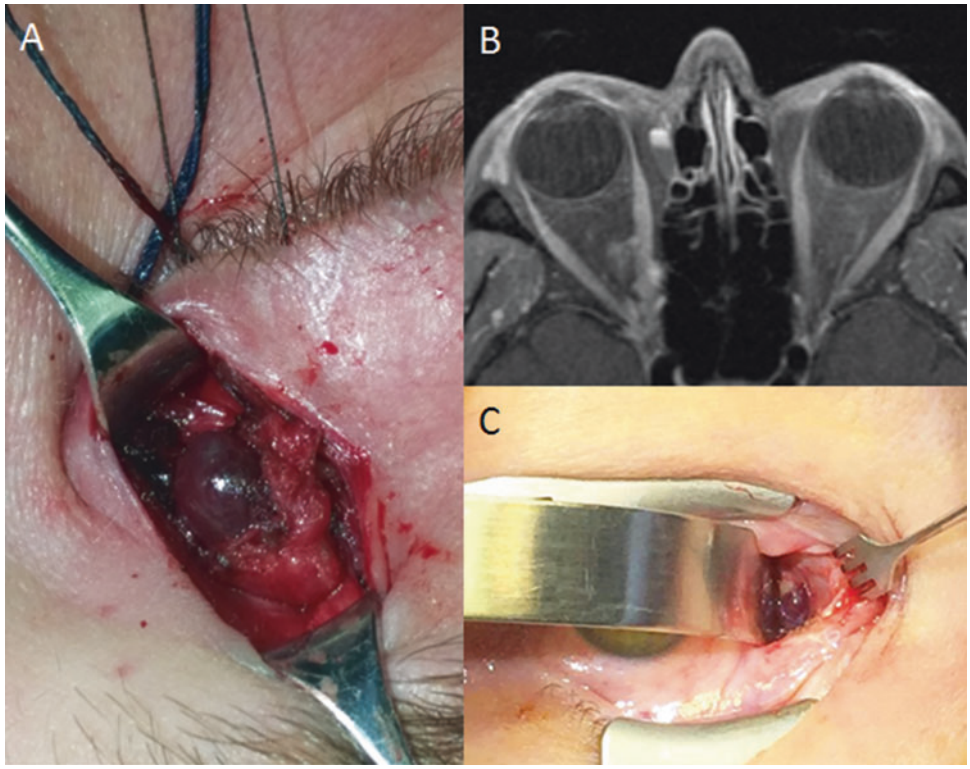
Most recently the transcaruncular approach was described and has become a popular approach to the medial orbit as it provides excellent access with a nearly imperceptible conjunctival incision between the caruncle and plica semilunaris. Dissection is carried medially in this space to reach the posterior lacrimal crest, which is subsequently incised, and the periosteum elevated posteriorly. Despite the minimal incision, this approach provides a surprising degree of access and exposure to the medial orbital space (Fig. 2b, c). Much like the Lynch incision (or lateral orbitotomy approaches described above), this incision commences its approach to the orbital contents from the subperiosteal space and therefore is particularly well suited for extraconal lesions.

For medially based, intraconal lesions, one may want to consider instead a transconjunctival approach in which a limbal incision with relaxing incisions is made and blunt dissection carried posteriorly in the sub-Tenon's space along the globe. The advantage of this approach is its direct access to the intraconal space, but it does have somewhat more limited exposure than a transcaruncular incision. This approach can also be used to access the optic nerve sheath for fenestration in conjunction with disinsertion of the medial rectus muscle. If the exposure for a particular lesion is too constricted by the eyelid, a lid-splitting procedure can also be performed with the transconjunctival approach. While this heals well and can provide ample exposure, some patients may still be cosmetically adverse to lid-splitting procedures.

Finally, while the extraorbital spaces such as the nose and sinus may be anatomic nuisances to the external medial orbital approaches, in some instances they provide excellent access to the medial orbital wall and floor. This is perhaps most frequently utilized in medial wall decompressions. However, some medially oriented tumors can and are removed via endoscopic approach. Endoscopic decompression of the medial orbit can also be utilized in concert with a lateral orbitotomy to create additional space when resecting particularly large or posterior orbital lesions.

Superior Approaches

For superiorly based lesions, lid crease or transconjunctival approaches as described above often provide sufficient access with maximal cosmesis



Surgical Spaces, Orbital, Fig. 2 Approaches to the medial orbit: medial lid crease approach to embolized varix (**a**) and transcaruncular approach to anterior tip of lymphatic malformation (**b** and **c**)

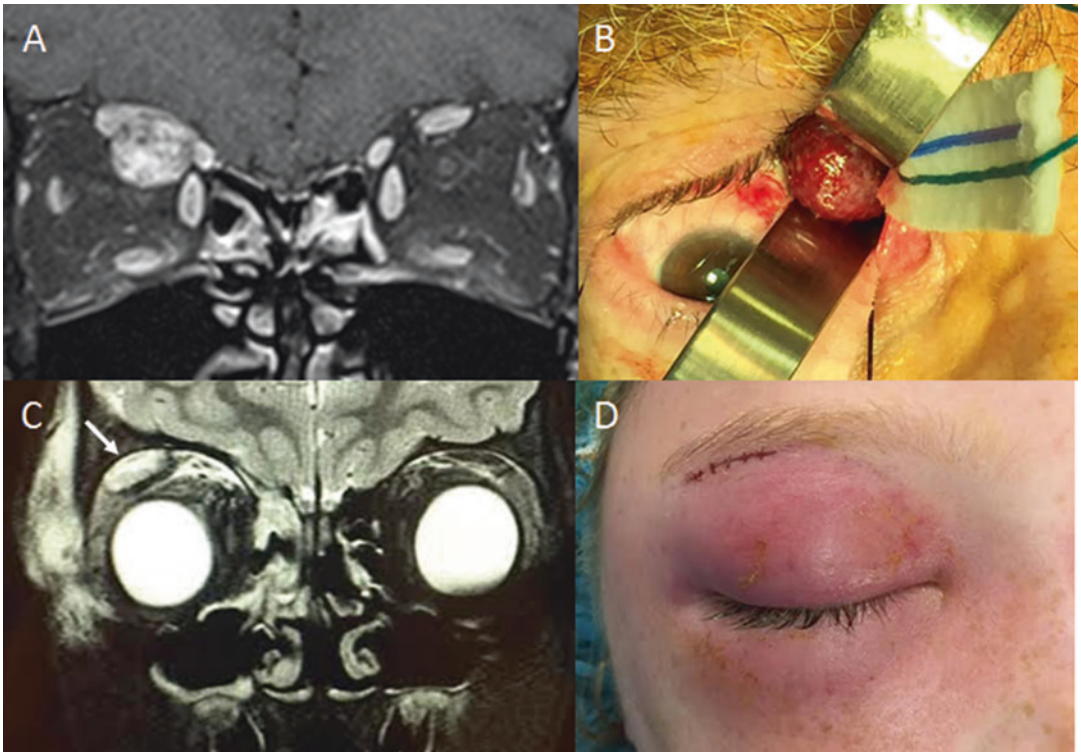
(Fig. 3a, b). However, a direct sub-brow incision may be considered and preferable in certain instances such as large dermoid cysts, frontal sinus mucoceles (not amenable to endoscopic treatment), and superiorly based subperiosteal abscesses (Fig. 3c, d). Much like the Lynch incision medially and the Kronlein incision laterally, this provides easy and direct access to the subperiosteal space, but is less cosmetically appealing and therefore is utilized in more limited instances.

While the majority of the superior orbit may be approached anteriorly, very posterior (i.e., apical) lesions or lesions with concomitant intracranial pathology may need to be approached transcranially (see section "Approaches to the Apex" below).

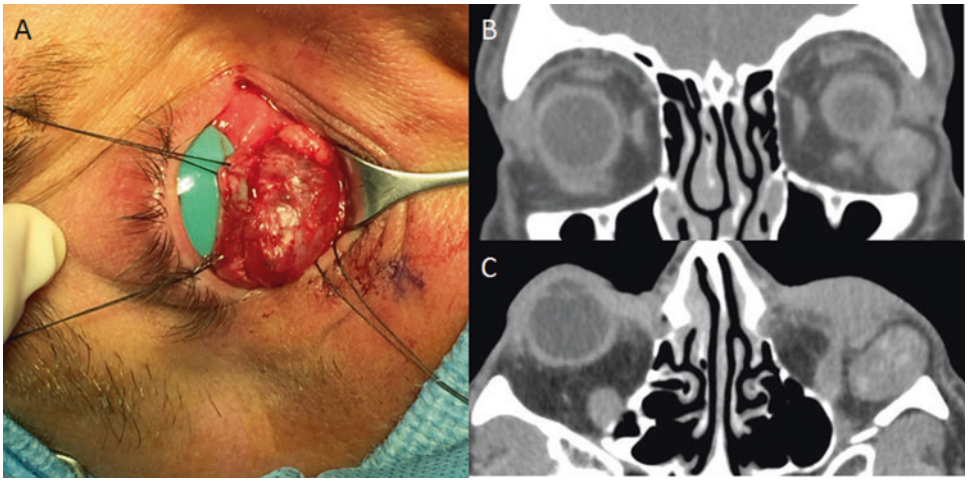
Inferior Approaches

Transconjunctival approaches to the orbit are frequently used due to their innocuous incision and ample access to the orbital floor. It may be combined with a lateral canthotomy and cantholysis ("swinging eyelid procedure") in eyelids with minimal laxity so as to avoid iatrogenic marginal tears during retraction. After a transconjunctival incision is made well below the level of the tarsus in the inferior fornix, a preseptal plane is bluntly followed to the inferior orbital rim where the periosteum is incised and elevated superiorly. This approach is used most frequently in orbital floor fracture repair, but can also be used for inferior rectus muscle biopsies or any inferiorly located tumors (Fig. 4a).

A subciliary approach may also be used by a similar dissection along a preseptal plane to the inferior orbital rim (Fig. 4b, c), though this approach is used less frequently primarily due to the excellent exposure that can be achieved with a more concealed transconjunctival approach, but also in part due to the risk of postoperative lower eyelid retraction.



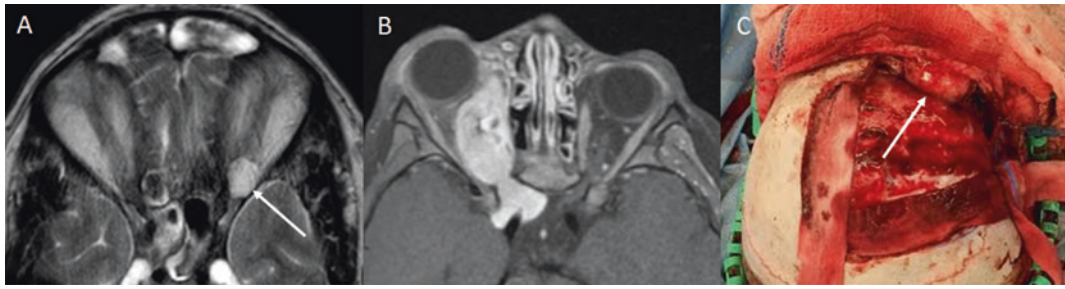
Surgical Spaces, Orbital, Fig. 3 Superior approaches to the orbit: transconjunctival approach to superomedial cavernous hemangioma (**a** and **b**) and a superior subperiosteal abscess (*arrow*) drained via a subrow incision (**c**–**d**)



Surgical Spaces, Orbital, Fig. 4 Inferior approaches: transconjunctival incision to access cystic inferior orbital mass (**a**) and clinical example of inferior orbital lesion (cavernous hemangioma) accessed via a subciliary incision (**b** and **c**)

Approaches to the Apex

As one travels more posteriorly within the orbit, the space becomes increasingly confined and difficult to visualize. Much as the boney walls converge, so too do the cranial nerves, muscles, and arteries. Thus, apically located lesions are



Surgical Spaces, Orbital, Fig. 5 Approaches to the apex: clinical example of apical cavernous hemangioma (*arrow*) approached transcranially (**a**), transcranial approach to an optic nerve glioma extending beyond the optic nerve canal (**b** and **c**, with *arrow* pointing to superior orbital contents)

both more difficult to access and more dangerous to remove. This constellation of difficulty often precludes an anterior approach.

In these instances, transcranial access is frequently the preferred approach. A craniotomy carries increased surgical risk independent of those risks associated with orbital surgery, and therefore the surgical threshold for apical lesions that cannot be approached anteriorly is higher. Nevertheless, when required, transcranial approaches can provide superb exposure to the orbital roof and apex, thereby providing the best chance for a safe orbital dissection (Fig. 5).

A particularly challenging orbital location to access is the inferior apex. As mentioned previously, one should make every attempt to craft a surgical approach that does not require crossing the path of the optic nerve. In these instances of posterior lesions located inferior to the optic nerve, endoscopic approaches may provide a safer alternative, though at the expense of exposure and direct visualization.

Surgically Induced Astigmatism

Oliver K. Klaproth and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

SIA

Definition

Any change (increase or decrease) in astigmatism (subjective or objective, direction or magnitude, as indicated by vector analysis, e.g., as described

by Alpins (2001)) caused by a surgical intervention is called surgical induced astigmatism (SIA). In the majority of cases, however, the phrase refers to a change in corneal astigmatism caused by the incision in cataract surgery, refractive lens exchange (RLE), or phakic intraocular lens (PIOL) implantation. Nevertheless, the correction of astigmatism in excimer laser surgery or the reducing of astigmatism in keratoconus patients using intracorneal ring segments use, among many others, of course also SIA.

Epidemiology

Not applicable.

History

Focusing on the change of astigmatism due to the incision in cataract surgery, RLE, or PIOL implantation, different authors have provided data. The very first systematic description of SIA refers to refractive surgery. *Lans* in Leiden showed the effect of corneal incisions to correct corneal astigmatism in 1896, *Sato* in Tokyo followed in 1939. This procedure was later extensively used and modified by *Fjodorov*, beginning in the 1970s, to correct ametropia (RK – refractive keratotomy). Due to sub-prime visual results, regression, and severe adverse events, RK today is an obsolete procedure. Nevertheless, the development of corneal relaxing incisions to correct astigmatism went on, and today these methods are still in use in refractive and especially in cataract surgery (LRI, AK). Recently, many authors evaluated the SIA in cataract surgery and PIOL implantation. Either as regular astigmatism (Kohnen and Klaproth 2009, 2011) or referring also to higher order aberrations (which can be seen as irregular astigmatism) (Bühren et al. 2004).

Clinical Features

Corneal, limbal, or scleral incision in cataract surgery, refractive lens exchange, or PIOL implantation cause a change in corneal astigmatism. The magnitude of this change is determined by the size and location of the incision. The more central the incision is placed, the more SIA is caused. Further on temporal incisions cause less astigmatism and show better predictability than nasal or superior incision. Temporal clear-cornea incisions of 2.5 mm or less cause almost no significant change in corneal astigmatism. Astigmatism neutral incisions allow the surgeon to plan surgery without using nomogrames for SIA, which increases the predictability of the refractive outcome (Kohnen and Klaproth 2009, 2011). Today the problem of irregular SIA arises for any type of surgery that requires primary only one clear-cornea, limbal, or scleral incision larger than 2.5. Example for nonfoldable PIOL implantation is determined by the smallest implant diameter, which is usually the optics diameter. Such incisions of, e.g., 6 mm lengths cause significant (irregular) SIA at the site of the incision (Bühren et al. 2004) (Fig. 1).

When planning implantation of such lenses, the SIA has to be taken into account preoperatively.

Tests

To quantify SIA pre- and postoperative assessment of astigmatism is required. This can either be performed subjectively by means of manifest refraction or by objective methods, such as keratometry or, more precise, Placido and/or Scheimpflug topography.

Treatment

The treatment of choice for surgical induced astigmatism is (a) to avoid it by performing surgery with microincisional surgery (<2.5 mm) or (b) to use its occurrence in a controlled manner to correct preexisting corneal astigmatism. Such options are the positioning of the incision on the steep meridian, the enlargement of the incision, opposite clear corneal incisions (OCCI), and limbal relaxing incisions (LRI). Different nomograms have been published on this topic; Table 1 shows an example by Wang et al. (2003).

Synonyms

Everting sutures

Definition

Quickert sutures are double-armed full-thickness sutures placed within the eyelids that exert an everting force upon the eyelid and were first described by Quickert and Rathburn in 1971 (Quickert and Rathbun 1971).

Indication

Quickert sutures are indicated in the surgical management of acute eyelid entropion, mild or intermittent involutional entropion, and congenital epiblepharon. Due to its simplicity and its suitability as an office procedure, Quickert sutures are often used as a temporizing method to achieve eyelid eversion prior to more permanent procedures in involutional entropion. In spastic entropion, the easy reversibility of the procedure allows for effective and temporary correction of acute entropion.

Quickert sutures may also be combined with more invasive procedures that surgically correct eyelid entropion in the operating room. Quickert sutures advance lower eyelid retractors, result in anterior rotation of the eyelid margin, and counteract overriding of the preseptal orbicularis by inducing fibrotic adhesion between the orbicularis and the lower eyelid retractors (Quickert and Rathbun 1971; Barnes et al. 2006). Quickert sutures do not address horizontal eyelid laxity and as a result have been noted to be especially effective in combination with procedures that reduce horizontal laxity such as the tarsal strip procedure (lateral tarsal strip) (Barnes et al. 2006).

Contraindication

Quickert sutures are contraindicated in eyelid ectropion. Quickert sutures are simple, minimally invasive, and easily reversible and are thus considered to be a relatively low-risk procedure. With exception to situations where there is greater operative risk to the patient, Quickert sutures are not commonly performed in isolation when more permanent correction of entropion is desired, due to long-term recurrence associated with the procedure.

Techniques and Principles

The Quickert procedure, as described by Quickert and Rathburn in the 1971 Archives of Ophthalmology manuscript, is as follows:

1. After skin preparation, infiltrate locally administered anesthetic agent subcutaneously and subconjunctivally along the inferior border of the tarsus.
2. Pass one needle of a double-armed 4-0, 5-0, or 6-0 suture adjacent to the inferior border of the tarsus from the conjunctival side, bringing it out through the skin in the same horizontal plane while pulling the skin inferiorly with light traction while the needle penetrates the orbicularis muscle and skin.
3. Pass the second arm of the suture similarly through the fornix 3 mm from the first needle, on the same horizontal plane.
4. Complete the suture over skin using the two ends of the double-armed suture. The knot should be tied as tight as possible without a bolster.
5. Repeat steps 2–4 and place a total of two to three sutures within the lateral aspect of the eyelid.

Outcome

The Quickert procedure is a relatively safe, low-risk procedure that is particularly useful in the management of acute entropion. However, it has been associated with long-term recurrence of entropion when used alone. When long-term correction of entropion is desired, other more invasive surgical procedures such as the Wies procedure, Jones procedure, and lateral tarsal strip procedure have traditionally been preferred. These procedures lack the simplicity of the Quickert procedure and are generally performed in the operating room, but have been shown to have a lower rate of long-term recurrence.

Often, the Quickert procedure provides a temporary option in the management of complications associated with eyelid entropion in the acute setting, such as keratopathy, prior to more invasive surgical correction. Furthermore, there have been numerous reports describing the use of the Quickert procedure in combination with the other surgical methods of entropion correction. The Quickert procedure has been described in combination with the lateral tarsal strip procedure (Barnes et al. 2006) and has been shown to be a procedure that was effective yet simple enough for use by a comprehensive ophthalmologist. A prospective randomized controlled trial that evaluated Quickert sutures alone versus lateral tarsal strip with everting sutures noted that Quickert sutures alone were associated with more long-term recurrence, consistent with findings noted from prior studies.

Complications

By nature of its simplicity and low-risk profile, serious complications associated with the Quickert procedure are uncommon. However, as with any surgical procedure, there is the risk of failure of achieving the intended purpose of surgery, or adequate correction of entropion with the Quickert procedure. Long-term recurrence, overcorrection with secondary ectropion, bleeding, infection, and injury to surrounding structures are other complications that may be associated with the procedure. With the eye within close proximity, exceptional care should be utilized to prevent injury to the globe, especially when the procedure is performed under local anesthesia without muscular paralysis that would reduce the risk of unexpected movements from the patient. The use of a suture confers a risk of granuloma formation, cheese wiring, and risk of wound dehiscence.

Sweat Glands of Eyelid

B. Ranjodh Singh[1], Kristen E. Dunbar[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

The sweat glands of the eyelid are eccrine or apocrine, located close to the eyelid skin surface and can give rise to various eyelid pathologies.

Structure

The skin of the eyelid is thinner than other parts of the body and contains both sweat glands and hair. Eccrine glands are the most common sweat gland on the body and consist of a single duct with a deeper coiled component, known as the glomerulum. The apocrine sweat glands, on the contrary, are located mostly in the axilla, nipple, external ear, external genitalia, and eyelids. The apocrine glands are larger than eccrine glands and are more numerous in the lower eyelid, and their ductal openings are closely associated with eyelashes. The eyelid also contains glands of Moll, which are modified apocrine sweat glands found at the margin of the eyelid, next to the base of the eyelashes and anterior to the meibomian glands.

Function

As in other parts of the body, the primary function of eccrine sweat glands on the eyelid is thermoregulation by secreting sweat. The eccrine glands also produce secretions to create a slightly acidic film on the surface of the skin that serves as a barrier to harmful microbial colonization. The apocrine glands largely begin to function during puberty and produce a secretion that is thicker than eccrine glands, which provides nutrients for healthy bacteria on the skin surface. The exact function of glands of Moll is unknown; however, these glands contain bacteriolytic enzyme lysozyme, membrane-associated mucin 1, immunoglobulin A, and its secretory component, which suggests a function in local immune defense (Stoeckelhuber et al. 2003).

Clinical Relevance

The sweat glands of the eyelid can give rise to various pathologies. Syringomas are benign lesions of the eyelid sweat glands, which are more common in women and classically present as crops of small, firm, skin colored papules (Ciarloni et al. 2016). A hydrocystoma is a translucent cyst located near the lid margin, usually resulting from blockage of the sweat glands of the eyelid.

There are a number of tumors and cysts that are derived from the eyelid sweat glands (Baker et al. 2016). The pathology of the tumors is varied and includes mucinous carcinoma, microcystic adnexal carcinoma, endocrine mucin-producing sweat gland carcinoma, eccrine carcinoma, apocrine carcinoma, poorly differential adnexal carcinoma, and hidradenocarcinoma. Most of these lesions can be managed using Mohs micrographic excision with excellent outcomes.

Synonyms

Apocrine cystadenoma; Apocrine retention cyst; Black hidrocystoma; Moll's cyst; Sudoriferous cyst; Tumors of apocrine origin; Tumors of eccrine origin

Definition

Apocrine glands in the eyelids or the glands of Moll are located near the eyelid margin. They are composed of a secretory coil, an intradermal duct, and an intraepithelial duct. The secretory cells project their cytoplasm into a coiled lumen, which releases these secretions into the ducts, a process called decapitation secretion. Apocrine glands respond to sympathetic adrenergic stimuli and first become functional at puberty via hormonal stimulation. The primary function of eccrine glands is thermoregulation, through the cooling effects of evaporation of sweat on the skin's surface (Shields and Shields 1999; Albert and Jakobiec 2008).

Characteristics

Apocrine hidrocystoma is a very common smooth cyst from the gland of Moll. It is freely mobile and translucent and transilluminates light. It has been reported to be associated with ectodermal dysplasia. Treatments involve marsupialization for smaller lesions and complete excision for deeper lesions.

Cylindroma is a benign apocrine sweat gland lesion. It is dome-shaped, skin-colored nodule that occurs on the face and scalp. Multiple cylindromas can be autosomal dominantly inherited and can cover the entire scalp, known as a turban tumor. Treatment involves surgical excision.

Adenocarcinoma of the gland of Moll is an extremely rare apocrine sweat gland carcinoma. Many presumed cases have been confirmed to be sebaceous carcinoma and the pathology in reported cases has been disputed.

Eccrine hidrocystoma is a common translucent cystic lesion that clusters around the lower eyelids. They are considered ductal retention cysts and enlarge with perspiration, heat, and humidity. Treatment involves surgical excision.

Syringomas are benign eccrine tumors commonly found on young females. They are characterized as bilateral, small, waxy, pale yellowish nodules on the lower eyelids or upper cheeks. They tend to occur during puberty and are also found also in the axilla and sternal regions. Treatment involves surgical excision.

Eccrine spiradenoma is an uncommon benign lesion that presents as a deeper nodule beneath normal skin, which may be tender and painful. It tends to occur in early adulthood. Treatment is surgical excision.

Eccrine acrospiroma or clear cell hidradenoma is a rare, solid or cystic, mobile, skin- to red-colored nodule, just beneath the skin. Treatment is surgical excision.

Primary mucinous carcinoma or adenocystic carcinoma is an eccrine sweat gland carcinoma. It may present as a firm, flesh-colored nodule that transilluminates light; however, findings may be variable. Mucinous adenocarcinoma may infiltrate locally and extend into the orbit. Treatment involves wide resection with frozen sections (Shields and Shields 1999; Albert and Jakobiec 2008).

Sympathetic Nerves/Pathway, Orbit Supplied by

Elizabeth Marlow[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Structure

Sympathetic innervation of the orbit regulates pupillary dilation, vasoconstriction, hidrosis, and smooth muscle function of the eyelids and orbit. The hypothalamus is the origin for sympathetic activity, from which orbit-bound sympathetic fibers descend through the brainstem before entering the spinal cord to synapse in the ciliospinal center of Budge-Waller located at spinal levels C8-T2. Second-order preganglionic neurons that are destined for the head and neck then exit the spinal cord and travel in the cervical sympathetic chain through the brachial plexus, over the lung apex, to synapse in the superior cervical ganglion, which is located near the angle of the mandible and the bifurcation of the common carotid artery (Black et al. 2012). Third-order postganglionic neurons leave the superior cervical ganglion and ascend within the adventitia of the internal carotid artery, collectively known as the carotid plexus, and enter the cavernous sinus. There, the postganglionic oculosympathetic fibers separate from the carotid plexus and join the ophthalmic division of the trigeminal nerve (V1) to enter the orbit. These fibers run though the superior orbital fissure and merge with the long and short ciliary nerves (derived from the nasociliary branch of V1) before

passing through the ciliary ganglion on their way to innervate the dilator muscle of the iris and the superior tarsal (Müller's) and inferior tarsal muscles. The ciliary ganglion is a tissue mass located behind the eye, which contains three roots: sympathetic, parasympathetic (motor), and sensory. The sympathetic fibers have their cell bodies located in the superior cervical ganglion, so they do not synapse on their passage through the ciliary ganglion (Ropper and Brown 2005; Kardon 2005).

Function

Sympathetic fibers are responsible for innervating the periorbital blood vessels, sweat glands, pupil dilator muscle, ciliary muscle, superior tarsal muscle, inferior tarsal muscle, and orbitalis. At the ciliary body, sympathetics activate beta-2 receptors to stimulate relaxation and an increase in ciliary body size. As the aperture of the ciliary body widens with relaxation, the zonules that connect the periphery of the lens to the ciliary body become tauter and cause the lens to flatten. Thus, when the ciliary body is relaxed, the refractive power of the lens is reduced to optimize for far distance vision. In contrast, a decrease in sympathetic innervation to the ciliary body will lead to increased tone of the ciliary body, more relaxed zonules, and a rounder lens with greater refractive power that is ideal for near vision.

In the upper eyelid, the levator palpebrae is responsible for the majority of eyelid elevation and is innervated by the oculomotor nerve (CN 3). In contrast, motor innervation to superior tarsal muscle is supplied by sympathetic fibers and provides 2 mm of eyelid lift. The analogous structure in the lower eyelid is the inferior tarsal muscle, which is also supplied by sympathetics and arises from the capsulopalpebral fascia.

Clinical Relevance

Interruption of the sympathetic chain at any level along this pathway will produce miosis and ptosis, the most common presenting signs of Horner's syndrome. Additional features of the disorder include elevation of the lower eyelid, anhidrosis, and vasodilation. Central Horner's is caused by lesions to the first- and second-order sympathetic neurons. Injuries can be localized along the sympathetic pathway based on the presence and distribution of anhidrosis. In central Horner's, the face, arm, and trunk will show decreased sweating. This is because the sudomotor and vasomotor fibers to the face separate out at the superior cervical ganglions and thus would not be affected by postganglionic lesions (Kennard and Leigh 2011).

Diagnostic tests for subtle Horner's syndrome include topical cocaine and apraclonidine. The application of topical cocaine blocks reuptake of norepinephrine from the synaptic cleft leading to pupil dilation if the sympathetic innervation is intact. One hour after, two drops of 10% cocaine is applied to both eyes, the normal pupil will dilate more than the Horner's pupil causing an increase in anisocoria.

In contrast, apraclonidine is an adrenergic agonist and causes pupillary dilation in the Horner's pupil. Apraclonidine is a selective alpha-2 adrenergic agonist and has only weak alpha-1 properties. When the sympathetic input to the pupillary dilator muscle is decreased secondary to a lesion, an up-regulation of alpha-1 receptors causes denervation supersensitivity. Thus, the application of topical apraclonidine will dilate the abnormal pupil while the normal pupil is unchanged, effectively causing a reversal of anisocoria.

Topical hydroxyamphetamine is used to distinguish pre- and postganglionic Horner's, as it prompts a release of norepinephrine from intact adrenergic nerve endings causing pupillary dilation. One hour after instillation, dilation of both pupils indicates a lesion of the first- or second-order neuron. However, if the smaller pupil does not dilate, a lesion of the postganglionic neuron is indicated.

Depending on the etiology of the Horner's syndrome, ptosis may not be reversible. In these cases, it can be surgically corrected by shortening the superior tarsal muscle with either the Putterman procedure (conjunctival-Muller's muscle resection) or the Fasanella-Servat procedure (tarsoconjunctival resection) (Guthoff and Katowitz 2010).

Definition

Syphilis is a chronic infectious disease caused by a spirochete, usually venereal in origin but often congenital. Syphilis can affect almost any body organ if left untreated.

Etiology

Syphilis is caused by the spirochete *Treponema pallidum*. Currently, the main route of transmission is sexual contact with infectious lesions. Other less prevalent routs are congenital transmission from mother to fetus in utero, blood product transfusion, and direct contact of skin breaks with infectious lesions.

Clinical Presentation

Patients with untreated infection may experience four stages of disease. The most common manifestation of primary syphilis is a single painless lesion (chancre) usually on the external genitalia. Lip, mouth, and fingers are less common sites of ulcers. Condylomata lata, painless large fleshy lesions in warm moist body areas, are characteristic of secondary syphilis. Left untreated, secondary syphilis may progress to the subclinical latent stage, in which positive serologic test is the only clue of syphilis. Tertiary syphilis refers to gummatous- or granulomatous-like lesions and cardiovascular syphilis. Central nervous system manifestations such as cognitive dysfunction, motor or sensory deficits, ophthalmic or auditory symptoms, cranial nerve palsies, and meningitis can occur during any stage of syphilis.

Ocular Manifestation of Syphilis

Ocular involvement in syphilis may occur in any stages; however, it typically affects ocular structures in the secondary or tertiary stages. Syphilis usually mimics other diseases, which leads to misdiagnosis and delay in the treatment. Any ocular structure can be affected by syphilis. The most common ocular manifestation in both early and

late syphilis is anterior uveitis. Patients with anterior uveitis typically have ocular symptoms such as ocular pain, redness, and photophobia. Papulosquamous lesions of the eyelids, temporary loss of eyebrows, diffuse papillary conjunctivitis, scleroconjunctivitis, granulomatous or nongranulomatous intraocular inflammation, interstitial keratitis, chorioretinitis, retinal vasculitis, papillitis, and neuroretinitis are other common ocular findings in syphilis. Central nervous system involvement may lead to ocular motor palsies and visual field defects.

Chorioretinitis typically presents during secondary syphilis. Patients usually do not have the complaint of ocular pain, but their visual loss may be very severe. A focal or multifocal chorioretinitis with variable degree of vitritis is the most common manifestation. Syphilitic posterior placoid chorioretinitis is another ocular finding pathognomonic of secondary syphilis. It presents with yellowish confluent lesion at the level of RPE with a faded center and surrounding stippled hyperpigmentation of the RPE. Solitary or multifocal lesions are accompanied by variable amount of vitreous inflammation and may be associated with superficial hemorrhages, retinal vasculitis, disk edema, and serous detachment of the RPE. Healed lesions of chorioretinitis manifest with atrophy of the choroid and the retina, along with areas of hyperpigmentation.

Many patients with syphilis have concurrent HIV infection. These patients experience more rapidly progressive and more extensive ocular disease. Their ocular manifestations are usually bilateral and more common in males. The ophthalmologist should evaluate any HIV-infected patients with uveitis for syphilis infection, because syphilis is the most common bacterial eye infection in HIV-positive patients.

Congenital Syphilis

Common presentations of congenital syphilis are bone and cartilage abnormalities (saddle nose, palatal perforation, saber shins, and frontal bossing), circumoral rhagades, persistent rhinitis, hepatosplenomegaly, jaundice, and pneumonia. The patient may present with Hutchinson triad of interstitial keratitis, eighth nerve deafness, and Hutchinson teeth (notched incisors).

Ocular manifestations of congenital syphilis may present at birth or decades later. The most common ocular finding in early congenital infection is multifocal chorioretinitis, which may lead to bilateral salt-and-pepper fundus appearance. The classic ophthalmic finding in untreated congenital syphilis is bilateral non-ulcerative interstitial keratitis, which develops late in the first decade of life. Stromal infiltration starts within superior sector of the cornea and spreads centrally, if left untreated. Interstitial keratitis may lead to deep stromal neovascularization, which gives the cornea a "salmon patch" appearance. The sequel of interstitial keratitis is corneal thinning, scar formation, and stromal ghost vessels. Other less common ocular manifestations in congenital syphilis include retinal vasculitis, optic neuritis, glaucoma, and congenital cataract.

Diagnosis

Dark-field microscopy of glass slides prepared after abrading the active chancre is the most specific technique for diagnosing syphilis. Nontreponemal tests, including rapid plasma reagin (RPR) and venereal disease reference laboratory (VDRL), are routinely used for screening syphilis, although it has false-positive in case of pregnancy, autoimmune disorders, and infections. Treponemal-specific tests, including the enzyme immunoassay, the *T. pallidum* hemagglutination test, the microhemagglutination test, the fluorescent treponemal antibody-absorption test, and the enzyme-linked immunosorbent assay, are used to confirm the diagnosis. False-positive results can occur in case of systemic lupus erythematosus or Lyme disease. Unlike treponemal tests, which remain reactive for life, nontreponemal tests may become nonreactive with effective treatment. Patients suspicious to have neurosyphilis should have a cerebrospinal fluid examination. Positive nontreponemal test in the cerebrospinal fluid examination is in favor of neurosyphilis.

Differential Diagnosis

Differential diagnoses of syphilitic chancre are condyloma acuminata, drug eruptions, genital warts, granuloma inguinale, genital herpes simplex, herpes zoster, HIV disease, lymphogranuloma venerum, urinary tract infection, and varicella-zoster virus. Interstitial keratitis may occur with infectious agents such as mycobacterium tuberculosis, leishmania, *Borrelia burgdorferi*, and Epstein-Barr virus. Necrotizing syphilitic retinitis associated with one or more yellow-white patches of necrosis, vasculitis, vitreous inflammation, and discrete anterior segment inflammation closely mimics acute herpetic retinal necrosis syndrome (Gupta et al. 2009). To make the critical diagnosis of acute syphilitic posterior chorioretinitis, the ophthalmologist should rule out acute posterior multifocal placoid pigment epitheliopathy and atypical serpiginous choroidopathy (Ryan et al. 2013).

Prophylaxis

Using a condom during vaginal, oral, and anal sex may protect from transmission of the infection from skin lesions.

Therapy

Injectable benzathine penicillin G is drug of choice for the treatment of primary, secondary, latent, and tertiary syphilis. Crystalline penicillin G (18–24 million units per day for 10–14 days) is recommended for neurosyphilis and syphilitic uveitis. Alternatives for patients with allergy to penicillin and ocular syphilis are ceftriaxone or chloramphenicol (Skuta 2010).

Prognosis

With penicillin treatment, primary, secondary, and early latent syphilis can be cured successfully. Antibiotics treatment will not repair any organ damage in later stages. Involvement of central nervous system in tertiary syphilis has a very high mortality rate. Maternal syphilis can cause miscarriage and stillbirth. Keratitis, arthritis, deafness, and central nervous system damage may cause severe morbidity for patients with congenital syphilis.

Epidemiology

Syphilis accounts for less than 0.5% of new patients in a referral eye care practice and 0.05% of general ophthalmic outpatients (Krachmer et al. 2011). Concomitant HIV and syphilis infections are prevalent among men who have sex with men and injection drug users. Primary, secondary, and congenital syphilis have been diagnosed more in the past decade (Mattei et al. 2012). Syphilis coinfection with human immunodeficiency virus has also become more common (Mattei et al. 2012).

Definition

A T1-weighted (T1W) image is a basic pulse sequence in magnetic resonance (MR) imaging and depicts differences in signal based upon intrinsic T1 relaxation time of various tissues. Clinically, T1-weighted images generally are better for depicting normal anatomy and can accentuate pathology when gadolinium contrast is provided (Damadian 1971; Bitar et al. 2006). For example, fat demonstrates high signal intensity on T1-weighted images, while fluid demonstrates low signal intensity (Bitar et al. 2006). The fat can be suppressed on T1W MRI using fat saturation techniques to allow pathologic T1W hyperintensity to be seen in the orbit without the normal signal created by normal orbital fat.

Basic Characteristics

Physics Fundamentals

The physics of MR imaging are complex and beyond the scope of this chapter, but the concepts required to understand the acquisition and formation of a T1-weighted image will be explained in brief. MR imaging is based on the electromagnetic activity of atomic nuclei (Bitar et al. 2006). These nuclei are made up of protons and neutrons, which have spins. MR-active nuclei are those with a net spin because they are odd numbered and the spins of their protons and neutrons do not cancel each other out (Bitar et al. 2006). In clinical MR imaging, hydrogen (^{1}H) nuclei are used most often because of their abundance in the body (Bitar et al. 2006). Thus, it is necessary to have a source of hydrogen protons (protons in the nuclei of hydrogen atoms, which are associated with fat and water molecules) in order to form an MR signal (Pooley 2005). The hydrogen proton is positively charged and spins about its axis (like a child's spinning top). This positively charged spinning proton acts like a tiny magnet; the hydrogen protons in our body thus act like many tiny magnets (Pooley 2005).

A strong magnetic field is applied in MR imaging, and the main magnetic field of an MR system comes from a large electric current flowing through wires that are formed into a loop in the magnet of the imaging system (Pooley 2005). A typical clinical MR system has a magnetic field strength of 1.5 tesla (T) or 3.0 T, but higher strength magnets are becoming increasingly developed.

Putting these concepts together, there are protons in the body, positively charged and spinning about their axes, and acting like tiny magnets (Pooley 2005). When these protons are placed in a strong magnetic field (so-called B_0), some will tend to align in the direction of the magnetic field, and others will align opposite to the magnetic field. The magnetic fields from most of these protons will cancel out, but a slight excess of protons will align with the main magnetic field (Pooley 2005). The cumulative effect of all the magnetic moments of the nuclei is the "net magnetization" vector that is aligned parallel to the main magnetic field (Pooley 2005; Bitar et al. 2006).

This net magnetization becomes the source of our MR signal and is used to produce MR images (Pooley 2005). The way this works is that once net magnetization is achieved, a radiofrequency (RF) pulse is applied (a component of the MR scanner), causing the net magnetization vector to flip by a certain angle, producing two magnetization vector components, longitudinal and transverse magnetization (Bitar et al. 2006). The transverse component of the net magnetization vector induces a current in the receiver coil (another component of the MR scanner). This current ultimately becomes the MR signal (Bitar et al. 2006).

When the RF energy source is turned off, the net magnetization vector realigns with the axis of B_0 through the process of T1 recovery, during which the longitudinal magnetization increases in magnitude, or recovers (Bitar et al. 2006). Simultaneously, the transverse magnetization decreases (decays) through additional mechanisms known as T2* and T2 decay (Bitar

et al. 2006). Different tissues have different characteristic T1, T2, and T2* values, which is in large part what allows the differentiation of tissues and disease processes in clinical imaging. Fat has a shorter T1 (i.e., recovers faster) and a shorter T2 (i.e., decays faster) than water, which has a relatively long T1 and T2. T2* decay occurs very quickly in both fat and water (Bitar et al. 2006). Tissues with an inherently short T1 time appear bright on T1-weighted images (such as fat), while tissues with a long T1 time will appear dark (such as air) (Hathout 2009). Along the same lines, tissues with a long T2 time will appear bright on T2-weighted images (such as water), while tissues with a short T2 time will appear dark (such as the cortical bone).

On a final technical note, two key parameters – repetition time (TR) and echo time (TE) – are key to the creation of image contrast (Bitar et al. 2006). While further discussion of these values is beyond the scope of this chapter, TR and TE can be adjusted to emphasize a particular type of contrast (i.e., T1, T2). T1 weighting is produced by utilizing short TR and TE times. In T1-weighted MR imaging, while images show all types of contrast, T1 contrast is accentuated (Bitar et al. 2006).

Uses for T1 Weighting

Clinically, T1-weighted images best depict anatomy and can accentuate pathology when contrast is provided (Damadian 1971; Bitar et al. 2006). As stated previously, with MR imaging only hydrogen protons are visualized. The MR imaging contrast agent most frequently utilized is gadolinium. Gadolinium is a paramagnetic material that produce "contrast enhancement" by shortening the T1 time of hydrogen protons in their vicinity, thus causing them to appear bright on T1-weight MR images, in just the same fashion that protons within intrinsically short T1 time constants, such as hydrogen protons in fat, are bright on T1-weighted MR imaging (Hathout 2009). A smaller concentration of gadolinium is required to achieve this T1 shortening in MR imaging than the concentration of iodine needed to achieve appreciable increases in density on contrast CT examinations. Thus, a mass may appear as non-enhancing on contrast CT, yet as avidly enhancing on contrast MR imaging (Hathout 2009).

T2-weighted images, on the other hand, provide the best depiction of disease, because most tissues involved in a pathologic process have a higher water content than normal, and fluid causes affected areas to appear bright on T2-weighted images (Bitar et al. 2006). In regard to neuroimaging, white matter has a very short T1 time and relaxes rapidly; cerebrospinal fluid (CSF) has a long T1 and relaxes slowly. Gray matter has an intermediate T1 and relaxes at an intermediate rate (Pooley 2005). If an image were created at a time when the T1 curves for these tissues were widely separated, an image with high contrast between these tissues would be formed. White matter contributes to brighter pixels, CSF contributes to darker pixels, and gray matter contributes to pixels with intermediate shades of gray; this type of contrast mechanism is termed T1-weighted contrast (Pooley 2005). A summary of the appearance of various tissues on T1-weighted images is provided below (Bitar et al. 2006) Table 1.

T1-Weighted Image, Table 1 Appearance of tissues on T1-weighted images

Signal intensity	Tissues
Dark	Air, mineral-rich tissue (cortical bone, stones), fast-flowing blood
Low	Collagenous tissue (ligaments, tendons, scars), high free water tissue (kidneys, gonads, edema, fluids [urine, bile], simple cysts, bladder, gallbladder, spleen, CSF), high bound-water tissues (liver, pancreas, adrenals, hyaline cartilage, muscle)
Intermediate	Proteinaceous tissue (abscess, complex cysts, synovial fluid)
Bright	Fat, fatty bone marrow, blood products (methemoglobin, slow-flowing blood, radiation change, paramagnetic contrast agents)

Definition

A T2-weighted image is a basic pulse sequences in magnetic resonance (MR) imaging that depicts differences in the T2 relaxation time of various tissues. Clinically, T2-weighted images provide the best depiction of disease, because most tissues involved in a pathologic process have a higher water content than normal, and fluid (e.g., cerebrospinal fluid, vitreous humor) causes affected areas to appear bright on T2-weighted images (Bitar et al. 2006).

Basic Characteristics

Physics Fundamentals

The physics of magnetic resonance (MR) imaging are complex and beyond the scope of this chapter,

but the concepts required to understand the acquisition and formation of a T2-weighted image will be explained in brief. MR imaging is based on the electromagnetic activity of atomic nuclei (Bitar et al. 2006). These nuclei are made up of protons and neutrons, which have spins. MR-active nuclei are those with a net spin because they are odd numbered, and the spins of their protons and neutrons do not cancel each other out (Bitar et al. 2006). In clinical MR imaging, hydrogen (^{1}H) nuclei are used most often because of their abundance in the body (Bitar et al. 2006). Thus it is necessary to have a source of hydrogen protons (protons in the nuclei of hydrogen atoms, which are associated with fat and water molecules) in order to form an MR signal (Pooley 2005). The hydrogen proton is positively charged and spins about its axis (like a child's spinning top). This positively charged spinning proton acts like a tiny magnet; the hydrogen protons in our body thus act like many tiny magnets (Pooley 2005).

It is also a prerequisite to apply a magnetic field in MR imaging; the main magnetic field of an MR system comes from a large electric current flowing through wires that are formed into a loop in the magnet of the imaging system (Pooley 2005). A typical clinical MR system has a magnetic field strength of 1.5 tesla (T) or 3.0 T.

Putting these concepts together, there are protons in the body, positively charged and spinning about their axes, acting like tiny magnets (Pooley 2005). When these protons are placed in a strong magnetic field (so-called B_0), some will tend to align in the direction of the magnetic field and others will align opposite to the magnetic field. The magnetic fields from most of these protons will cancel out, but a slight excess of protons will align with the main magnetic field (Pooley 2005). The cumulative effect of all the magnetic moments of the nuclei is the "net magnetization" vector that is aligned parallel to the main magnetic field (Pooley 2005; Bitar et al. 2006).

So how does this relate to the images we are used to seeing in clinical practice? This net magnetization becomes the source of our MR signal and is used to produce MR images (Pooley 2005). The way this works is that once net magnetization is achieved, a radiofrequency (RF) pulse is applied (a component of the MR scanner), causing the net magnetization vector to flip by a certain angle, producing two magnetization vector components, longitudinal and transverse magnetization (Bitar et al. 2006). The transverse component of the net magnetization vector induces a current in the receiver coil (another component of the MR scanner). This current ultimately becomes the MR signal (Bitar et al. 2006).

When the RF energy source is turned off, the net magnetization vector realigns with the axis of B_0 through the process of T1 recovery, during which the longitudinal magnetization increases in magnitude, or recovers (Bitar et al. 2006). Simultaneously, the transverse magnetization decreases (decays) through additional mechanisms known as T2* and T2 decay (Bitar et al. 2006). Different tissues have different characteristic T1, T2, and T2* values, which are in large part what allow the differentiation of tissues and disease processes in clinical imaging. Fat has a shorter T1 (i.e., recovers faster) and a shorter T2 (i.e., decays faster) than water, which has a relatively long T1 and T2. T2* decay occurs very quickly in both fat and water (Bitar et al. 2006). Tissues with an inherently short T1 time appear bright on T1-weighted images (such as fat), while tissues with a long T1 time will appear dark (such as air) (Hathout 2009). Along the same lines, tissues with a long T2 time will appear bright on T2-weighted images (such as water), while tissues with a short T2 time will appear dark (such as cortical bone).

On a final technical note, two key parameters – repetition time (TR) and echo time (TE) – are key to the creation of image contrast (Bitar et al. 2006). While further discussion of these values is beyond the scope of this chapter, TR and TE can be adjusted to emphasize a particular type of contrast (i.e., T1, T2). T2 weighting is produced by utilizing long TR and TE times (Bitar et al. 2006).

Uses for T2 Weighting

Clinically, T2-weighted images provide the best depiction of disease, because most tissues

involved in a pathologic process have a higher water content than normal, and fluid causes affected areas to appear bright on T2-weighted images (Bitar et al. 2006). This is in contrast to T1-weighted images, which best depict anatomy and can accentuate pathology when contrast is provided (Damadian 1971; Bitar et al. 2006). In regard to neuroimaging, white matter has a short T2 and dephases rapidly; cerebrospinal fluid (CSF) has a long T2 and dephases slowly (Pooley 2005). Gray matter has an intermediate T2 and dephases intermediately. Clinically these differences can be taken advantage of, and images based on this contrast mechanism may be produced, called "T2-weighted contrast" (Pooley 2005). If an image were created at a time when transverse magnetization curves were widely separated, then high contrast between the tissues would be obtained. CSF would be associated with brighter pixels, white matter with darker pixels, and gray matter with intermediately gray-level pixels (Pooley 2005). A summary of the appearance of various tissues on T2-weighted images is provided below (Bitar et al. 2006) (Table 1).

T2-Weighted Image, Table 1 Appearance of tissues on T2-weighted images

Signal intensity	Tissues
Dark	Air, mineral-rich tissue (cortical bone, stones), fast-flowing blood
Low	Collagenous tissue (ligaments, tendons, scars), bone islands
Low to intermediate	High bound water tissues (liver, pancreas, adrenals, hyaline cartilage, muscle)
Intermediate to bright	Fat, fatty bone marrow
Bright	High free water tissue (kidneys, gonads, edema, fluids [urine, bile], simple cysts, bladder, gallbladder, spleen, CSF). Proteinaceous tissue, blood products (oxyhemoglobin, extracellular methemoglobin)

Tamsulosin

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Flomax™

Definition

Selective alpha-1 adrenergic blocker.

Indication

Management of lower urinary tract symptoms in men with moderate to severe urinary symptoms due to benign prostatic hyperplasia.

Contraindication

Tamsulosin capsules are contraindicated in patients known to be hypersensitive to tamsulosin hydrochloride or any component of tamsulosin capsules.

Use and Dosage

Tamsulosin 0.4 mg once daily is recommended as the dose for the treatment of the signs and symptoms of benign prostatic hyperplasia. For those patients who fail to respond to the 0.4 mg dose after 2–4 weeks of dosing, the dose of tamsulosin can be increased to 0.8 mg once daily.

Adverse Reactions

Intraoperative floppy iris syndrome in cataract surgery is strongly correlated with systemic use of tamsulosin. The syndrome consists of poor pupillary dilation, progressive intraoperative miosis with billowing of the iris, and increased risk of iris prolapse through the corneal incisions and is therefore associated with increased risks of surgical complications. Therefore, the use of pupil dilators should be considered in patients with a history of tamsulosin medication. The deleterious effects of tamsulosin on cataract surgery can persist for years after discontinuation. The signs and symptoms of orthostasis (postural hypotension, dizziness, and vertigo) are detected more frequently in tamsulosin-treated patients. As with other alpha-adrenergic blocking agents, there is a potential risk of syncope.

Interactions

Doses of tamsulosin higher than 0.4 mg (e.g., 0.8 mg) should not be used in combination with strong inhibitors of CYP3A4 (e.g., ketoconazole).

Tangier Disease, Corneal Changes

Allen O. Eghrari
Johns Hopkins University School of Medicine, Baltimore, MD, USA
Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Familial alpha-lipoprotein deficiency; Hypoalphalipoproteinemia

Definition

Bilateral stromal opacities in the setting of Tangier disease.

Etiology

A defect in the ABCA1 cellular membrane transporter in Tangier disease prevents adequate removal of cholesterol from cells. Cholesterol and phospholipid esters accumulate over time in the corneal stroma due to its relatively low temperature and lack of vascularity. The disease is inherited in an autosomal recessive fashion due to mutations in the ABCA1 gene in chromosome 9q31.

Clinical Presentation

Corneal changes in Tangier disease appear as bilateral corneal opacifications limited to the stroma and generally present in adult life. Deposits appear small and granular, distributed with relatively similar density through the anterior and posterior stroma. Although the rarity of cases prevents generalization, early findings may involve increased density in the nasal and temporal quadrants, later involving the paracentral and peripheral cornea. Endothelial cell density is not affected. Patients may also demonstrate conjunctival perivascular deposits. Decrease in visual acuity may correlate with opacification and is variable, ranging from relatively mild to marked visual impairment. Comorbidities reported include keratitis, ectropion, and incomplete eye closure, but an association with Tangier disease is unclear.

Diagnosis

Serum lipid analysis reveals minimal levels of high-density lipoproteins (HDL), and genetic analysis for the ABCA1 mutation can confirm the presence of Tangier disease. Slit-lamp biomicroscopy should be utilized to identify and localize the presence of corneal opacities. Conjunctival biopsy shows birefringent lipid particles in vascular pericytes but is generally not required for diagnosis. Detailed medical and surgical history should be acquired, with consideration for systemic associations, including yellow-orange tonsils, splenomegaly, hepatomegaly, cardiovascular disease, and neuropathy.

Differential Diagnosis

The differential diagnosis for bilateral stromal opacities includes ▶ Schnyder corneal dystrophy, ▶ lipid keratopathy, and ▶ corneal arcus; HDL deficiencies such as lecithin-cholesterol acyltransferase deficiency and fish eye disease; and other crystalline deposits such as cystinosis, gout, mucolipidosis, and mucopolysaccharidosis. Tangier disease is marked by its autosomal recessive transmission, unlike Schnyder corneal dystrophy which is autosomal dominant.

Prophylaxis

No method of prophylaxis is known at this time.

Therapy

Mild opacities may be observed. Corneal transplantation can be considered for severe cases, with option of either deep anterior lamellar keratoplasty or penetrating keratoplasty, although outcomes are unclear. Patients should undergo systemic evaluation and treatment of lipid abnormalities.

Prognosis

Visual acuity ranges from mildly to severely affected, correlates with corneal opacities, and slowly decreases over years to decades.

Epidemiology

Rare. First described in a patient from Tangier Island, Virginia, approximately 50 cases have been identified globally. The prevalence of corneal changes among these patients is unclear.

[2]Department of Ophthalmology, University of South Florida College of Medicine, Tampa, FL, USA

Synonyms

Palpebral conjunctiva

Definition

The conjunctiva proper is a translucent mucous membrane covering the anterior surface of the eye and posterior side of the eyelid. The conjunctiva becomes continuous with the corneal epithelium. The conjunctiva can be divided into the palpebral conjunctiva, fornices, and bulbar conjunctiva. Specifically, the palpebral conjunctiva lines the posterior surface of the eyelid.

Structure

The palpebral conjunctiva can be subdivided into the marginal, tarsal, and orbital conjunctiva (Goldman 2011).

The marginal conjunctiva posteriorly and the skin anteriorly form the surface of the eyelid margin. The transition zone between these structures is known as a mucocutaneous junction. The marginal conjunctiva is continuous with the tarsal conjunctiva and more inferiorly the sub-tarsal sulcus.

The tarsal conjunctiva is a vascular structure tightly adherent to the tarsal plates in both upper and lower eyelids (Goldman 2011).

The orbital conjunctiva is a loose covering between the tarsal plate and the fornix, lying over the Muller's muscle in the upper eyelid and the lower lid retractors in the lower eyelid.

Function

The palpebral conjunctiva contains accessory lacrimal glands and goblet cells producing tears and mucus, respectively, contributing to the maintenance of the healthy pre-corneal tear film. It is also critical for proper function of the specialized sebaceous glands of the tarsus, meibomian glands, which contribute to the lipid layer of the tear film. It serves as a reservoir for tears and provides oxygen to the cornea. The palpebral conjunctival also contributes to immune surveillance and forms a protective barrier over the anterior portion of the globe (Takahashi et al. 2013).

Clinical Relevance

The sub-tarsal sulcus is a common site for foreign body lodgement (Fonolla et al. 2001). Furthermore, the palpebral conjunctiva represents an area where reactive pathology of the conjunctiva can be seen. Follicle formation occurring in the palpebral conjunctiva is associated with viral and chlamydial infections, as well as toxic conjunctivitis

(Pacharn et al. 2013). Papillae formation within the palpebral conjunctiva is associated with allergic diseases, but can also be associated with non-pathological conditions such as prolonged contact lens use (Pacharn et al. 2013). Many cicatrizing and inflammatory conditions such as Steven's Johnson's syndrome or ocular cicatricial pemphigoid affect the palpebral conjunctiva. These processes can lead to entropion, forniceal shortening, and trichiasis, with eventual corneal scarring and blindness (Chiou et al. 1998). Multiple surgical incisions used to gain entrance to the orbit and eyelids are performed through the palpebral conjunctiva to camouflage the scar (Goldman 2011).

Tarsal Fracture Operation, for Cicatricial Entropion

Ru-ik Chee[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Transverse tarsotomy with lid margin rotation

Definition

The tarsal fracture operation refers to a surgical procedure where the eyelid tarsus is iatrogenically fractured with a full-thickness tarsal incision, allowing for independent rotation of both segments of the eyelid above and below the incision, which can be utilized in the surgical repair of eyelid malposition.

Indication

The tarsal fracture operation is indicated for the surgical repair of mild to moderate cicatricial entropion (Bercovici et al. 1977; Kersten et al. 1992). A full-thickness incision through the tarsus is made from the posterior or conjunctival aspect of the eyelid "fractures" or mechanically dissociates the superior and inferior portions of the tarsus and allows the eyelid to "bend." In the case of entropion, the eyelid margin is everted or bent away from the globe with the use of everting sutures. External rotation of the eyelid margin redirects eyelashes away from the cornea and globe, reducing the incidence of ocular surface irritation, keratopathy, epithelial defects, corneal ulcers, and even corneal perforation

Contraindication

The tarsal fracture operation is not usually performed in cases of involutional entropion where chronic tarso-conjunctival inflammation and cicatrisation are not present. Other contraindications to the tarsal fracture operation, which is usually performed under general anesthesia, are mostly related to the general medical condition and operative risk of the patient. The tarsal fracture procedure may be contraindicated in patients with concurrent uncontrolled medical conditions, systemic anticoagulation, or other conditions that interfere with appropriate positioning or safe management of the patient in the operating room. In such situations, simpler less invasive methods of eyelid malposition correction such as the Quickert

procedure for entropion may be preferred, even if they may be associated with higher long-term recurrence.

Techniques and Principles

1. After skin preparation, infiltrate locally administered anesthetic agent subcutaneously and subconjunctivally along the lower border of the inferior tarsus or superior border of the superior tarsus.
2. Stabilize the eyelid by placing a 4-0 silk traction suture through the eyelid margin, and evert the eyelid using a Jaeger lid speculum, exposing the posterior conjunctival aspect of the eyelid.
3. Using a 15 blade, fashion a horizontal full-thickness tarsal incision from the conjunctival aspect 2 mm inferior to the eyelid margin in the lower lid, or 2 mm superior to the eyelid margin in the upper lid.
4. Place 2-3 Quickert everting sutures to fixate and rotate the eyelid margin away from the globe

Outcome

A retrospective review of the tarsal fracture operation reported a favourable outcome rate of in 94% of cases of mild to moderate cicatricial entropion. The same study found a lower success rate of 55% in cases of severe cicatricial entropion (Kersten et al. 1992). Several studies have reported that overall success rates increase after reoperations in cases of recurrence, even in severe cases, suggesting that tarsal fracture may still be considered as an acceptable procedure in the initial management of severe cicatricial entropion (Kersten et al. 1992; Pombejara and Tirakunwichcha 2011).

Other techniques reported for the surgical management of severe cicatricial entropion include posterior lamellar eyelid reconstruction techniques with the use of tissue grafts. Additional tissue used in these techniques aids with improving outcomes and reducing recurrence. Buccal, hard palate, and nasal turbinate mucosa have been used as donor graft tissue for posterior buttress eyelid reconstruction (Bartley and Kay 1989; Goldberg et al. 1999). In these studies, successful treatment of eyelid malposition was achieved in 86% of patients.

Complications

The tarsal fracture operation is a relatively simple operation. Complications of the tarsal fracture operation include failure of entropion correction, recurrence, ectropion overcorrection, granuloma formation, infection, bleeding, and wound dehiscence. Careful burying of deep sutures while minimizing dead space aids in the reduction of suture granuloma formation and suture extrusion. Attention to appropriate surgical technique, good placement of sutures, and secure knots maximizes the chances of surgical success. Avoidance of trauma in the postoperative period, good patient hygiene, and use of topical antibiotic ointment may also contribute to minimizing complications. Patients should also be counselled by the anesthesiologist regarding the risks and complications of general anesthesia.

Tarsal Kink

Bryan Seiff
Delaware Eye Institute, Rehoboth Beach, DE, USA

Synonyms

Congenital entropion

Definition

Tarsal kink is a form of congenital entropion characterized by a horizontal fold in the tarsus along the inferior third of the upper eyelid.

Etiology

The etiology of tarsal kink is unclear but possibilities include a primary tarsal defect, an aponeurotic defect, overacting orbicularis fibers, an exogenous mechanical force in utero, or an eyelid disjunction defect in utero.

Clinical Presentation

Tarsal kink presents as a unilateral or bilateral upper eyelid entropion at birth. It is usually associated with marked blepharospasm and an absent lid crease. Corneal ulceration is present in roughly half of patients.

Diagnosis

Diagnosis of tarsal kink is made clinically. Associated corneal ulcers, present in roughly half of patients, may be cultured. The most common causative organisms are *S. Aureus* and *S. Epidermidis*.

Differential Diagnosis

Congenital entropion without tarsal kink

Therapy

Treatment of tarsal kink involves "unfolding" of the kink by patching or surgical rotation. In general, surgical procedures are geared towards weakening the kink, rotating it with sutures, and closing with supratarsal fixation to re-form the eyelid crease. Surgical procedures include suture rotation over bolsters, full-thickness horizontal kink excision, skin and muscle excision or repositioning, tarsal excision with suture rotation, lamellar tarsectomy with flip, and tarsal incision with suture rotation and supratarsal fixation.

Prognosis

The majority of patients will continue to have normal visual development following tarsal kink repair. Factors leading to poor visual outcomes include the presence of an ulcer or a delay in diagnosis.

Epidemiology

Rare

Tarsal Muscles, Inferior

B. Ranjodh Singh[1], Kristen E. Dunbar[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Inferior tarsal muscle

Definition

The inferior tarsal muscle and the capsulopalpebral fascia make up the lower eyelid retractors.

Structure

The lower eyelid retractors include the inferior tarsal muscle and the capsulopalpebral fascia, both of which attach to the tarsal plate. The inferior tarsal muscle is innervated by the sympathetic nervous system and gets its blood supply from the inferior palpebral artery. The capsulopalpebral fascia originates from the inferior rectus muscle fascia and wraps anteriorly around the inferior oblique muscle to reach the Lockwood ligament. From here the capsulopalpebral fascia courses forward to reach the lower margin of the tarsus and the subcutaneous tissue. Running deep to the capsulopalpebral fascia is the inferior tarsal muscle. The inferior tarsal muscle is approximately half the size of the superior tarsal muscle (4–5 mm vs. 9–10 mm), but both are similar in length and thickness, and both are lined posteriorly with densely adherent conjunctiva (Sand et al. 2016).

Function

The inferior tarsal muscle helps in lower eyelid retraction.

Clinical Relevance

Disruption in lower eyelid retractors can cause entropion and ectropion, where the lower eyelid is folded inward toward the eye or outward from the eye, respectively (Kakizaki et al. 2009). These conditions occur more readily with disruption of the capsulopalpebral fascia, since this serves as the primary lower lid retractor. Disrupting the inferior tarsal muscle alone may cause eyelid malposition, but is not classically seen in patients.

Knowledge of lower eyelid retractors is needed for successful outcomes in cosmetic and reconstructive lower eyelid surgery. When the lower eyelid retractors are the targets of certain eyelid malposition surgeries, the surgeon should carefully look for the retractors in the posterior layer, which is where the main retractional component lies. Appropriate advancement of the posterior layer may provide good outcomes in lower eyelid entropion surgery, or occasionally in ectropion surgery in the absence of retraction.

Tarsal Plate

► Tarsal Plates/Tarsus

Tarsal Plates/Tarsus

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Synonyms

Tarsal plate; Tarsoligamentous sling; Tarsus

Definition

Fibrous plates providing structural integrity to the upper and lower eyelids

Structure

Recent immunohistochemical studies suggest that the tarsus is a "transitional tissue" with features of both dense fibrous connective tissue and cartilage. It contains fibroblastic cells in an extracellular matrix dominated by type I and III collagen and proteoglycans. Chondrocytes and type II collagen are notably absent. Aggrecan and chondroitin sulfate, however, are present in relative abundance (Milz et al. 2005).

The horizontal dimension of the tarsal plates is slightly narrower than that of the palpebral fissure (25–30 mm) (Bedrossian 2006). Maximum tarsal thickness is approximately 1 mm centrally. Height in the midpupillary axis is 10–12 mm in the upper eyelid and 4–6 mm in the lower eyelid. Approaching the medial and lateral commissures, the plates in both lids taper to a height of 2 mm before merging with the canthal tendons.

The lateral canthal tendon joins with the lateral horn of the levator, lateral rectus check ligament, and Lockwood's ligament to form the lateral retinaculum. This inserts on Whitnall's tubercle, a bony prominence inside the orbital rim. The medial canthal tendon splits to form anterior and posterior limbs. These limbs insert on the anterior and posterior lacrimal crests, respectively, straddling the lacrimal sac within its bony fossa. The accompanying deep heads of the pretarsal and preseptal orbicularis muscle also insert on the posterior lacrimal crest.

Palpebral conjunctiva is firmly adherent to the internal surface of the tarsal plates. Mulller's muscle and capsulopalpebral fascia insert on the respective antimarginal tarsal borders. The levator aponeurosis inserts on the anterior surface of the superior tarsal plate, interdigitating with orbicularis to form the eyelid crease. The pretarsal orbicularis muscle is relatively adherent to the the anterior tarsal plates.

The upper eyelid contains 30–40 meibomian glands, while the lower contains 20–30. The gland orifices are located between the gray line (muscle of Riolan) and eyelid myocutaneous junction.

Function

A fibrous skeleton consisting of the tarsal plates and canthal tendons maintains the structural integrity of the eyelids (the "tarsoligamentous sling"). It keeps the lids closely approximated to the ocular surface and plays a vital protective role. The indwelling meibomin glands are holocrine glands responsible for producing the lipid layer of the precorneal tear film.

Clinical Relevance

Knowledge of tarsal anatomy is crucial for eyelid reconstruction following trauma or Mohs surgery. When using free taral grafts or pedicle flaps (e.g., Hughes), it is important to leave 4 mm of marginal tarsus in the upper lid and 2 mm in the lower lid in order to to avoid destabilization. When portions of tarsus are missing, the cut ends should be trimmed perpendicular to the lid margin in order to prevent notching.

The tarsal plate becomes lax in floppy eyelid syndrome (FES), permitting the lid to evert easily. Histopathological studies demonstrate a decreased abundance of mature elastic fibers (Ezra et al. 2011). Ordinarily, these fibers are principally distributed around the meibomian glands and extend toward the muscle of Riolan (Kakizaki et al. 2011). This dropout may therefore contribute to the abnormal lipid secretion and lash ptosis seen with FES.

Tarsal Strip Procedure

Ru-ik Chee[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Lateral tarsal strip procedure

Definition

The tarsal strip procedure refers to the surgical shortening of the lateral canthal tendon or lateral edge of the tarsal plate. The procedure results in a superior and lateral distraction of the lax eyelid.

Indication

The tarsal strip procedure reduces horizontal eyelid laxity and corrects eyelid malposition through direct mechanical shortening of the canthal tendon. The tarsal strip procedure was first described by Anderson and Gordy in 1979 for the surgical repair of paralytic or senile upper or lower eyelid laxity, lateral canthal tendon laxity or malposition, and iatrogenic phimosis associated with recurrent entropion or ectropion (Anderson and Gordy 1979). Since then, the tarsal strip procedure has also been reported to be used in the correction of lax eyelid syndrome, mild post-enucleation socket syndrome, orbital decompression, repair of lateral canthotomy in the swinging eyelid flap for orbital floor implants, lower eyelid transcutaneous or trans-conjunctival blepharoplasty, sub-orbicularis oculi fat pad (SOOF) lift, and cicatrical ectropion when combined with a free skin graft (Olver 1998).

Recently, the tarsal strip procedure has been increasingly combined with Quickert everting sutures, which aids with eyelid eversion in the

surgical management of eyelid entropion (Ho et al. 2005). This procedure, described as a lateral tarsal strip with everting sutures, has been described and shown to be an effective and simple procedure suitable for use by a comprehensive ophthalmologist.

Contraindication

Contraindications to the tarsal strip procedure, which is usually performed under general anesthesia, are mostly related to the general medical condition and operative risk of the patient. The tarsal strip procedure may be contraindicated in patients with concurrent uncontrolled medical conditions, systemic anticoagulation, or other conditions that interfere with appropriate positioning or safe management of the patient in the operating room. In such situations, simpler less invasive methods of eyelid malposition correction such as the Quickert procedure for entropion may be preferred, even if they may be associated with higher long-term recurrence.

Techniques and Principles

The tarsal strip procedure is performed as follows:

1) After skin preparation, infiltrate locally administered anesthetic agent subcutaneously and subconjunctivally along the lateral periorbital region.
2) Use a blade to make a 0.5–1.0 cm superficial skin-orbicularis incision along a skin crease, exposing the fascia overlying the periosteum of the lateral orbital rim.
3) Perform an upper or lower limb lateral canthotomy and cantholysis, depending on which eyelid surgery is intended upon.
4) Split the anterior and posterior lamellae of the eyelid along the gray line by an extent to which eyelid shortening is desired.
5) Excise the anterior mucocutaneous junction of the strip and excess skin using scissors.
6) De-epithelialize the tarso-conjunctival epithelium with gentle cautery and scraping with a blade.
7) Secure the tarsus to the lateral orbital rim using nonabsorbable 5-0 Prolene sutures.
8) Close the orbicularis and skin layers separately with 6-0 and 8-0 Vicryl sutures respectively.

Outcome

The tarsal strip procedure is an effective surgical procedure for the correction of eyelid malposition. A clinical series of tarsal strip procedures reported a 92–95% rate of success with few complications (Riedel and Beyer-Machule 1991). The tarsal strip procedure with everting suture procedure used in involutional entropion has been reported to have recurrence rates of 2–9.4% (Olver 1998; Ho et al. 2005). Horizontal or vertical eyelid laxity, eyelid retractor attenuation or disinsertion, and overriding of the preseptal orbicularis oculi are three main components leading to involutional entropion. Effective surgical repair of involutional entropion often involves correction of at least two of the three main components of entropion, and the tarsal strip procedure reduces both horizontal eyelid laxity and retractor attenuation.

In addition to the effectiveness in correcting eyelid malposition, the tarsal strip procedure maintains the natural anatomic configuration of the lateral canthal angle, which translates to excellent cosmetic results. The procedure is relatively simple and minimally invasive compared to other eyelid malposition surgical procedures that involve full-thickness wedge resections, which leads to a favorable postoperative recovery course.

Complications

Complications of the tarsal strip procedure include conjunctival cysts, granuloma formation, suture extrusion, infection, bleeding, slippage of lateral canthal tendon, and wound dehiscence. Cautery of the tarsoconjunctival epithelium ablates epithelial and mucin-producing Goblet cells, reducing the rate of conjunctival cyst formation. Careful burying of deep sutures while minimizing dead space aids in the reduction of suture granuloma formation and suture extrusion.

Attention to appropriate surgical technique, good placement of sutures, and secure knots reduces the occurrence of tendon slippage and wound dehiscence. Avoidance of trauma in the postoperative period, good patient hygiene, and use of topical antibiotic ointment may also contribute to minimizing complications.

Tarsorrhaphy

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Synonyms

Temporary suture tarsorrhaphy (TST)

Definition

A surgical procedure designed to protect the ocular surface by narrowing or closing the palpebral aperture.

Indication

Central tarsorrhaphies are generally a temporary measure to treat non-healing epithelial defects and neurotrophic ulcers. They may also be required in critically ill, intubated patients with lagophthalmos. Aggressive lubrication and moisture chambers are typically used as primary interventions, but tarsorrhaphy becomes necessary with evidence of progressive exposure keratitis.

Lateral tarsorrhaphies are used to reduce ocular surface evaporation by narrowing the horizontal palpebral aperture. They may be used in patients with facial nerve palsies or other pathologies expected to result in long-term exposure-related problems.

Contraindication

Tarsorrhaphies are contraindicated in patients with active bacterial infection, though they may be used as an adjunct for treated ulcers with delayed epithelial healing. Extended lateral tarsorrhaphies are relatively contraindicated in patients who are good candidates for procedures

that may offer a better cosmetic result, such as lower lid tightening and lid weight insertion.

Techniques and Principles

Suture tarsorrhaphies can be divided into two categories: those with bolsters and those without. Bolsters are designed to distribute pressure over a larger surface area. They are required when sutures are passed through the skin as well as the lid margin, rather than through the lid margin alone. Popular bolster materials include intravenous tubing, cotton fluff, and foam suture packaging material. The standard technique entails passing both ends of a double-armed silk suture through the first bolster, then through the upper and lower lid skin and tarsal plates, and finally through a second bolster. Tying the two free ends results in complete lid closure. A bow closure allows the tarsorrhaphy to be opened for eye inspection. An alternative method known as the "drawstring temporary tarsorrhaphy" uses a sliding third bolster to open and close the eye (Kitchens et al. 2002). A bolsterless tarsorrhaphy entails taking tarsal bites through the meibomian gland orifices with a single-armed silk suture. The free ends are then tied, apposing the lids (McInnes et al. 2006). This type of tarsorrhaphy is harder to open without cutting.

Lateral tarsorrhaphy entails sharply separating the anterior and posterior lamellae of the eyelids over the desired distance. The posterior lamellae are then sutured together, often after the cutaneous margins have been excised to permit the adhesion of raw tarsal margins.

Outcome

Temporary suture tarsorrhaphy is generally very effective. Cosar and colleagues reported a 91% success rate for the treatment of non-healing epithelial defects (Cosar et al. 2001). Alternatives such as cyanoacrylate glue, tape, and upper eyelid appliques have not been widely adopted because they lack the durability and efficacy of tarsorrhaphy (Ehrenhaus and D'Arienzo 2003; Robinson et al. 2006).

Complications

Bolster suture tarsorrhaphies are prone to cheesewiring if they are frequently and aggressively manipulated or if the tarsal bites are not substantial. Lateral tarsorrhaphies can be divided sharply at a later date, but may result in lid scarring, trichiasis, and a suboptimal cosmetic outcome.

[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Lateral tarsotomy; Transverse tarsotomy procedure; Wies procedure

Definition

A surgical procedure involving an incision and sometimes excision of the tarsal cartilages.

Indication

Transverse tarsotomy and lid margin rotation is a procedure that is effective in repositioning and everting a lid margin without requiring external incisions or grafting. This procedure may be used to evert the upper or lower eyelids for treatment of trichiasis and involutional and cicatricial entropion. Congenital and acute spastic entropion may spontaneously resolve with medical management and without surgical repair.

Recently, lateral tarsotomy has been used to increase lateral access to the orbit without the need for lateral canthotomy, which can have the major disadvantage of difficulty in resuspension of the lateral canthal tendon, leading to unaesthetic outcomes (Emam et al. 2016).

Contraindication

Contraindications to the tarsotomy procedure are mostly related to general medical condition and preoperative risk to the patient. The procedure may be contraindicated in patients with uncontrolled medical comorbidities, high systemic anticoagulation, or conditions that interfere with appropriate positioning or safe management of the patient during the procedure.

Techniques and Principles

A standard tarsotomy procedure for a lower lid entropion is performed as follows:

1. After skin preparation, infiltrate the entropic lid with local anesthetic consisting of a 50:50 mixture of 2% lidocaine w/epinephrine 1:100,000, 0.75% bupivacaine, and 150 U hyaluronidase.
2. Drape patient in a sterile fashion and place a protective contact lens in the eye being operated on.
3. Retract the lower lid with a 4-0 silk traction suture and make an incision across the inferior tarsal border.
4. Bluntly dissect in the suborbicularis plane down to the inferior orbital rim.
5. If scar tissue is present, e.g., in the case of a cicatricial entropion, dissect the scar tissue off the retractors and elevate the edge of the retractors.
6. Beginning laterally, pass both arms of a 6-0 Vicryl suture anteriorly to posteriorly first through the edge of the retractors and then through the superior edge of the conjunctiva. Then, reverse the needles, enter the inferior tarsal border, and exit through the skin just below the lashes.
7. Place identical sutures centrally and medially across the lid and tie each of the sutures, which rotate the lid margin outward.
8. If horizontal lid laxity is present, a tarsal strip procedure (see "▶ Tarsal Strip Procedure" chapter) may be incorporated during the tarsotomy procedure.

*Tarsotomy for an upper lid entropion would be performed using the steps outlined above but in the anatomical mirror image.

A modified tarsotomy technique may be used to treat *severe* cicatricial entropion. A simple modification involving "two backcuts" at both ends of the transverse tarsotomy allows the distal tarsal fragment to move more freely, which may increase the success rate in cases of severe cicatricial entropion (Chi et al. 2016).

In cases where trichiasis is limited to a small segment of the lid, tarsotomy with lid margin rotation restricted to the affected lid area may be indicated.

Outcome

Transverse tarsotomy produces excellent cosmetic and functional results when used to treat patients with entropions and severe trichiasis.

The tarsotomy procedure has a reported 94% success rate for mild to moderate nontrachomatous cicatricial entropion with trichiasis and a 55% success rate for severe cicatricial entropion with trichiasis (Kersten et al. 1992). The modified tarsotomy outlined above may have a higher success rate in the treatment of severe cicatricial entropion (Chi et al. 2016). A randomized clinical trial comparing bilamellar tarsal rotation (BTR) versus transverse tarsotomy with lid margin rotation (TTR) found that TTR and BTR were successful in 95% and 86% of eyelids with minor trachomatous trichiasis, respectively, and in 84% and 86% of eyelids with major trachomatous trichiasis, respectively. Overall, the TTR group had fewer complications than BTR at 3 months of follow-up (Adamu and Alemayehu 2002). Another study reported an 89% success rate at 6 months for the correction of trichiasis and cicatricial entropion secondary to trachoma (Ali et al. 2012).

Complications

Complications of the tarsotomy procedure include failure of entropion correction or recurrence, and typical surgical risks such as infection, bleeding, and wound dehiscence. Attention to appropriate surgical technique and careful burying of deep sutures aid in the reduction of suture granuloma formation and minimizes complications.

Tay-Sachs Disease (GM2 Gangliosidosis Type I)

Aazim A. Siddiqui[1] and Allen O. Eghrari[2,3]
[1]Imperial College London School of Medicine, South Kensington Campus, London, UK
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[3]Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Amaurotic familial idiocy; GM2 gangliosidoses; β-Hexosaminidase A deficiency

Definition

Tay-Sachs disease (TSD) is a rare inherited neurodegenerative disorder. It is the most common of

the three variants of a heterogenous group of lysosomal lipid storage disorders known as GM2 gangliosidoses. Each variant refers to a different underlying defect of the enzyme complex required for the GM2 ganglioside catabolism. TSD is characterized by an excessive accumulation of the GM2 ganglioside substrate within neuronal lysosomes and leads to eventual cell death. The main features of the disease are neurological and ocular deterioration. It is classified based on the age of onset:

1. Infantile acute TSD (Type I GM2 gangliosidosis)
2. Juvenile subacute TSD (Type III GM2 gangliosidosis)
3. Late infantile subacute-to-chronic TSD (B1 variant of GM2 gangliosidosis)
4. Adult chronic-type TSD (GM2 gangliosidosis)

Etiology

GM2 ganglioside accumulation in TSD occurs due to specific absence or defect of the alpha subunits of β-hexosaminidase A (Hex A). An autosomal recessive mutation in *Hex A* (15q23-q24), which codes for the Hex A enzyme necessary for GM2 ganglioside degradation, is responsible for disease. This process leads to systemic GM2 ganglioside accumulation primarily in the neurons of the central nervous system and retina leading to neurodegeneration and blindness, respectively (Goldman and Schafer 2012).

Clinical Presentation

The "classic" infantile acute TSD generally manifests by the age of 6 months, but precursor symptoms such as hyperacusis may be present from birth. By the age of 3–6 months, neurological symptoms and signs begin to emerge with the development of hypotonia and evidence of delayed child development. By the age of 1 year, affected patients may be unable to sit, stand, and vocalize, and may develop spasticity and convulsions. They may also develop ataxia, muscle wasting with motor degeneration, and deafness. GM2 ganglioside accumulation of 200 times the normal levels in the brain results in macrocephaly. Death occurs by the age of 3–4 years, usually due to pneumonia.

The most common ocular findings in infantile acute TSD are a macular cherry-red spot and optic atrophy. Histologically, corneal endothelium may be filled with vacuoles; however, corneal clouding has not been reported. It is more likely to occur in closely related Sandhoff disease of similar pathophysiology and aggregation of GM2 ganglioside. Supranuclear neurological involvement of TSD can also manifest as nystagmus and dysconjugate eye movements. The onset of blindness usually occurs later in the first year of life.

The macular cherry-red spot is characteristic hallmark for TSD, which simultaneously presents at 6 months of age with neurological signs and symptoms. This is a result of gangliosidic accumulation within intracytoplasmic membranous bodies of perifoveal retinal ganglion cells. This leads to a deterioration of the inner retinal transparency and causes production of a creamy halo outlying the ganglion cell-free portion of the macula. By the age of 1 year, the cherry-red spot diminishes as a result of retinal ganglion cell death and gliosis along with optic atrophy. Eventual blindness occurs by the age of 18 months as a consequence of optic atrophy and cortical disease.

In contrast to the infantile acute TSD, juvenile- and adult-onset TSD follow a prolonged course with no ethnic predilection. Patients may develop dysarthria and gait disturbances. Other clinical features may include cerebellar atrophy with ataxia, peripheral neuropathy, tonic-clonic or myoclonic seizures in some children, and psychiatric disturbances. It is important to note that vision remains intact with no optic disk atrophy.

Diagnosis

A definitive diagnosis of TSD mainly relies on assaying Hex A enzyme in serum, leukocytes, or cultured skin fibroblasts. A finding of decreased total Hex A is diagnostic for TSD.

An ophthalmic evaluation showing evidence of macular cherry-red spot can also help diagnose

TSD. Diagnosis of infantile acute TSD is usually suspected in an infant with neurological features and a macular cherry-red spot.

Differential Diagnosis

The clinical presentation of TSD is similar to the other two variants of GM2 gangliosidoses: Sandhoff disease and hexosaminidase activator deficiency. These disorders may be clinically indistinguishable in some cases. GM1 gangliosidoses also present with similar signs and symptoms such as hyperacusis at birth. Other metabolic storage diseases should be considered where macular cherry-red spot is a feature such as Niemann-Pick disease.

Prophylaxis

Carrier screening of all couples with at least one member of Ashkenazi Jewish descent is recommended before pregnancy to identify couples at risk. The test targets couples of Ashkenazi Jewish, French Canadian, and Cajun descent due to increased prevalence of TSD carriers in these population subsets. The level of Hex A activity in peripheral leukocytes or plasma is used to establish carrier state in couples. DNA analysis for selected alleles may also be performed.

Additional molecular studies should be conducted in identified carriers to elucidate exact molecular defect. This facilitates more specific identification of carriers within the family and prenatal diagnosis in high-risk couples via enzymatic and genotypic studies.

Prenatal amniocentesis or chorionic villus sampling test for Hexosaminidase A in first trimester of pregnancy serves as an accurate and reliable screening test in carrier-state couples.

Therapy

No treatment currently exists for TSD. Current therapeutic techniques are symptomatic and aimed at managing associated conditions. A multidisciplinary approach involving medical geneticists, neurologists, psychiatrists, and ophthalmologists is essential (Kliegman et al. 2011; Goldman and Schafer 2012; Copeland and Afshari 2013).

Prognosis

Infantile acute TSD is often fatal by the age of 3–4 years. Juvenile TSD is fatal by the age of 10–15 years. Most patients with adult chronic-type TSD have a slightly decreased life expectancy of 50–60 years (Miller et al. 2005; Swaiman et al. 2012).

Epidemiology

The prevalence of TSD is highest among patients with Jewish descent, especially those of Eastern European Ashkenazic origin, who have a carrier frequency of 1 in 25. Populations of French Canadian and Cajun descent are also considered to be high risk.

In the general population, the incidence of TSD has been approximated to be 1 in 112,000 live births. The prevalence of TSD was 1 in 3900 live births among Ashkenazi Jews, but prenatal screening tests for TSD have shown marked reduction in this figure (Miller et al. 2005; Swaiman et al. 2012).

TBUT

▶ Tear Breakup Time

Tear Breakup Time

Jessica Selter
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Breakup time (BUT); Fluorescein breakup time (FBUT); TBUT

Definition

The tear breakup time is a diagnostic procedure that examines the time that it takes for dry spots to appear on the corneal surface after blinking (Savini et al. 2008).

Purpose

The purpose of the TBUT is to evaluate the stability of the tear film and to detect the presence of evaporative dry eye. A TBUT greater than 10 s is considered normal. A value of less than 5 s indicates significant dry eye disease (Asbell and Lemp 2006).

Principle

The TBUT is performed as follows (Kastelan et al. 2013):

- Fluorescein dye (1–5 μl of 2% sodium fluorescein) is added to the lower fornix of the eye using a pipette or strip.
- The patient is asked to blink a few times in order to distribute the fluorescein and then is instructed to abstain from blinking.
- The tear film is then observed under a slit lamp using a broad beam with a cobalt blue filter.
- The presence of black spots will indicate dry spots on the tear film.
- The tear breakup time is the time it takes after the patient starts to abstain from blinking until the dry spots appear on the corneal surface.
- The patient is then asked to blink freely until repeating the test. The mean of three trials is recorded.

Indication

The TBUT is used to diagnose tear film instability and is part of the diagnostic workup for dry eye disease.

Contraindication

No noted contraindications to perform the TBUT.

Advantage/Disadvantage

Advantages (Savini et al. 2008):

- Widely used
- Commercially available
- Easy to perform
- Less expensive than noninvasive techniques

Disadvantages (Savini et al. 2008):

- Lack of standardized procedure for applying the fluorescein:
  (a) Adding the fluorescein has to be done carefully, in order to avoid reflex tearing. Reflex tearing could artificially lengthen the tear breakup time.

(b) Uncontrolled volumes of fluorescein given could also artificially lengthen the tear breakup time.
- Invasive because it involves using fluorescein in the eye.
- Findings of TBUT often do not correspond to symptom severity.

Tear Film (Tears)

Eileen Wang[1] and Tara Uhler[2]
[1]Department of Ophthalmology, Thomas Jefferson University Hospital/Wills Eye Hospital, New York, NY, USA
[2]Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Definition

A dynamic and complex precorneal gel that protects and supports the ocular surface.

Structure

Traditionally the tear film was described as having three distinct layers – an inner mucin layer, an aqueous layer, and an outer lipid layer. This concept has evolved over the years; the current model of the tear film consists of a mixed inner aqueous-mucins gel with an outermost lipid layer (Pflugfelder et al. 2000; Rolando and Zierhut 2001; Lemp 2008; Peters and Colby 2013).

The aqueous component of the aqueous-mucins gel is mainly produced by the main and accessory lacrimal glands (Rolando and Zierhut 2001).

The mucin portion of the aqueous-mucin gel is comprised of both transmembrane and secretory mucins. Mucins are glycoproteins which have a negative charge; as such they are also highly hydrophilic and able to mix well with the aqueous portion of the tear film. They are more densely distributed closer to the ocular surface. Transmembrane mucins are produced by the corneal and conjunctival epithelial cells and anchored to the ocular surface epithelial cells. These mucins also interact with the overlying secretory mucins in the tear film. Secretory mucins are further subdivided into gel-forming (produced by the conjunctival goblet cells) and soluble (produced by the lacrimal gland) mucins (Lemp 2008; Peters and Colby 2013).

The remaining composition of the aqueous-mucin gel has not been completely determined, but it contains a complex mixture of electrolytes, immunoglobulins, enzymes, antimicrobial proteins, hormones, vitamins, cytokines, and growth factors (Pflugfelder et al. 2000; Rolando and Zierhut 2001; Peters and Colby 2013). The outermost lipid layer is secreted by the Meibomian glands. The portion adjacent to the aqueous-mucin gel consists of hydrophilic polar lipids, while the lipids overlying this base layer are hydrophobic nonpolar lipids. The two layers of lipids contain hydrophobic bonds between them (Pflugfelder et al. 2000; Peters and Colby 2013).

Function

The tear film is critical to the integrity of the ocular surface by performing many roles including:

Allowing nutrients and oxygen to reach the corneal and conjunctival epithelia
Protecting the cornea from mechanical damage from lid forces Lubricating the ocular surface
Preventing adhesion of material (cells, pathogens, debris) to the ocular surface
Defending against infection
Serving as the first encountered refractive surface of the eye (Rolando and Zierhut 2001; Peters and Colby 2013).

Clinical Relevance

Abnormalities in the tear film can increase the risk of infection, cause dry eye and its sequelae, and reduce vision.

Tearing (Epiphora)

Maria J. Suarez
Ocular Pathology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Epiphora

Definition

It is characterized by an abnormal chronic overflow of tears onto the cheeks, generally due to lacrimal drainage impairment or excessive lacrimal production.

Etiology

Tearing is part of the normal eye function; it provides not only a lubricated layer to protect the ocular surface but also is a natural barrier enriched with immunoglobulins and lysosomes to prevent any potential infection (Krachmer et al. 2011).

Many different conditions have been associated to cause epiphora and have been classified into chronic overproduction of tears, outflow obstruction, and failure of the tear pump (Krachmer et al. 2011).

Occurrence

Abnormal tear outflow is often unilateral. Overall, patients complain of ocular discomfort and blurry vision. A wide variety of medical conditions affecting the ocular surface, iatrogenic surgical manipulation of the lacrimal system, and the use of some

medications present with epiphora (Millodot 2009; Krachmer et al. 2011; 2013–2014 Basic and Clinical).

Classification

In general, tear dysfunction can cause chronic ocular irritation, hence epiphora. Disorders in the ocular surface causing irritation present with abnormal tearing including blepharitis; allergic, atopic, and vernal conjunctivitis; superior limbal keratoconjunctivitis; inflamed pterygium; conjunctival neoplasm; and corneal foreign bodies, among others (Krachmer et al. 2011). Furthermore, chronic eye exposure such as malposition of the globe in the case of proptosis secondary to thyroid eye disease, intraorbital neoplasia, or nonspecific chronic inflammation and eyelash and eyelid contour abnormalities or malposition such as epiblepharon, lower lid entropion or ectropion, and trichiasis have also been described as causes of ocular exposure leading to epiphora (Krachmer et al. 2011).

Abnormal tear outflow due to lacrimal system obstruction can also present with epiphora. Punctal stenosis, which is often associated with punctual entropion, can be in some cases severe and results in epiphora (Millodot 2009). Other disorders involving the puncta size like occlusion, stenosis, or secondary enlargement most of the times, after surgical procedures, can also lead to abnormal tearing (Millodot 2009). Several ocular conditions have been associated with punctal stenosis, congenital absence, or any particular defect or dysgenesis of any portion of the lacrimal outflow system. Conjunctivochalasis, enlarged caruncle, chronic ocular surface cicatrizing disease (Stevens-Johnson syndrome or pemphigoid), chronic exposure, and external beam radiation can also lead to punctal stenosis or complete punctum closure leading to epiphora (Millodot 2009; Krachmer et al. 2011).

Obstruction at the canaliculus secondary to trauma, tumor excision, idiopathic scarring, topical ocular medications, and use of chemotherapeutic agents that can lead to secondary sclerosing canaliculitis, such as docetaxel, used as therapy in patients with metastatic breast cancer, can cause canalicular stenosis and secondary obstruction of the tear outflow (Krachmer et al. 2011; 2013–2014 Basic and Clinical).

Lacrimal sac obstruction secondary to neoplasia and other inflammatory conditions including Wegener's granulomatosis and sarcoidosis can also present with chronic abnormal tearing.

Finally, when the lacrimal pump is abnormal or presents some sort of failure like in paralytic ectropion where the stretched or paretic orbicularis muscle fibers on the lower eyelid, particularly, Horner's muscle, are unable to generate enough pressure in order to pump the tears out through the nasolacrimal duct and subsequently, epiphora.

Tearing, Reflex, Absorption of Ocular Medication

Behin Barahimi and Tara Uhler
Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Definition

Reflex tearing is the stimulated production of tears beyond the normal basal secretion; it may be stimulated by ocular discomfort including irritation from topically applied ocular medication.

Structure

The main lacrimal gland receives both neural and humoral stimulation. It is innervated by parasympathetic, sympathetic, and sensory nerves. Secretion from the lacrimal gland occurs during reflex tearing in response to ocular surface irritation, psychogenic tearing, or aberrant regeneration.

Stimulation of sensory nerves in the cornea or conjunctiva initiates the afferent limb of the tear reflex arc, and the efferent parasympathetic and sympathetic fibers stimulate lacrimal gland secretion.

Tears drain into the nasolacrimal system, and lacrimal outflow is facilitated by the blink mechanism.

The normal human tear volume is approximately 11 μl and the inferior conjunctival cul-de-sac can hold up to approximately 30 μl. Tear volume may expand physiologically during reflex tearing described above or with administration of eye drops. Excess volume spills over the lid margins onto the cheek and the rest exits via the puncti into the nasolacrimal system.

Function

Reflex tearing protects the ocular surface.

Clinical Relevance

The majority of eye medications are administered topically in the form of eye drops. The goal of this mode of drug delivery is to maximize concentrations in the ocular tissue and to minimize systemic absorption which could lead to toxicity.

Reflex tearing adversely affects drug absorption. The inferior cul-de-sac that holds the drug reservoir has a limited volume. Reflex tearing drives overflow onto the skin or into the nasolacrimal system. This decreases the amount of drug delivered and the contact time of the drug with the cornea. Improper instillation of drops as well as the composition of the medication or preservatives may cause ocular irritation resulting in reflex tearing.

The preferred method of drop instillation is to gently pull the lower lid away from the globe creating a cul-de-sac. A single drop should be placed in the cul-de-sac, and the tip of the bottle should not touch the cornea or eyelashes (Fig. 1).

Blinking also decreases the bioavailability of medication. Each blink promotes drainage of the tear lake into the nasolacrimal system. Absorption of the drug through the highly vascularized nasal mucosa can result in systemic toxicity.

Not blinking but keeping the eyes closed after drop instillation increases bioavailability and decreases systemic absorption. Further benefit is obtained with digital compression over the medial canthus (Fig. 2). Punctal occlusion can reduce by 65% the amount of drug entering the nasolacrimal system.

It is important to educate patients about proper drop instillation and punctual occlusion to limit ocular irritation and reflex tearing and to ensure maximal ocular absorption.

Other methods to improve bioavailability include increasing the frequency of drop instillation and adjusting the lipid solubility, osmolarity, and pH of medications. Use of ointments, sustained-release gels, collagen corneal shields,

Tearing, Reflex, Absorption of Ocular Medication, Fig. 1 Eye drop administration: The head should be tilted back while gently pulling the lower lid away from the globe. The patient should look up to prevent the drop from falling on the cornea, which would stimulate tearing. One drop should be placed in the cul-de-sac taking care that the bottle does not touch the eyelashes or eyelids

Tearing, Reflex, Absorption of Ocular Medication, Fig. 2 Punctal occlusion: Using the thumb and forefinger, the patient applies pressure to the medial canthal region with the lids closed for 2 min

and prodrugs may increase bioavailability. In addition, for some medications and diseases, alternate routes of local administration include intraocular or periocular injections.

Tectonic Graft

▶ Tectonic Penetrating Keratoplasty, for Herpetic Keratitis

Tectonic Penetrating Keratoplasty, for Herpetic Keratitis

Alireza Eslampoor
Eye Research Center, Khatam-al-anbia Eye Hospital, Mashhad, Razavi Khorasan, Iran

Synonyms

Reconstructive corneal graft; Tectonic graft

Definition

A type of corneal graft intended to restore the integrity of the globe, or normal corneal thickness, such as in diseases-causing corneal thinning and perforation. Untreated or unresponsive HSV keratitis especially in the form of "necrotizing stromal keratitis" may result in stromal melting with subsequent corneal thinning and perforation. Another scenario for corneal perforation secondary to herpetic keratitis is a patient with persistent epithelial defect due to neurotrophic postherpetic keratitis. This latter group of patients has little or no active stromal inflammation. Perforated corneal ulcer needs immediate intervention to protect the ocular integrity and prevent subsequent complications such as endophthalmitis or secondary glaucoma. Small corneal perforation can be managed conservatively with a therapeutic soft contact lenses or adhesive glue. If the perforation is too large for gluing or fails to be sealed satisfactorily after gluing, it may be necessary to repair the perforation site with a full thickness or lamellar tectonic graft. This procedure is defined as tectonic patch graft.

Indication

1. Perforated herpetic corneal ulcer
2. Herpetic corneal ulcer with severe stromal necrosis and corneal thinning impending to perforation
3. Descemetocele formation secondary to necrotizing herpetic keratitis impending to perforation
4. Corneal perforation secondary to persistent epithelial defect with little or no active stromal inflammation (Copeland and Afshari 2013)

Contraindication

Active inflammation and infection before grafting are relative contraindications. All attempts should be made for subsiding any inflammation and infection before surgery, although this may not be possible if the need for grafting is urgent (Copeland and Afshari 2013).

Small corneal perforations especially peripheral ones that could be managed with glue, conjunctival flap or a lamellar patch graft for restoring globe integrity, and then later perform a PKP (Copeland and Afshari 2013).

The surgery should be postponed in children if there are alternative options for restoring globe integrity and also if there is not any risk of amblyopia, in order to avoid complications of pediatric keratoplasty.

Techniques and Principles Outcome

Patients with acute corneal perforations that need tectonic keratoplasty should be admitted to the hospital and not receive any food or drink by mouth until the surgery would be performed.

In suspected situations, gentle B-scan ultrasonography could be performed in order to detect the presence of hemorrhagic choroidal detachments. If present, surgery should be postponed because of the increased risk for expulsive hemorrhage. Also, prompt consultation with a vitreoretinal surgeon should be done.

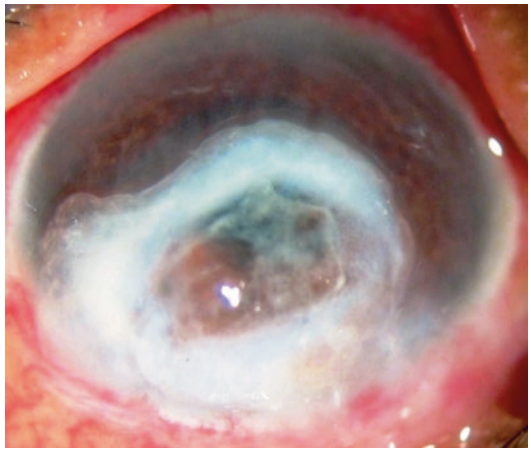
General anesthesia is usually preferred, with the anesthesiologist well aware that the globe is open. An eyelid speculum is then inserted, making sure that there is no external pressure on the globe.

The size of recipient trephination is generally determined by the size and location of the existing corneal perforation. The minimum size of trephine capable of incorporating the entire perforation site and all of infected or ulcerated border is generally chosen. This size could vary between 6.0 and 11.0 mm, with 7.5–8.0 mm being optimal. The donor size is generally considered 0.50 mm more than the recipient trephination size. Viscoelastic could be used for reforming the anterior chamber before trephination and also in maintaining tissue planes.

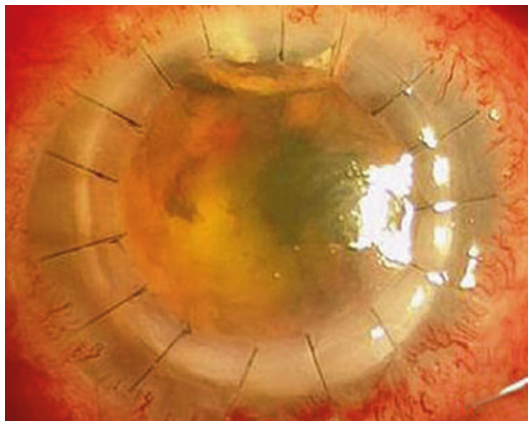
In general, trephination is much more difficult in a perforated eye. The standard handheld trephine without a guard may be preferred. The surgeon should take great care to avoid any external pressure causing protrusion of ocular contents through the perforation site. Alternative option is marking the superficial cornea with the trephine and deepens the mark freehand with a blade. The cornea is entered through the deepened trephination mark.

Another method involves the use of a suction trephine system such as the Hessburg-Barron trephine. In this way, pressure should be exerted outward, avoiding direct pressure on the open globe. Once the trephine is secured on the cornea by suction, trephination is performed by simply rotating the blade of the trephine. Some surgeons have advocated the use of tissue adhesive with or without scleral or corneal patches minutes before trephination to restore the anterior chamber. In this manner, regular trephination could be accomplished in a safer, more effective way (Figs. 1 and 2).

Curved corneal scissors could be used to excise the recipient cornea, with extreme care to avoid cutting the iris or lens. Also, this step is more difficult than usual because corneal opacification and ulcer may hinder the surgeon's view. Once the recipient button is removed, the anterior chamber should be evaluated to detect any peripheral anterior synechiae, posterior synechiae, and cataract. In general, cataract extraction should be postponed because there is an increased risk of



Tectonic Penetrating Keratoplasty, for Herpetic Keratitis, Fig. 1 Perforated corneal ulcer



Tectonic Penetrating Keratoplasty, for Herpetic Keratitis, Fig. 2 Tectonic penetrating keratoplasty

expulsive hemorrhage, vitreous loss, endophthalmitis, and sequestered organisms at the time of the initial procedure. Peripheral anterior synechia and posterior synechiae should be gently lysed, and one or multiple peripheral iridectomies should be performed. Then BSS is used for irrigating the anterior chamber to remove any necrotic or inflammatory debris. A small amount of viscoelastic should be placed in the angle and over the iris and pupil. The donor cornea is then placed over the recipient and secured with at least 16 interrupted 10-0 nylon sutures. Interrupted sutures are preferred due to the tendency of the corneal wound to heal asymmetrically in vascularized or scarred corneas and also the risk of premature suture loosening. The anterior chamber should be reformed with balanced salt solution. The peripheral iris should be swept with the tip of the cannula or cyclodialysis spatula to avoid peripheral anterior synechia formation. Subconjunctival injections of antibiotic and or steroid can be given in the inferior fornix (Krachmer et al. 2011).

Because there is an increased risk of poor epithelial healing after herpetic keratitis, a temporary tarsorrhaphy and/or punctal occlusion are often indicated.

In general, the aim of tectonic keratoplasty is to restore the integrity of globe. Surgery tends to be more successful if the corneal inflammation and infection has been subsided before surgery. Eyes with corneal perforation secondary to persistent neurotrophic herpetic keratitis have better outcomes compared with those of stromal necrotizing keratitis. If the eye still has good visual potential, long-term visual rehabilitation can be attempted later, using anterior segment reconstruction and corneal re-grafting.

Complications

Persistent epithelial defect
Recurrence of herpetic keratitis
Allograft rejection
Secondary graft failure
Glaucoma
Secondary infections
Wound dehiscence (Copeland and Afshari 2013)

Telecanthus

Matthew Nguyen[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

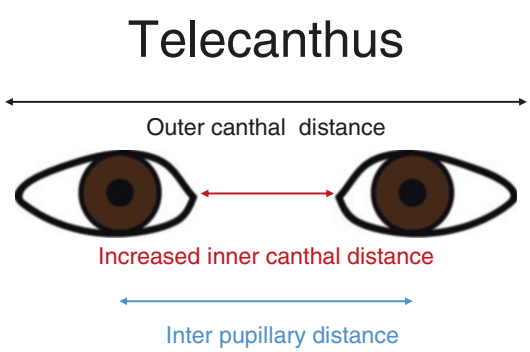
Pseudo-hypertelorism

Definition

Telecanthus derives from tele, which means far, and canthus, which means the corner of the eye. The term was introduced by JC Mustardé in 1963. It describes an increased distance between the medial canthi of the eyes. In primary telecanthus, the interpupillary distance is normal. When the interpupillary distance is greater than normal, it is called secondary telecanthus, which is synonymous with telorbitism. It is important to differentiate telecanthus from telorbitism or orbital hypertelorism, which mean an increased distance between the medial orbital walls.

Structure

Telecanthus is due to displacement of the medial canthi laterally which results in the covering of the medial aspect of the eyes. Unlike hypertelorism, the medial orbital walls are not abnormally separated.



Telecanthus, Fig. 1

Clinical Relevance

Telecanthus may be found in isolation or as part of a syndrome. It makes up part of the syndrome of blepharophimosis as well as many others, including Down syndrome and Ehlers-Danlos syndrome. It can also be due to medial encephaloceles and trauma. It can be treated surgically with medial canthopexy as well as correction of any underlying medial orbital abnormality. In medial canthopexy, generally wires are used transnasally to bring the medial canthal tendons closer together to correct the telecanthus (Fig. 1).

Orbital hypertelorism

Definition

Telorbitism, or orbital hypertelorism, is the term used to describe an increased distance between the medial orbital walls. The concept was first described by David Grieg in a lecture in 1924.

He described an increased interpupillary distance with the term ocular hypertelorism. However, since exophoria can cause an increased interpupillary distance without orbital involvement, the term has been refined to orbital hypertelorism. Orbital hypertelorism refers to an increased medial orbital wall distance. There is no consensus on how to measure telorbitism, and various measurements have been made using interpupillary distance and medial orbital wall distance. The dacryon, which is where the lacrimal, maxillary, and frontal bone meet at the most medial part of the orbit, has also been used to measure this orbital distance. The diagnosis of telorbitism is definitively made radiographically.

Structure

Telorbitism is derived from defects in the face and skull that cause deformation of the orbits laterally. The nasal, frontal, sphenoid, and ethmoid bones may all be involved in this process.

Clinical Relevance

Any condition that causes deformation of the facial bones of the orbit and involves the ethmoid can cause telorbitism. It is found in hundreds of disorders, including in Crouzon, Apert, and Down syndrome. Telorbitism is treated surgically. Several methods of surgical treatment are used and include orbital box osteotomy and facial bipartition surgery. In an orbital box osteotomy excess intervening ethmoid and nasal material are removed. The anterior roof, walls, and floor of the orbit are separated and then are brought together using hardware. Facial bipartition surgery involves resection medially of excess material and also dividing the palate, allowing medial rotation of each superior half of the face which are then connected with hardware (Fig. 1).

Temporal Arteritis

► Arteritic Ischemic Optic Neuropathy

Temporal Artery, Eye Supplied by

B. Ranjodh Singh[1], Kristen E. Dunbar[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

The temporal artery, specifically the frontal or anterior branch of the superficial temporal artery, anastomoses with several other arteries to supply the eyelid and plays an important role in suitable flap design for orbital surgery.

Structure

The superficial temporal artery arises from the external carotid artery behind the neck of the mandible and passes superficially over the zygomatic process of the temporal bone. The pulse of the superficial temporal artery can be palpated superiorly to the zygomatic arch, just anterior and superior to the tragus of the ear. The mean diameter of the superficial temporal artery at the zygomatic arch is 2.73 ± 0.51 mm (Pinar and Govsa 2006). Approximately 36.9 ± 14.24 mm superior and 17.2 ± 8.2 mm anterior to the posterior-most point of the tragus (Lee et al. 2015), the superficial temporal artery divides into the frontal branch (means size 2.14 ± 0.54 mm), coursing toward the forehead, and the parietal branch (mean size 1.81 ± 0.45 mm), coursing toward the side of the head.

The zygomatico-orbital artery, which can also arise directly from the superficial temporal artery, usually runs parallel to the zygomatic arch to supply the orbicularis oculi. The zygomatico-orbital artery also anastomoses with the transverse facial artery and the frontal branch along its course.

Function

The frontal branch of the superficial temporal artery anastomoses with the supraorbital, superior palpebral, and lacrimal arteries to supply the eyelid. The zygomatico-orbital artery supplies the orbicularis oculi, which is responsible for closing the eye.

Clinical Relevance

The superficial temporal artery is a common site for giant-cell arteritis and therefore is the primary site of biopsy when giant cell arteritis is suspected.

Areas supplied by the superficial temporal artery and its branches may serve as suitable flaps for facial reconstruction. For example, superficial temporal artery island flap combined with auricular cartilage graft may be useful in reconstructions of full-thickness lower eyelid defects. The frontal branch of the superficial temporal artery might be particularly useful in creating local or distant flaps for reconstruction of the forehead or scalp. The zygomatico-orbital artery may serve as a suitable the axial artery of the frontotemporal flap and may also serve as recipient vessel in head and neck reconstruction. However, the zygomatico-orbital artery is absent in 8–9% of patients, which may limit its clinically usefulness.

The frontal branch of the superficial temporal artery may also serve as a landmark for locating the course of the temporal branch of the facial nerve during a facelift. Damage to the temporal branch of the facial nerve causes paralysis of the frontalis, orbicularis oculi, and corrugator muscles, and appropriate identification of this nerve is therefore particularly important. Clinicians

performing botulinum toxin and dermal filler injections should be careful to avoid the frontal branch of the temporal superficial artery to prevent iatrogenic trauma and blood flow obstruction to its supplied tissues.

Synonyms

Local advancement flap; Semicircular advancement flap; Semicircular flap; Semicircular temporal advancement flap; Tenzel advancement flap

Definition

A tenzel flap is a semicircular local advancement flap, which is often utilized in the reconstruction of full thickness eyelid defects. It allows recruitment of tissues lateral to the lateral canthus to allow medial mobilization of the eyelid and direct wound closure.

Indication

A Tenzel advancement flap is indicated in the reconstruction of moderate upper or lower full

thickness eyelid defects involving approximately 1/3 to 1/2 of the eyelid. The tenzel advancement flap is most commonly employed in eyelid reconstruction following resection of a neoplasm at the eyelid margin or in cases of trauma with full thickness tissue loss.

Contraindications

The defect size and laxity of the individual patient's tissues dictate which reconstructive options are available to the surgeon. Large full thickness eyelid defects, usually greater than 50 % of the eyelid, require reconstructive techniques other than a Tenzel flap to allow recruitment of adequate tissue for reconstruction.

Techniques and Principles

The eyelid defect is assessed and the appropriate reconstructive technique determined. Full thickness eyelid defects encompassing approximately 1/3 to 1/2 of the eyelid, and having intact eyelid structures at the lateral canthus which can be advanced medially, are generally good candidates for reconstruction with a Tenzel flap. A semicircular flap of appropriate size is marked beginning at the lateral canthus. The flap typically extends approximately 1/2 to 2/3 the distance from the lateral canthus to the hairline depending on the extent of advancement required. The flap is created with a superior semicircular incision and rotated inferiorly for lower eyelid defects, or conversely, created with an inferior semicircular incision and rotated superiorly for upper eyelid defects. Lateral canthotomy in combination with cantholysis are performed to free the lateral eyelid and allow mobilization nasally. The wound margins are apposed by direct closure in a standard fashion for full thickness eyelid repair ensuring that excess tension on the wound has been relieved via mobilization of the lateral eyelid segment. Suturing the flap to the orbital rim periosteum can help to form the lateral eyelid contour. The lateral canthus is fixated and the conjunctiva is undermined and advanced to the flap edge if necessary.

Outcome

A semicircuclar incision extending temporally from the lateral canthus with reconstruction of the full thickness eyelid defect is the final result. The lateral most aspect of the reconstructed eyelid will be devoid of eyelashes secondary to the medial advancement of the eyelid tissues formerly residing at the lateral canthal region.

Complications

Excess tension on the newly reconstructed full thickness eyelid defect can result in wound dehiscence. Phimosis and rounding of the lateral canthus can occur with healing particularly if excess wound tension is present. Damage to the zygomatic branch of the facial nerve with resultant orbicularis occuli weakness secondary to deep dissection in the lateral canthal region is possible.

Gary Joseph Lelli
Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Teratoid cyst; Teratoid tumor

Definition

Orbital teratoma is a rare, congenital choristoma consisting of all three germinal layers in various stages of maturity.

Basic Characteristics

Epidemiology

Orbital teratoma is an uncommon disorder; a report from 1980 cited 51 cases previously documented in the literature. Almost all cases are unilateral; there is a 2:1 female to male preference.

Clinical Presentation

This rare, congenital orbital tumor typically presents with progressive unilateral proptosis in the neonatal period. Massive growth can lead to degenerative changes and distortion of the eye and surrounding bony structures. The walls of the orbit enlarge to accommodate the large mass, and nearby facial structures can exhibit gross deformity. Bony destruction is uncommon. While the eye itself is often structurally normal, proptosis and exposure can lead to keratopathy, erosion, chemosis, and optic atrophy. The enlarging mass can cause stretching and or swelling of the eyelids, and when palpable, the tumor is variably described as fluctuant, cystic, or solid. Glandular epithelial structures with the tumor cysts are responsible for dramatic and rapid growth.

No exposure or environmental risk factor has been identified as causative. Patients typically have normal prenatal and birth history and are otherwise healthy.

Tumors may arise in the orbit and extend secondarily into the cranial cavity or sinuses or present as secondary extension from a large intracranial primary mass.

Etiology

Orbital teratomas are derived from germinal cells. Surface ectoderm is the most prominent germ layer present and gives rise to tumor cystic components, hair follicles, and sweat glands.

Histopathology varies greatly depending on tissue type present in the lesion. Cysts lined by stratified squamous and respiratory epithelium have been reported. Hair follicles, glands, cartilage, teeth, muscle fibers, intestinal material, neural structures, and other tissue types are found within lesions.

Diagnostics

CT and MRI can be used to further evaluate the enlarging orbital mass, though caution should be exercised when using CT scans in young children due to radiation effect. On both CT and MRI, orbital teratomas appear heterogeneous due to the varied tissue components. On CT, the multiloculated mass may contain cysts with fat-fluid levels, solid-enhancing components, and focal calcification secondary to bony elements. While bony orbital enlargement is more common than bone destruction, the mass can extend into adjacent sinuses or intracranial space. Erosion of the sphenoid wing has been reported. On T1-weighted MRI images, fat components and areas of inflammation appear hyperintense to vitreous, whereas on T2-weighted images, fat within cyst walls is hypointense when compared to vitreous and lower water-keratin fluid levels. Solid areas and the rim of the lesion enhance with gadolinium.

Lesions can be biopsied for histopathologic diagnosis prior to resection.

Differential Diagnosis

Suspected in the differential diagnosis should be alternative causes for enlarging orbital mass present at birth. These include rhabdomyosarcoma, retinoblastoma, hemangioma, lymphangioma, plexiform neurofibroma, neuroblastoma, neurofibroma, meningocele, congenital cystic eye, microphthalmos with cyst, congenital glaucoma, and cephalocele.

Therapy

In typical benign lesions, goals of therapy should be to preserve visual function, allow normal orbital-facial development, and optimize aesthetic result. With concern for malignant transformation, the primary concern becomes total tumor resection tumor. When exenteration is warranted, lid-sparing techniques are preferred. If visual function is demonstrated, and the tumor is benign, a conservative approach is pursued. Reports have shown excellent functional and cosmetic results with eye preservation surgery in patients with smaller lesions. Aspiration of the cyst contents may precede complete tumor excision to reduce tumor bulk. Additional craniofacial reconstructive surgery may be necessary following tumor excision.

Prognosis

Orbital teratomas are thought to be benign lesions. Morbidity and mortality increase with tumor invasion of other sites. Teratomas in the head and neck portend a poorer prognosis due to incidence of airway compromise.

Terrien Marginal Degeneration

Shipra Gupta[1] and Rony R. Sayegh[2]
[1]Department of Ophthalmology, University Hospitals-Case Medical Center, Cleveland, OH, USA
[2]Department of Ophthalmology, University Hospitals, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Definition

Terrien marginal degeneration is an uncommon, noninflammatory condition that manifests as slowly progressive bilateral thinning of the peripheral paralimbal cornea.

Etiology

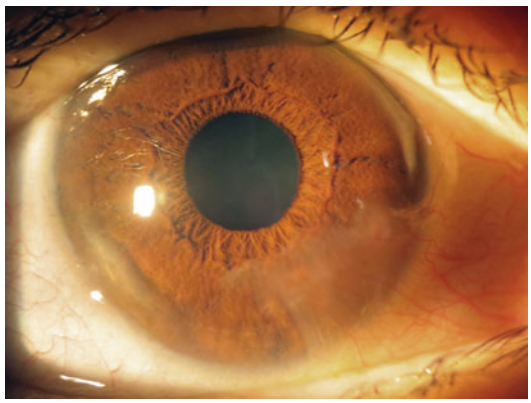
The cause of Terrien marginal degeneration is unknown.

Clinical Presentation

Terrien marginal degeneration classically presents as bilateral peripheral corneal thinning with a

leading edge of lipid. These changes begin superiorly and spread circumferentially. Initially, fine punctate white anterior stromal opacities appear superonasally with a clear space separating them from the limbus. These opacities may later coalesce and extend circumferentially or centrally, and progressive thinning and ectasia may develop. Fine superficial vessels connect these lesions to the limbal arcade. The overlying corneal epithelium remains intact throughout the process. The gutter has a steep central edge and a sloping peripheral edge and becomes wider and more vascularized with time. Lipid deposits form a yellow line central to the advancing edge of the gutter.

Other manifestations of Terrien marginal degeneration have been described. The peripheral ectatic areas can lead to bulging of the cornea and result in breaks in Descemet's membrane. These breaks may lead to the formation of aqueous pockets in the cornea which occasionally connect with the subconjunctival space and result in filtering bleb formation and hypotony. In 20% of patients, pseudopterygia can appear early in the disease state when thinning is minimal. Characteristically, the pseudopterygia occur at either 3 o'clock or 9 o'clock and grow obliquely onto the cornea (Fig. 1). Against-the-rule astigmatism which is characteristic of the disease may also occur, and corneal topography reveals flattening of the peripheral thinned cornea. Although spontaneous perforations are rare, minor trauma to these diseased corneas may result in perforation. An association with other corneal conditions such as posterior polymorphous dystrophy, keratoconus, anterior basement membrane dystrophy, and erythema elevatum diutinum has also been reported.



Terrien Marginal Degeneration, Fig. 1 Terrien marginal degeneration. The classic appearance includes circumferential peripheral thinning with an intact overlying epithelium and a leading edge of lipid. Pseudopterygia can be seen in 20% of patients

Terrien marginal degeneration is a painless condition and the eye classically remains quiet with no evidence of inflammation. However, a rare form of the disease can occur in young individuals with severe pain and recurrent episodes of inflammation, episcleritis, or scleritis. This condition is treated with steroids.

Diagnosis

Terrien marginal degeneration is distinguished from other peripheral corneal thinning diseases by the lack of inflammation, intact epithelium, and slowly progressive course over years. The presence of superficial vascularization and an advancing linear deposition of lipid also aid in the diagnosis. There are no known systemic associations with Terrien marginal degeneration.

Histopathologically, the epithelium is intact with the exception of the basal layer which contains degenerated epithelial basal cells. Bowman layer and the corneal lamellae may be split, fibrillated, fragmented, or absent and replaced with loose vascularized connective tissue. The vessels originating at the limbus migrate centrally within the superficial connective tissue, loop at the central margin of the gutter, and cruise back anteriorly to Descemet's membrane toward the limbus. The lipid line consists of cholesterol crystals deposited anterior to the vascular arcades. Furthermore, histiocytes line the blood vessels and are laden with lipid, collagen and ground substance. The histiocytes demonstrate high levels of lysosomal activity which is evidenced by the continual degradation of corneal tissue. Higher levels of

lysosomal enzymes are present in the tear film of these patients as compared to age-matched controls. Descemet's membrane usually remains intact but may be either thickened or thinned. The endothelium may be normal or attenuated.

Differential Diagnosis

Fuchs superficial marginal keratitis
Marginal furrow degeneration
Arcus senilis
Dellen
Corneal melt associated with collagen vascular diseases
Pellucid marginal degeneration
Sclerokeratitis
Keratoconjunctivitis sicca
Staphylococcal marginal keratitis
Mooren's ulcer
Infectious corneal ulcer

Therapy

Usually no treatment is needed unless perforation occurs or is imminent. Mild astigmatism may be managed with glasses or rigid contact lenses. Surgical correction is indicated for impending perforation of the cornea due to progressive thinning or when severe astigmatism significantly limits the visual acuity. Crescent-shaped lamellar or full-thickness tectonic keratoplasty is most commonly used and has been shown to halt the progression of severe astigmatism for up to 20 years in some cases. Gradual thinning of the grafts may subsequently occur many years later. Annular lamellar keratoplasty grafts may be required in cases of 360° marginal degeneration. Protection with polycarbonate glasses is essential, especially in advanced cases.

Prognosis

Most patients with Terrien marginal degeneration do not progress to corneal perforation and can be managed successfully with glasses or contact lenses. However, approximately 15% of patients present with a perforation and are managed as outlined above. It should be noted that the second eye may be affected decades after the initial eye presents.

Epidemiology

Terrien marginal degeneration is predominant in males, with a 3:1 male to female ratio. It typically occurs in the second or third decade of life.

Synonyms

Terson's syndrome

Definition

Terson syndrome (TS) is any intraocular hemorrhage associated with subarachnoid hemorrhage and elevated intracranial pressures. It is most commonly associated with subarachnoid hemorrhages caused by ruptured cerebral aneurysms. Originally, TS was defined as vitreous hemorrhage caused by subarachnoid hemorrhage but now includes any intraocular hemorrhage caused by subarachnoid hemorrhage. Intraocular hemorrhage includes the development of retinal, subretinal, preretinal, subhyaloidal, or vitreal blood. The most common presentation for TS is in the subhyaloidal space (Ou and Yoshizumi 2015).

Epidemiology

A review of reports of TS dating back over a 100 years shows that the combination of subarachnoid hemorrhage and vitreous hemorrhage occurred in 13% of hospital admissions. Bilateral vitreous hemorrhage was reported in 56% of those patients. There is no evidence of correlation between gender and vitreous hemorrhage or subarachnoid hemorrhage (Ou and Yoshizumi 2015).

History

A German ophthalmologist, Moritz Litten, first described an intraretinal hemorrhage associated with subarachnoid hemorrhage in 1881 (Litten 1881). However, Albert Terson's description of vitreous hemorrhage following subarachnoid hemorrhage in 1900 is associated with this syndrome (Terson 1900).

Clinical Features

Visual acuities range from 20/20 to light perception in patients where testing is possible. The intraocular hemorrhage is usually superficial to the retina, and in about 56% of patients it occurs bilaterally. Intraretinal and subretinal hemorrhages have been reported. Some preretinal hemorrhages can develop into vitreous hemorrhages within weeks (Medele et al. 1998).

Tests

A reduced red reflex is helpful in evaluating patients who are comatose. Additionally, a B-scan ultrasound can help establish the extent of vitreous hemorrhage. Computed tomography (CT) scan, magnetic resonance imaging (MRI) of the brain, or angiography may be necessary in the evaluation of intracranial hemorrhage (Medele et al. 1998).

Differential Diagnosis

- Subarachnoid hemorrhage especially due to cerebral aneurysm
- Papilledema
- Reduced red reflex

Etiology

TS is commonly caused by subarachnoid hemorrhages due to ruptured cerebral aneurysms. Statistical analysis has not correlated it with a specific aneurysmal location. Other causes include strangulation, trauma, hypertension, tumor, and perioperative and postoperative intracranial bleeding (Ou and Yoshizumi 2015).

Treatment

The intraocular hemorrhage commonly clears spontaneously. Resolution may take months. It may be helpful to elevate the head with bed rest and avoid anticoagulation medication. Nonspontaneous clearing of a large hemorrhage may require a vitrectomy to facilitate clearing. The development of amblyopia is a consideration for early vitrectomy in pediatric cases. It is generally recommended to avoid anticoagulants if possible postoperatively (Ou and Yoshizumi 2015).

Thermal Cautery

Mahsa Sohrab[1] and Matthew B. Goren[2]
[1]Northwestern University, Evanston, IL, USA
[2]Cornea and External Diseases, Department of Ophthalmology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Synonyms

Diathermy; Electrocautery

Definition

There are many surgical applications of thermal cautery, but this discussion is limited to its use in dry eye disease. This is done by occlusion of one or more puncta using heat. The heat of thermal cautery is generated by a direct or alternating current passing through a resistant metal wire electrode (Hutnik and Probst 1998). This heat is applied to the treatment area, causing localized tissue destruction.

Indication

Dry eye disease
Graft-versus-host syndrome
Intolerance of punctual plugs

Contraindication

Nasolacrimal duct obstruction
Correction with reversible techniques (e.g., punctual plugs) (Ohba et al. 2011)

Techniques and Principles

The lower puncta are typically treated first, with consideration of further treatment of upper puncta if the desired effect has not been fully achieved. Local anesthetic such as 2% lidocaine can be injected in the surrounding skin and conjunctiva, but this is rarely necessary. A sterile, disposable handheld cautery device is used so that the tip is inserted into the punctum. The device is then activated until the punctal tissue becomes white, then saline can be applied to cool the device, and the cautery device is gently removed. No suture is required, and a topical antibiotic is used for several days.

Outcome

Permanent punctal occlusion using thermal cautery has very low recanalization rates (Vrabec et al. 1993; Yaguchi et al. 2012). The goal is improvement in corneal surface with decreased punctate staining as well as symptomatic improvement with less injection, pain, and foreign body sensation.

Complications

The most common complication is epiphora from lack of effective tear drainage. Severe complications are rare and include burns to surrounding tissue, infection, and the inability to reopen the canalicular system if epiphora is bothersome.

Thermal Injury: Overview

Allen O. Eghrari
Johns Hopkins University School of Medicine, Baltimore, MD, USA
Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Heat injury

Definition

Thermal injury refers to ocular trauma from radiant energy in the form of heat.

Etiology

Thermal injury is often secondary to trauma such as from hot liquids or gases, explosive materials, or projectiles, and severity varies based on the extent of tissue penetration. In a study of 127 burn patients with ocular involvement at a hospital in the United States, explosions represented the most common etiology, followed by house fires and gasoline (Stern 1996). Iatrogenic burns can also occur during phacoemulsification or with the use of argon laser.

Clinical Presentation

Due to the traumatic etiology of thermal insult, patients may present with multiple ocular injuries, including the eyelid, cornea, and conjunctiva. Eyelids are frequently involved, affecting almost half of the patients examined in the large study referred to above (Stern 1996). Thermal injury to the ocular surface may present with an irregular or missing epithelium; however, a rapid corneal reflex often limits the depth of thermal damage.

In contrast, iatrogenic burns during phacoemulsification may cause significant intraocular injury, as temperature near the phacoemulsification tip may exceed 100 °C (Sugar 1999). Patients with corneal tissue shrinkage near or around the wound may present postoperatively with significant corneal astigmatism or, in severe cases, endothelial failure.

Diagnosis

A thorough history is required to identify etiologic traumatic agents, and penlight examination of the face and eyelids utilized to determine external injuries. Slit-lamp examination is essential to evaluate the distribution and depth of ocular surface burns. Evaluation of the corneal surface with fluorescein to determine the severity of epithelial defects guides therapy and monitors healing.

Differential Diagnosis

Patients with thermal trauma may present with concomitant chemical injury, in which case pH measurement and irrigation of the ocular surface are important.

Prophylaxis

Patients presenting with thermal trauma should be counseled on the use of eye protection and safety precautions to prevent future injuries. Attention to intraoperative fluidics to ensure proper flow of fluid around the phacoemulsification handpiece and evacuation of viscoelastic from the anterior chamber will assist cataract surgeons to minimize thermal trauma to the cornea.

Therapy

Initial treatment of thermal injuries requires immediate evaluation and management of airway and breathing issues, particularly in the setting of facial trauma. Once stable, if chemical exposure is suspected in addition to thermal injury, the eye should be thoroughly irrigated.

Eyelid burns should be covered with ointment, and frequent checks are required to ensure proper coverage of the ocular surface as the eyelid heals, with the use of tarsorrhaphy as needed for severe burns. Frequent lubrication of the cornea with topical antibiotic ointment, such as erythromycin or bacitracin, assists with both infectious prophylaxis and lubrication. Additional lubrication can be provided with artificial tears or gel. In addition, cycloplegics such as atropine or homatropine may assist with comfort.

In advanced thermal corneal burns with limbal stem cell dysfunction, amniotic membrane grafting or conjunctival allograft (if unilateral injury) may assist with epithelial closure, although more data are required to measure the extent of its effectiveness (Clare 2012). Corneal opacity may require corneal transplantation.

Prognosis

Prognosis of thermal trauma depends on rapid intervention and prompt treatment. Eyelid thermal injuries often result in contracture and should be addressed surgically if needed to avoid compromise of the ocular surface, and ocular surface lubrication initiated early to optimize outcomes. In a retrospective review of 66 patients with facial burns, the rate of ocular surgery was reduced by one-third in patients for whom ocular surface lubrication was initiated prophylactically (Spencer 2002), but initial, acute corneal burn with epithelial defect was not associated with a particularly poor prognosis.

Epidemiology

Approximately 16% of ocular burn cases are caused by thermal burns; ocular burns, in turn, represent up to 18% of eye injuries seen in hospital emergency departments.

Thiel-Behnke Dystrophy

Marcus Neuffer
Department of Ophthalmology, Keesler Medical Center, Biloxi, MS, USA

Synonyms

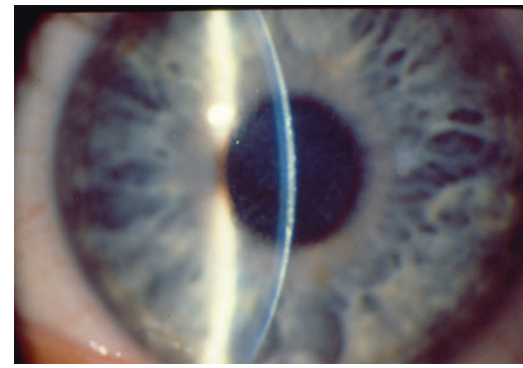
Anterior limiting membrane dystrophy, type II; Corneal dystrophy of Bowman's layer, type II (CDB2); Curly fiber corneal dystrophy; Honeycomb-shaped corneal dystrophy; Waardenburg-Jonkers corneal dystrophy

Definition

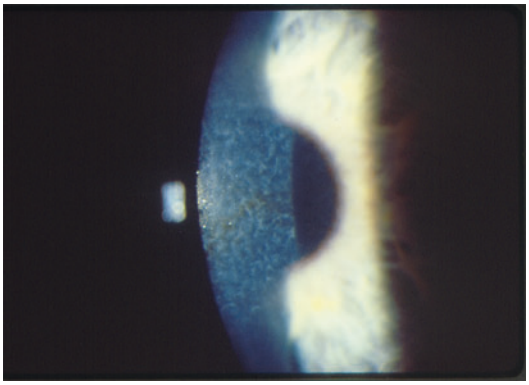
A corneal dystrophy of Bowman's layer characterized by reticular or "honeycomb" opacities and recurrent erosions that lead to ocular pain and visual loss (Figs. 1 and 2).

Etiology

Inheritance is autosomal dominant (Krachmer et al. 2011).



Thiel-Behnke Dystrophy, Fig. 1 Subepithelial "honeycomb" opacities similar to Reis-Bücklers



Thiel-Behnke Dystrophy, Fig. 2 Magnification of subepithelial "honeycomb" opacities

Clinical Presentation

Patients are born with normal corneas and begin to develop signs and symptoms during the first and second decade of life. Symmetrical subepithelial honeycomb-like opacities appear in the central cornea with the peripheral cornea uninvolved. Patients suffer from pain and redness from recurrent erosions and their vision gradually deteriorates (Weiss et al. 2008). The condition is very similar to Reis-Bücklers dystrophy disease, and distinguishing between the two by clinical examination is difficult.

Diagnosis

Differentiation between Thiel-Behnke dystrophy and Reis-Bücklers dystrophy is best made through light and electron microscopy. In Thiel-Behnke dystrophy, light microscopy demonstrates the replacement of Bowman's layer by a fibrocellular layer that has a unique wavy "saw-toothed" pattern. Electron microscopy reveals pathognomonic curly fibers in the region of Bowman's membrane (Krachmer et al. 2011). Confocal microscopy also contributes to the diagnosis by identifying reflective irregular deposits in Bowman's layer and deposits in the basal epithelium with dark edges and homogenous reflectivity (Weiss et al. 2008).

Differential Diagnosis

Differential diagnosis includes Reis-Bücklers dystrophy disease, map-dot-fingerprint dystrophy disease, recurrent corneal erosion disease, macular corneal dystrophy, Fuchs' dystrophy disease, and herpes simplex.

Prophylaxis

No prophylaxis is known; however, topical lubricants are used to prevent corneal erosions.

Therapy

Treatment is initially focused on recurrent erosions. Topical lubrications, contact lenses, and patching are used during this time. Eventually, as corneal scarring develops, superficial keratectomy or phototherapeutic keratectomy (PTK) may be performed. A keratoplasty, lamellar or penetrating, is reserved for when the scarring becomes severe and deep. The dystrophy frequently recurs in the graft (Krachmer et al. 2011).

Prognosis

Progression may be less aggressive than with Reis-Bücklers dystrophy. Recurrent erosions lessen with time. Vision slowly progressively deteriorates until surgical treatment is necessary (Weiss et al. 2008).

Epidemiology

The condition is rare and prevalence unknown.

Synonyms

CN III palsy; Oculomotor nerve palsy

Definition

All of the cranial nerves (CN) controlling extraocular muscle function (CN III, IV, VI) arise from separate nuclei located within the brain stem. The dorsal midbrain contains the nuclei and fascicles for CN III at the level of the superior colliculus. A lesion of CN III can affect all or only a portion of the nerve (i.e., complete or partial CN III palsy). A complete CN III palsy would thus be expected to produce an ipsilateral dilated pupil (internal ophthalmoplegia), ptosis, and an external ophthalmoplegia involving all of the extraocular muscles innervated by CN III (i.e., superior rectus, inferior rectus, inferior oblique, and medial rectus muscles). Thus, the ocular deviation is usually ipsilateral exotropia and hypotropia (i.e., "down and out" position) due to unopposed action of the remaining functioning extraocular muscles (lateral rectus and superior oblique muscles). Affected patients however may not always complain of diplopia due to ptosis which can act as an occluder of the affected eye.

The anatomic course of the third nerve begins at the nucleus, located within the dorsal midbrain. A lesion at this level might produce a "nuclear" CN III palsy. The nuclear innervation to the levator muscle in the upper eyelid is controlled by a single, central caudal subnucleus, and thus, nuclear third lesions produce either no ptosis or bilateral ptosis. In addition, the superior rectus muscle is innervated by the contralateral subnucleus, and thus, a unilateral CN III palsy presenting with a contralateral superior rectus palsy is an obligatory sign of a nuclear CN III palsy unless there are multiple lesions involved.

From the nucleus, the third nerve fibers course together to form the fascicle within the midbrain parenchyma. The nerve then exits the midbrain ventrally and travels anteriorly toward the cavernous sinus in the lateral dural wall, through the superior orbital fissure to the orbital apex, and finally to the CN III innervated extraocular muscles. The third nerve closely follows the path of the posterior communicating artery in the subarachnoid space and in this location is vulnerable to aneurismal compression. The third nerve also carries the parasympathetic pupillary fibers to the iris sphincter from the Edinger-Westphal nucleus in the dorsal midbrain. These fibers are located very superficially in the third nerve as it courses in

close proximity to the posterior communicating artery; thus, an aneurysm of the posterior communicating artery often produces a pupil-involving CN III palsy. The third nerve also contains the somatic ocular motor fibers that innervate the inferior oblique, medial rectus, superior rectus, inferior rectus, and levator palpebrae superioris muscles.

Etiology

Microvascular ischemia is a common underlying etiology of an isolated CN III palsy in adults and represents up to 17–35% of cases in large retrospective pooled series of third nerve palsies (Rucker 2012). Compressive lesions (e.g., aneurysm and neoplasm), however, are responsible for up to 19% of cases (Rucker 2012). A pupil-involved CN III palsy is a red flag for an underlying aneurysm, most commonly at the posterior communicating artery-internal carotid artery junction (34–61% of cases), but basilar tip aneurysms or intracavernous internal carotid artery aneurysms can also produce a CN III palsy (Rucker 2012).

Although meningioma and other benign cavernous sinus lesions can produce a CN III palsy, other more malignant neoplastic causes such as lymphoma or metastases should also be suspected in patients with acute presentations especially in patients with a previous cancer or lymphoma diagnosis. ► Myasthenia gravis should also be considered in any painless, pupil-spared ophthalmoplegia including what might appear to be a pupil-spared CN III palsy. Pituitary adenomas with cavernous extension, other less common neoplastic etiologies (e.g., third nerve schwannoma, intracavernous hemangioma/hemangiopericytoma), and vascular lesions (e.g., intracavernous aneurysm, carotid cavernous fistula) may also occur. Giant cell arteritis should also be considered in the differential diagnosis of new diplopia, including CN III palsy, in elderly patients, especially those with typical symptoms of headache, jaw pain, or concomitant visual loss. Trauma is an uncommon cause, but can also result in a CN III palsy, although this comprises less than 1% of cases in pooled retrospective series (Rucker 2012).

Clinical Presentation

A complete loss of third nerve function results in unopposed action of the lateral rectus muscle (innervated by the sixth cranial nerve) and the superior oblique muscle (innervated by the fourth cranial nerve). This results in the classic presentation in a CN III palsy of an eye that is "down and out" (i.e., the affected eye is abducted and depressed in primary position). Additionally, partial or complete ptosis may be present. A poorly reactive or nonreactive, dilated pupil can also result from loss of parasympathetic iris sphincter innervation. This produces anisocoria that is greater in the light due to the affected pupil's inability to constrict properly. The lid, pupil, or extraocular muscle function can be variably involved or spared in partial third nerve palsies.

As noted above, ipsilateral compression by a posterior communicating artery aneurysm typically involves the pupil because the superficial pupillary fibers are the first to be compromised by an adjacent compressive lesion. In contrast, diabetic (and other small vessel ischemic etiologic) third nerve palsies often spare the pupil, as ischemia affects the deeper penetrating vasa nervorum vessels to a greater extent than the superficial pupillary fibers. Some diabetic ischemic third nerve palsies, however, can involve the pupil, albeit typically with less anisocoria (<1 mm).

Although the "rule of the pupil" states that a pupil-involving CN III palsy is a posterior communicating artery aneurysm until proven otherwise, the absence of pupil involvement does not rule out an aneurysm, as up to 33% of all posterior communicating artery aneurysms do not have pupillary involvement on presentation (Rucker 2012). In some cases, the pupil is not involved because only a portion of the third cranial nerve is affected (e.g., partial palsy or superior division only); thus, the "rule of the pupil" should not be extrapolated to clinically define "pupil sparing" in a partial palsy of CN III.

Diagnostics

Although somewhat controversial, a complete, isolated, acute, painless, CN III palsy in a vasculopathic patient without pupillary involvement could be observed for improvement, as microvascular ischemia is the most likely culprit. Some authors, however, recommend neuroimaging for all CN III regardless of ischemic risk factors. In contrast, if the CN III palsy presents with a "blown" (dilated) pupil, the pretest likelihood for aneurysm is high. In most centers, the best initial imaging study for any patient in an acute, emergent setting, especially in patients with severe pain (e.g., "worst headache of my life"), or altered mental status, is computed tomography (CT) of the brain (non-contrast) to first evaluate for subarachnoid hemorrhage followed with contrast CT angiography (CTA) of the brain. The two CT studies can be combined at most institutions. Unfortunately, CT/CTA is not sufficient to exclude nonvascular causes of CN III palsy, and magnetic resonance imaging (MRI) of the brain and orbits with and without contrast and fat suppression as well as magnetic resonance angiography (MRA) might still be necessary in unexplained CN III palsy. Although CTA is believed to be superior to MRA at most centers, variability in technique, availability of neuroradiologic expertise, variability in interpretation, and sometimes the intrinsic imaging characteristics of the aneurysm itself (e.g., thrombosis, partial flow) can make one technique better than the other in any one individual patient. Specific, customized, individualized discussion and review of the neuroimaging studies with the neuroradiologist is recommended. Standard catheter contrast angiography (CA) should be considered even if the MRI/CT and MRA/CTA combination is negative for aneurysm if there is still sufficiently high pretest suspicion (e.g., painful, pupil-involved CN III palsy) or if the posttest (CTA/MRA) likelihood of aneurysm remains high or uncertain (e.g., CTA or MRA had artifact obscuring a complete 3D rotational view of the posterior communicating artery) (Lee et al. 2009).

Although both MRA and CTA have a sensitivity of close to 98% for the detection of an aneurysm producing a CN III palsy, structural MRI with contrast can better detect nonvascular causes of CN III palsy (e.g., tumor, meningeal disease). Complete CN III palsy with partial pupil involvement (e.g., a larger but reactive pupil or a postsurgical pupil) or partial CN III palsy without pupillary involvement typically requires an imaging study (e.g., CT/CTA then MRI/MRA). However, CA may not be necessary in such cases if the index of suspicion is not as high for aneurysm after adequate non-catheter cranial and cerebrovascular imaging (Lee et al. 2009).

MRI without contrast alone is not recommended because enhancing lesions of the third cranial nerve, meningeal disease, and some tumors (e.g., meningioma) might be missed without gadolinium contrast. Some patients, however, have contraindications (e.g., renal failure or contrast allergy) that may preclude contrast administration. MRA (as opposed to contrast CTA) can be performed with or without contrast. Thus, a non-contrast MRA could be a reasonable second choice to CTA if needed in selected cases especially with MRI contrast contraindications.

Although many authors believe that initial observation for resolution without initial neuroimaging is reasonable for an acute, isolated, painless, pupil-spared CN III palsy in a vasculopathic patient, pain, progression, lack of improvement, or development of aberrant regeneration or any new signs or symptoms during the observation period (i.e., first few weeks to months) should prompt consideration for neuroimaging. On the other hand, MRI/MRA with and without contrast of the head would not be unreasonable even in cases of acute, isolated, painless, pupil-spared, and presumed vasculopathic CN III palsy because some of these patients can harbor an underlying etiology. However, the decision to image in this setting remains controversial because most of these cases will eventually come to imaging because of lack of spontaneous improvement.

Differential Diagnosis

1. Ischemic
2. Aneurysm (posterior communicating artery, intracavernous carotid artery, basilar artery)
3. Orbital apex lesion
4. Uncal herniation (secondary to increased intracranial pressure)
5. Neoplasm (schwannoma, meningioma, pituitary apoplexy)
6. Giant cell arteritis
7. Myasthenia gravis (painless, pupil spared)
8. Ophthalmoplegic migraine (rare)
    1. *Ischemic CN III palsy*: An acute, unilateral, painless, pupil-spared, CN III palsy is most often caused by microvascular ischemia in adults. Typically, there is no pupillary involvement as ischemia involves the deeper penetrating vasa nervorum vessels and not the superficial pupillary fibers. Some diabetic ischemic third nerve palsies, however, do involve the pupil, albeit with mild anisocoria (<1 mm). Most cases of ischemic CN III palsy resolve spontaneously and do not require treatment, with up to 80% resolving in 3 months (Akagi et al. 2008).
    2. *Aneurysm*: The most common location of an aneurysm producing a CN III palsy is the posterior communicating artery-internal carotid artery junction (34–61% of cases), but basilar tip aneurysms can also produce a unilateral or bilateral CN III palsy (Rucker 2012). Ipsilateral compression by a posterior communicating artery aneurysm typically produces pupil involvement. The lack of pupillary involvement in a partial CN III palsy, however, does not obviate the need to rule out a posterior communicating artery aneurysm, as up to 33% of all posterior communicating artery aneurysms do not have pupillary involvement on presentation. Typically, the best initial imaging studies are brain CT/CTA, but MRI/MRA with and without contrast might still be necessary to exclude other non-aneurysmal causes of CN III palsy. However, catheter angiogram still remains the gold standard for excluding aneurysm.
    3. *Orbital apex lesion*: Please see the section on "► Orbital Apex Syndrome" for a more detailed explanation of this disorder.
    4. *Uncal herniation*: The third nerve may be involved in uncal herniation from an expanding mass lesion in which the uncus, located in the medial portion of the temporal lobe, herniates through the foramen magnum, directly compressing the third cranial nerve at the tentorium and causing a CN III palsy. The dilated and poorly reactive pupil associated with uncal herniation is sometimes known as a "Hutchinson pupil."
    5. *Neoplasm (schwannoma, meningioma, pituitary apoplexy)*: Pituitary apoplexy results from acute hemorrhage or necrosis occurring within a preexisting pituitary adenoma. This can cause rapid enlargement of the pituitary gland and compression of the surrounding structures. The most common structures involved by apoplexy are the cavernous sinus (which may result in an acute CN III palsy – see the section on "► Cavernous Sinus Syndrome") and the optic nerves or chiasm, resulting in loss of vision unilaterally or bilaterally.
    6. *Giant cell arteritis (GCA)*: Although GCA typically presents with unilateral or bilateral visual loss (often with pallid optic disc edema), third nerve palsies associated with GCA have rarely been reported. Please see the section on "► Arteritic Ischemic Optic Neuropathy" for more details on this disorder.
    7. *Myasthenia gravis*: The possibility of neuromuscular disease, such as myasthenia gravis, should also be considered in any painless, pupil-spared, ophthalmoplegia which can include the extraocular muscles involved in a typical CN III palsy. Myasthenia gravis is a disease of the neuromuscular junction and can produce any pattern of pupil-spared, non-proptotic ophthalmoplegia and can mimic a CN III palsy. Please

see the section on "▶ Myasthenia Gravis" for more details on this disorder.

8. *Ophthalmoplegic migraine*: Migraine is always a diagnosis of exclusion and is characterized by recurrent episodes of a CN III palsy (or rarely other ocular motor cranial nerve palsies) in a younger patient with a known history of migraines. Because ophthalmoplegic migraine is rare and a diagnosis of exclusion, typically brain and orbit MRI with and without contrast with MRA are necessary to exclude other etiologies.

Prophylaxis

Not applicable.

Therapy

Patching of the affected eye and the use of temporary Fresnel prisms are first-line treatments for an acute cranial third nerve palsy, as they are both noninvasive and reversible. Surgical treatment should be considered only after the diagnostic evaluation is completed. If the deviation fails to improve and fails conservative or prismatic therapy, and the orthoptic measurements have remained stable for at least several months, then strabismus surgery could be considered.

Surgical correction of CN III palsy-related ptosis and strabismus is notoriously difficult. The precise surgical procedures selected depend on the exact pattern of strabismus. Some strabismic procedures commonly employed to alleviate symptomatic diplopia include transposition of the superior oblique tendon, medial rectus resection, and lateral rectus recession (Yonghong et al. 2008). The efficacy of botulinum toxin injection in the treatment of an acute CN III palsy is controversial, but is believed by some to allow medial rectus recovery by relaxing the lateral rectus muscle. Botulinum toxin can also be effective in temporarily treating symptomatic diplopia if the patient is not ready to proceed with more permanent surgical procedures.

Prognosis

Almost half of all idiopathic CN III palsy resolve partially or completely (Rucker 2012). A presumed vasculopathic cranial third nerve palsy has a high rate of spontaneous resolution, with up to 80% resolving in 3 months (Akagi et al. 2008). As a result, in contrast to long-standing deviations that might produce an anomalous head or face position, ischemic CN III palsy typically does not typically result in painful torticollis.

Multiple simultaneous or rapidly sequential cranial neuropathies are atypical and should prompt further evaluation for additional diagnoses with neuroimaging (i.e., "a diabetic patient is allowed only one ocular motor cranial neuropathy at a time"). Aberrant regeneration is essentially never seen after ischemic CN III palsy, and thus if aberrant regeneration is present, this should prompt neuroimaging, including evaluation for neoplasm (especially cavernous sinus) or aneurysm.

Epidemiology

Third nerve palsies represent up to 30% of all cranial nerve palsies in adults (Rucker 2012).

Synonyms

Three-dimensional computer tomography volume rendering

Definition

Three-dimensional (3D) computed tomography (CT) combines advances in spiral CT with computer hardware, software, and display technology to create 3D renderings of anatomical structures.

Purpose

3D CT is a useful imaging modality in the evaluation of orbital disease and in preoperative planning for orbital procedures.

Principle

3D CT relies on the same basic physical principles as a spiral CT, which includes the use of x-ray emissions in a cone-beam or fan-beam pattern with a detector to generate cross-sectional images of the body that can be reconstructed in any given plane. Using the conventional fan-beam CT device, the patient is placed horizontally and slowly passed through a circular metal frame that contains an x-ray source and detector. Images are taken as "snapshots" that are aggregated and reconstructed to provide a continuous set of images. Cone-beam CT is particularly useful for craniofacial anatomy and allows for better resolution with lesser radiation compared to the conventional fan-beam CT devices.

In addition to a basic spiral CT, 3D CT relies on computer algorithms to convey 2D images as 3D renderings. The fundamental principle is to carefully compare multiple 2D images to best represent their internal spatial relationship to provide a 3D image. A classic example is a 3D cube, which when imaged using CT shows up as multiple 2D images in various cross sections. 3D rendering techniques, such as, shaded surface display (SSD) and maximum intensity projection (MIP), rely on mathematical formulas that compare these 2D images to display certain image features over others to best represent the 3D spatial relationship. Each 3D rendering technique differs in how the image features are selected, weighed, and projected, which leads to slight variations in the 3D images (Calhoun et al. 1999).

Indication

Orbital trauma, orbital fractures, orbital tumors, orbital infections, thyroid eye disease, proptosis, globe malposition, and preoperative planning.

Contraindication

3D CT has no contraindications separate from a CT in general. These include patients with iodine or contrast allergies, patients with significant renal disease, and pregnant patients.

Advantages/Disadvantages

A spiral CT allows for rapid evaluation and is therefore the preferred modality in emergent situations. 3D CT may add additional clinically relevant data during emergent cases, such as clear visualization of the fracture line and bony displacement of the orbit. 3D CT allows for exquisite visualization of orbital anatomy and is therefore particularly useful in preoperative planning (Sinanoglu et al. 2016).

Metallic objects, such as dental fillings, lead to image artifacts on CT that may obscure key structures. Since CT is classically best for bone assessment, it has limited utility in detailing orbital soft tissue and the orbital apex as compared to MRI. Radiation exposure is another disadvantage, but this can be reduced by 15 times when using cone-beam CT compared to fan-beam CT for orbital assessment (Karatas and Toy 2014). Cost of obtaining a CT machine and the necessary software for 3D rendering may not be feasible for all centers. Lastly, each 3D rendering technique uses slightly different algorithms that may cause variations in 3D images.

[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Septic thrombosis of orbital veins; Superior ophthalmic vein thrombophlebitis

Definition

Orbital vein thrombophlebitis is a complication of orbital or periorbital infection in which venous drainage is blocked by infectious elements. Most commonly, thrombophlebitis is caused by bacterial infection, but fungi, mycobacteria, and

parasites may also cause venous occlusion. Orbital vein thrombophlebitis may be a sign of concurrent or impending cavernous sinus thrombosis, a serious and potentially deadly infection.

Etiology

Orbital vein thrombosis may result as a consequence of any orbital or periorbital infection. Orbital thrombophlebitis has been reported in the setting of facial cellulitis, orbital cellulitis, dacryocystitis, sinusitis, odontogenic infections, and in Lemierre's syndrome (internal jugular vein thrombophlebitis) (Sanchez et al. 1997; Walker et al. 2002; Schmitt et al. 2005).

Orbital vein thrombosis is a severe and potentially life-threatening complication of orbital cellulitis – because the orbital veins lack valves – infectious thrombophlebitis may track posteriorly into the cavernous sinus.

The zygomyses are feared and potentially life-threatening cause of orbital vein thrombophlebitis. Fungal infections, such as mucormycosis, are angioinvasive and often involve the orbital veins and cavernous sinus.

Clinical Presentation

The orbital veins are valveless and communicate directly with the cavernous sinus, allowing infections to travel directly to the cavernous sinus. A unilateral orbital cellulitis that becomes bilateral is highly suggestive of a cavernous sinus thrombosis arising from septic orbital vein thrombosis (Black and Smith 2012).

Examination findings in the setting of orbital vein thrombophlebitis may include signs and symptoms of orbital cellulitis, such as pain, proptosis, limited extraocular movements, chemosis, ptosis, and optic neuropathy in severe cases. Exam may also reveal dilation of periocular and scleral vessels and periphlebitis or dilatation and engorgement of retinal veins on fundoscopic examination. Cavernous sinus thrombosis may develop as a result of orbital vein thrombophlebitis, and patients may present with high fever, leukocytosis, headache, vision loss, ophthalmoplegia, meningeal signs, and bilateral orbital involvement. Neurologic deficits signify intracranial life-threatening intracranial involvement and may include altered mental status, seizure or focal neurologic deficits (Black and Smith 2012).

Diagnosis

Blood cultures are essential in suspected thrombophlebitis. Positive cultures identify a causative organism and allow for targeted antimicrobial therapy. Any discharge may also be cultured for a causative organism.

Imaging Findings

On CT imaging, the involved orbital vein appears thickened and has nondistinct borders. Contrast-enhanced CT angiography, MR angiography, and MR venography may all demonstrate proximal dilation and distal flow of the affected orbital vein. Imaging may demonstrate a low-density signal within the vein, representing the thrombus. Imaging may also demonstrate signs of associated infection such as proptosis, orbital fat stranding, abscess, or adjacent sinusitis.

In orbital mucormycosis, MRI may demonstrate diffuse orbital findings including proptosis, diffuse abnormal enhancement of the orbital fat, and dilation of the superior ophthalmic veins (Black and Smith 2012).

Differential Diagnosis

The differential for orbital vein thrombophlebitis includes infectious orbital cellulitis (bacterial, fungal, mycobacterial, parasitic, viral), non-infectious orbital inflammation (idiopathic orbital inflammation, sarcoidosis, thyroid eye disease, scleritis, granulomatosis, and polyangiitis), neoplasms, and vascular lesions (carotid-cavernous

fistula, lymphangioma, cavernous sinus thrombosis) (Black and Smith 2012).

Prophylaxis

Appropriate, timely treatment of periocular and orbital infections may prevent these infections from spreading through the orbital veins and causing orbital vein or cavernous sinus thrombophlebitis.

Therapy

Intravenous antibiotic therapy is required for orbital vein thrombosis. Empiric therapy should provide broad coverage for gram-positive organisms, including MRSA, as these bacteria represent the most common causes of orbital cellulitis and orbital infections. Anaerobic and gram-negative organisms have also been implicated. Initial therapy typically includes a third- or fourth-generation cephalosporin, metronidazole, and a penicillinase-resistant penicillin. Vancomycin may be started in patients with penicillin allergy and in suspected MRSA infections. Empiric antimicrobial therapy may also include antifungals where indicated, such as in immunosuppressed patients and poorly controlled diabetics, where fungal disease is suspected (Black and Smith 2012).

The role of anticoagulation remains controversial. Anticoagulation has been proposed as an adjunctive therapy in order to prevent extension of thrombophlebitis and to increase antibiotic penetration. Given the risk of intracranial and systemic hemorrhage, anticoagulation should be instituted with caution, and patients should be monitored carefully.

Prognosis

Orbital vein thrombosis represents a serious complication of orbital or periorbital cellulitis and may be fatal. In the classification system of orbital cellulitis proposed by Chandler in 1970, cavernous sinus thrombosis is classified as group V – the most severe classification (Black and Smith 2012).

Epidemiology

Orbital vein thrombophlebitis is a rare complication of orbital or periorbital infections.

Thygeson's Superficial Punctate Keratitis

Luis Santiago-Caban and Mark Mifflin
Department of Ophthalmology and Visual Sciences, John A. Moran Eye Center, University of Utah School of Medicine, Salt Lake City, UT, USA

Synonyms

Thygeson's superficial punctate keratopathy

Definition

Thygeson's superficial punctate keratitis (TSPK) is an uncommon, chronic, bilateral epithelial keratitis characterized by coarse, elevated, and discrete corneal epithelial lesions.

Etiology

The etiology of Thygeson's superficial punctate keratitis is unclear. Some experts have hypothesized a viral etiology due to its resemblance to other viral keratitis. No studies have proved the relationship between TSPK and a virus using cultures or PCR.

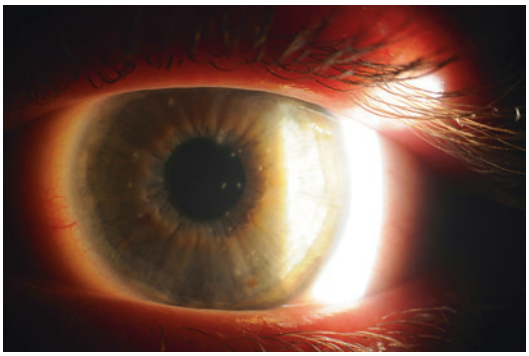
TSPK has been postulated to be an immune-mediated disease. Its response to topical steroid therapy supports the idea of a possible inflammatory etiology. Studies have shown an association between HLA-DR3, HLA-DW3, and TSP-K. These antigens have been described in inflammatory conditions (i.e., Graves' disease and IDDM). No studies have shown a direct relationship between systemic inflammatory conditions and Thygeson's superficial punctate keratopathy.

Allergy has also been postulated as a possible etiology, although no signs of ocular allergic disease are seen during exacerbations.

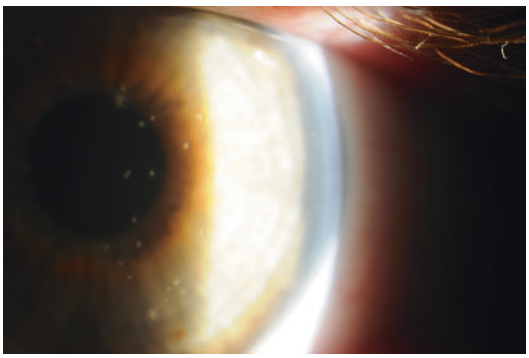
Clinical Presentation

Patients with TSPK present with symptoms of photophobia, foreign body sensation, pain, and tearing. The conjunctiva is usually quiet or mildly injected. The disease is usually chronic and recurrent.

Symptoms are usually worse than the clinical findings. Slit lamp examination shows numerous, discrete, fine, oval opacities located in corneal epithelium (Figs. 1 and 2). Lesions are usually located in the central cornea, averaging 15–20 per eye. They stain with fluorescein and rose bengal during exacerbations. Mild epithelial and subepithelial edema may be seen.



Thygeson's Superficial Punctate Keratitis, Fig. 1 Thygeson's superficial punctate keratopathy



Thygeson's Superficial Punctate Keratitis, Fig. 2 Thygeson's superficial punctate keratopathy, higher magnification

Exacerbations are self-limited but they can take 1–2 months to resolve. Between attacks, cornea may show no abnormalities or mild subepithelial scars.

Diagnosis

Diagnosis is made clinically.

Differential Diagnosis

Differential diagnosis includes viral keratitis (herpes simplex, varicella zoster, adenovirus), dry eye syndrome, keratoconjunctivitis sicca, filamentary keratitis, staphylococcal blepharokeratitis,

pneumococcal conjunctivitis, neurotrophic and vernal keratitis, recurrent erosions, and allergic and toxic keratitis.

TSPK has a very distinctive presentation, different from the presentations of each of the conditions mentioned above.

Therapy

TSPK is a self-limited disease. Therapy institution depends on patient's symptomatic tolerance. Low-dose steroids are usually first-line therapy. Some experts think steroid therapy may prolong the disease natural course.

Other therapies that have been used with good results include bandage contact lens and cyclosporine A.

Prognosis

Visual prognosis in Thygeson's superficial punctate keratitis is excellent.

Epidemiology

TSPK has no sex predilection. It usually affects patients in their second and third decades.

Synonyms

Graves' eye disease; Graves' ophthalmopathy; Thyroid-associated ophthalmopathy

Definition

Thyroid eye disease (TED) is a common manifestation of a systemic autoimmune process in which autoantibodies target receptors (e.g., thyroid-stimulating hormone receptor (TSH-R)) present on thyrocytes. Systemically, these autoantibodies can induce the production of excess thyroid hormone resulting in Graves' disease and hyperthyroidism, and in the orbit, they induce secondary and inflammatory effects including glucosaminoglycan (GAG) deposition, muscle edema, and fibrosis and adipogenesis. This systemic autoimmune hyperthyroid condition is known as Graves' disease. Although TED is commonly associated with hyperthyroidism (i.e., Graves' disease), up to 20% of patients can be hypothyroid (e.g., Hashimoto's thyroiditis or treated Graves' disease), and up to 3% of TED cases are completely euthyroid.

Etiology

TED is an inflammatory and autoimmune disease, and the secondary increase in the size of the extraocular muscles and/or orbital fat results from a complex interaction between fibroblasts, inflammatory cytokines, other immune cells, autoantibodies, and other environmental (e.g., smoking) and genetic factors. The antigens that are involved in TED are still ill defined, but it is hypothesized that the thyroid and orbital tissues share a common antigen. These potential cross-reacting antigenic targets include thyroglobulin, TSH receptor, insulin-like growth factor (IGF-1) receptor, or extraocular muscle antigens.

Smoking increases both the incidence and the severity of TED, and smokers have up to five times greater risk of developing TED than nonsmokers. Genetic factors have also been thought to play a role in TED. Twenty to sixty percent of patients have a positive family history of TED, and patients may have a personal or family history of other autoimmune disorders. HLA-B8, DR3, and DQA1*0501 haplotypes may increase susceptibility to the disease, and HLA-DR β1*07 may offer protection, but the clinical significance of these genetic associations remains controversial, and we do not routinely test patients for these genetic markers.

Clinical Presentation

TED may present before the onset of thyroid dysfunction (23%), during thyroid dysfunction (39%), or when the patient is euthyroid (37%). The most frequent and distinctive lid sign in TED is eyelid retraction which affects up to 98% of patients. In addition, the temporal contour of the retracted upper lid often shows lateral flare. Lid retraction in TED may be due to sympathetic stimulation of Müller's muscle, or contraction and fibrosis of the levator muscle with secondary scarring between the lacrimal gland fascia and levator. Other findings associated with lid retraction in TED are lid lag (the eyelid lags behind eye movement on downgaze) and lagophthalmos (incomplete closure of the eyelid especially with sleep). The absence of lid retraction and lid lag should be a "red flag" clinically in patients suspected of having TED.

Many patients with TED develop dry eye-type symptoms (e.g., grittiness, foreign body sensation, lacrimation, photophobia) and are at risk for the development of secondary exposure keratopathy from the widened palpebral aperture and incomplete blinking. The orbital and periorbital inflammation and GAG deposition may cause tissue swelling in the orbit, proptosis, edema, and erythema. Enlargement and inflammatory edema of the extraocular muscles in TED can cause ocular motility dysfunction, ophthalmoplegia, and symptoms of diplopia (typically hypotropia and/or esotropia from restrictive involvement of the inferior and medial recti muscles).

The visually threatening complication of TED is compressive optic neuropathy (CON) due to extraocular muscle enlargement and compression of the optic nerve at the orbital apex. CON in TED is seen in up to 5% of clinical TED patients. In addition, some patients with TED may have an optic neuropathy from "stretching" of the optic nerve due to severe proptosis without direct CON at the orbital apex.

There are several severity scoring systems that have been proposed in TED. One of the earliest was the modified NOSPECS and more recently the clinical activity score (CAS) and the vision loss (optic neuropathy) inflammation/congestion, strabismus, and appearance/exposure (VISA) classification. These scoring systems assess lid retraction, soft tissue inflammation, proptosis, extraocular muscle involvement, corneal defects, and optic nerve compression. The NOSPECS received some criticisms leading to the development of the newer classifications. The CAS includes pain, redness, swelling, and impaired visual function. VISA classification includes subjective and objective components (vision, inflammation, strabismus, restriction, and appearance/exposure).

Diagnostics

The diagnosis of TED is typically made clinically based upon lid and orbital findings in the setting of known systemic thyroid disease. Laboratory investigation for thyroid function includes thyroid-stimulating hormone (TSH) levels, free thyroxine (T4), and free triiodothyronine (T3). Euthyroid or hypothyroid patients who have suspected TED may need further testing to confirm the autoimmune nature of the eye findings (e.g., antithyroglobulin antibodies, TSH-R antibodies (thyroid-stimulating immunoglobulin), thyroid peroxidase (TPO) antibodies, and antimicrosomal antibodies).

Orbital imaging in TED is useful for confirming the clinical diagnosis of CON by documenting the crowding by the enlarged extraocular muscles at the orbital apex. Orbital ultrasonography, CT, and MRI are all reasonable imaging options with different strengths and weaknesses. Ultrasonography, which is low cost and radiation free, can be used to measure extraocular muscle involvement and may also be useful for differentiating between myositis and TED. Orbital CT scan is the most common utilized imaging technique used in the evaluation of TED. It has the advantage of short investigation time with precise imaging of the orbital apex and the bony anatomy, is of moderate cost, and can document enlargement of extraocular muscles. It is usually indicated when CON due to TED is suspected. CT may be more sensitive than MRI in identifying extraocular muscle enlargement and is better for orbital bony anatomy if surgery is being planned. There is a theoretical risk of giving a large iodinated contrast load to patients with active hyperthyroidism, and the contrast material is not generally required for the diagnosis of TED. Orbital MRI is more sensitive than CT for soft tissue signal changes such as interstitial edema within the recti muscles in active disease but is a more expensive method for monitoring disease than CT. The main clinical caveat in ordering an imaging study in TED is to order a CT or MRI of the orbit rather than a brain study as TED does not affect the brain and a cranial imaging study could miss the orbital findings of TED.

Differential Diagnosis

1. Myositis
2. Orbital cellulitis
3. Scleritis
4. Idiopathic orbital inflammatory disease
5. Carotid cavernous fistula

Prophylaxis

Non-applicable.

Therapy

TED management should include a multidisciplinary approach. The goals of management of TED are to control symptoms efficiently and, from an endocrine perspective, to achieve a euthyroid state if possible. Patients should be counseled regarding the risks of smoking and the benefits on TED of smoking cessation.

Most patients with mild-moderate ophthalmopathy usually require no intervention other than conservative treatment, restoration of

euthyroidism, discontinuing smoking, and topical lubricants. For moderate or severe TED, corticosteroids are typically the mainstay of short-term treatment. The response rate to steroids is variable from 63% to 77% improvement in some series. IV corticosteroids have been shown to have higher efficacy and a better side effect profile in comparison to oral steroids in several studies. Many authors recommend however that the cumulative dose of IV steroids should probably not exceed 6–8 g. Corticosteroid therapy may be complicated however by multiple side effects, including decreased bone density, weight gain, liver failure, hypertension, systemic infections, gastric ulcers, and glucose intolerance. It has been our practice to recommend short-course oral or IV steroids for moderate-to-severe TED, but if no response is noted within a few weeks, we generally taper the steroids quickly to avoid systemic side effects. We also use corticosteroids in patients with CON from TED prior to orbital decompression.

Radiation therapy has also been used in the management of TED. Radiotherapy is thought to have both a nonspecific anti-inflammatory effect and a predilection for lymphocyte effects. The most common dose is 20 Gy per orbit distributed in divided daily fractions over a 2-week period. Orbital radiotherapy may be associated with transient exacerbation of inflammation, which may be reduced with concomitant steroid use. The efficacy of radiotherapy remains controversial however, and there is conflicting data from the literature in sham radiation therapy-controlled trials. Several studies have shown that radiotherapy in combination with steroids may produce a better clinical response rate than either therapy alone.

Other steroid sparing immunosuppressive drugs have been used anecdotally for TED. Cyclosporine has been evaluated in the management of TED but was not as effective as oral steroids in reducing inflammation in one series. However, the combination of oral steroid and cyclosporine may be superior to oral steroids alone. Rituximab is an anti-CD20 chimeric, humanized, monoclonal antibody that targets mature B cells. It has been shown in anecdotal reports to decrease CAS in moderate-to-severe TED resistant to IV steroids. Other treatment modalities that have been shown in scattered reports to decrease CAS include antitumor necrosis-α antibody (TNFα), intravenous immunoglobulin (IVIG), plasma filtration, colchicine, and rapamycin. Unfortunately, there are no randomized control trials evaluating the efficacy of these treatment modalities.

The indications for surgical intervention in TED include optic neuropathy (typically CON but also proptosis-related stretch optic neuropathy in TED), severe ophthalmoplegia/diplopia, marked proptosis/corneal exposure, and reconstructive/cosmetic issues. Surgical procedures include orbital decompression for CON, strabismus repair, and correction of eyelid abnormality. Traditionally, if a patient with TED requires all three surgeries, then orbital decompression is performed initially, followed by strabismus surgery, and then eyelid repair as orbital surgery can cause or worsen strabismus, and strabismus surgery can affect the lid position. Some patients require surgery in the order of most importance and symptom relief. Most decompression surgery is performed when the patient has been in stable inactive state for at least 6 months. However, urgent decompression may be needed for CON or severe proptosis refractory to other treatment. Orbital fat decompression has also been used to reduce proptosis in TED.

Prognosis

Fortunately, moderate-to-severe (6%) and sight threatening TED (0.8%) complications are uncommon at presentation, and only 3–5% of TED patients develop CON. In addition, most patients (>80%) with no TED at baseline do not develop TED on follow-up, but this is variable and unpredictable.

Epidemiology

TED is the most common disease affecting the orbit. It is present in up to 40% of patients with

Graves' disease. It usually presents in the third to fifth decade and is more common in women. The estimated incidence is 16 per 100,000 person years in females and 3 per 100,000 person years in males.

Although TED disease is more common in women, the proportion of men increases as severity of disease increases from 9.3:1 in mild TED to 1.4:1 in severe TED. The risk and severity of TED may be increased by tobacco use, genetics, type of hyperthyroidism treatment, TSH-R Ab levels, advanced age, and stress. Smoking is the strongest modifiable risk factor for TED. Myasthenia gravis has been found to be up to 50 times more common in TED; it also may signify a worse prognosis. The diagnosis of concomitant MG should be suspected in TED when there is concomitant ptosis (rather than lid retraction) or exotropia (rather than esotropia or hypotropia).

Tight Orbit

Paul Petrakos[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Orbital compartment syndrome

Definition

Orbital compartment syndrome is a rare, but emergent, acute rise in orbital pressure that may to damage of ocular and intraorbital structures causing irreversible blindness.

Etiology

Tight orbit is most commonly secondary to an orbital trauma, surgery, or local injection causing a retrobulbar hematoma. It may also be seen with fulminant orbital cellulitis, intraorbital abscess, orbital emphysema, inflammation, or tumor. Less commonly it can be seen following large-volume resuscitation after burn injury, spontaneous bleeding from vascular anomalies, extravasated contrast material, and position-dependent edema causing an acute rise in orbital pressure.

Clinical Presentation

Signs and symptoms include decreased visual acuity, afferent pupillary defect, periorbital pain, ocular pain, diplopia, restricted ocular motility, proptosis, ecchymosis, chemosis, decreased visual fields, optic disc edema, retinal venous congestion, central retinal artery pulsation, pale optic disc, and a cherry-red macula.

Diagnosis

Diagnosis is primarily clinical examining visual acuity, pupillary response, intraocular pressure, extraocular motility, and fundoscopic examination. In the setting of rapidly progressing signs and symptoms with vision loss and an afferent pupillary defect, there should be no delay for imaging or testing. When clinically appropriate, imaging with a CT or MRI of the orbits may confirm the diagnosis.

Differential Diagnosis

Idiopathic orbital inflammation
Thyroid eye disease
Ruptured dermoid cyst
Orbital neoplasm
Direct injury from surgical dissection
Anterior ischemic optic neuropathy
Endophthalmitis
Globe rupture

Prophylaxis

Avoiding nose blowing, Valsalva, or coughing may minimize the risk of orbital hemorrhage or emphysema in patients with orbital trauma.

Avoiding platelet inhibitors and blood thinners when possible in patients undergoing orbital surgery. Intraoperative meticulous hemostasis should be achieved and excision of orbital fat should be performed under direct visualization in order to avoid excess traction into deep orbital fat.

Gentle awakening for general anesthesia with adequate pain and nausea control and suppression of the cough reflex to minimize straining.

Prompt antibiotics or anti-inflammatory agents in cases of orbital cellulitis or inflammation may minimize orbital pressure.

Therapy

Treatment of acute vision loss with orbital compartment syndrome should be done emergently with lateral canthotomy and inferior cantholysis for orbital decompression. If it fails to relieve orbital tension and restore perfusion to the optic nerve and retina, superior cantholysis should be performed. If there is no improvement within a few minutes, then the orbital septum should be divided from its attachment to the orbital rims. Other indications for decompression include intraocular pressure (IOP) greater than 40 mmHg, relative afferent pupillary defect, ophthalmoplegia, cherry-red macula, and optic nerve head pallor.

In postoperative tight orbit due to orbital hemorrhage decompressing the surgical incision, evacuating the hematoma and cauterizing bleeding vessels.

In most patients, the lateral canthus will heal spontaneously; however, if a cosmetic deformity or lower lid ectropion persists, repair can be performed.

Pharmacologic therapy with ocular hypotensive medications including beta-blockers (i.e., timolol), alpha-agonists (i.e., brimonidine), and carbonic anhydrase inhibitors (i.e., dorzolamide or acetazolamide). May also consider corticosteroids to decrease inflammation and antimicrobials for infectious etiology.

Prognosis

Delaying treatment with orbital decompression is more likely to result in permanent vision loss.

Epidemiology

Tight orbit is rare, but occurs most commonly following orbital trauma or postoperative complications of eye surgery.

Tissue Adhesives, Cyanoacrylate, for Anterior Segment

Vishal Jhanji[1,2] and Rasik B. Vajpayee[2]
[1]Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Kowloon, Hong Kong, China
[2]Centre for Eye Research Australia, University of Melbourne, Parkville, VIC, Australia

Synonyms

Adhesive; Glue

Indications

Corneal perforations <3 mm diameter, fixation of conjunctival graft during pterygium surgery, fixation of amniotic membrane graft.

Contraindications

Active infection; large perforations; allergy to glue constituents.

Techniques and Principles

The use of tissue adhesives in ophthalmology can be dated back to 1950 (Tassman 1950; Bhatia 2006). A variety of synthetic and biological tissue adhesives are available; however, only a few of these are being used on an off-label basis. Ocular adhesives can be grouped as (1) cyanoacrylate based, (2) fibrin/blood based, and (3) polyethylene glycols.

Cyanoacrylate-Based Adhesives

Cyanoacrylate is the most commonly used ocular tissue adhesive possibly related to its ease of availability and low cost as compared to other adhesives. Although the initial use was limited to closure of corneal perforation, they have been used for cataract wound closure, leaking blebs, retinal detachment surgery, scleral reinforcement, attachment of muscles to ocular prosthetics, temporary tarsorrhaphy, punctal occlusion, blepharoplasty, and skin closure after DCR.

Available preparations of corneal glue for clinical use include the following:

- Indermil (butyl-2-cyanoacrylate; Sherwood, Davis and Geck, St Louis, MO, USA)
- Histoacryl (butyl-2-cyanoacrylate; B. Braun, Melsungen, Germany)
- Histoacryl Blue (*N*-butyl-2-cyanoacrylate; B. Braun)
- Nexacryl (*N*-butyl-cyanoacrylate; Closure Medical, Raleigh, NC, USA)
- Dermabond (2-octyl-cyanoacrylate; Closure Medical)

Commercially available "super glue" (methyl-2-cyanoacrylate) appears to be more toxic than the other acrylate derivatives.

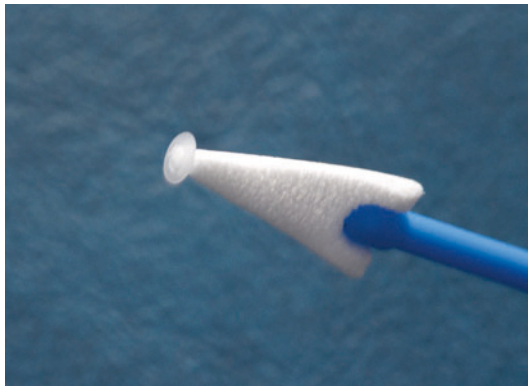
Cyanoacrylate glue provides a bacteriostatic effect at the time of application. It can inhibit polymorphonuclear neutrophil migration, therefore preventing or delaying stromal melting. Cyanoacrylate glue can be used for corneal perforations

related to herpes simplex, keratoconjunctivitis sicca, alkali burns, radiation keratitis, rheumatoid arthritis, and Stevens-Johnson syndrome. In cases with corneal perforation <3 mm in diameter, direct early application of cyanoacrylate adhesive to the ulcer bed and adjacent basement membrane plus a bandage contact lens is effective in the interruption of progressive corneal stromal melting. A small amount of glue should be applied in a controlled manner, avoiding excessive spillage. An alternative method involves creation of a mesh with 10-0 nylon sutures at the site of corneal perforation before the application of glue.

Surgical Technique

Glue application should be performed in a sterile environment preferably under an operating microscope. Application can be performed in selected cases on slit lamp as well. A 2- to 3-mm dermatological punch is used to trephine a circular disk from a sterile disposable drape (Fig. 1). A small amount of chloramphenicol ointment or K-Y jelly is placed on the flat end of a cotton-tipped applicator, and the disk is then stuck onto the ointment (Fig. 2). A few drops of topical anesthesia are applied to the eye. A non-compressing lid speculum is used to separate the lids gently. The loose epithelium and necrotic tissue around the perforation site are removed carefully. The perforation site should be as dry as possible for the glue to stick. If the anterior chamber is flat, a small amount of air or viscoelastic may be injected to form the chamber to avoid incarceration of iris or other tissues to the adhesive. One drop of adhesive is then applied to the trephined disk, and with further drying, the adhesive is directly applied to the area of perforation. The polymerization process will take place in several minutes. If a small leak remains, additional applications adjacent to the existing plug may be applied. Multiple reapplications are not recommended because this will enlarge the defect. After solidification, the area should be dried and examined with fluorescein dye for further leaks. A bandage contact lens is applied at the end of the procedure. The patient should be examined a few minutes later to ensure the glue/disk contact lens complex is in situ and the anterior chamber is deepening. A protective shield should be placed.

Tissue Adhesives, Cyanoacrylate, for Anterior Segment, Fig. 1 Corneal gluing set



Tissue Adhesives, Cyanoacrylate, for Anterior Segment, Fig. 2 Plastic, circular disk stuck to the tip of a sponge with chloramphenicol ointment

The postoperative treatment includes topical antibiotic therapy and an aqueous suppressant. In cases of infectious perforations, patients should continue their medications. Ideally the glue should remain in position for as long as possible, but careful monitoring is required because the risk of glue dislodgement and re-perforation is high.

Fibrin-Based Adhesives

The Food and Drug Administration has approved the use of fibrin glue for hemostasis; however, the ophthalmic use of fibrin glue has increased tremendously in the past few years. It has been used for closure of impending as well as frank corneal perforations and penetrating corneal transplant wounds, sealing of traumatic lens capsule lacerations, conjunctival closure after surgery, lamellar keratoplasty, repair of leaking blebs, and wound closure in blepharoplasty. It is being widely used to anchor amniotic membrane grafts as well as conjunctival autografts after pterygium surgery.

The main advantages of fibrin tissue adhesives over cyanoacrylate-based tissue adhesives in that they solidify quickly and cause less discomfort. As compared to cyanoacrylate glue, biological glues start to degrade faster and have no bacteriostatic effects. There is a risk of transmission of prion/viral diseases with the use of bovine products in its constituents. The fibrinogen in commercial preparations is vapor-heated and freeze-dried to minimize the risk of pathogen transmission.

Outcomes

The outcomes of corneal gluing have been reported to be very promising especially if used early in the course of diseases. Successful corneal gluing may obviate the need for other surgical treatments. Jhanji et al. (2011) have shown improved visual outcomes with reduced enucleation rate. However, another report showed that the success of cyanoacrylate corneal gluing might not be high in cases with herpetic corneal perforations (Moorthy et al. 2010).

Fibrin glue has been increasingly used in pterygium surgery to fix the conjunctival graft on bare sclera. The grafts secured with fibrin glue during pterygium surgery were found to be stable. The use of fibrin glue was associated with less inflammation as compared to sutures (Srinivasan et al. 2009).

Complications

Complications have been reported with the use of fibrin-based adhesives after pterygium surgery, most commonly graft dehiscence or loss. A potential complication for fibrin glue is viral transmission although it has not been reported so far.

Synonyms

Adie syndrome; Adie's tonic pupil; Holmes-Adie syndrome; Little old Adie's pupil

Definition

The tonic pupil is characterized by a pupil that poorly reacts to light but reacts better and tonically to near. The tonic pupil can be caused by damage to the parasympathetic innervation of the ciliary ganglion and postganglionic fibers to the eye.

Etiology

Damage to the parasympathetic ciliary ganglion or the postganglionic nerves produces a tonic pupil. After damage in this location, denervation supersensitivity develops. Because 30 times more axons innervate the ciliary body than the pupil, reinnervation may cause axons to accidently reroute to the pupil rather than to the ciliary body. This aberrant reinnervation produces accommodation-induced tonic near reaction. Adie's pupil is typically regarded as idiopathic. Up to 20% of Adie's pupils present bilaterally with an annual rate of 4% bilateral involvement/year (Figs. 1 and 2).

Clinical Presentation

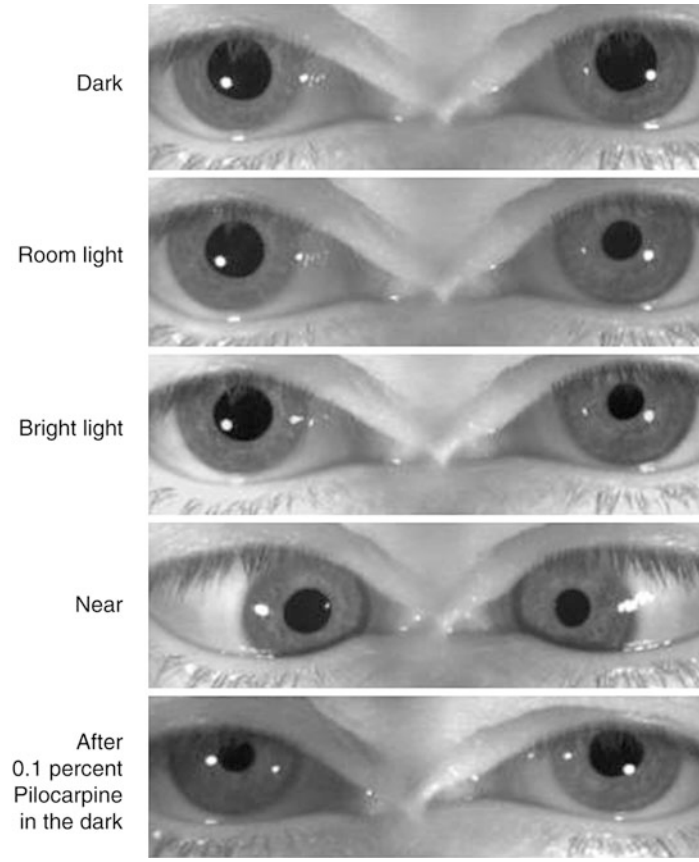
Patients with the tonic pupil usually present with anisocoria. On examination, the tonic pupil shows poor or no pupillary light reaction but a better near reaction (i.e., light-near dissociation).

Diagnostics

The anisocoria in the tonic pupil is worse in the light and better in the dark. Examining old photographs can help in distinguishing whether the anisocoria is an acute or chronic process.

Pharmacological Testing

Topical 0.1% pilocarpine often reveals cholinergic supersensitivity in the tonic pupil. Pilocarpine should be applied in both eyes with the fellow eye



Tonic Pupil (Adie's Pupil), Pharmacological Testing for, Fig. 1 Adie's pupil in R. eye – (**a**, **b**) anisocoria greater in the light than in the dark; (**c**) improved constriction to light-near dissociation than to light; (**d**) improved constriction after 0.1 % pilocarpine application due to denervation supersensitivity (from the University of Iowa Neuro-ophthalmology division)

Tonic Pupil (Adie's Pupil), Pharmacological Testing for, Fig. 2 Bilateral Adie's pupil (National Institute of Neurological Disorders and Stroke 2013)

acting as a control. Pupillary constriction to low-dose pilocarpine is evidence for denervation supersensitivity. Only 80% of patients with Adie's pupil however demonstrate cholinergic supersensitivity. In addition, cholinergic supersensitivity has also been noted in patients with CN III preganglionic lesions.

Differential Diagnosis

Local orbital syndrome and autonomic neuropathies (e.g., Charcot-Marie Tooth disease and Guillain-Barre syndrome), orbital infection and inflammation, trauma, surgery local anesthesia due to an inferior dental block, or retrobulbar

alcohol injection can present with a tonic pupil. Damage to the ciliary ganglion including surgery and laser therapy may result in a tonic pupil as well.

Prophylaxis

There is no prophylaxis for Adie's pupil.

Therapy

Most patients do not require treatment; however some patients with tonic pupil may benefit from reassurance, bifocal glasses (unilateral frosted or unequal power), or intermittent as needed low-dose pilocarpine.

Prognosis

Most tonic pupils are Adie's pupils and thus are benign and only require supportive care. **In many cases**, **the pupil may constrict even further over time**, **leading to a "little old Adie's" pupil**.

Epidemiology

Idiopathic Adie's pupils predominate in females with a 2.6:1 ratio. The mean age is 32 years, although it has been found to appear in all ages. Adie's pupils occur in about 0.2% of the population at any given time.

Topical Anesthesia in Eye Surgery

Armin Wolf[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians Universität München, München, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Surface anesthesia; Topical anesthesia

Definition

Application of local anesthetics to the surface in order to block nociception. In ophthalmology, this is used for anesthesia of the cornea and the anterior part of the globe.

Indication

There is a wide indication for topical anesthesia (TA). It ranges from foreign body extraction to cataract surgery, keratoplasty, and glaucoma surgery.

Contraindication

Several groups of contraindications have to be distinguished:

Medical contraindications: These include allergy to anesthetics as well as abuse of local anesthetics to treat chronic ocular pain. This may result in corneal ulceration.

Surgical contraindications: Topical anesthesia does only block nociception within the anterior part of the globe, i.e., corneal, conjunctival, and anterior scleral anesthesia. Procedures that involve rather posterior structures are therefore not subject to topical anesthesia. Additionally, the durance of local anesthesia is somewhat shorter than in needle block anesthesia. In case of prolonged surgery time (due to procedure or inexperienced surgeon) needle block anesthesia is therefore of advantage.

Topical anesthesia does not cause motor block. Therefore, full mobility of globe as well as patient movements due to increased discomfort are limitations of TA. TA should therefore be restricted to planned and easy procedures in otherwise healthy patients. Procedures should be performed by experienced surgeons.

Use and Dosage

Local anesthetic is put on the surface of the eye either as drop or gel until a sufficient anesthesia is achieved. Some authors also perform intracameral anesthesia in order to aid topical anesthesia.

Adverse Reactions

Local anesthetics – even though only in contact with conjunctiva may cause allergic reactions. Long-term use to treat ocular pain is strictly contraindicated. In rare cases, corneal epithelial, endothelial, and retinal toxicity have been described.

Interactions

Local anesthetics may interact with other topical drugs, for example, antiglaucomatosa, if applied shortly thereafter.

TASS

Definition

Sterile inflammatory reaction of unknown incidence that can occur after anterior segment surgery.

Etiology

Administration of solutions of inappropriate chemical composition during anterior segment surgery.

Various entities have been shown to cause toxic anterior segment syndrome. These include, but are not limited to, endotoxin; denatured ophthalmic viscosurgical devices; preservatives such as benzalkonium chloride, bisulfites, and metabisulfites; heavy metal residue; fine-matter particulates; and substances introduced into the anterior chamber that are at a pH or concentration that is toxic to the endothelial cells. In addition, residue of materials used in the cleaning and sterilization of ophthalmic instruments are a cause of toxic anterior segment syndrome.

Occurrence

After administration of solutions of inappropriate chemical composition during surgery, a sterile anterior chamber inflammation develops 12–48 h after surgery. Endophthalmitis as a differential diagnoses should be ruled out by bacterial cultures. Toxic anterior segment syndrome responds to steroid treatment. Patients may present with blurred vision and pain, but most cases are asymptomatic. Clinically, edema of the cornea can be observed. Inflammatory cells with hypopyon, fibrous reaction, and aqueous flare may be found as a consequence of the breakdown of the blood-aqueous barrier. Inflammation of the trabecular meshwork may cause a rise of intraocular pressure. Prognosis is variable according to the degree of toxic damage.

Classification

Cases limited to the corneal endothelium are called toxic endothelial cell destruction syndrome.

Synonyms

Chemical-induced optic neuropathy; Drug-induced optic neuropathy; Nutritional amblyopia; Tobacco-alcohol amblyopia

Definition

Visual impairment due to optic nerve damage from toxic optic neuropathy (TON). TON typically preferentially affects the papillomacular bundle bilaterally by a nutritional deficiency or accumulation of a toxic substance to the optic nerve.

Etiology

Causes of nutritional/toxic include:

I. Nutritional deficiency including commonly deficiencies in vitamin B_{12} (cyanocobalamin) and folate as well as less commonly other vitamins (e.g., thiamine, pyridoxine, niacin, riboflavin)
II. Substance/drug toxicity
    1. Drug-induced (e.g., most commonly ethambutol but also isoniazid, linezolid, disulfiram, tamoxifen, quinine, chloramphenicol, amiodarone, dapsone, 5-fluorouracil).
    2. Chemical-(toxin) induced (e.g., methanol, ethylene glycol)
    3. Heavy metal poisoning (e.g., chronic lead exposure, thallium, arsenic)

Poor diet (e.g., alcohol consumption, strict vegan diet, eating disorder), bariatric or other gastrointestinal surgery (partial or complete ileum resection) and autoimmune (e.g., pernicious anemia) disorders can cause vitamin deficiency states. Pernicious anemia is an autoimmune disease that produces autoantibodies against intrinsic factor that leads to impaired vitamin B_{12} absorption. Like vitamin B_{12} deficiency, a poor diet and alcohol abuse can also lead to separate or concomitant folate deficiency.

Ethambutol (EMB) is antituberculosis (TB) agent and is also used against other mycobacterium (e.g., mycobacterium avium complex). EMB causes a dose-dependent toxic optic

neuropathy bilaterally. The incidence of EMB-induced optic neuropathy ranges from 1% to 5% and the risk factors associated with toxicity include diabetes mellitus, chronic renal failure, alcoholism, elderly patients, children, other concomitant ocular defects, the presence of EMB-induced peripheral neuropathy, and a dose greater than 15 mg/kg/day. Other toxic optic neuropathies are usually diagnosed by an appropriate exposure history.

Clinical Presentation

Nutritional/toxic optic neuropathy typically presents as a, painless, slowly progressive bilateral, simultaneous generally symmetric loss of central vision often preceded or accompanied by color vision deficits (dyschromatopsia). Since the papillomacular bundle is predominantly affected by these disorders, patients typically present with central or cecocentral scotoma, dyschromatopsia, and normal disk appearance at onset but eventual temporal pallor of the optic disks OU. The color vision deficits can present early due to the high concentration of color sensitive cones within the macula. Due to the systemic nature of the problem, the vision loss is typically bilateral, central, and symmetric. Therefore, typically no relative afferent visual field defect (RAPD) is present, but the pupillary response may be sluggish bilaterally. An RAPD may be present, however, in bilateral but asymmetric disease.

Many of the drug-induced toxic neuropathies present with similar clinical symptoms. EMB produces a dose-dependent toxic optic neuropathy in which patients often present with visual symptoms at 2–8 months after initiation of the drug. Some believe that the earliest sign of visual dysfunction is dyschromatopsia (especially blue yellow). As in other toxic-nutritional optic neuropathies, the most common visual field defects are bilateral central or cecocentral scotomas. However, other visual field defects are possible as well such as peripheral defects (e.g., peripheral periaxial toxicity) or even pseudobitemporal hemianopsia from break out of the central or cecocentral scotoma into the temporal periphery bilaterally. Patients with pseudobitemporal hemianopsia from EMB toxicity, however, present with concomitant loss of central visual field and visual acuity OU.

Other causes of toxic optic neuropathy include methanol or less commonly ethylene glycol poisoning. Unlike in most other nutritional and toxic optic neuropathies, chemical-induced optic neuropathies (i.e., methanol or ethylene glycol poisoning) present with an acute, bilateral and severe vision loss sometimes progressing to complete blindness. The history of exposure is usually diagnostic in these cases.

Diagnostics

The first step in diagnosing a patient with suspected toxic-nutritional optic neuropathy is a detailed history of the patient's medical/surgical history (e.g., gastric bypass, abdominal surgery), diet (e.g., alcohol intake, eating disorder, vegan diet), and medications (e.g., EMB, other). A comprehensive review of systems should also be performed including symptoms and signs of toxicity (e.g., peripheral sensory symptoms, anemia, mental status changes, nyctalopia, and gait disturbance).

The examination should include a complete eye exam, but formal visual field testing is crucial to show the specific type of visual field defect (e.g., central or cecocentral scotoma with preservation of peripheral fields or less commonly peripheral visual field loss in periaxial forms). Fundus examination is typically normal in toxic-nutritional and hereditary optic neuropathy at onset but may eventually show temporal pallor OU. Optical coherence tomography (OCT) might demonstrate retinal nerve fiber layer dropout in the papillomacular bundle OU over time.

Suggested lab testing depending on the clinical history and exam might include: complete blood

count (CBC) with differential, serum B_{12}, serum and red blood cell (RBC) folate and if indicated other vitamin levels. If the level of vitamin B_{12} is low or borderline, obtaining plasma homocysteine and methylmalonic acid levels can confirm more long-standing B_{12} deficiency states. Even with borderline B_{12} levels, both homocysteine and methylmalonic acid can be elevated – proving a functional deficiency of the nutrient. If only homocysteine is elevated, then a concomitant folate deficiency may also be present. These findings are due the fact that cobalamin (B_{12}) is a cofactor in the conversion of homocysteine to methionine as well as methylmalonyl-CoA to succinyl-CoA. Folate is involved in the methylation of cobalamin to methylcobalamin that in turn methylates homocysteine to methionine. Folate is not involved in the conversion of methylmalonyl-CoA to succinyl-CoA.

Patients starting on ethambutol or isoniazid should receive a baseline initial screening ophthalmic evaluation including formal visual field testing, color vision, dilated fundoscopic exam, visual acuity, and other baseline screening modalities (e.g., optical coherence tomography (OCT) of the optic nerve). OCT analysis of the retinal nerve fiber layer of the optic disk in EMB toxic optic neuropathy may show nerve fiber layer thinning that can appear prior to obvious changes in appearance of the fundus. Although generally an acute toxicity, retinal examination of patients with methanol poisoning can show edema of the peripapillary nerve fiber layer and optic disk that eventually leads to bilateral and severe optic atrophy.

Patients with clinical symptoms consistent with a proven diagnosis of toxic/nutritional or hereditary optic neuropathy may still require further testing including a neuroimaging study and preferably magnetic resonance imaging (MRI) of brain and orbit with and without contrast with fat saturation. Some patients with progressive unexplained optic neuropathy may need lumbar puncture and further evaluation for infectious, inflammatory, ischemic, infiltrative, or paraneoplastic etiologies. Leber hereditary optic neuropathy (LHON) mitochondrial DNA mutation testing and heavy metal screening could be considered even in patients with B_{12} or folate deficiency as some patients have multifactorial disease.

Differential Diagnosis

1. Compressive optic neuropathy/infiltrative optic neuropathy
2. Maculopathy/macular dystrophy
3. Bilateral inflammatory/infectious e.g., syphilis
4. Bilateral demyelinating optic neuropathy
5. Radiation optic neuropathy

Prophylaxis

Non applicable

Therapy

The first step in the treatment of nutritional deficiency is vitamin replacement. In addition, the ophthalmologist should recommend discontinuation of smoking/alcohol use. When drug or substance toxicity is suspected, the offending agent (e.g., EMB) should be discontinued but only in consultation with the prescribing physician. Treatment should then depend on the cause of the disorder. Treatment for chemical-induced optic neuropathies includes correction of the concomitant acute systemic deficiencies and correction of electrolyte abnormalities including metabolic acidosis with administration of IV sodium bicarbonate. In methanol poisoning, although ethanol can also be administered to compete with the metabolism of methanol into its more destructive and toxic by-products, fomepizole is generally considered first line. Hemodialysis is indicated if methanol is detected at blood levels over 50 mg/dL.

Treatment for isoniazid-induced optic neuropathy includes administration of pyridoxine 25–100 mg/day to help stabilize or possibly reverse the neuropathy and may occur independent simultaneously with EMB toxicity.

Prognosis

Depending on the duration and severity of the findings, many cases of nutritional optic neuropathy have a favorable prognosis. However, permanent optic atrophy or temporal disk pallor can occur depending on the timing of diagnosis and start of treatment. Patients usually see improvement within 1–2 months of nutritional supplementation although in some individuals' improvement may not occur for 1 year.

Patients with ethambutol toxicity may still recover normal visual function after drug discontinuation. However, if significant optic disk pallor is already present, visual recovery is less likely to occur. Thus, early recognition and discontinuation of the drug are critical before the development of irreversible optic atrophy.

Synonyms

Autosomal dominant optic atrophy; Autosomal recessive optic atrophy; Chemical-induced optic neuropathy; Drug-induced optic neuropathy; Leber's hereditary optic neuropathy (LHON); Nutritional amblyopia; Tobacco-alcohol amblyopia

Definition

Visual impairment due to optic nerve damage that preferentially affects the papillomacular bundle bilaterally by a nutritional deficiency, accumulation of a toxic substance to the optic nerve, or an inherited genetic mutation that may act independently or together.

Etiology

Causes of nutritional/toxic and hereditary optic neuropathies include:

I. Nutritional deficiency including deficiencies in vitamin B12 (i.e., cyanocobalamin), folate, and other vitamins (e.g., thiamine, pyridoxine, niacin, riboflavin)
II. Substance/drug toxicity
    1. Drug induced (e.g., most commonly ethambutol but also isoniazid, linezolid, disulfiram, tamoxifen, quinine, chloramphenicol, amiodarone, dapsone, 5-fluorouracil, etc.)
    2. Chemical (toxin)-induced (e.g., methanol, ethylene glycol)
    3. Heavy metal poisoning (e.g., chronic lead exposure, thallium, arsenic)
III. Hereditary
    1. Leber's hereditary optic neuropathy (LHON)
    2. Autosomal dominant optic atrophy (ADOA), commonly Kjer optic neuropathy
    3. Autosomal recessive (infantile) optic atrophy (AROA)
    4. Rare other inherited forms (X-linked)

While nutritional optic neuropathies are often associated with multiple vitamin deficiencies, vitamin B12 and folate are the most common causes. Poor diet (e.g., alcohol consumption, strict vegan diet, eating disorder), bariatric or other gastrointestinal surgery (partial or complete ileum resection) and autoimmune (e.g., pernicious anemia) can cause vitamin deficiency states. Pernicious anemia is an autoimmune disease that produces autoantibodies against intrinsic factor that leads to impaired vitamin B12 absorption. Like vitamin B12 deficiency, a poor diet and alcohol abuse can also lead to separate or concomitant folate deficiency.

Ethambutol (EMB) is an antituberculosis (TB) agent and is also used against other mycobacteria (e.g., mycobacterium avium complex). EMB cause a dose-dependent toxic optic neuropathy bilaterally. The incidence of EMB-induced optic neuropathy ranges from 1% to 5%, and the risk factors associated with toxicity include diabetes mellitus, chronic renal failure, alcoholism, elderly patients, children, other concomitant ocular defects, the presence of EMB-induced peripheral neuropathy, and a dose greater than 15 mg/kg/day. Other toxic optic neuropathies are usually diagnosed by an appropriate exposure history.

LHON is a rare disease caused by the inheritance of maternal mitochondrial DNA mutations (95% of LHON) at positions 11778, 14484, or 3460, predominately affecting young adult males. Production of dysfunctional adenosine triphosphate (ATP) occurs as a result of these mutations, leading to defective oxidative phosphorylation in the highly energy-dependent optic nerve. LHON can be precipitated by many environmental factors including nutritional deprivation, alcohol consumption, smoking, acute illness, and psychological stress. ADOA is the most common cause of the hereditary optic neuropathies with an estimated disease prevalence of 1:12,000–1:50,000. Other less common hereditary optic neuropathies are AD, AR, and X-linked.

Clinical Presentation

Nutritional/toxic optic neuropathy typically presents as a painless, slowly progressive bilateral, simultaneous generally symmetric loss of central vision often preceded or accompanied by color vision deficits (dyschromatopsia). Since the papillomacular bundle is predominantly affected by these disorders, patients typically present with central or cecocentral scotoma, dyschromatopsia, and normal disk appearance at onset but eventual temporal pallor of the optic disks OU. The color vision deficits can present early due to the high concentration of color-sensitive cones within the macula. Due to the systemic nature of the problem, the vision loss is typically bilateral, central, and symmetric. Therefore, typically no relative afferent visual field defect (RAPD) is present, but the pupillary response may be sluggish bilaterally. An RAPD may be present however in bilateral but asymmetric disease.

Many of the drug-induced toxic neuropathies present with similar clinical symptoms. EMB produces a dose-dependent toxic optic neuropathy in which patients often present with visual symptoms at 2–8 months after initiation of the drug. Some believe that the earliest sign of visual dysfunction is dyschromatopsia (especially blue-yellow). As in other toxic-nutritional optic neuropathies, the most common visual field defects are bilateral central or cecocentral scotomas. However, other visual field defects are possible as well such as peripheral defects (e.g., peripheral or periaxial toxicity) or even pseudo-bitemporal hemianopia from breakout of the central or cecocentral scotoma into the temporal periphery bilaterally. Patients with pseudo-bitemporal hemianopia from EMB toxicity however present with concomitant loss of central visual field and visual acuity OU.

Other causes of toxic optic neuropathy include methanol or less commonly ethylene glycol poisoning. Unlike in most other nutritional and toxic optic neuropathies, chemical-induced optic neuropathies (e.g., methanol or ethylene glycol poisoning) present with an acute, bilateral, and severe vision loss sometimes progressing to complete blindness. The history of exposure is usually diagnostic in these cases.

Patients with LHON are typically young males (aged 11–30) who present with sudden, painless, bilateral simultaneous, or rapidly sequential central/cecocentral scotomas. In contrast, the other hereditary optic neuropathies (e.g., ADOA) classically begin during childhood, often insidiously, and then the visual loss OU progressively worsens throughout life. It characteristically presents with central or centrocecal scotomas OU with decreased color vision and is often detected by childhood vision screening exams as mild reduction in visual acuity. Hereditary optic neuropathies can be associated with other neurologic deficits such as congenital or progressive deafness or ataxia. Patients with autosomal recessive (infantile) optic atrophy (AROA) typically present with much more severe visual loss OU with nystagmus at birth or within 2 years of age. AROA can also be associated with congenital deafness, spastic quadriplegia, and dementia.

Diagnostics

The first step in diagnosing a patient with suspected toxic-nutritional optic neuropathy is a detailed history of the patient's medical/surgical history (e.g., gastric bypass, abdominal surgery), diet (e.g., alcohol intake, eating disorder, vegan diet), and medications (EMB, other). A family history is crucial for detecting hereditary optic neuropathies and for describing the pedigree to define the inheritance pattern. Many patients with LHON however have no family history of visual loss. A comprehensive review of systems should also be performed including symptoms and signs of toxicity (e.g., peripheral sensory symptoms, anemia, mental status changes, nyctalopia, and gait disturbance).

The examination should include a complete eye exam, but formal visual field testing is crucial to show the specific type of visual field defect (central or cecocentral scotoma with preservation of peripheral fields). Fundus examination is typically normal in toxic-nutritional and hereditary optic neuropathy at onset but may eventually show temporal pallor OU. Optical coherence tomography (OCT) might demonstrate retinal nerve fiber layer drop out in the papillomacular bundle OU over time.

Suggested lab testing depending on the clinical history and exam might include complete blood count (CBC) with differential, serum B_{12}, serum and red blood cell (RBC) folate, and syphilis serology. If the level of vitamin B12 is low or borderline, obtaining plasma homocysteine and methylmalonic acid levels can confirm more long-standing B12 deficiency states. Even with borderline B12 levels, both homocysteine and methylmalonic acid can be elevated – proving a functional deficiency of the nutrient. If only homocysteine is elevated, then a concomitant folate deficiency may also be present. These findings are due the fact that cobalamin (B12) is a cofactor in the conversion of homocysteine to methionine as well as methylmalonyl-CoA to succinyl-CoA. Folate is involved in the methylation of cobalamin to methylcobalamin that in turn methylates homocysteine to methionine. Folate is not involved in the conversion of methylmalonyl-CoA to succinyl-CoA.

Patients starting on ethambutol or isoniazid should receive a baseline initial screening ophthalmic evaluation including formal visual field testing, color vision, dilated fundoscopic exam, visual acuity, and other baseline screening modalities (e.g., optical coherence tomography (OCT) of the optic nerve). OCT analysis of the retinal nerve fiber layer of the optic disk in EMB toxic optic neuropathy may show nerve fiber layer thinning that can appear prior to obvious changes in appearance of the fundus. Although generally an acute toxicity, retinal examination of patients with methanol poisoning can show white striated edema of the peripapillary retina that eventually leads to bilateral and severe optic atrophy.

Patients with clinical symptoms consistent with a proven diagnosis of toxic/nutritional or hereditary optic neuropathy may still require further testing including a neuroimaging study and preferably magnetic resonance imaging (MRI) of the brain and orbit with and without contrast with fat saturation. Some patients with progressive unexplained optic neuropathy may need lumbar puncture and further evaluation for infectious, inflammatory, ischemic, infiltrative, or paraneoplastic etiologies. Leber hereditary optic neuropathy (LHON) mitochondrial DNA mutation testing and heavy metal screening could be considered even in patients with B12 or folate deficiency as some patients have multifactorial disease.

Differential Diagnosis

1. Compressive optic neuropathy/infiltrative optic neuropathy
2. Maculopathy/macular dystrophy
3. Bilateral inflammatory/infectious, e.g., syphilis
4. Bilateral demyelinating optic neuropathy
5. Radiation optic neuropathy

Therapy

The first step in the treatment of nutritional deficiency is vitamin replacement. In addition, the ophthalmologist should recommend discontinuation of smoking/alcohol use. When drug or substance toxicity is suspected, the offending agent (e.g., EMB) should be discontinued but only in consultation with the prescribing physician. Treatment should then depend on the cause of the disorder. Treatment for chemical-induced optic neuropathies includes correction of the concomitant acute systemic deficiencies and correction of electrolyte abnormalities including metabolic acidosis with administration of IV sodium bicarbonate. In methanol poisoning, ethanol can also be administered to compete with the metabolism of methanol into its more destructive and toxic by-products but has largely been supplanted by fomepizole. Hemodialysis is indicated if methanol is detected at blood levels over 50 mg/dL.

Treatment for isoniazid-induced optic neuropathy includes administration of pyridoxine 25–100 mg/day to help stabilize or possibly reverse the neuropathy and may occur independent of our simultaneously with EMB toxicity. Although there is no proven treatment for LHON, discontinuation of metabolic stressors (e.g., smoking and excessive alcohol use), vitamin supplementation, and perhaps treatment with coenzyme Q10 analogs may be helpful. A few clinical trials with idebenone have shown modest limited benefit but have been advocated by some authors.

Prognosis

Depending on the duration and severity of the findings, some cases of nutritional optic neuropathy have a favorable prognosis. However, permanent optic atrophy or temporal disk pallor can occur depending on the timing of diagnosis and start of treatment. Patients usually see improvement within 1–2 months of nutritional supplementation although in some individuals, improvement may not occur for 1 year.

Patients with EMB toxicity may still recover normal visual function after drug discontinuation. However, if significant optic disk pallor is already present, visual recovery is less likely to occur. Thus, early recognition and discontinuation of

the drug are critical before the development of irreversible optic atrophy.

There is currently no treatment for LHON; however, the prognosis of the disease can depend on the timing of diagnosis and the exact mutation of the gene. Patients with the 14484 mutation can have recovery of their vision but not until several months after the initial onset of vision loss. Patients with the 11778 mutation however have a much less favorable prognosis with over 75% becoming legally blind in both eyes.

Tractional Retinal Detachment

Francesco Boscia[1,2], Ermete Giancipoli[1,3] and Giuseppe D'Amico Ricci[1,2]
[1]A.O.U Sassari, Sassari, Sardegna, Italy
[2]Department of Surgical, Microsurgical, and Medical Sciences, Section of Ophthalmology, University of Sassari, Sassari, Italy
[3]Department of Ophthalmology, University of Bari Medical School, Bari, Italy

Definition

Retinal detachment is, by definition, a condition in which subretinal fluid accumulates in the space between the neurosensory retina and the underlying retinal pigment epithelium (RPE), causing the separation of the two layers. There are different types of retinal detachment, depending on the mechanism of subretinal fluid accumulation. Tractional retinal detachment (TRD) is the second most common type after rhegmatogenous retinal detachment (RRD). A tractional retinal detachment occurs when scar tissue or other abnormal tissue grows, pulling the retina away from the layer beneath. Sometimes retinal tears can develop as a consequence of the mechanical traction on the retina, but they do not represent the leading cause for the detachment.

Etiology

The retinal surface can be considered a scaffold for abnormal tissue growth into the vitreous cavity in different pathological conditions. The strict connection existing between the inner retina and the abnormal intravitreal tissue, combined with a progressive contraction of the latter, generates an inward mechanical force responsible for the separation of the neurosensory retina from the underlying RPE.

Different pathologies can generate this condition, often as a late stage complication.

Proliferative vitreoretinopathy (PVR) is the clinical syndrome associated with retinal traction and detachment in which cells with proliferative potential multiply and contract on retinal surfaces and in the vitreous compartment. PVR presents with a spectrum of severity ranging from subtle retinal wrinkling, to fixed folds and tears with rolled edges, and to total rigid retinal detachment, retinal shortening, and advanced periretinal proliferation.

PVR is characterized by proliferation of cells derived from retinal pigment epithelium, glia, or inflammatory recruitment on the retinal surfaces and within the vitreous gel. These metaplastic cells transdifferentiate and assume contractile properties through internal cellular contractile proteins and by laying down extracellular collagen. They multiply and grow along available scaffolding, either the retinal surfaces or elements of residual vitreous gel. Mass contraction leads to retinal wrinkles, folds, tears, and traction retinal detachment.

PVR is the most common cause of failure in retinal detachment surgery. It can occur in untreated eyes with retinal detachment, especially with vitreous hemorrhage, or after cryotherapy or even laser retinopexy, pneumatic retinopexy, scleral buckling or vitrectomy, and after a variety of surgical complications. It is common after penetrating injuries and a variety of conditions associated with prolonged inflammation.

Proliferative diabetic retinopathy is characterized by new vessel formation, usually arising from retinal veins, that grows into the vitreous cavity. VEGF, overexpressed by the ischemic retina, is the main driver of the neovascularization process.

Once the stimulus for the growth of new vessels is present, the path of subsequent growth taken by neovascularization is along the route of least resistance.

Neovascularization seems to grow more easily on a preformed connective tissue framework. Thus, a shallowly detached posterior vitreous face is a frequent site of growth of new vessels. The new vessels usually progress through a stage of further proliferation, with associated connective tissue formation.

As PDR progresses, the fibrous component becomes more prominent, with the fibrotic tissue being either vascular or avascular. The fibrovascular variety usually is found in association with vessels that extend into the vitreous cavity or with abnormal new vessels on the surface of the retina or disc. The avascular variety usually results from organization or thickening of the posterior hyaloid face. Vitreous traction is transmitted to the retina along these proliferations and may lead to traction retinal detachment.

The same mechanism can explain a late onset of a tractional retinal detachment as a complication of other retinal vascular pathologies such as retinal vein occlusion, sickling hemoglobinopathies, and retinopathy of prematurity (ROP).

Clinical Presentation

Vitreoretinal traction develops insidiously in most cases.

The visual field defect progresses slowly and may become stationary for months or years.

If the macula becomes involved, the patient will experience a drop in vision.

The retinal detachment has a concave configuration, with the highest elevation of the retina occurring in the site of traction. Tractional retinal detachment is shallower than the rhegmatogenous one, and the retina appears to be more rigid. Usually retinal breaks are absent and, even if in some cases, isolated, or multiple retinal breaks can be detected.

Extensive PVR has fixed folds with retinal detachment especially inferiorly and fine membranes bridging the valleys between folds, as well as decreased mobility of the detached retina. Advanced PVR with posterior vitreous detachment results in the eventual formation of a funnel-shaped detachment with a contracted equatorial membrane.

In proliferative diabetic retinopathy, two types of retinal detachments occur: those that are caused by traction alone (nonrhegmatogenous) and those caused by retinal break formation (rhegmatogenous). Characteristics of nonrhegmatogenous

(traction) detachment in PDR include the following:

- The detached retina usually is confined to the posterior fundus and infrequently extends more than two thirds of the distance to the equator.
- The detached retina has a taut and shiny surface.
- The detached retina is concave toward the pupil.
- No shifting of subretinal fluid occurs.

Occasionally, a spontaneous decrease in the extent of a traction detachment may occur, but this is the exception rather than the rule. Traction on the retina also may cause focal areas of retinoschisis, which may be difficult to distinguish from full-thickness retinal detachment; in retinoschisis, the elevated layer is thinner and more translucent.

Diagnosis

Tractional retinal detachment has to be differentiated from other forms of retinal detachment:

- Rhegmatogenous retinal detachment
- Exudative retinal detachment

An accurate fundus evaluation can be enough to separate these conditions.

Since different retinal vascular disorders, all leading to a tractional retinal detachment as a late step of their natural history, are sometimes clinically difficult to differentiate, ancillary exams are advocated:

- B-scan ultrasonography
- Fluorescence angiography
- OCT

Differential Diagnosis

- Rhegmatogenous retinal detachment
- Exudative retinal detachment
- Proliferative vitreoretinopathy
- Proliferative diabetic retinopathy
- Retinal vein occlusion
- Eales disease
- Retinopathy, hemoglobinopathies
- Retinopathy of prematurity

Prophylaxis

Patients with retinal vascular disorders should be strictly monitored in order to assess the progression of the disease. If neovascularization develops, a complete pan-retinal photocoagulation has to be performed. Several studies have shown that laser photocoagulation of ischemic retina, prior to the development of new vessels, does not reduce the risk of neovascularization and further related complications.

In retinopathy of prematurity, a close follow-up is strongly indicated. Patients should be treated with photocoagulation as indicated.

Therapy

Surgical intervention is the only therapeutic modality for this ocular condition.

In case of tractional retinal detachment without retinal breaks, the main surgical goal is to relieve traction in order to let the neurosensory retina get in contact with the retinal pigment epithelium.

In those cases in which both a tractional and a rhegmatogenous component are detected, the purpose of the surgery is not only to relieve the traction but also to seal the breaks.

Pars plana vitrectomy represents the technique of choice.

A complete vitrectomy with epiretinal membrane peeling (with forceps and/or vitrectomy probes) is indicated in cases of severe PVR. Perfluorocarbon liquid can be used during the procedure, in order to stabilize the posterior retina. Care must be taken during epiretinal membrane dissection in order not to create iatrogenic retinal breaks. If traction is generated by a subretinal membrane, this can sometimes be removed by using a vitreoretinal forceps after a small

retinotomy has been created to give access to the subretinal space.

If residual traction remains, subretinal membranes may not be excised and a relaxing retinectomy can be created.

Pars plana vitrectomy is also indicated in case of severe diabetic retinopathy, late stages of retinal vein occlusion with neovascularization and retinal detachment, and retinopathy of prematurity.

Particular care must be taken during the fibrovascular membrane dissection not to generate intraoperative bleeding (endodiathermy of neovascular tissue) and/or retinal breaks.

Intravitreal bevacizumab has been reported as a preoperative adjunct in vitrectomy for PDR. Anti-VEGF drugs seem to reduce the bleeding associated with the segmentation and delamination of fibrovascular membranes. However, in eyes with severe ischemia, the neovascularization regresses rapidly, but the resulting fibrous scar tissue may lead to the development or progression of TRD.

Prognosis

Visual prognosis depends on the underlying cause of TRD. In case of a macular involved retinal detachment, prognosis is quite poor, even after the anatomical integrity of the eye has been restored (retinal reattachment rate 80–90%).

Epidemiology

PVR is responsible for most failures of retinal reattachment surgery. It occurs in about 7% of eyes after retinal reattachment surgery. In 1 year, approximately 1,600 new cases of PVR are seen.

Diabetic retinopathy is the leading cause of blindness in the working age group. In the 1960s, prior to the advent of laser photocoagulation, up to 50% of patients with PDR were legally blind. With new techniques, currently only 5% of patients with PDR progress to legal blindness.

A recent estimate of the overall incidence of ROP is 0.17%, but it is nearly 16% for premature infants.

Overall, 65.8% of infants developed some degree of ROP, and 6% reached threshold.

The median onset of stage 1 ROP was 34 weeks GA. The median onset of threshold disease was 37 weeks, with a range of 33.6–42 weeks GA.

Transcaruncular Route, for Anterior Orbitotomy

Yasaman Mohadjer

The Aesthetic Institute of West Florida, Largo, FL, USA

Definition

A transconjunctival orbitotomy through the caruncle designed to access the medial orbital wall and extraperiosteal space.

Indications

This procedure is a very useful and direct approach to access the medial wall for medial wall decompressions, subperiosteal abscess drainage, or orbital fracture repair. This incision avoids skin incisions and vastly reduces the risk of visible scarring.

Contraindication

Contraindications for patients with any chronic or acute conjunctivitis or uncontrolled disease of the conjunctiva, such as ocular cicatricial pemphigoid. Also contraindicated in patients who are not medically stable for surgery (Cockerham et al. 2001; Nerad 2001; Levine 2003).

Techniques and Principles

In the operating room under sedation or general anesthesia, a Westcott scissors is used to make a vertical caruncular incision approximately in the middle of the caruncle. This may extend for approximately 10–15 mm and may be combined with an inferior transconjunctival incision for broader exposure. Blunt and sharp dissection is then carried out posteriorly and medially to avoid damage to the medial rectus until the area of interest is reached, usually the medial wall. At the end of the procedure, one or two chromic sutures may be used to close the caruncular incision (Cockerham et al. 2001; Nerad 2001; Levine 2003).

Outcome

Direct access to the medial wall with simple closure and minimal risk of scarring.

Complications

Risks include anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, and need for additional procedures.

Transconjunctival Route

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Definition

An anterior orbitotomy performed by creating incisions through the conjunctiva for access to a particular area, usually the inferior orbita or medial intraconal space.

Indications

To gain access to the orbit for optic nerve sheath fenestration medially or inferiorly for orbital fracture repair, decompression, abscess drainage, etc.

Contraindication

Lesion deeper in the orbit or not able to be accessed via anterior orbitotomy. Scarring diseases of the conjunctiva such as cicatricial pemphigoid. Any medical contraindication to surgery.

Techniques and Principles

A transconjunctival medial orbitotomy is performed with an incision made at the corneal limbus as a partial peritomy. The medial rectus can temporarily be disinserted from its origin for access to the medial intraorbital space (Fig. 1). This is often used for optic nerve fenestration or biopsy, or for medial rectus biopsy.

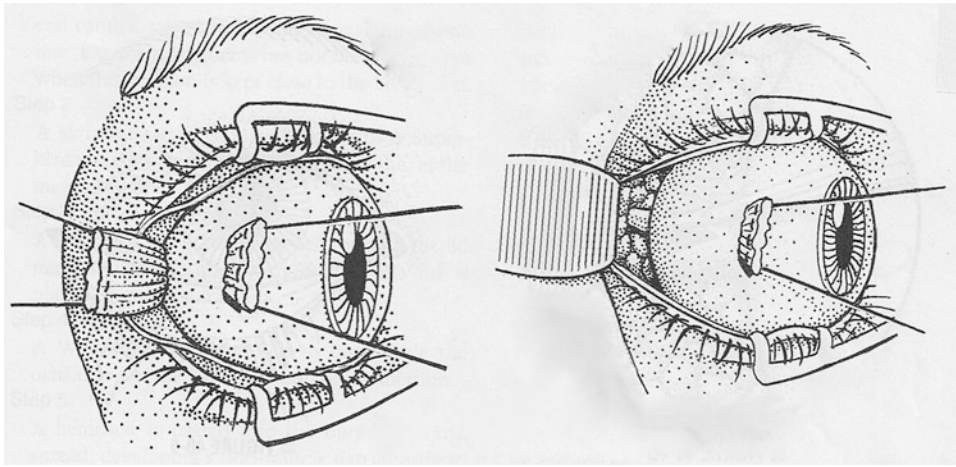
A transconjunctival lower eyelid orbitotomy is performed by an incision placed 1–2 mm beneath the inferior tarsal border dividing the retractors and the septum as necessary. The inferior extraconal space can be approached easily in this fashion without an external incision, eliminating the risk of potential scar. Furthermore, this approach may reduce the risk of lower eyelid retraction that may be more common with a transcutaneous, infraciliary incision. Furthermore, the transconjunctival incision can be combined with a lateral canthotomy and cantholysis for even broader access into the lateral orbit (Fig. 2) (Nerad 2001; Levine 2003).

Outcome

Allows exposure of the orbital contents while eliminating external incisions and therefore reducing risk of visible scarring.

Complications

Risks of the transconjunctival approach include risks associated with anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, ptosis, eyelid retraction, cicatricial entropion, and need for additional procedures.



Transconjunctival Route, Fig. 1 The transconjunctival approach to the medial orbitotomy. A peritomy has been performed and the medial rectus identified and disinserted from the globe (*left*). Transcutaneous Routes

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Synonyms

Eyelid crease incision; Infraciliary incision; Subciliary incision

Definition

An orbitotomy, usually anteriorly, approached via a skin incision. This may be through the upper eyelid crease or infraciliary line. It allows access to a specific area of the anterior 2/3 of the orbit, generally.

Indications

To access an area of the orbit for biopsy of a lesion, removal of a lesion, removal of a foreign body, or for fat or bony orbital decompression. The goal is to provide the most direct route within incisions that follow natural skin lines and minimizing the risk of scarring.

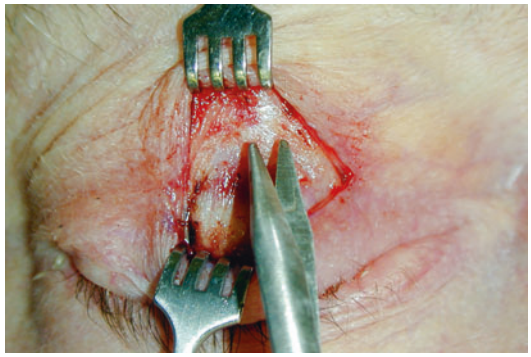
Contraindication

Lesion deeper in the orbit or not able to be accessed via anterior orbitotomy. Any medical contraindication to surgery.

Techniques and Principles

This procedure is generally performed in the operating room under sedation or general anesthesia. For superior lesions, an eyelid crease is marked (Fig. 1) and dissection is carried posteriorly

Transcutaneous Routes, Fig. 1 An eyelid crease incision is marked



Transcutaneous Routes, Fig. 2 Sharp and blunt dissection is carried out posteriorly. Here the Westcott scissors are aimed towards the septum for release and dissection in the transseptal plane

(Fig. 2), usually involving a transseptal incision to reach further back in the orbit or involving the lacrimal gland. More anterior lesions may not require opening of the septum. An inferior lesion may be approached via a transcutaneous incision in the subciliary area (Cockerham et al. 2001; Nerad 2001; Levine 2003).

Outcome

Allows for biopsy, lesion removal, foreign body removal, drainage of orbital abscess, and orbital decompression as necessary.

Complications

Risks of the transcutaneous approach include risks associated with anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, ptosis, eyelid retraction, and need for additional procedures (Cockerham et al. 2001; Nerad 2001; Levine 2003).

Transepithelial Photorefractive Keratectomy

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

T-PRK

Definition

Photorefractive keratectomy, in which the epithelial removal is performed by an excimer laser prior to stromal ablation.

Epidemiology

No epidemiological data available.

History

Transepithelial photorefractive keratectomy followed shortly after the first regular PRK was introduced in 1988.

Clinical Features

The corneal epithelium can be removed with a rotating brush, a surgical blade, an alcohol, or the excimer laser.

Please refer to the PRK section in this book for a detailed description of the PRK treatment and the features of the laser.

Tests

Thorough examination of the anterior segment with the slit lamp and corneal topography, pachymetry, and measurement of uncorrected and best spectacle-corrected visual acuity are mandatory to maintain best possible postoperative results.

Differential Diagnosis

Other types of surface ablation during PRK:

- PRK with alcohol, brush, and surgical blade

Etiology

See History section in the PRK chapter.

Treatment

After Bowman's layer is exposed, the excimer laser is focused on the surface in order to remove the right tissue. For myopic ablations, the central cornea is involved; for hyperopic ablations, the mid-periphery; and for astigmatic ablations, an area around the pupil. After the procedure, the surface is covered with a bandage contact lens, and postoperative medication is given.

Transient Light-Sensitivity Syndrome

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Delayed acute photophobia; Good acuity plus photophobia; TLSS

Definition

An episode of acute photophobia after femtosecond laser LASIK in absence of other clinical signs and symptoms. The onset of TLSS is typically 2–4 weeks postoperatively (Stonecipher et al. 2006), and virtually no signs at the slit lamp have been described. In most cases, visual acuity is not affected. A good response to topical steroids suggests an inflammatory origin.

Higher laser energy settings (raster and side cut energy) in the early days of femtosecond laser LASIK were associated with the higher incidence of TLSS. A reduction of the laser energy led to significant decrease of TLSS incidence.

Histology

Anecdotal reports of confocal in vivo microscopy showed a higher prevalence of activated keratocytes at the flap stroma (Stonecipher et al. 2006).

Differential Diagnosis

Another condition that lead to photophobia after LASIK is, in particular, diffuse lamellar keratitis (DLK) (Linebarger et al. 2000). An increased incidence of DLK in eyes with TLSS has been reported. Other differential diagnoses are dry eye syndrome and infectious keratitis.

Synonyms

TVOs

Definition

Transient visual obscurations (TVOs) manifest as transient or brief darkening, blackening, or graying out of vision lasting seconds at a time. The episodes of typical TVOs are different in quality and duration than typical ischemia-related transient visual loss and are often described as fleeting and very short in duration (i.e., typically seconds). TVOs typically occur after bending over or altering head position. Disruption in axonal transport, the intracellular process through which axons are supplied with products synthesized in cell bodies, is thought to cause TVOs.

TVOs are commonly seen in patients with papilledema but may also occur in other optic nerve head disorders (e.g., pseudopapilledema). The short and diffuse nature of the episodes is more suggestive of TVO as compared with ischemic amaurosis fugax episodes from hypotension, hypoperfusion, thrombosis, or embolic disease.

Synonyms

CLAL; CLAU; DALK; DLEK; DMEK; DSAEK; DSEK; KLAL; PK; Scleral patch graft, corneal patch graft

Definition

An operation moving an organ from a donor to the recipient. The donor tissue may consist of cornea, conjunctiva, or amniotic membrane and can be either an allograft or an autograft.

Indication

Corneal pathology such as visually significant scarring, ectatic disease, and Fuchs dystrophy are all surgical indications for a lamellar or penetrating keratoplasty. In cases of partial or total limbal stem-cell deficiency, pterygia, or symblepharon, conjunctival or amniotic membrane transplantation can be done.

Contraindication

Poor surgical candidates from a systemic standpoint and operating on an NLP eye (unless there is psychological contraindication to enucleation or evisceration) would be absolute contraindications. Relative contraindications include ocular surface disorders like uncontrolled dry eye and meibomian gland disease, trichiasis, entropion and ectropion, lagophthalmos, limbal stem-cell deficiency, neurotrophic disease, and pemphigoid (Brightbill et al. 2009).

Techniques and Principles

When an allograft is transplanted, the donor tissue is recognized by the recipient's immune system. This activation can result in formation of specific antibodies and lymphocytes directed toward the donor tissue, resulting in rejection. Typically, the cellular antigens that cause this response are human leukocyte antigens (HLA). HLA matching between donor and recipient is common in most organ transplants, but for corneal transplants, studies such as the collaborative cornea transplantation study (CCTS) showed no benefit to HLA matching. The CCTS also found that ABO-compatible corneas showed no benefit in rejection rates as compared to ABO-incompatible corneas, though there was a higher failure rate in the incompatible group (The Collaborative Corneal Transplantation Studies (CCTS) 1992). The reasons for this include a lack of vascularization in the normal cornea with associated "immune privilege," anterior chamber-associated immune deviation (ACAID), and a lack of antigen-presenting (Langerhans) cells in the central cornea (Krachmer et al. 2005). Typically, rejection can be avoided with topical steroids.

For conjunctival and scleral allografts, vascularization at the site of transplantation can cause a more pronounced immune response. As a result, living-related donors are preferable if an autograft is not possible. HLA matching and ABO typing can even be used to find the best familial match. For surgeries such as KLALs or high-risk corneal transplants, oral immunosuppressive agents may be required.

Tissue is procured from organ donors and processed at eye banks throughout the world. Typically, the death to preservation time is about 6 h, and the tissue can be stored in different storage media which allow a window for the tissue to be used without fear of oxidative damage or contamination. This time period is approximately 7–10 days in the United States and approximately 4 weeks in Europe. Hypothermic storage is typically used (Armitage 2011).

Techniques specific to each procedure can be found in the appropriate cross-referenced article.

Outcome

Outcomes vary depending on the particular transplant being performed and the risk factors.

Complications

Infection, hemorrhage, graft rejection, wound dehiscence, expulsion of intraocular contents, glaucoma, retinal detachment, cataract, and risks of general anesthesia.

Transplantation, Amniotic Membrane

Deepak Raja
Department of Ophthalmology, University of Central Florida, College of Medicine, Orlando, FL, USA
Orlando Eye Institute, Orlando, FL, USA

Synonyms

Amnion

Definition

Amniotic membrane is the innermost layer of the placenta that lines the amniotic cavity. It contains a thick basement membrane that provides nourishment and encourages epithelial cell growth. The avascular stromal matrix suppresses TGF-beta and proliferation of fibroblasts, thereby decreasing scarring. The tissue is harvested from pregnant mothers undergoing caesarian section. These women are screened for HIV, hepatitis B and C, and syphilis to ensure healthy tissue (Krachmer et al. 2005). The tissue is harvested, washed in BSS, soaked in antimicrobial solution for 24 h, and then rewashed in BSS. The amniotic membrane is stripped from the chorion, placed on nitrocellulose strips, cut into small pieces, and frozen at −80 °C. Besides the wet form of AMT, the tissue can be dehydrated after being stripped from the chorion. Many surgeons feel this dehydrated form is easier to handle intraoperatively. Because of some concerns about the true sterility of the amniotic membrane harvest process, a freeze-dried dehydrated amniotic membrane is also available. This tissue is similarly procured, but is exposed to gamma radiation, effectively denuding the tissue (Nakamura et al. 2004).

Indication

Because of its efficacy is promoting healing, it has been used as a graft for conjunctival disorders such as conjunctivochalasis, symblepharon, pterygium, bleb leaks, scleral melts, and lid and orbit reconstruction. It can also be used as a graft for corneal disorders such as partial limbal stem cell deficiency, persistent corneal defects, chemical burns, band keratopathy, and bullous keratopathy. Amniotic membrane can also be used as a patch for Stevens-Johnson syndrome, preventing scars after PRK or PTK or for persistent keratitis recalcitrant to other treatment (Tseng 2001).

Contraindication

Amniotic membrane transplantation (AMT) only helps promote healing, so it requires the host

tissue to supply epithelial and mesenchymal cells. Total limbal stem cell deficiency, severe aqueous tear deficiency, severe neurotrophic state, stromal ischemia, and diffuse keratinization are contraindications.

Techniques and Principles

Once an area to be treated with AMT has been defined, it is important to first achieve meticulous hemostasis. The defect must then be measured. The amniotic membrane comes in a sterile pouch, which can be opened and removed using non-toothed forceps. The membrane can be cut to the desired size. Some surgeons prefer to cut a size slightly larger than the measured defect. To help with orientation, amniotic membrane comes with a watermark on the tissue. When the series of letters is read appropriately, the surgeon knows that the tissue is oriented with the stromal side down. This is the most popular orientation, though it is debatable. If the membrane is dehydrated, a few seconds of lubrication will cause the tissue to swell, which eases the manipulation. The tissue can be adhered to the eye by fibrin glue or by permanent or dissolvable sutures. Again, non-toothed forceps are recommended, as toothed forceps can macerate the tissue. If fibrin glue is used, it is important to remove any excess glue and to ensure that there are no adhesions to the lid speculum. Otherwise, removing the lid speculum at the end of the case could result in accidental removal of the membrane. An AMT done in this fashion is typically done in the OR. To facilitate clinical use for nonhealing epithelial defects, an amniotic membrane with a thermoplastic ring set (Prokera) can be applied similar to a large contact lens.

Outcome

The membrane often dissolves in 1–2 weeks, expediting epithelial healing and preventing scarring.

Complications

Infection, hemorrhage, early disintegration and dehiscence, and no beneficial effect have all been reported.

Transposition Flaps, for Lateral Canthal Defects

Ronald Mancini[1] and Nicole Khadavi Kohan[2]
[1]Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA
[2]Jules Stein Eye Institute, David Geffen School of Medicine at UCLA, University of California Los Angeles, Los Angeles, CA, USA

Synonyms

Bilobed flap; Local advancement flap; Rhombic transposition flap; Z plasty

Definition

Transposition flaps are defined as local flaps, which are transposed from one area to another, usually over an intervening segment of normal tissue. Classic transposition flaps include rhombic transposition flaps, bilobed flaps, and z-plasty.

Indication

In the lateral canthus, transposition flaps are indicated for the repair of anterior lamellar (skin and muscle) deficiencies in which there is inadequate tissue available for direct simple closure. These defects are most commonly secondary to cancer resection surgery, including Mohs surgery, and trauma.

Contraindications

In trauma patients, eyelid surgery should be deferred until the patient is stable and a suitable candidate. Also more serious injuries, such as a ruptured globe, take precedence and should be repaired prior to the eyelids. The donor tissue to be transposed must be healthy and viable. Injury to the lateral canthal tendon should be assessed and surgically repaired if present.

Techniques and Principles

In designing an appropriate transpositional flap, the surgeon must carefully select the most favorable flap design for a given defect while considering local skin mobility. In general tissue, it is transposed from an area of relative excess to an area with insufficient tissue to allow closure. The orientation of relaxed skin tension lines can help in choosing the transposition flap design which will result in the least conspicuous scar.

A transposition flap from the upper eyelid based laterally can be transposed to fill a lateral canthal and partial lower eyelid defect. If the lateral canthal defect is large and involves the thicker skin of the upper cheek, a transposition flap from the area just superior to the eyebrow can be developed and rotated in position.

The rhombic flap is commonly utilized for reconstruction of lateral canthal defects owing to the presence of mobile tissue lateral to the lateral canthus and the ability to camouflage the acute angles which result from the repair in the lateral canthal rhytids. The defect is converted into a rhombus, which is defined as an equilateral parallelogram. In the classic rhombic flap, the angels of this parallelogram are opposing 60° and 120° angles. A line, equal in length to the short diagonal, is then extended as a continuation of the short diagonal. A line parallel to and equal in length to a side of the parallelogram is then extended from the tip of this previously drawn line. The lines are incised with a scalpel and the flap is undermined to the layer of the subcutaneous tissue plane then rotated and advanced to fill the skin defect.

A bilobed flap is a double transposition flap in which two successively smaller lobular shaped flaps are transposed to fill a single, often circular, defect. The bilobed flap is less useful in the lateral canthus because the geometry of the curved scars which result is often more conspicuous than the acutely angled linear scars which result from the use of rhombic transposition flaps.

Z plasty is a modified transposition flap and can be adapted for use in the lateral canthus as well.

Outcome

Transposition flaps allow for recruitment of anterior lamellar tissues (skin and muscle) for reconstruction of lateral canthal defects. The desired outcome is a functional lateral canthus which provides adequate support for normal eyelid function.

Complications

Any excess tension on the flap can result in wound dehiscence or flap necrosis. Phimosis and rounding of the lateral canthus can occur with healing, particularly if the lateral canthal tendon has been violated. Damage to the zygomatic branch of the facial nerve, with resultant

orbicularis occuli weakness, can occur with dissection in the lateral canthal region.

Transseptal Route, for Anterior Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Synonyms

Postseptal incision

Definition

An orbitotomy, usually anteriorly, approached via a transcutaneous (upper eyelid) or transconjunctival (lower eyelid) incision involving opening of the septum. This allows access to a specific area of the anterior 2/3 of the orbit, generally.

Indications

To access an area of the orbit for biopsy of a lesion, removal of a lesion, removal of a foreign body, or for fat or bony orbital decompression. The goal is to provide the most direct route within incisions that follow natural skin lines and minimizing the risk of scarring. The septum is released to allow more posterior exposure of the orbit (Cockerham et al. 2001; Nerad 2001; Levine 2003).

Contraindication

Lesion deeper in the orbit or not able to be accessed via anterior orbitotomy. Any medical contraindication to surgery.

Techniques and Principles

This procedure is generally performed in the operating room under sedation or general anesthesia. For superior lesions, an eyelid crease is marked and dissection is carried posteriorly. The septum is released and dissection is carried posteriorly or medially into the orbit. This allows access to the optic nerve for optic nerve fenestration, and any lesion in the anterior orbit for biopsy or removal. An inferior lesion may be approached via a transcutaneous incision in the

infraciliary area. The septum is released allowing prolapse of the fat and access to anterior lesions. This also allows fatty decompression in Graves' Ophthalmopathy (Cockerham et al. 2001; Nerad 2001; Levine 2003).

Outcome

Allows for biopsy, lesion removal, foreign body removal, drainage of orbital abscess, and orbital decompression as necessary.

Complications

Risks of the transseptal approach include risks associated with anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, ptosis, eyelid retraction, and need for additional procedures.

Definition

The intracranial lateral (transverse) venous sinuses (right and left) drain venous blood from the confluence of sinuses to the sigmoid sinuses. Thrombosis of the transverse (lateral) sinus can lead to reduced drainage of venous blood and secondary reduction in absorption of cerebrospinal fluid. As a result, transverse sinus thrombosis can lead to increased intracranial pressure (ICP), venous hypertension, or secondary hydrocephalus.

Symptoms of transverse sinus thrombosis can develop acutely and may mimic idiopathic intracranial hypertension (IIH). Typical symptoms of increased ICP include headache, diplopia associated with cranial nerve (CN) VI palsy,

papilledema, nausea, and vomiting. Furthermore, patients might also exhibit CN VII or CN VIII dysfunction.

Trauma, Canalicular

Kira L. Segal, Benjamin Levine and Gary Joseph Lelli
Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

Trauma of the eyelid that involves the canalicular system.

Etiology

Blunt or penetrating trauma to the eyelid, orbit, or midface can cause injury to the canalicular system. The canalicular portion of the eyelid is weak and tears easily with forceful, laterally directed traction. Medial upper or lower eyelid lacerations are a common cause of canalicular trauma. Canalicular system damage can occur in association with medial canthal degloving injury due to anatomic proximity (Figs. 1 and 2).

Trauma, Canalicular, Fig. 1 Left upper lower lid eyelid injury with medial canthal involvement

Trauma, Canalicular, Fig. 2 Right upper eyelid laceration with medial canthal involvement secondary to strike with a fist

Clinical Presentation

With any acute injury to the medial portion of the eyelid, particularly lacerations or avulsion, canalicular trauma must be suspected. More remote injuries may present with chronic epiphora.

Diagnostics

The primary objective following orbital trauma is to evaluate and treat any sight-threatening injuries. Ruling out a ruptured globe is essential as manipulation of the eyelids to examine a laceration can cause expulsion of intraocular contents. Attention can then be directed to the eyelid and canalicular system.

Visual inspection is first performed to assess the nature and extent of injury. If canalicular damage is suspected, probing or irrigation of the canalicular system can demonstrate if the integrity of the lacrimal system has been compromised. Irrigation leaking through the wound site or flowing retrograde through the punctum indicates a canalicular laceration. When the Bowman probe is passed through the punctum, the wound is examined to determine if the tip is present. Eyelid trauma in children may require examination under anesthesia to fully evaluate extent of injury.

CT can be used to evaluate for presence of foreign body. MRI should be avoided with any concern for metallic foreign body. Naso-orbital-ethmoid (NOE) fractures often accompany damage to the lacrimal system.

Differential Diagnosis

Injury to the medial eyelid without damage to the canalicular system

Dacryocystitis

Canaliculitis

Prophylaxis

Safety eyewear

Therapy

Surgical reconstruction of the canalicular system at the time of primary eyelid repair is recommended to prevent chronic epiphora. Surgical repair should be undertaken within 24 h of the injury to prevent fibrosis and scarring. Surgical reconstruction can performed in the operating room under general anesthesia or with local anesthesia in a cooperative patient. Regardless of systemic anesthesia type, the area is locally anesthetized using lidocaine with epinephrine to minimize hematoma formation. Visual inspection of the injury is first performed, as the injury can be much larger than is evident on initial clinical exam. Debridement with copious irrigation removes foreign material. The upper and lower canalicular systems are dilated using Bowman probes to confirm the damaged canalicular system and to identify the cut end of the system. The alternate end of the canalicular system in the lacrimal sac is identified, and a silicone stent is

passed through the lacerated system into the distal system, through the lacrimal sac and into the nose. The silicone stents are typically left in place for weeks to months and then removed in the office.

Tetanus booster and systemic antibiotics may be recommended depended on the nature of the injury.

Prognosis

If stenting of the canalicular system is performed successfully, the prognosis is good. Not surprisingly, chronic epiphora is more common with combined upper and lower canalicular injuries. If repair is delayed, scarring of canalicular system can make intubation with stents more challenging.

Epidemiology

Canalicular trauma occurs most commonly in young adult males. Strike from a fist is the most common cause of canalicular laceration overall. Dog bits are the most common cause in children.

Trauma, Lacrimal Sac and Nasolacrimal Duct

Kira L. Segal[1], Apostolos J. Tsiouris[2] and Gary Joseph Lelli[3]
[1]Department of Ophthalmology, Weill Cornell Medical College, New York, NY, USA
[2]Weill Cornell Medical College, New York, NY, USA
[3]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

Trauma of the lacrimal sac and nasolacrimal duct.

Etiology

Etiology of lacrimal sac and nasolacrimal duct trauma is typically mechanical – be it penetrating laceration, avulsion, or blunt injury. High impact blunt trauma causing naso-orbital-ethmoid (NOE), Le Fort II, and Le Fort III type fractures are often associated with osseous or soft tissue injuries to the lacrimal sac and nasolacrimal duct. In 7–15% of all facial traumas, bony fractures of the nasolacrimal duct are discovered. Injury to the nasolacrimal system may be structural at the time of initial trauma or may develop from fibrosis and subsequent dacryostenosis. Iatrogenic causes of trauma to the lacrimal sac and nasolacrimal duct include probing, lacrimal intubation, and sinus surgery.

Clinical Presentation

Lacerations to the medial portion of the eyelid can be associated with soft tissue injury to the lacrimal sac. Patients may not develop tearing immediately and dacryocystitis or nasolacrimal duct

obstruction (NLDO) can be delayed complications caused by progressive fibrosis. Patients present to the ophthalmologist with symptoms of epiphora, mucopurulent discharge from the puncta, pain over the lacrimal sac, cellulitis, and dacryocystitis. Unilateral tearing suggests functional blockage as tearing from keratopathy typically results in symmetric hypersecretion. Whenever a patient presents with complaint of tearing, history taking should elicit remote history of facial trauma.

Diagnostics

Prior to evaluation of lacrimal system injuries, the patient should be stabilized from a medical perspective and examined for a ruptured globe. Trauma to the midface or medial eyelids, and/or CT scan demonstrating lacrimal fossa fracture, NOE fracture, or Le Fort II or III fractures raises suspicion for lacrimal sac or nasolacrimal duct injury. Thin volumetric CT imaging through the lacrimal sac fossa down through the inferior turbinate can be obtained with multiplanar and three-dimensional volume rendered reconstructions. MRI may be contraindicated if there is the potential for an occult metallic foreign body.

Irrigation of the lacrimal system demonstrates intact function of the tear drainage system when fluorescein is observed at the inferior turbinate or passes easily into the nasopharynx. With severe midface trauma, patent irrigation alone is not sufficient to rule out injury to the lacrimal sac or nasolacrimal passage as fluid may extravasate into the nose through a site of bony injury. Probing with a Bowman probe can more definitely assess the patency of the system in this setting. The distance and site of blockage in the upper system can be measured directly as the Bowman probe is held or marked at the site of obstruction. Observation of elevated tear lake and the dye disappearance test are not helpful in the setting of trauma due to high false positive rate.

With complaint of tearing in the outpatient setting, full history and ophthalmic exam must be undertaken to rule out hypereflexive or alternative etiologies of epiphora. History taking should include question of prior sinus surgery, facial trauma, radiation history, blood in tears, and medications. Full anterior segment examination with focus on lid position, puncta, and lacrimal sac should be performed. Palpation of the lacrimal sac revealing mucopurulent discharge indicates a patent common canaliculus and valve of Rosenmüller. Dye disappearance test is often the initial test performed to confirm a blocked tear nasolacrimal system. One drop of fluorescein dye into the fornix and, after 5 min, greater presence of dye in the fornix of the affected eye compared to the normal side suggests impaired drainage. The Jones I test can be performed simultaneously after the fluorescein is given. In the Jones I test, a cotton tip applicator is placed at the inferior turbinate at 2 and 5 min. If fluorescein is present on the cotton tip, the system is patent. This test is limited by a high false negative rate.

With a negative Jones I test, the Jones II test can more accurately identify the site and extent (complete/partial) of obstruction. Clear saline is flushed through the lacrimal sac using an irrigating cannula through the canaliculus. After forceful irrigation is performed, the patient is asked to spit or blow their nose into a tissue. Recovery of any fluid indicates a partial rather than complete blockage. Recovery of fluorescein indicates that the punctal and cananilcular anatomy are patent, as dye has accumulated in the lacrimal sac. A partial blockage is presumed to be in the lower system, either at the entry of the lacrimal sac to the nose or in the duct. If clear saline is recovered, a stenotic punctum or canalicular blockage is implicated as the fluorescein from the Jones I test never penetrated the lacrimal sac. Regurgitation of fluorescein from the upper lid puncta indicates complete blockage at the lacrimal sac. Regurgitation of clear saline from the upper lid puncta indicates obstruction at the common canaliculus. Palpation of the lacrimal sac also provides diagnostic utility. If the sac dilates during

irrigation, but no fluid passes into the nasopharynx, obstruction of the lower system is suggested. If there is sac fibrosis or scarring, the lacirmal sac may not dilate during irrigation.

Contrast dacryocystogram (DCG), CT dacryocystography, or MRI with topical Gadolinium has been used to image the nasolacrimal system. DCG is helpful for locating the site of anatomic obstruction but does not show any detail regarding surrounding soft tissue. Radionucleotide dacryoscintigraphy is less practical for identifying site of obstruction but provides information of physiologic functioning. Nasal endoscopy can be helpful to examine for nasal tumors, rhinitis, or nasal polyps causing blockade of the distal end of the nasolacrimal duct.

Differential Diagnosis

Eyelid malposition
Dacryocystitis
Other cause of acquired nasolacrimal duct obstruction
Primary acquired nasolacrimal duct obstruction
Hypersecretion of tears.

Prophylaxis

Safety eyewear.

Therapy

Tetanus booster and systemic antibiotics may be recommended depending on the nature of the injury.

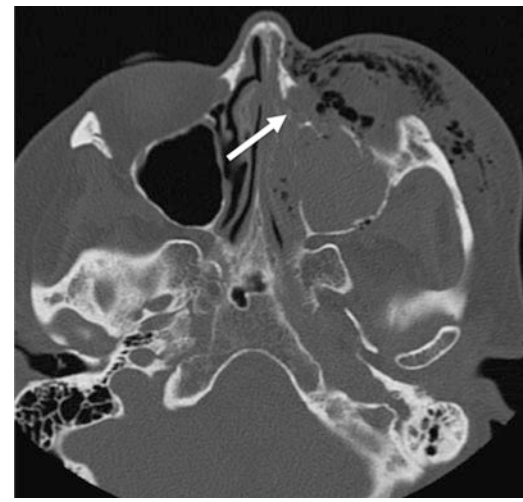
Repair of soft tissue damage in the context of the initial trauma is not usually possible. If the trauma is severe, with gross obstruction of the nasolacrimal system or displacement of bony anatomy, bicanalicular stents can be placed prophylactically. Midface reconstruction or plating of facial fractures can be performed in concurrence with or following silicone intubation with minimal disruption. The silicone tubes are then left in place for 3–6 months as is standard and can be removed in the office. With minimal damage, but suspicion of NLDO, dacryocystorhinostomy (DCR) or conjunctivo-DCR (C-DCR) can be performed at a later date. Symptoms of epiphora can also resolve over time as swelling in the system resolves, relieving transient blockage.

Prognosis

Success rate for surgical correction of epiphora related to NLDO is surprisingly high. DCR has demonstrated success in 92–100% of patients with NLDO following NOE fracture. Reports indicate that primary repair of midfacial fractures within 2 weeks of injury, typically by wide open reduction and fixation, reduces the incidence of NLDO following injury.

Epidemiology

Fractures of the nasolacrimal duct are reported in 7–15% of all facial traumas. NLDO following NOE fracture ranges in incidence from 29–68%.



Trauma, Lacrimal Sac and Nasolacrimal Duct, Fig. 1 Axial CT image in bone windows demonstrates a complex facial fracture with extension through the lacrimal bone and nasolacrimal duct (*arrow*), causing expansion of the lacrimal sac

Trauma, Lacrimal Sac and Nasolacrimal Duct, Fig. 2 Coronal CT in soft tissue algorithm demonstrates a comminuted fracture through the anterior orbital rim with a bony fragment (*black arrow*) disrupting the nasolacrimal duct following trauma caused by a blow to the orbit with a baseball bat. Also seen in this image is a globe rupture (*white arrow*) and extensive soft tissue hemorrhage, edema, and subcutaneous emphysema. Clinical exam revealed lacrimal system involving lower eyelid laceration

In one study, 17% of patients went on to DCR following severe naso-orbito-ethmoid injury.

Injuries are more common in young adult males. Mechanism of injury varies but most often includes fist, motor-vehicle accident, or animal associated injury (Figs. 1 and 2).

Acute contusion glaucoma

Definition

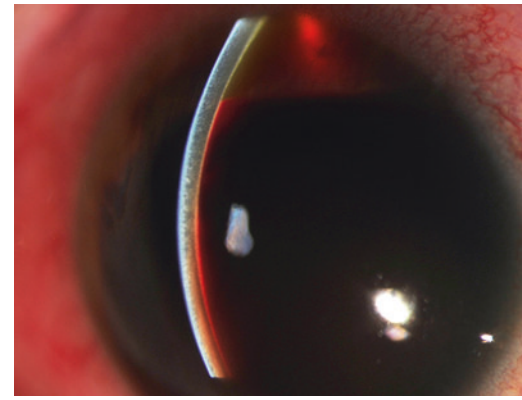
Trauma can cause IOP elevation by inflammation, red blood cells (hyphema), or direct injury of the trabecular meshwork or the lens with lens (sub) luxation (De Leon-Ortega and Girkin 2002). Each of these or a combination of them can be the reason for traumatic glaucoma. Normally, the IOP elevation is of short duration but could be prolonged with a risk of nerve damage (Herschler and Cobo 1982).

Etiology

Ocular trauma is the reason for the development of traumatic glaucoma.

Clinical Presentation

Hyphema (Fig. 1) often with rebleeding during the first week may cause IOP elevation by obstruction of the trabecular meshwork. The risk of elevated IOP increases by the amount of hyphema. On the other hand, a small hyphema can also cause a marked IOP raise, especially in an additionally and otherwise compromised angle (Schlote and Rohrbach 2005).



Traumatic Glaucoma, Fig. 1 Traumatic Glaucoma with Hyphema and Hematocornea

A posttraumatic inflammation may also lead to traumatic glaucoma caused by the same pathophysiologic mechanism, namely, the obstruction of trabecular meshwork by inflammatory cells, fibrin, and debris.

Direct injury of the trabecular meshwork may cause both hypertony and hypotony of the eye.

Diagnosis

Anamnesis and biomicroscopy.

Therapy

Local antiglaucomatous drugs are useful as a first-line therapy regimen supplemented by anti-inflammatory drugs (NSAR and corticosteroids) (Stamper et al. 2009).

Prognosis

Often depends on the underlying injury of the eye.

Epidemiology

Depends on the population.

Treacher Collins-Franceschetti Syndrome (Mandibulofacial Dysostosis)

Sherveen Salek
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Franceschetti-Zwahlen-Klein syndrome; Mandibulofacial dysostosis; Treacher Collins syndrome

Definition

Treacher Collins-Franceschetti syndrome (TCFS) was first described in 1900 and is an autosomal dominant condition that is characterized by general craniofacial soft tissue and skeletal hypoplasia of the first and second branchial arches, with a wide spectrum of deformities.

Etiology

The disorder is caused by a mutation in the TCOF gene on chromosome 5q32-33.1, which encodes the treacle protein. Deletions in this gene cause haploinsufficiency in an autosomal dominant genotype, with deficiencies in ribosomal DNA transcription causing increased apoptosis of neural crest cells.

Clinical Presentation

The primary feature of TCFS is mandibular retrognathia, soft and hard tissue malar deficiency, downward-slanting palpebral fissures, euryblepharon with or without coloboma, and conductive hearing loss. The orbital region is

characterized by hypoplasia of the superior and inferior orbital rims, along with hypoplasia of the zygomatic bone. This creates the appearance of protruding globes, which along with euryblepharon of the lower lids, can predispose patients to development of exposure keratopathy. The orbicularis oculi muscles and meibomian glands along eyelid margins can be attenuated or absent, which can give the eyelid significant laxity. The absence of lashes in the medial third of the lower lid is a pathognomonic finding. Strabismus and congenital cataracts have been reported, and amblyopia can also result from corneal scarring.

Diagnosis

Prenatal ultrasound has been used for diagnosis of Treacher Collins, usually after 30 weeks of gestational age when most facial structures are visible, although most cases are diagnosed readily at birth through recognition of its clinical and radiographic features. The disorder can be diagnosed through mutations in the TCOF gene, although commercial assays are not available at the time of this publication.

Differential Diagnosis

Mandibulofacial dysostosis with microcephaly, Nager syndrome, Miller syndrome, Genee-Wiedemann syndrome.

Prophylaxis

There is no prophylaxis available for this genetic craniofacial condition. Infants should receive an ophthalmologic examination within 3 months of birth. Several interventions can be undertaken to prevent the development of exposure keratopathy, including lateral tarsorrhaphy or lower lid skin grafts. However, lower eyelid grafting is preferably deferred until later childhood when there is sufficient upper eyelid tissue available for grafting in order to address the lid coloboma.

Therapy

Interventions for TCFS require a multidisciplinary approach between ophthalmology and otolaryngology, plastic surgery, craniofacial specialists, pediatrics, orthodontics, speech and language pathology, and psychology. Starting at birth, there should be an airway evaluation, as well as monitoring of feeding progress. An ophthalmologist should evaluate the condition of the cornea within the first 3 months to determine whether any intervention is warranted at that point. CT imaging should be performed within the first 6 months in order to identify the cause of hearing loss, as mild cases with only ossicular discontinuity may be responsive to banded hearing aids and, after age 4, bone-anchored hearing aids. Eyelid reconstruction can be performed later in childhood when there is adequate tissue available for grafting. Distraction of the mandibular angle is performed later in childhood, followed by orthognathic surgery.

Prognosis

Through proper management, involvement of multidisciplinary teams, and appropriate intervention at various stages, reconstructive treatment and addressing hearing and vision issues can help patients lead productive lives, especially given that most patients with TCFS do not have neurodevelopmental impairment. As far as vision is concerned, early examination within the first 3 months can prevent development of corneal scarring and help surgical teams plan appropriate timing of eyelid and orbital reconstructive surgery.

Epidemiology

TCFS is present in 1 in 25,000–50,000 births. There is no gender, racial, or geographic predisposition to TCFS.

Treatment for Lid Retraction

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Definition

Management of lid retraction based on the etiologic factors underlying the retraction.

Indication

In some cases, eyelid retraction may resolve spontaneously without any intervention. However, in most cases supportive treatment is indicated for exposure keratopathy secondary to eyelid retraction. This includes artificial tears, lubricants, ointments, and punctual plugs. In addition, retraction associated with systemic disease may improve with appropriate systemic therapy. For example, lid retraction related to Graves' disease may show improvement with corticosteroids or radiotherapy. In select cases, surgical management may be required to restore normal eyelid position or to correct severe exposure keratopathy. Surgery is usually indicated only after serial measurements have established stability of the disease for at least 6 months.

Contraindication

Surgical repair is contraindicated if preoperative serial lid measurements are fluctuating unless vision-threatening corneal decompensation is present.

Techniques and Principles

The approach to surgery is directed by etiologic factors or deficiency underlying the retraction. For upper eyelid retraction, excision of Müller's muscle with recession of levator aponeurosis may be performed. Spacers may be used to lengthen the upper eyelid and may include contralateral torus and autologous sclera. Fascia lata, ear cartilage, or alloplastic materials are also used.

For lower eyelid retraction, the surgical technique depends on whether anterior, middle, or posterior lamellar deficiency is present and severe cases require use of a spacer such as auricular cartilage or hard palate mucosa. Correction may also require repair of canthal tendon laxity with lateral canthal tightening or elevation.

Outcome

The goal of surgical repair of lid retraction is restoration of normal eyelid position and minimization of secondary corneal exposure.

Complications

The most common postoperative complications for eyelid retraction are undercorrection and overcorrection of lid position. Postoperative shrinkage of spacers such as sclera may result in recurrence of lid retraction. Spacers can also cause corneal irritation and abrasion.

Trichiasis

Roomasa Channa
Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Misdirected eyelashes

Definition

Trichiasis is misdirection of the eyelashes so that they turn inward toward the cornea and conjunctiva, with or without inward turning of the eyelid (entropion). The inward turning of the lashes toward the cornea and conjunctiva can lead to irritation and inflammation of these ocular structures.

Etiology

Causes of trichiasis can be broadly divided into the categories of inflammation/infection (chronic blepharitis, trachoma, herpetic disease), tumors (basal cell carcinoma, capillary hemangioma, conjunctival amyloidosis), medications (epinephrine, pilocarpine, trifluridine, vidarabine), systemic autoimmune disorders (ocular cicatricial pemphigoid, erythema multiforme, Steven-Johnson syndrome), and trauma (chemical injury, thermal burn, surgical trauma) (Cat and Burkat 2011).

Clinical Presentation

The patient may present with symptoms of eye irritation, foreign body sensation, or blurred vision. However, trichiasis itself may be a manifestation of numerous disease processes as mentioned in the etiology section, and a careful clinical exam and work-up may be needed to determine the cause.

Diagnosis

Trichiasis can be a manifestation of a serious disease process and recognition, and diagnosis of the underlying disease pathology is key in its management, and a biopsy should be performed whenever indicated.

Differential Diagnosis

The differentials of trichiasis include the different disease processes that can manifest as trichiasis as noted in the etiology section.

Prophylaxis

Trichiasis from recurrent trachoma infections can be prevented by treating trachoma with antibiotics and implementing hygienic measures (Prevention 2013).

Therapy

When trichiasis is associated with symptoms or is leading to damage to the ocular tissues, it should be treated. Electrolysis, cryotherapy, mechanical epilation, surgery, and argon laser lash ablation are some of the treatment modalities that have been employed in the treatment of trichiasis. The mode of treatment depends on various factors including disease etiology, pattern, and extent of involvement (i.e., segmental or diffuse and the number of lashes involved) and whether there is coexisting entropion present.

Mechanical epilation is convenient and associated with low cost. The extremely high recurrence rate makes it a suboptimal method for long-term control of the disease process. However, it is a good approach for a patient who comes in to the clinic with 1 or 2 lashes affected and no prior history of trichiasis (Kersten and McCulley 2011).

Electrolysis destroys the lash follicle with electrical current. It can lead to eyelid scarring, and the recurrence rate remains high.

Cryotherapy can lead to complications such as loss of all lashes, trichiasis in adjacent areas, loss of meibomian glands, loss of skin pigment, reactivation of herpes zoster, as well as eyelid complications such as eyelid edema and lid notching (Kersten and McCulley 2011).

Argon laser can also be used for ablation of aberrant eyelashes. Bartley et al described their experience in using argon laser for treatment of trichiasis in 44 patients with follow-up intervals ranging from 1 month to over 4 years. They reported that ablation of misdirected lashes was accomplished with one treatment in over half the patients. They noted that the laser treatment may be less effective than cryotherapy for treatment of trichiasis but it incited less post-procedural inflammation and maybe useful in cases such as ocular pemphigoid (Bartley and Lowry 1992).

Basar et al described their experience in using argon laser for treatment of 60 eyelids of 45 patients with trichiasis. They used topical anesthesia, 1 watt power for 0.20 seconds and 100 micron beam diameter which was directed coaxially to the lash follicle to create a 2-3mm crater, once a crater was observed the laser settings were changed to 1.2watt power for 0.2 seconds and 200 micron beam diameter. Patients were followed for an average of 6 months and 25% had recurrence. Side effects of treatment included mild hypopigmentation in three cases and mild lid notching in another three (Basar et al. 2000).

When trichiatic lashes involve the entire lower eyelid margin, there is usually associated cicatrization of the conjunctiva. Tarsotomy is an effective procedure in case of diffuse trichiasis. Tarsotomy can be performed with local anesthesia and involves rotating the eyelid margin using sutures passed from the conjunctival surface to the skin surface adjacent to the lashes. Another surgical technique that can be used is called the "4-snip" procedure. This involves a full thickness eyelid resection in the area of trichiasis in conjunction with lid margin rotation (Allen 1991).

Prognosis

If left untreated, trichiasis can lead to multiple ocular complications including corneal scarring leading to blindness (Thylefors et al. 1995).

Epidemiology

Trichiasis when associated with trachoma is the leading infectious cause of blindness worldwide. It is estimated that active trachoma affects 150 million people worldwide, and of these over 10 million have trichiasis, and about 6 million have blinding corneal scarring (Thylefors et al. 1995).

Trichinella spiralis Trichinosis, Orbital Infection Caused by

Michael T. Yen[1] and Emmanuel Chang[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Retina and Vitreous of Texas, Houston, TX, USA

Definition

Trichinosis is an infection by any of the three species of roundworm: *Trichinella spiralis* (predominantly infects pigs), *Trichinella pseudospiralis* (parasite of raccoons, cats, mice, and birds), or *Trichinella britovi* (parasite of foxes) (Capo and Despommier 1996).

Etiology

All three species of *Trichinella* may infect humans; however, *T. spiralis* is the most common (Harms et al. 1993). Infection occurs by consuming raw or improperly cooked meat, containing the encysted larvae, particularly pork. The worms are 1.2–4 mm long and approximately 40–60 μm in diameter. Female worms are larger than male worms. After consumption of infected meat, the encysted larvae quickly mature over 36 h into an adult form. The adult *T. spiralis* mates in the small intestine of the host where the male worms die after copulation, and the female worms live in the small intestinal crypts to give birth to thousands of immature first-stage larvae which gain entrance to the systemic circulation through the portal system. These larvae then migrate to skeletal muscles including extraocular muscles where they encyst (Capo and Despommier 1996; Roos 2005).

Epidemiology

This parasite is endemic to areas of Africa, Mexico, Central and Northern South America, and Southeast Asia. Trichinosis is one of the more common helminthic zoonoses worldwide. There are eight *Trichinella species*; five species are encapsulated and three are nonencapsulated. Only three *Trichinella* species are known to cause trichinosis: *Trichinella spiralis* (predominantly infects pigs), *Trichinella pseudospiralis* (parasite of raccoons, cats, mice, and birds), or *Trichinella britovi* (parasite of foxes). Approximately 11 million individuals worldwide are infected with *Trichinella.* It is rare to find trichinosis today in developed countries. From 1997 to 2001, an annual average of 12 cases per year was reported in the United States (Roos 2005).

Clinical Presentation

Clinical features are divided into three phases (Capo and Despommier 1996; Roos 2005). The first phase (enteric phase) occurs after consumption and consists of gastrointestinal symptoms

generally within 48 h of ingestion. The second phase (invasive phase) occurs during larvae migration in systemic circulation and provokes a systemic allergic response with the "classic features" of high fever (~104 °F), myalgia, palpebral eyelid and facial edema, and eosinophilia over the course of 2–8 weeks. This high fever is atypical of other helminthic infections. The larvae may disseminate into multiple organs such as the brain, heart, lung, and kidneys. Larvae migration to the eye frequently invades the extraocular muscles (Roos 2005). When extraocular muscles are involved, ophthalmoplegia, proptosis, and pain with eye movements develop. Other ocular findings such as subconjunctival hemorrhage, conjunctival chemosis, retinal hemorrhages, chorioretinitis, and optic neuritis may occur. CNS infection, if present, usually requires large numbers of organisms with accompanying myocarditis. The clinical manifestations of trichinosis are found in the following frequency: muscular (90%), ocular (59%), neurological (52%), and psychological (52%). The third phase coincides with cyst formation (encystment phase).

Diagnostics

Since it is rare to recover this organism in the feces, diagnosis is made based on clinical history and by biopsy of striated muscle (often from the calves) or intestinal tract or serologically by ELISA. Eosinophilia and country of origin are important clinical information to have a high index of suspicion of this disease entity since eosinophilia is usually the earliest indicator of infection. Elevated creatinine phosphokinase may also be seen due to myositis (Capo and Despommier 1996).

Differential Diagnosis

- ▶ Contact Dermatoblepharitis
- ▶ Diplopia in Multiple Sclerosis
- ▶ Intraocular Lymphoma
- ▶ Pseudotumor Cerebri

Prophylaxis

None. Always eat well-cooked meats by cooking to an internal temperature of 165 °F (74 °C) for a minimum of 15 s. Freezing pork less than 6 in. thick for 20 days at 5 °F will also kill any worms.

Treatment

Treatment is targeted at encysted larvae and adult forms with anthelmintics: mebendazole (200–400 mg three times a day for three days) or albendazole (400 mg twice a day for 8–14 days) are given to treat trichinosis (Roos 2005). Common side effects of these medications are nausea, vomiting, diarrhea, and abdominal pain. High drug dosages may cause liver enzyme elevations, agranulocytosis, and alopecia. However, no specific treatment exists against encysted larvae. Caution should be taken when treating trichinosis due to a severe inflammatory response secondary to antigens released, in particular if larvae are present in the brain. Prednisone has been utilized to decrease tissue damage; however, its use is controversial. Common dosage of prednisone ranges from 20 to 60 mg per day. NSAIDs may be used to help control symptoms. The primary mainstay of treatment is aimed at prevention.

Prognosis

The vast majority of patients (90–95%) who acquire trichinosis have minor symptoms. These patients do well and do not develop complications. Patients who acquire more serious systemic infections have unclear prognosis, especially with CNS involvement since the encysted larva may persist for many years.

Trichoepithelioma

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Solitary trichoepithelioma

Multiple adenoid cystic epithelioma or Brooke's tumor.

Definition

A benign adnexal tumor of hair follicle origin and most commonly found on the face and eyelids.

Etiology

Sporadic when solitary or possibly genetic, especially in the inherited (autosomal-dominant) form with multiple lesions (Albert and Jakobiec 2008; Shields and Shields 2008).

Clinical Presentation

Solitary or with multiple lesions. Typically occurring in young to aging adults; however, the hereditary form may be seen in younger individuals.

Solitary trichoepithelioma appear as an asymptomatic, flesh-colored, firm nodular, lesions, usually on the face. Telangiectatic vessels may be seen. This nonhereditary tumor may be difficult to distinguish from a basal cell carcinoma; ulceration may occur rarely. Multiple trichoepitheliomas generally begin during early childhood or at puberty as firm skin-colored papules and nodules (2–8 mm) on the nasolabial folds, facial skin, and eyelid. They may gradually increase in size and number (Albert and Jakobiec 2008; Shields and Shields 2008).

Diagnostics

Based on history, clinical examination, and confirmed by histopathological examination after biopsy.

Differential Diagnosis

Differential diagnosis includes ► basal cell carcinoma, ► angiofibroma, ► syringoma, and ► trichofolliculoma

Prophylaxis

Unknown.

Therapy

Surgical excision. Carbon dioxide laser may be an alternative.

Prognosis

Slow growth is characteristic. Although rare, malignant transformation may occur. In cases of multiple facial lesions, cosmetic disfigurement may be of concern (Albert and Jakobiec 2008; Shields and Shields 2008).

Epidemiology

Unknown.

Cross-References

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Hamartoma of hair follicle

Definition

Trichofolliculoma is a benign neoplasm of hair follicles.

Etiology

The precise etiology is uncertain but seems to develop spontaneously and with no association with systemic disease or other skin disorders (Albert and Jakobiec 2008; Shields and Shields 2008).

Clinical Presentation

Solitary, slow growing tumors, most commonly found on the face, scalp, neck, or on the eyelid margin. The lesion is a firm, small, slightly elevated, skin-colored nodule with a central pore or depression containing keratinous material or a wisp of wool-like or cottony hairs, usually white and short, protruding from or growing out of it (Albert and Jakobiec 2008; Shields and Shields 2008).

Diagnostics

By characteristic appearance of central umbilication and protruding hair. Confirmed by histopathological examination.

Differential Diagnosis

Differential diagnosis includes ▶ basal cell carcinoma, ▶ molluscum contagiosum, ▶ syringoma, ▶ trichoepithelioma, ▶ sebaceous cyst, and ▶ nevus.

Prophylaxis

Unknown.

Therapy

Surgical excision.

Prognosis

Excellent. If incompletely excised, recurrence may occur.

Epidemiology

Rare.

Synonyms

Gasserian ganglion; Semilunar ganglion; Trigeminal ganglion

Definition

Afferent sensory fibers of the trigeminal nerve originate from cell bodies within the *trigeminal ganglion*. A fold of dura, named Meckel's cave, houses the sensory trigeminal ganglion also known as the Gasserian or semilunar ganglion. Two of the three branches (V1 and V2) of the trigeminal nerve serve solely as sensory nerves, whereas the mandibular division (V3) of the trigeminal nerve has both motor and sensory fibers.

The sensory root of CN V exits the pons ventrally and fans out to form the trigeminal ganglion; meanwhile, the motor fibers of CN V remain separated. Three separate sensory divisions then come off the trigeminal ganglion and continue as the ophthalmic nerve (V1), maxillary nerve (V2), and mandibular nerve (V3).

Trypan Blue

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Dye derived from toluidine.

Indication

Staining of the anterior capsule in cataract surgery, in pediatric cataract surgery, and in cataract surgery lacking a good red fundus reflex (e.g., white cataracts, corneal opacities) and staining of epiretinal membranes in vitreoretinal surgery.

Contraindication

Trypan blue should only be used in pregnant women when the potential benefit justifies the potential risk to the fetus.

Use and Dosage

For capsulorhexis, trypan blue ophthalmic solution is usually applied in a concentration of 0.06%. However, concentrations up to 1% have been applied (Farah et al. 2009). The dye is injected directly on top of the anterior lens capsule under an air bubble. The air bubble limits contact of the dye to the iris and the anterior capsule. Alternatively, trypan blue may be mixed with viscoelastic or instilled under viscoelastic. After approximately 5 s of staining, the anterior chamber is irrigated using balanced saline solution prior to performing capsulorhexis. In chromovitrectomy, trypan blue is applied to stain epiretinal membranes, and it also stains the internal limiting membrane to some degree. Trypan blue (0.06–0.15%) is injected into the posterior pole after fluid–air exchange and is washed out with balanced salt solution (Heilweil et al. 2010).

Adverse Reactions

Trypan blue is labeled by the FDA as a mutagen in the Ames test and as a carcinogen in rats. However, there are data that confirm that the dye is safe and effective as an adjunct for capsule visualization in cataract surgery (Jacobs et al. 2006). There are anecdotal reports that permanent discoloration of a hydrophilic acrylic intraocular lens requiring explantation of the lens has occurred (Saini et al. 2003). Clinical studies and morphologic analysis of trypan blue-assisted vitreoretinal surgery revealed no toxic effect to the human retina. However, there is controversy in experimental data suggesting a dose-dependent retinal damage after trypan blue exposure (Werner et al. 2002).

Definition

Ulcerative keratitis refers to the disruption of the corneal surface and/or deeper layers, often associated with inflammation.

Etiology

Ulcerative keratitis may be sterile or infectious. Infectious keratitis may be caused by bacterial, viral, fungal, or parasitic organisms. Important historical clues for an infectious etiology include contact lens use, trauma, foreign body, previous ocular surgery, and exposure to contaminated water (Karp and Forster 2011). Bacterial keratitis usually only develops after ocular immune defenses have been compromised. However, there are some bacteria that are able to penetrate a normal corneal epithelium. These bacteria include *Neisseria gonorrhoeae*, *N. meningitidis*, *Corynebacterium diphtheriae*, and *Haemophilus influenzae.* The most common pathogens are *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Streptococcus* (Kanski and Bowling 2011).

Contact lens use and abuse has been a major contributor to the development of ulcerative keratitis. Extended wear contact lenses have been associated with an increased risk of keratitis. Outdoor trauma involving soil or vegetation may be suggestive of an infection involving fungi or another fastidious organism (Karp and Forster 2011). Diseases, such as herpes simplex keratitis and keratoconjunctivitis sicca, may be complicated by ulcerative keratitis (Ferri 2009). Up to 60% of corneal ulcers in developing countries may be complications of herpes simplex virus infections (Kanski and Bowling 2011).

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

Stromal keratitis may result from impaired local host defenses. Chemical injury, neurotrophic disease, tear insufficiency, stem cell deficiency, bullous keratopathy, previous herpetic disease, topical anesthetic use, and topical corticosteroid use are important historical factors that suggest impaired local defenses (Karp and Forster 2011). Systemic diseases, such as acquired immunodeficiency syndrome (AIDS), diabetes mellitus, malnutrition, and alcoholism, may contribute to increased risk of keratitis. Immunosuppressive treatments for systemic inflammatory diseases, such as rheumatoid arthritis, Wegener's granulomatosis, and Sjogren's syndrome, may also predispose patients to keratitis development (Karp and Forster 2011). Ulcerative keratitis may be associated with collagen vascular disease or exophthalmos secondary to thyroid disease (Ferri 2014).

Mooren's ulcer is a rare, idiopathic condition that causes peripheral stromal ulceration that progresses centrally. There are two types of Mooren's ulcers. One type affects older individuals predominantly and tends to be unilateral. This type tends to respond well to medication. The second type is more aggressive, affects younger individuals, tends to be bilateral with severe pain, and is less responsive to treatment. The second type is thought to have an autoimmune mechanism, and there is often a history of corneal insult that is thought to act as a trigger in susceptible individuals (Kanski and Bowling).

Clinical Presentation

Ulcerative keratitis is characterized by sloughing of the corneal epithelium and keratolysis, also known as corneal melting (Soukiasian 2014). It presents as a localized, well-demarcated lesion with a corresponding focal ulcer or yellow-white stromal suppuration with thick mucopurulent exudate and edema. The eye is typically red with infiltration in the surrounding cornea. The corneal ulcer may be painful with associated conjunctival edema and infection (Ferri 2009). Affected individuals may experience foreign body sensation, pain, and photophobia when the corneal epithelium erodes and ulcerates. Vision may be impaired if the inflammation involves the central cornea or from induced astigmatism. Anterior uveitis may be associated with ulcerative keratitis, and it contributes to photophobia and visual impairment. The characteristic features include epithelial loss, various degrees of stromal infiltration, and thinning secondary to keratolysis. Mooren's ulcer tends to be chronic and extremely painful. It begins in the periphery, adjacent to the sclera with a steep, undermined, or overhanging central margin with an occasionally infiltrated leading central border. It is not typically associated with scleritis (Soukiasian 2014).

S. aureus infections typically progress slowly (Karp and Forster 2011). Staphylococcal marginal ulcers begin as an infiltrate adjacent to the limbus with a clear zone between, which progresses and leads to ulceration (Soukiasian 2014). Streptococci tend to cause an acute and highly suppurative reaction with deep central stromal ulceration and an advancing edge of infection. Infectious crystalline keratopathy (ICK) is a unique presentation of streptococcal infection that occurs at the graft-host junction following keratoplasty (Karp and Forster 2011). Viral keratitis is often highly contagious (Ferri 2014).

Sterile neurotrophic ulcers are typically associated with tissue breakdown but no pain (Ferri 2009). Stromal ulceration secondary to immune-related pathology may present with varying degrees of cellular infiltration. Such ulceration may be associated with scleritis, episcleritis, or iritis (Karp and Forster 2011). Corneal melting occurs in response to enzymatic activity in peripheral ulcerative keratitis (Kanski and Bowling 2011). Once corneal melting begins, the process may progress rapidly. Ulcerative keratitis may progress to perforation if left untreated. It may be life threatening when associated with a systemic autoimmune condition (Soukiasian 2014).

Diagnosis

A thorough history should be obtained, including history of ocular infections, contact lens wear, current and previous medications, trauma, and

previous eye surgery or laser vision correction procedures (Soukiasian 2014). Microscopic examination of both eyes should be done with a slit lamp and fluorescein staining (Ferri 2014). The lids, lashes, and conjunctiva should be evaluated for inflammation secondary to rosacea, seborrhea, and mechanical lid dysfunctions. The lacrimal system should be assessed for adequate tear function and underlying dacryocystitis or canaliculitis that may compromise corneal health. Careful evaluation of the corneal stroma of the fellow eye should be performed to rule out a peripheral immune-mediated marginal keratitis (Karp and Forster 2011). Culture of ulcer scrapings should be done for definitive etiologic diagnosis (Ferri 2009).

Differential Diagnosis

The differential diagnosis for ulcerative keratitis includes various infections. More virulent pathogens include *Pseudomonas* and pneumococcus. *Moraxella*, *Staphylococcus*, and alpha-hemolytic *Streptococcus* are less virulent pathogens that may be involved. Viruses, such as herpes simplex, may cause infection leading to ulceration. Contact lens ulcers should also be considered (Ferri 2009). Peripheral immune-mediated marginal keratitis may be seen in rheumatoid arthritis, Wegener's granulomatosis, and Mooren's ulcer. These are rarely infectious (Karp and Forster 2011). Patients with autoimmune disease-associated ulcerative keratitis may become secondarily infected, and thus infectious causes must be ruled out by the initial work-up. Ulceration without inflammation and typically an intact corneal epithelium is suggestive of a noninflammatory etiology, such as Terrien's marginal degeneration, pellucid marginal degeneration, and marginal furrow (Soukiasian 2014).

Prophylaxis

Prophylactic topical antibiotics are sometimes used to prevent secondary infections in cases of peripheral ulcerative keratitis (Soukiasian 2014).

Therapy

Ulcerative keratitis therapy includes warm compresses and patching of the affected eye. Contact lens wear should be discontinued. Intense antibiotic and antiviral therapy should be initiated (Ferri 2009). Bacterial infections may be treated with subconjunctival cefazolin or gentamicin (Ferri 2014). NSAIDs may be used. In cases of fungal infections, patients should be hospitalized, and topical antifungal agents should be initiated (Ferri 2009). Topical anesthetics or steroids should never be used in cases of ulcerative keratitis. Anesthetics and steroids may aggravate fungal or herpetic ulcers, leading to perforation of the cornea (Ferri 2014).

Systemic corticosteroids such as oral prednisone are commonly used in the acute management of severe peripheral ulcerative keratitis secondary to autoimmune etiologies. If the ulceration progresses, pulsed administration of methylprednisolone may be effective. The prolonged use of systemic corticosteroids may result in significant systemic side effects. In cases of potential perforation, systemic corticosteroids may be combined with immunosuppressive therapy. Systemic immunomodulatory therapy becomes necessary when local therapy fails; there is an associated collagen vascular disease or bilateral Mooren's disease. The presence of a vasculitis, particularly suggested by a concurrent associated scleritis, is a key factor in deciding to initiate treatment with immunosuppressive agents as it suggests systemic collagen vascular disease. Peripheral ulcerative keratitis secondary to Wegener's granulomatosis is treated with an immunosuppressive, such as cyclophosphamide, with corticosteroids. Methotrexate would be useful in maintenance therapy. The efficacy of biological agents, such as anti-tissue necrosis factor (TNF) and anti-B cell monoclonal antibodies, has not been established for treatment of peripheral ulcerative keratitis, but the established efficacy of these drugs in treatment of systemic inflammatory diseases is promising (Soukiasian 2014).

Surgical treatments may be used palliatively in peripheral ulcerative keratitis to maintain the integrity of the globe. Surgery is not effective as

a monotherapy as it does not affect the underlying immunologic process. Conjunctival resection may temporarily remove the local cellular mediators and collagenases that cause progression of the disease process. Cyanoacrylate adhesive combined with immunosuppressive therapy may help to delay impending perforation and the need for tectonic corneal surgery (Soukiasian 2014).

Prognosis

Ulcerative keratitis secondary to an immune-related process may maintain good visual function if the inflammatory process is controlled without delay. The prognosis is more guarded if the ulceration is associated with systemic collagen vascular disease. Peripheral ulcerative keratitis with associated scleritis typically has a worse prognosis than scleritis alone. Significant visual impairment and ocular morbidity may result in cases of corneal perforation. Cataracts or glaucoma may result from the inflammatory process of peripheral ulcerative keratitis or the use of corticosteroids (Soukiasian 2014).

Epidemiology

Ulcerative keratitis affects men and women equally, and it can affect individuals of all ages. The average general ophthalmologist observes four to six cases of ulcerative keratitis each month (Ferri 2014). Almost 50% of individuals with peripheral ulcerative keratitis have an associated systemic disease, most commonly a collagen vascular disease. Up to 25% of peripheral ulcerative keratitis patients experience ulcerative keratitis as a presenting feature of a potentially undiagnosed systemic vasculitis. Rheumatoid arthritis is the most common collagen vascular disease associated with peripheral ulcerative keratitis (Soukiasian 2014).

Ulcerative Keratopathy, Toxic

Rabia Karani
Johns Hopkins School of Medicine, John Hopkins University, Baltimore, MD, USA

Synonyms

Toxic ulcerative keratopathy

Definition

The most severe manifestation of toxic keratoconjunctivitis (keratoconjunctivitis medicamentosa) (Albert et al. 2008).

Etiology

Toxic ulcerative keratopathy is a result of overtreatment by topical ophthalmic medication (Schwab and Abbott 1989). Preservatives in eye drops such as benzalkonium chloride and thimerosal are the most common cause of toxicity. Preservatives serve as antimicrobials in solution but can lead to epithelial toxicity and irreversible corneal edema (Holland et al. 2013).

Over-the-counter eye drops, glaucoma medications (e.g., pilocarpine, carbachol), antivirals (e.g., trifluorothymidine), antibiotics (e.g., gentamicin), and anesthetics (e.g., proparacaine) are all examples of medications that may cause toxic ulcerative keratopathy by interfering with epithelial cell membrane physiology.

Toxicity can be caused by the medication itself, from preservatives in solution or from its degradation products (Schwab and Abbott 1989; Krachmer et al. 2010). Solutions can be toxic to the ocular surface due to photosensitization of the eye, osmolarity of the solution, or sensitivity to the pH of the solution. Ophthalmic treatments may be directly toxic by initiating a cascade of events in the eye that manifest after a threshold of toxicity is reached. Toxicity can also be indirect by manifesting as a result of a condition caused by the ophthalmic medication. For example, decreased tear production and cytotoxicity to goblet cells can lead to epithelial effects. Antimicrobial preservatives in solution can sometimes create an environment favorable to the growth of bacteria. Toxicity can be caused by a combination of various mechanisms or can be the result of a single mechanism. It can develop either immediately or after many years of use of ophthalmic medication (Holland et al. 2013). Toxicity may be self-induced (factitious) by the abuse of over-the-counter or prescription eye drops or iatrogenic (Albert et al. 2008).

Clinical Presentation

Toxic keratoconjunctivitis can be a precursor to the development of toxic ulcerative keratopathy. The effects of keratoconjunctivitis are localized to the inferonasal quadrant but are still more diffuse than the effects of toxic ulcerative keratopathy. The disease usually manifests as coarse and punctuate epithelial lesions with heaps and swirls of opaque epithelium. Pseudodendrites resembling herpetic dendrites may also develop (Krachmer et al. 2010).

Toxic ulcerative keratopathy is the most severe manifestation of toxic keratoconjunctivitis. Patients present with a characteristic oval epithelial defect located mainly in the inferonasal quadrant, where there is usually maximal contact between the drug and the surface of the eye (Krachmer et al. 2010; Holland et al. 2013). These defects can be round to oval without being ragged or irregular. The edges of the defect are gray and rolled up without prominent margins. The disease can be characterized by a "comet's impact crater," with the epithelial defect as the crater, surrounded by a severe, coarse superficial keratitis (Schwab and Abbott 1989). The most severe keratopathy is closest to the crater. Stromal edema is usually present, and epithelial edema may be a characteristic as well. Mucous threads, intense ciliary flush, papillary tarsal response, and chemosis may also be present (Krachmer et al. 2010).

Diagnostics

Recognition of toxicity is essential to treatment. Toxicity should be considered in the case of a chronic ocular irritation that does not improve with treatment. When toxicity is not recognized, increased doses of medication can exacerbate the underlying toxic ulcerative keratopathy. The patient interview is fundamental to gaining awareness of factitious cases of toxicity (Krachmer et al. 2010). Patients often neglect mentioning the use of over-the-counter eye drops, particularly in cases of abuse (Holland et al. 2013). Examination of clinical symptoms is also essential in diagnosis. Epithelial defects in the conjunctiva and cornea stain well with fluorescein and rose bengal dyes (Schwab and Abbott 1989; Albert et al. 2008).

Lab tests such as conjunctival biopsy, conjunctival scraping, and impression cytology, though not commonly performed, can also be used to assess toxicity. Conjunctival biopsies are not well tolerated by patients and test for autoimmunity and toxicity. A common finding of such biopsies regarding toxic damage shows squamous metaplasia of the conjunctival epithelium, subconjunctival inflammation, and fibrosis, particularly in patients who used glaucoma medications. Conjunctival scraping is typically only used to test

for allergy and infection but can also test for toxicity. Impression cytology provides a homogenous cell layer for studies that determine the cell types, cytokines, and membrane, and cytoplasmic inflammatory markers present in the conjunctival epithelium (Holland et al. 2013).

Differential Diagnosis

Differential diagnoses include punctate keratopathy and neurotrophic keratitis, which presents with an ulcer with rolled edges, similar to ulceration in toxic ulcerative keratopathy (Holland et al. 2013). Patients with iatrogenic toxic ulcerative keratopathy often present with other ocular diseases such as herpes simplex infection, herpes zoster infection, previous ocular surgery, and ▶ keratoconjunctivitis sicca. Toxic ulcerative keratopathy may be misconstrued as worsening of the disease for which the drops were administered (Schwab and Abbott 1989).

Prophylaxis

Unclear

Therapy

Treatment involves terminating the use of the offending medication and replacement with oral medication or preservative-free topical solution. Non-preserved ointments may provide symptomatic relief. Patching with the use of viscoelastic agents or therapeutic soft contact lenses are also useful in the treatment of epithelial defects (Schwab and Abbott 1989). In severe cases, conjunctival flap procedures or keratoplasty may be needed (Krachmer et al. 2010). In factitious cases, counseling, therapy, or psychiatric help may be warranted (Schwab and Abbott 1989).

Prognosis

Most patients heal, with only a slight vortex fluorescein-staining pattern on the epithelium (Schwab and Abbott 1989).

Epidemiology

Toxic keratoconjunctivitis is one of the most-frequent problems seen by corneal specialists. Toxic ulcerative keratopathy is a more rare manifestation of toxic keratoconjunctivitis (Albert et al. 2008).

Ulcers

Carrie Happ
Department of Ophthalmology, University of Pittsburgh School of Medicine, Eye and Ear Institute, Pittsburgh, PA, USA

Synonyms

Ulcerative keratitis

Definition

A loss of corneal tissue with associated inflammation.

Etiology

A corneal ulcer rarely occurs in healthy tissue and is usually associated with alteration in one of the

following: structure, immunity, innervation, or defense mechanism. The key question in initial diagnosis is if the ulcer is infectious or sterile. Risk factors include contact lens use, previous surface disease, trauma, and previous surgery (Green et al. 2008).

Infectious causes include bacterial, viral, fungal, and protozoan. The most common species of each group varies on geographic location. However, generally gram-positive cocci and gram-negative rods are common.

In the United States, the most common bacterial organisms are *Staphylococci* and *Pseudomonas*. Fungal causes include *Fusarium* and *Aspergillus*. Herpes simplex virus (HSV) and varicella zoster virus (VZV) are common viral causes. *Acanthamoeba*, a protozoa, is a relatively rare cause of corneal infection but deserves mention due to the difficulty in management and severe vision loss that results (Mascarenhas et al. 2014).

Sterile causes are due to systemic inflammatory conditions and neurotrophic cornea. If a sterile cause is suspected, it is important to obtain a complete medical history including a history of rheumatoid arthritis (RA), Wegener's granulomatosis, and Sjögren's syndrome. A neurotrophic cornea is usually due to a fifth nerve palsy or from recurrent infections usually with HSV or VZV. It results in impaired epithelial healing leading to inflammation and at times a secondary microbial infection.

Clinical Presentation

Presentation is variable depending on many factors including infectious organism, length of infection, immune status, corneal status, and history of antibiotic and steroid use. Corneal ulcers often present with red eye, decreased vision, ocular pain, tearing, and photophobia. These symptoms are usually rapid in onset. By diagnosis, all corneal ulcers have an epithelial defect and an inflammatory infiltrate which would be evident on slit-lamp exam.

Infectious ulcers generally are associated with corneal infiltration and are more purulent. There is also a higher chance of an anterior chamber reaction (AC) causing a hypopyon and corneal endothelial plaques.

Fungal ulcers often have satellite lesions and are more feathery in appearance. *Acanthamoeba* ulcers usually have pain out of proportion to exam, pseudodendrites early in presentation, and a ring infiltrate in later presentation (Mascarenhas et al. 2014).

Inflammatory ulcers also have an infiltrate associated but without a purulent reaction. There is also a less of an AC reaction.

Diagnostics (Lab Diagnostics)

The presence of epithelial defect and corneal infiltrate on slit-lamp exam. Initial exam should be detailed with measurements of both the infiltrate and epithelial defect. Measurements are followed closely to monitor for resolution.

Corneal scrapings for cultures and staining should be obtained especially for ulcers that have a chronic appearance, if the infiltrate is large, central, or deep. Polymerase chain reaction can also be done for viral diagnosis and if there is an atypical appearance with concern for fungal, protozoan, or mycobacterial causes (Krachmer and Mannis 2011).

For culture, topical anesthetic can be used. It is advised to use proparacaine hydrochoride 0.5% as other anesthetics can inhibit organism recovery. There are several instruments to choose from to obtain corneal scrapings including Dacron/calcium alginate or sterile cotton swab, a sterilized platinum spatula, or No. 15 Bard-Parker blade or jeweler's forceps. To obtain a maximum yield, several areas from the borders of the ulcers should be sampled. It is not sufficient to obtain only purulent material. If possible and/or clinically indicated, a culture of the patient's contact lenses, case, and solution may also be helpful in diagnosis of the causative organism (Krachmer and Mannis 2011).

Differential Diagnosis

Infectious versus noninfectious causes, corneal abrasion, corneal trauma, chemical injury, and foreign body.

Prophylaxis

Proper care for contact lenses.

Therapy

Wide-spectrum antibiotic drops are the mainstay in the initial treatment for infectious ulcers. Antibiotic ointments can be useful for less severe ulcers or as adjunctive therapy. The treatment should be tailored based on the response to antibiotics and also to results from cultures and sensitivities.

HSV and VZV are treated systemically with oral antiviral medications and occasionally with topical antivirals and topical steroids.

Fungal ulcers are treated with both oral and topical antifungal medications most commonly amphotericin B and natamycin.

Acanthamoeba is typically treated with the biguanides and chlorhexidine.

Sterile ulcers resulting from inflammatory conditions are treated with steroids. For resolution, the systemic condition must be treated and under control.

Mydriatic agents can also be used to dilate the patient to help with discomfort from photophobia.

Prognosis

Prognosis is dependent on many factors including causative organism, time to treatment, and compliance with treatment. Typically, prognosis is good, but this condition can be vision threatening due to perforation and opacification (Sirikul et al. 2008).

Epidemiology

Epidemiology varies depending on geographic location, type of ulcer, patient population, and climate (Sirikul et al. 2008). There are 30,000 cases of bacterial keratitis annually in the United States. Around 10–30 people in 100,000 contact lens wearers develop bacterial keratitis yearly in the United States (Krachmer and Mannis 2011).

Ultrasonic Pachymetry

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Ultrasound pachymetry

Definition

Measurement of corneal thickness with ultrasound.

Purpose

Assessment of corneal thickness prior to refractive surgery or cross-linking. Corneal thickness plays also a role in the interpretation of the measured intraocular pressure in glaucoma assessed with applanation tonometry.

Principle

Ultrasonic pachymetry is based upon the differential return of the ultrasonic waves by varying tissue types in the eye. Sound waves are emitted by a piezoelectric crystal and delivered with a probe. For axial measurements, the probe is placed perpendicular to the corneoscleral surface. Ultrasonic pachymetry can either be performed with the contact method when direct contact between the corneal surface and probe is made or with immersion biometry applying an eyecup between the eyelids filled with immersion fluid (e.g., balanced salt solution, methylcellulose).

Indication

Keratorefractive surgery, glaucoma.

Advantage/Disadvantage

Ultrasonic pachymetry is a reliable method for measurement of corneal thickness. A correct position of the probe is mandatory during measurement, and the results depend on the experience of the examiner. In contrast to optical biometry, ultrasound biometry can be performed even with an opaque cornea. Compared with optical pachymetry, ultrasound pachymetry is more time-consuming and requires topical anesthesia of the eye. Optical pachymetry produces thickness maps which may be more useful in identifying early thickness changes, such as in forme fruste keratoconus. However, corneal thickness measurements differ between optical and ultrasound pachymetry. This has to be taken into account when results are interpreted.

Ultrasonography, in Orbital Evaluation

Paul Petrakos[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Ultrasound

Definition

Orbital ultrasonography is a diagnostic imaging technique that uses the application of sound to evaluate orbital pathology.

Purpose

Orbital ultrasonography is a useful imaging modality in the evaluation of patients with orbital disorders.

Principle

Ultrasonography uses sound waves generated at frequencies greater than 20,000 Hz. The sound waves are reflected back to the transducer by tissue in its path, and a piezoelectric crystal in the transducer vibrates when it returns. This results in electrical impulses that are translated into data. Orbital tissue can be evaluated based on the principles of sound waves. Higher frequency waves penetrate less tissue but allow for better resolution, while lower frequency waves penetrate more tissue at the cost of resolution. Sound waves have higher velocity when traveling through solids than liquids. When they travel between tissue interfaces with different acoustic impedance, they can scatter, reflect, or refract. The sound waves that return to the transducer, or echoes, can be distinguished as hyperechoic, hypoechoic, or anechoic.

There are two main types of ultrasound used in ophthalmology. An A-scan, or time-amplitude scan, generates sound waves at 8 MHz and converts them into spikes that correspond with tissue interface zones. A B-scan, or brightness amplitude scan, generates sound waves at 10 MHz and produces a corresponding image. A B-scan allows for the assessment of the position and shape of a lesion. It also provides a description of its borders, the internal architecture of the structure, its reflectivity, and sound attenuation characteristics. In combination, they can accurately locate and diagnose many orbital pathologies.

Indication

Orbital tumors
Localization of foreign bodies
Thyroid eye disease
Orbital infection
Proptosis or globe malposition

Contraindication

Ruptured globe is a relative contraindication.

Advantage/Disadvantage

The advantage of ultrasonography in orbital evaluation is that it is minimally invasive with no exposure to radiation or contrast dyes, widely accessible, and relatively inexpensive. It does not require sedation or anesthesia for successful examination of an infant. It also provides real-time information to the clinician including compressibility, mobility, and vascularity of a lesion.

Disadvantages include significant interoperator variability and limited value in assessing lesions in the posterior orbit because of sound attenuation.

Upper Lid Retraction

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Definition

Eyelid retraction is the displacement of the normal position of the upper eyelid margin with respect to the limbus.

Basic Characteristics

Clinical Features

In most normal individuals, the upper eyelid margin rests 1–2 mm below the superior limbus. In upper eyelid retraction, the lid margin is elevated superiorly above this level, usually at or above the limbus, often with visible sclera. Lid retraction can lead to lagophthalmos and corneal exposure, leading to secondary epiphora and dry eye symptoms.

Examination

A complete ocular examination is indicated including measurements of the position of the upper eyelid with relation to the limbus. Other important measurements include the height of the palpebral fissure, degree of lagophthalmos, associated proptosis, levator muscle function, and distance from upper eyelid margin to the central corneal reflex. Radiological imaging such as computed tomography or magnetic resonance imaging may be helpful in the diagnosis of thyroid disease and orbital tumors.

Etiology

Eyelid retraction has many diverse causes including local, systemic, or central nervous system etiologies. In 1996, Bartley published a comprehensive classification scheme with three general mechanisms of lid retraction: myogenic, neurogenic, and mechanistic causes.

The myogenic causes of eyelid retraction include Graves' disease, which is the most common cause of both upper and lower eyelid retraction. Although the exact mechanism of retraction associated with Graves' disease is debated, histopathologic changes include inflammation, adipogenesis, and fibrous contraction of eyelid retractors. In addition, sympathetically innervated eyelid retractor muscles are preferentially affected. A common associated finding is lateral flare, in which the eyelid retraction is greater laterally than medially, resulting in an abnormal upper eyelid contour that appears to flare.

Other causes of myogenic eyelid retraction include botulinum toxin injection, congenital eyelid retraction, and postsurgical complications. The latter includes a change in eyelid position after vertical rectus muscle surgery, with anatomical connections between the superior rectus and levator muscles.

Neurogenic eyelid retraction is usually acquired but may be present at birth. More common causes include dorsal midbrain syndrome, aberrant regeneration or innervation of the oculomotor nerve, Guillain-Barre syndrome, and Marcus Gunn (jaw-winking) syndrome. This also includes pseudoretraction, which is commonly seen with contralateral blepharoptosis due to overcompensation in accordance with Hering's law.

The third major classification of eyelid retraction, mechanistic etiologies, includes causes related to structural changes in eyelid architecture. This includes congenital, cicatricial, traumatic, neoplastic, or postoperative causes.

Usher Syndrome

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Definition

Usher syndrome is an autosomal recessive disease that involves retinal degeneration in combination with sensorineural hearing loss.

Etiology

Etiology of Usher syndrome involves an abnormality in a dynamic protein complex that encodes for axonemal components, which are vital for ciliated structures in both photoreceptor cells of the retina and the hair cells of the inner ear. Multiple subtypes of abnormalities are known, and each can be differentiated according to specific gene and protein involved (Carr and Noble 1999; Gass 1997; Keats 2005; Weleber and Gregory-Evans 2006).

Clinical Presentation

Clinical signs of Usher syndrome involve fundus abnormalities common to other hereditary retinal diseases such as retinitis pigmentosa. These include attenuated retinal arterioles, peripheral pigment clumping, diffuse bone-spicule pigmentation, and waxy pallor of the optic nerve head (Fig. 1). Age of onset and degree of vision loss varies according to class of Usher syndrome. Currently, there are three types of Usher syndrome. Type 1 involves vestibular dysfunction, profound congenital sensorineural hearing loss, and childhood-onset retinopathy. Vestibular dysfunction may be the earliest sign and manifests as delayed walking (mean age of 20 months). Nyctalopia usually develops by 15 years of age. Type 1 patients lose vision quickly with only 77% of patients maintaining a visual acuity of 20/200 by the age of 40 years of age. Type 2 patients demonstrate nonprogressive partial congential

Usher Syndrome, Fig. 1 Color fundus photograph from an individual with Usher syndrome demonstrating typical fundus abnormalities of retinitis pigmentosa

deafness, later-onset mild retinopathy, and no vestibular dysfunction. Over 95% of patients with Type 2 disease maintain a visual acuity of 20/200 at 40 years of age. Type 3 is the least common class of Usher syndrome and is characterized by adult-onset progressive deafness (usually between the ages of 20–40), adult-onset retinopathy, and hyperopic astigmatism. Vestibular deafness and retinal degeneration are variable both in degree and age of onset in Type 3 Usher syndrome.

Diagnostics

Diagnosis of Usher syndrome begins with recognizing symptoms of a retinal degeneration in combination with hearing and vestibular dysfunction. Dilated ophthalmoscopy identifies the typical signs of retinal degeneration, and electroretinogram documents the degree of retinal dysfunction. Classically, the electroretinogram ranges between profoundly abnormal to nondetectable by non-averaging techniques in all types. Formal genetic studies are available to identify specific mutations and type of Usher syndrome. Formal visual field testing is helpful to evaluate degree of peripheral visual field loss and determine need for low vision aids and counseling.

Differential Diagnosis

Differential diagnosis of Usher syndrome includes disease with retinal abnormalities and hearing loss, including congenital rubella, Alport syndrome, Refsum disease, Hurler syndrome, Cockayne syndrome, Bardet-Biedl syndrome, Alstrom disease, Flynn-Aird syndrome, Friedreich ataxia, and Kearns-Sayre syndrome. Distinguishing features include mode of inheritance, prenatal history, spectrum of disease, and physical findings.

Prophylaxis

No prophylaxis is available.

Therapy

Currently, no cure is available for Usher syndrome. Therapy is aimed at maximizing auditory and visual function through the use of auditory and visual aids. For many patients, a team approach utilizing an ophthalmologist, otolaryngologist, audiologist, and social worker is required to help these patients maintain maximal functioning in their tasks of daily living.

Prognosis

Visual prognosis for Usher syndrome varies according to type of disease, but is overall generally poor. Type 1 produces severe progressive vision loss, with age of onset early in childhood. Type 2 disease produces less severe vision loss, with age of onset typically during second decade of life. Type 3 produces the most variable amount of vision loss, with age of onset being quite variable as well.

Epidemiology

Prevalence of Usher syndrome is estimated to be 3 cases per 100,000. Mode of inheritance is autosomal recessive with both sexes being affected equally.

Uvea (Uveal Tract)

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Uveal Tract

Definition

The uvea is a vascular, pigmented structure of the eye composed of three different parts: the iris, the ciliary body, and the choroid. It lies between the sclera and the neuroepithelium and contains melanocytes that give it its unique color.

Structure

The uvea consists of the iris, the ciliary body, and the choroid.

The iris is a pigmented diaphragm that lies just anterior to the crystalline lens and separates the anterior and posterior parts of the eye. The iris can be divided into three different layers: (1) the anterior border layer that creates the ridges and crypts of the iris surface, (2) the stroma which is the thickest layer and contains blood vessels and nerves, and (3) the posterior layer that consists of the dilator muscle, sphincter muscle, and pigmented epithelium.

The ciliary body adjoins the iris base anteriorly and is continuous with the choroid posteriorly. It can be divided into an anterior ring, the pars plicata, and a posterior ring, the pars plana. The pars plicata contains 70–75 fingerlike projections called the ciliary processes. Ciliary processes have an inner stroma that contains smooth muscle, vascular networks, melanocytes, and connective tissue. The pars plana is approximately 3.5–4.0 mm wide in an adult eye and extends from the pars plicata to the choroid. The ciliary body is covered by a bilayered epithelium. The innermost nonpigmented ciliary epithelium is the main source of aqueous humor in the eye. The zonula occludens of the outer pigmented ciliary epithelium creates the blood-aqueous barrier.

The choroid forms the posterior part of the uveal tract and lies between the sclera and retina and extends from the ora serrata to the optic nerve. The choroid consists of four different layers from anterior to posterior: Bruch's membrane, choriocapillaris, stroma, and suprachoroid. Bruch's membrane has five different layers: the basement membrane of the retinal pigment epithelium (RPE), the inner collagenous zone, an elastic layer, the outer collagenous zone, and the basement membrane of the choriocapillaris. The choriocapillaris is the capillary layer of the choroid and contains fenestrated vessels that provide the blood supply to the RPE and outer retina. The stroma contains larger, unfenestrated vessels, melanocytes, and fibroblasts. The suprachoroid is the outermost layer of the choroid where it adjoins the sclera and is a network of collagen fibers, fibroblasts, elastic fibers, melanocytes, ganglion cells, and nerve complexes.

Function

The uvea serves many functions in the eye. Blood to most of the eye is supplied by the uvea via the anterior and posterior ciliary artery branches of the ophthalmic artery. Dilation and constriction of the pupil result from sympathetic and parasympathetic stimulation of the dilator and sphincter muscles located in the posterior iris. Aqueous humor of the eye is produced by the nonpigmented ciliary body epithelium. Near accommodation is the result of ciliary body smooth muscle contraction which reduces zonular tension on the lens of the eye and shifts it forward. Ciliary body muscle contraction also increases aqueous outflow of the

eye by opening the trabecular meshwork. The choroid plays an important part in heat dissipation in the eye and nourishes the RPE and outer retina.

Clinical Relevance

Inflammatory changes can occur in the uveal tract as a result of infectious, traumatic, neoplastic, or autoimmune insults and result in uveitis. Both primary and metastatic neoplasms of the eye can occur in the iris, ciliary body, and choroid.

Uveal Melanoma

Evangelos Gragoudas, Anne Marie Lane and Ivana Kim
Department of Ophthalmology, Retina Service, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA, USA

Synonyms

Choroidal and/or ciliary body and/or iris melanoma; Intraocular melanoma; Ocular melanoma

Definition

Uveal melanomas arise from uveal melanocytes distributed throughout the stroma of the choroid, ciliary body, and iris. Malignant melanomas often develop from preexisting nevi.

Etiology

Uveal melanoma's etiology is poorly understood, but risk factors for uveal melanoma include pigmentation factors (light iris and complexion, propensity to sunburn), the presence of cutaneous and iris nevi (Seddon and McCannell 2013), and ocular or oculodermal melanocytosis. Genetic mutations including mutations in GNAQ or GNA11 have been demonstrated in greater than 80% of primary uveal melanomas (Harbour and Chao 2014).

Clinical Presentation

Diagnostics

The diagnosis of uveal melanoma is usually made based upon fundoscopic examination in conjunction with ultrasound and fluorescein angiography. Immediate treatment after diagnosis is routine. Until recently, biopsy was generally not indicated. However, many patients will elect to have a fine needle biopsy after diagnosis for the purpose of molecular prognostic testing, which reliably predicts the risk of metastatic disease.

In the USA, follow-up is completed every six months to annually after local treatment, and typically consists of ophthalmological examination, liver function tests, and/or imaging of the liver with CT scan, MRI, or ultrasound to monitor for metastasis. Although most metastases develop within 3–6 years of diagnosis, late recurrences are not unusual so long-term surveillance is prudent.

Differential Diagnosis

Choroidal nevus, choroidal metastasis, choroidal hemangioma, hemorrhagic RPE, or choroidal detachment.

Prophylaxis

None.

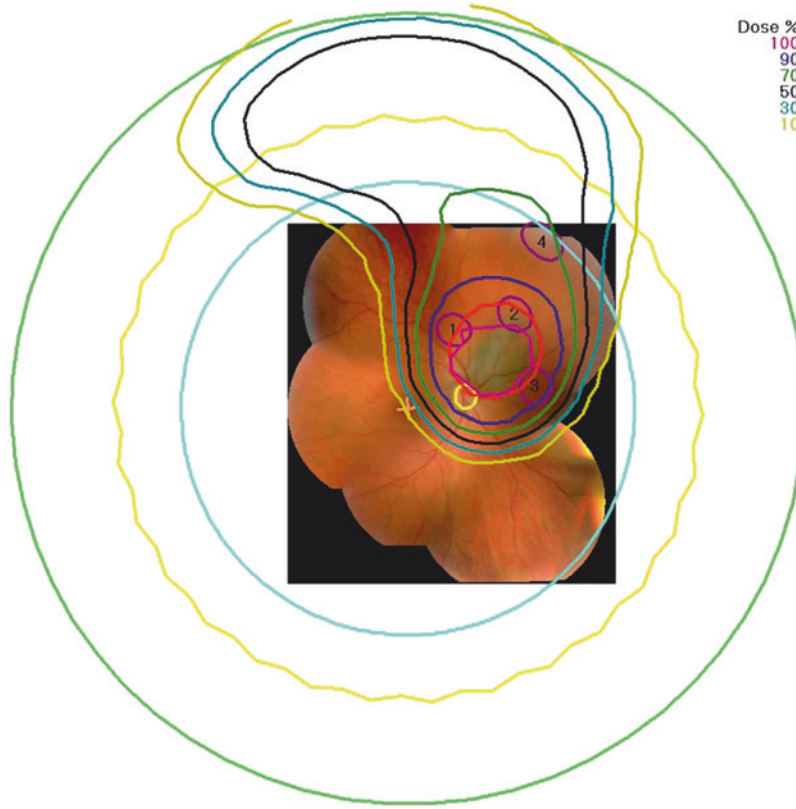
Therapy

Iris melanomas are either excised or treated with radiotherapy. Although some ciliary body melanomas are treated with cyclectomy, the majority of ciliary body melanomas and most choroidal melanomas are treated conservatively with one of two forms of radiotherapy (RT): brachytherapy using radioactive plaques or external beam RT (EBRT). Radiation therapy is hypothesized to cause lethal chromosomal injury to tumor cells. Additionally, it indirectly affects tumor viability by damaging the tumor vasculature that is necessary for tumor growth and systemic tumor cell dissemination. Local tumor control is achieved in nearly all cases, and survival rates are similar to those seen after enucleation.

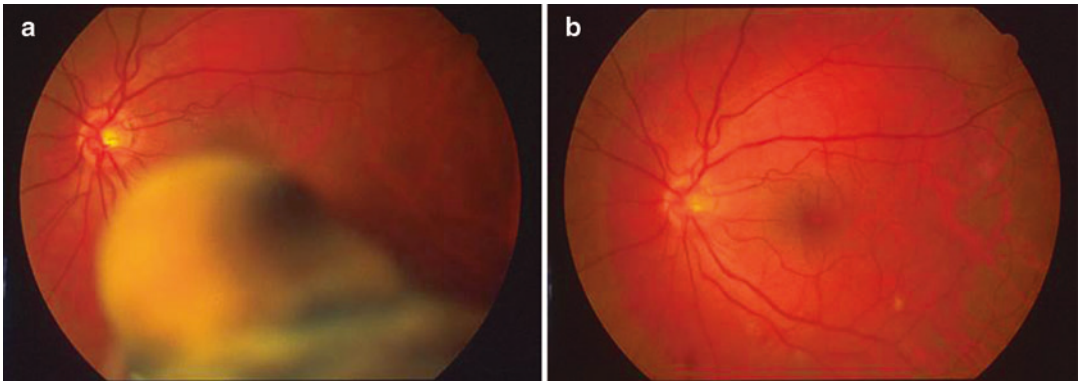
Depending on the clinical characteristics of the tumor, enucleation (very large tumors or cases with large extrascleral extension), resection, and thermotherapy (small tumors or as an adjunct to brachytherapy to reduce risk of tumor recurrence) may be considered as alternative therapies.

Proton Therapy

Charged particle irradiation is the most common type of EBRT. Although several types of charged particles (protons, carbon ions, helium ions) have been used to irradiate uveal tumors, proton irradiation is the only one used today. The highly localized and homogeneous dose distributions achieved with protons allow for the treatment of tumors located near the optic disk and fovea and large tumors, tumors that may be unsuitable for brachytherapy (Gragoudas et al. 2008) (Fig. 1).



Uveal Melanoma, Fig. 1 Proton Irradiation: Treatment Planning. A wide-angle view of the eye shows the position of the tumor (*red contour*), four tantalum markers (*purple ovals*), and the planned isodoses. In the background, a composite small-angle fundus image is registered to the eye model. The displayed eye structures are limbus (*green circle*), ora serrata (*wavy yellow line*), equator (*blue circle*), optic disk (*yellow circle*), and posterior pole (*orange cross*)



Uveal Melanoma, Fig. 2 Tumor Regression. Choroidal melanoma protruding through the vitreous in close proximity to both the optic nerve and macula. (**a**) Before proton irradiation. (**b**) After proton irradiation, tumor has significantly regressed

The tumor is controlled in 95% and the eye is maintained in 84% of patients after proton irradiation (Fig. 2). Approximately one-quarter of patients who undergo enucleation do so because the tumor has recurred (Gragoudas et al. 2002).

As with all types of RT, radiation retinopathy and optic neuropathy can develop after proton irradiation. For patients who have tumors located near the fovea or optic disk, some radiation exposure is inevitable, and the risk of radiation maculopathy, radiation papillopathy, and vision loss as a secondary complication is increased. Reported 5-year rates of maculopathy, papillopathy, and vision loss after proton irradiation in patients with tumors located in close proximity to these critical structures were 64%, 35%, and 68%, respectively (Lane and Gragoudas 2007).

Other complications that may significantly affect visual function include cataracts, neovascular glaucoma, and vitreous hemorrhage.

Prognosis

Iris melanomas have a more benign course than ciliary body and choroidal melanomas (10-year survival is approximately 95% for iris tumors compared to 77% for choroidal tumors). Survival rates are lower in patients who possess high-risk characteristics such as large tumor size, heavily pigmented tumors, or tumors originating in the ciliary body. Molecular prognostic testing with gene expression profiling or DNA analysis is now available and can accurately classify patients as having low or high risk of disease progression (Damato et al. 2007; Cassoux et al. 2014; Ganguly et al. 2014; Harbour and Chao 2014).

The 15-year cumulative probability of dying from metastasis, calculated using risk scores derived from logistic regression models of clinical prognostic factors, illustrate the variation in risk: the melanoma-related mortality rate was less than 10% in the group of patients with the lowest risk scores compared to over 50% in the highest risk score patient group (Gragoudas et al. 2002).

For patients who develop metastatic disease, the prognosis is poor. Effective treatments for hepatic metastasis, the most common site in uveal melanoma, are lacking. Nevertheless, more frequent monitoring of patients at high risk may be worthwhile so that patients can be referred for palliative care or experimental therapies.

Epidemiology

Uveal melanoma is rare, with an incidence of five cases per million annually in the USA. Approximately 95% of ocular melanomas arise in the uvea, and the most common location is the

choroid (more than 80% of cases). Uveal melanoma is the only life-threatening tumor of the eye in adults. It is more common in males than females and develops predominantly in white populations (Seddon and McCannell 2013).

Uveal Tract

► Uvea (Uveal Tract)

Uveitic Glaucoma

Friederike Mackensen
Interdisciplinary Uveitis Center, Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Synonyms

Secondary glaucoma in uveitis/inflammatory eye disease

Definition

Intraocular pressure (IOP) rise due to intraocular inflammation with associated optic nerve damage.

Etiology

Three possible mechanisms are involved in the pathogenesis of inflammatory hypertension or glaucoma adapted from (Radhakrishnan et al. 2010):

1. Direct inflammation of the trabecular meshwork or trabeculitis (IOP elevation parallels inflammatory activity)
2. Acute angle closure due to inflammatory changes
   1. Pupillary block (iris bombé caused by posterior synechiae)
   2. Non-pupillary block (forward movement of the lens-iris diaphragm due to ciliochoroidal effusion)
3. Chronic, mixed-mechanism ocular hypertension/glaucoma
   1. Chronic closed angle (anterior synechiae or vascular membranes)
   2. Open angle (increased outflow resistance due to chronic damage in the trabecular meshwork)

Friederike Mackensen: deceased.

Clinical Presentation (Listed by Supposed Etiology)

1. See other uveitis etiologies and Posner-Schlossman syndrome:
   1. Fibrinous uveitis forms such as acute anterior uveitis with HLA-B27
   2. Vogt-Koyanagi-Harada syndrome, scleritis, and sympathetic ophthalmia
2. For example, anterior uveitis associated to juvenile idiopathic arthritis (JIA), sarcoidosis, and Fuchs uveitis syndrome (FUS).

Diagnosis

The most important diagnostic tool is correct determination of IOP at each visit regardless of patient age or emergency setting. Goldmann applanation measurements are still the gold standard; in some patients which cannot be examined on the slit lamp, handheld tonometers can be helpful. Appropriate diagnostic steps when glaucoma is suspected: visual field examination and morphometric examination of the optic nerve head.

Differential Diagnosis

Inflammatory ocular hypertension syndromes not leading to optic nerve damage. Entities where noninflammatory materials block the trabecular pores, as, for example, lens material in phacolytic glaucoma or red blood cells in hyphema. Distinction of pupillary and non-pupillary block should usually be feasible by slit lamp exam; in some cases ultrasound biomicroscopy may be helpful. An important differential diagnosis is corticosteroid-induced IOP rise or glaucoma which may occur days to weeks after initiation of treatment. Therefore, it is of utmost importance to check the IOP of uveitis patients at the first visit!

Prophylaxis

To avoid scarring of trabecular meshwork, strict uveitis control is advisable. Patient counseling about the importance of regular medication. Visual field examination and morphometric examination of the optic nerve head should be repeated in regular intervals to monitor the treatment effect.

Therapy

Uveitis should be treated according to the suspected underlying mechanism and/or anatomic presentation. When in doubt regarding a potential role for corticosteroids in pressure rise, loteprednol may be an alternative or corticosteroid-sparing medication altogether. Care should be taken not to undertreat uveitis for the fear of corticosteroid-related side effects as then complications of chronic inflammation may develop. Antiglaucomatous medication can be chosen similar to treatment of POAG, except that prostaglandin analog should be reserved for third-line treatment as they may promote inflammation or macular edema. Still a small clinical trial found no disadvantage of a prostaglandin analog therapy (Markomichelakis et al. 2009) and better IOP control. So first beta-blockers (cave lung disease in sarcoidosis) and then carbo-anhydrase inhibitors followed by alpha agonists or prostaglandin analog should be used (Radhakrishnan et al. 2010). In cases of acute angle closure, laser peripheral iridotomy is the treatment of choice. In angle closure due to choroidal effusion, systemic corticosteroids and cycloplegia are indicated. In cases of chronic glaucoma, surgical treatment may be needed. Trabeculectomy with mitomycin C reaches similar success rates to POAG eyes (Kaburaki et al. 2009). In failures a filtering implant should be considered. Uveitis has to be controlled medically before surgical treatment can be done.

Prognosis

The prognosis of uveitic glaucoma depends on the complications already having taken place.

Epidemiology

Generally the incidence of chronic uveitic glaucoma is low, ranging in sarcoidosis-associated uveitis from 11 to 26%, in FUS up to 60%, and 6 to 8% in JIA-associated anterior uveitis (Heiligenhaus et al. 2007).

Synonyms

MS-associated uveitis

Definition

The uvea is the middle layer of the eye, divided anteriorly into the iris and ciliary body and posteriorly into the choroid. Inflammation of the anterior uveal tract is known as anterior uveitis or iritis. Uveitis posterior to the lens includes vitritis, intermediate uveitis, pars planitis (accumulation of yellow-gray inflammatory exudates at the pars plana and ora serrata), choroiditis, retinitis, chorioretinitis, and retinochoroiditis.

Simultaneous inflammation anterior and posterior to the lens is known as panuveitis.

Etiology

Though the etiology of multiple sclerosis (MS)-associated uveitis is not yet completely understood, the possibility of a genetic component is substantiated by the presence of a shared human leukocyte antigen (HLA). MS is associated with *HLA-DR2*, found in 50–70% of North American and European patients compared with 20–25% of controls, and the same *HLA-DR2* antigen has also been associated with intermediate uveitis. Malinowski et al. reported a positive *HLA-DR2* in 67.5% of 40 patients with pars planitis, compared with 28% of controls. Within this specific cohort, MS subsequently developed in 12.5%. The results of this study along with several others suggest an immunogenetic predisposition to pars planitis, MS, and MS-associated uveitis; however the relationship between *HLA* modulation and the pathogenesis of inflammation in both the eye and the central nervous system (CNS) remains ambiguous.

Though the association between MS and uveitis is well documented and has been reported since 1947, with the majority of descriptions being based on patients with pars planitis, the pathophysiological connection between MS and uveitis is unknown. Some have speculated that a process similar to the autoimmune demyelinating manifestations of MS occurs in the eyes of patients with MS-associated uveitis; however, certain inflammatory types occur in locations with no myelin present. Other theories have postulated a common, nonmyelin antigen in the CNS and the retina and/or uvea as the target of the inflammatory response, such as in the mouse model of MS where passively transferred autoreactive T cells against astrocyte-derived protein S100B stimulate both CNS inflammation and uveitis. In a larger study of 93 autopsied eyes in patients with MS, 7 eyes had lymphocytic or granulomatous retinal periphlebitis and 5 eyes had focal areas of lymphocytic or granulomatous retinitis. 44.7% had optic nerve atrophy, including all eyes with active ocular inflammation. Immunoperoxidase studies of the retinal veins showed a pervasive distribution not confined to areas with focal periphlebitis lesions. The authors thus concluded that this nonspecific inflammation was the result of the autoimmune response, though it is still unknown whether the inflammation is due to a primary vasculitis versus a secondary response against an unknown antigen.

Clinical Presentation

The most common type of MS-associated uveitis is intermediate uveitis (pars planitis), defined as inflammation predominantly of the vitreous cavity, though this prevalence varies. Additionally, a myriad of nonspecific clinical features have been reported, with early reports of uveitis in patients with MS highlighting retinal periphlebitis in association with vitreous inflammation and retinal edema. Significantly, not all patients with MS-associated uveitis present clinically with intermediate uveitis, and patients with MS have been reported to have all types of uveitis (anterior, intermediate, and posterior), as well as cataract, macular edema, and epiretinal membrane formation. A study examining both the clinical and radiological characteristics of patients with MS and coexisting uveitis noted no correlation between the type of uveitis and the type of MS, consequently concluding that patients with MS and coexisting uveitis have a clinical pattern no different than "typical" MS.

Diagnostics

Cranial magnetic resonance imaging (MRI) is the test of choice to support the clinical diagnosis of MS, but some patients require ancillary testing to support the diagnosis including lumbar

puncture (showing IgG abnormalities or oligoclonal bands).

Differential Diagnosis

Behcet disease
Syphilis
Sarcoidosis

Other infections (e.g., Lyme borreliosis, toxocariasis, tuberculosis, cat scratch disease, and West Nile viral infection)

Therapy

Treatment of MS-associated uveitis depends on both the location and degree of inflammation. For instance, intermediate uveitis may require no treatment when vision-threatening complications (e.g., macular edema) are absent due to the fact that the risk of therapy may outweigh the benefits. It is still unknown whether early treatment of MS-associated uveitis in patients who do not have vision compromise has any long-term benefit with regard to vision or MS itself. Similar to other types of uveitis, treatment options include topical, oral, periocular, and intravitreal steroids, in addition to immunosuppressants. In those patients who have snowbanking and in whom systemic or periocular steroids have been ineffective, cryotherapy to the retinal periphery has been employed. Likewise, laser photocoagulation has also been used in patients with pars planitis. These treatments carry the risk of augmenting inflammation and higher risk of rhegmatogenous retinal detachments.

One possible beneficial treatment option is the use of interferons (IFN). IFN-β has been used to alleviate the frequency and severity of MS flares and has also been shown to decrease ocular inflammation in experimental autoimmune encephalomyelitis. One small study of 13 patients examined this treatment in MS-associated uveitis and had visual acuity improve in 17 eyes (71%) during a median follow-up time of 24.6 months. The results are promising, but additional studies are needed.

Prognosis

Long-term visual outcomes and complications were examined in a study by Malinowski in patients with pars planitis and overall showed favorable prognoses. Patients that had significant cataracts appeared to have greater risks for retinal detachments. Periphlebitis at the time of pars planitis diagnosis increased the risk for future development of optic neuritis or MS.

The prognosis of MS-associated uveitis is dependent on the MS subtype and the severity of the uveitis. The relapsing-remitting form of MS is generally associated with a better prognosis than progressive disease. In those whom have the progressive form from the onset, irreversible disability occurred sooner when compared with those with the relapsing-remitting onset. In patients with the new-onset anterior uveitis, factors associated with a lower rate of treatment-free remission and persistent inflammation include bilateral uveitis and presentation with 1+ or more vitreous cells or visual acuity of 20/200 or worse.

Epidemiology

The incidence of MS-associated uveitis has wide variability and depends on numerous factors, including the patient population, type of uveitis, and diagnostic criteria for both MS and uveitis. Uveitis is significantly more common in patients suffering from MS, with some data reporting up to ten times the frequency encountered in the general population. Likewise, the frequency of MS in patients with uveitis is 0.5–14%, versus 0.02–0.12% found in the general population. Demographically, MS-associated uveitis is frequently bilateral, presenting in individuals between 20 and 50 years of age, with two of the larger pars planitis studies reporting a mean age of onset of uveitis reported between 22.4 and 22.6 years of age. These patients are frequently

female, which is in accordance with the female prevalence in MS and most forms of uveitis.

Synonyms

Ophthalmic division of the trigeminal nerve; Ophthalmic nerve; V1

Definition

The ophthalmic nerve (*V1*) or ophthalmic division of the trigeminal nerve contains afferent sensory fibers to the skin overlying the frontal and nasal bones. Similarly, the sensation to the cornea and the conjunctiva is supplied by V1.

Once the ophthalmic division of the trigeminal nerve comes off the trigeminal ganglion, V1 enters the cavernous sinus along with the maxillary division (V2); cranial nerves III, IV, and VI; and the internal carotid artery. Ocular sympathetic fibers on the internal carotid artery join the ophthalmic division within the cavernous sinus. After exiting the cavernous sinus, yet before entering the superior orbital fissure, the ophthalmic division splits into three separate branches: the lacrimal, frontal, and nasociliary nerves.

The lacrimal nerve goes to innervate the lacrimal gland after receiving autonomic fibers necessary for this gland's function. Autonomic fibers travel with the lacrimal nerve via a communicating branch of the zygomaticotemporal nerve and are responsible for lacrimal gland function. The lacrimal nerve supplies sensory fibers to parts of the lid and conjunctiva. The frontal nerve divides into the supraorbital nerve and supratrochlear nerves which provide sensory input to the upper eyelid, scalp, and forehead.

The nasociliary nerve provides sensory innervation to the globe and cornea through many

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

branches. A terminal branch of the nasociliary nerve, named the external nasal nerve, provides sensory input to the nose and may become involved in herpes zoster ophthalmicus (i.e., the shingles). When the tip of the nose is involved with herpes zoster virus (HZV), it has been referred to as the Hutchinson sign and may have prognostic importance for the development of ocular involvement. The long ciliary nerve (a branch of the nasociliary nerve) is also of interest as it does not synapse in the ciliary ganglia, yet serves to bring postganglionic sympathetic nerve fibers into the ciliary ganglion. These long ciliary nerve fibers are joined by postganglionic parasympathetic fibers and continue as short ciliary nerves. Sympathetic fibers from the long ciliary nerves innervate the dilatory pupillae muscle, whereas afferent sensory fibers travel though the ciliary ganglion to innervate the cornea and eyeball.

Synonyms

Maxillary division of the trigeminal nerve; Maxillary nerve; V2

Definition

The maxillary nerve (*V2*) provides sensory input to the conjunctiva, eyelid, and skin overlying the maxillary and zygomatic bones. Once the maxillary division of the trigeminal nerve comes off the trigeminal ganglion, V2 enters the posterior cavernous sinus along with cranial

nerves III, IV, V1, and VI, the ocular sympathetic fibers, and the internal carotid artery. After leaving the cavernous sinus, the maxillary division does not enter the superior orbital fissure. Instead, V2 exits the skull base via the foramen rotundum. Traveling anteriorly, the maxillary nerve sends a branch to the pterygopalatine ganglia but continues forward. Unlike cranial nerves V1, III, IV, and VI, the maxillary division enters the orbit through the inferior orbital fissure.

The zygomatic nerve splits into the zygomaticofacial and zygomaticotemporal nerves. The zygomaticofacial nerve is responsible for sensation of the cheek, while the zygomaticotemporal nerve is responsible for sensation in the temporal region. It is worth noting the zygomaticotemporal nerve sends a communicating branch to the lacrimal nerve carrying parasympathetic nerves to the lacrimal gland. After the zygomatic nerve branches off, the maxillary nerve continues and becomes the infraorbital nerve and travels through the inferior orbital fissure. The infraorbital nerve then branches several times to supply sensory input to the conjunctiva and skin of the inferior eyelid.

Synonyms

Mandibular division of the trigeminal nerve; Mandibular nerve; V2

Definition

The mandibular nerve (*V3*) provides sensation to the mandibular prominence and motor innervation to the muscles of mastication. Once the mandibular division (V3) of the trigeminal nerve comes off the trigeminal ganglion, V3 does not enter the cavernous sinus like the other two divisions of the trigeminal nerves (V1 and V2). Instead, motor fibers join the mandibular division

and V3 exits the calvarium through the oval-shaped canal named the foramen ovale.

After giving off the meningeal branch, the mandibular nerve splits into a posterior division and an anterior division. Eventually, these branches innervate the muscles of mastication and sensation to the mandibular prominence. Cutaneous sensory nerves that branch from the third division of the trigeminal nerve include the buccal, auriculotemporal, and mental nerves.

Type-II vascular malformation

Basic Characteristics

Definition

Orbital varices are a rare orbital vascular malformation, representing abnormally dilated orbital veins. Most commonly orbital varices involve the superior ophthalmic vein, although any orbital vein may be involved. Orbital varices account for approximately 1% of orbital tumors in histopathologic series (Karcioglu 2014).

Etiology

Congenital or acquired weakening of the vein wall leads to the development of orbital varices. Factors contributing to vessel weakening are poorly understood.

These varices are predisposed to thrombosis, owing to sluggish blood flow through the weakened vessel as well as pooling of blood. Orbital veins are valveless, increasing the tendency of blood to pool in these veins. When thrombosis occurs and further obstructs blood flow, there can be proximal distention and enlargement of the varix (Karcioglu 2014).

Clinical Features

Demographics

Orbital varices typically present in the second to fourth decade, although they may be present in any age group. Orbital varices are rare and comprise between 0% and 1.3% of orbital tumors (Karcioglu 2014).

Signs and Symptoms

Patients with orbital varices typically present with painless intermittent proptosis. Proptosis is often only present or exacerbated during activities that increase central venous pressure, such as coughing, straining, bending, prone positioning, and the Valsalva maneuver. Positional proptosis occurs because the varix is in communication with the systemic venous circulation and may not be seen in patients with non-distensible varices (Karcioglu 2014). Other clinical signs and symptoms may include widening of the palpebral fissure, eyelid ptosis, and even irregular astigmatism or optic nerve compression depending on the location of the lesion. Rarely, orbital varices may present acutely with sudden onset pain and proptosis as a result of hemorrhage or thrombosis. Hemorrhage into an orbital varix may cause an orbital compartment syndrome with pain, proptosis, and optic nerve compromise.

Categorization

Venous malformations are defined by the degree of vascular flow. Type-I lesions have no flow, Type-II lesions have slow venous flow, and Type-III lesions have rapid, arterial-type flow. Orbital varices are categorized as Type-II venous malformations with low-pressure flow through dilated venous channels.

Orbital varices are described as distensible or non-distensible. Varices are typically distensible, owing to the weakened vessel wall. Non-distensible lesions may not demonstrate the classic positional proptosis and are more likely to hemorrhage than distensible varices (Black and Smith 2012).

Orbital varices may be further classified as primary or secondary lesions. A primary orbital varix is an isolated lesion that is confined to the orbit and is not associated with any other pathology. In contrast, a secondary orbital varix develops as a consequence of an intracranial arteriovenous malformation shunting blood into the orbital veins and causing them to dilate (Karcioglu 2014).

Differential Diagnosis

The differential diagnosis for unilateral proptosis includes lymphangioma, capillary hemangioma, arteriovenous fistula, hemorrhage, trauma, thyroid eye disease, idiopathic orbital inflammation (orbital pseudotumor), lymphoma, and metastatic disease. The differential for spontaneous orbital hemorrhage includes lymphangioma, trauma, bleeding disorder, and cavernous hemangioma (Karcioglu 2010).

Diagnostic Workup

Clinical Evaluation

Patients with suspected orbital varices should undergo a complete ophthalmic examination including exophthalmometry to assess for proptosis. Exophthalmometry should be performed with the patient relaxed and then repeated with patient performing the Valsalva maneuver. Dynamic proptosis that increases with Valsalva suggests an orbital varix.

Imaging

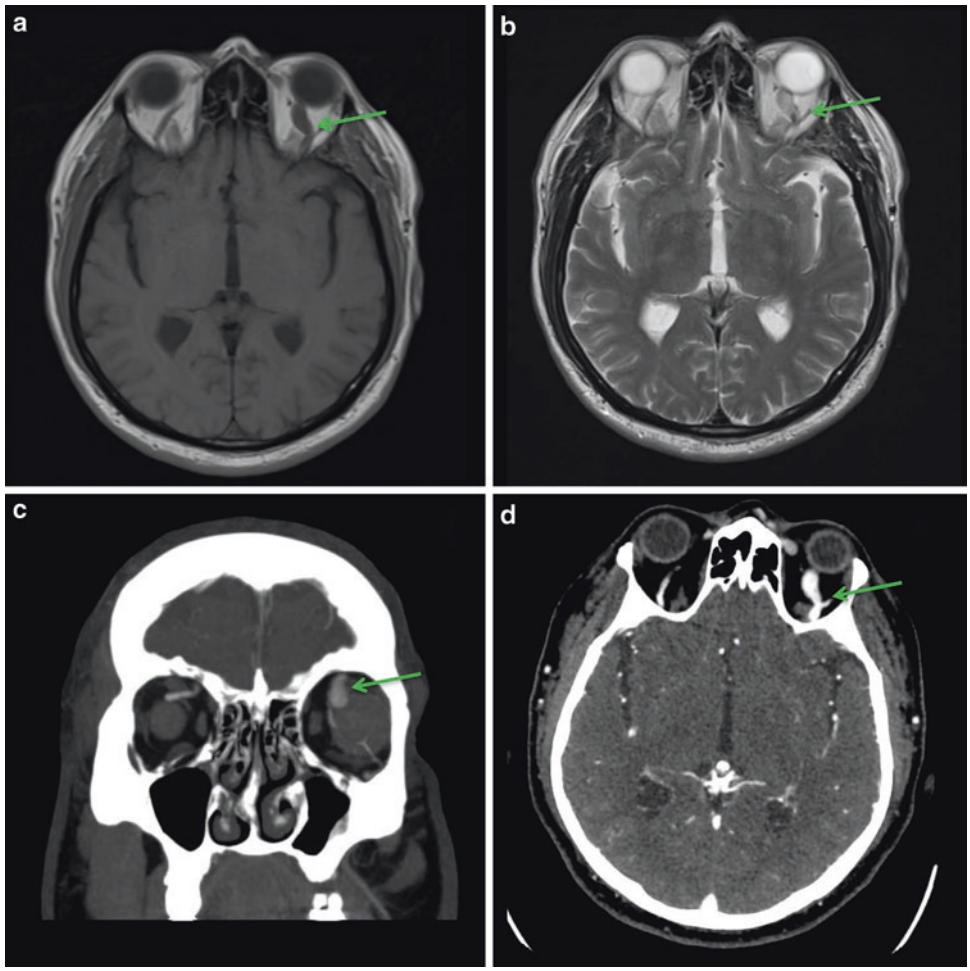
Multiple imaging modalities are available for the diagnosis and evaluation of orbital varices. The traditional "gold standard" for vascular malformations is digital subtraction angiography. However, catheter angiography carries a risk of stroke or vascular compromise to the eye and is difficult to perform given the small caliber of orbital vessels. In addition, catheter angiography does not provide visualization of surrounding orbital structures and has largely been replaced by noninvasive modalities including ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) (Black and Smith 2012). Brain imaging should also be performed as approximately 10% of patients have a non-contiguous intracranial vascular malformation (Karcioglu 2010).

Ultrasound On ultrasound imaging, orbital varices appear as dark, anechoic tubes. On A-scan ultrasound, varices demonstrate low internal reflectivity and expansion of the lesion with Valsalva. On B-scan ultrasound, varices appear as linear, channeled structures with an echolucent lumen. Color Doppler imaging may be utilized to observe venous flow and typically demonstrates dynamic change in the lesion size during

respiration and increased venous flow or flow reversal with the Valsalva maneuver (Karcioglu 2010).

Computed Tomography (CT) CT is noninvasive and provides excellent visualization of orbital structures. CT is relatively inexpensive and can be obtained rapidly but exposes the patient to radiation. CT angiography may be performed with the aid of iodinated contrast media, although caution must be exercised as some patients have a serious allergy to contrast. On CT, orbital varices appear as a dilated, tortuous vessel that tapers towards the orbital apex (Esmaeli 2010). CT is excellent at demonstrating phleboliths, which appear hyperintense. Dynamic CT and CTA can be performed with the patient performing the Valsalva maneuver and demonstrate enlargement of the lesion and changes in blood flow.

Magnetic Resonance Imaging (MRI) Similar to CT, MRI provides high-quality noninvasive imaging. MRI does not involve any radiation



Varices, Orbital, Fig. 1 Imaging characteristics of orbital varices. Imaging from patient with an incidentally discovered varix of the Left superior ophthalmic vein. **a** Axial T1 MRI demonstrating hypointense varix. **b** Axial T2 MRI with hyperintense varix. **c** Coronal CTA demonstrating contrast filling of dilated vein. **d** Axial CTA demonstrating contrast filling of dilated vein

exposure and carries a smaller risk of contrast allergy but is more expensive and takes longer to obtain relative to CT imaging. Similar to CT, MRI demonstrates a dilated, tortuous varix that expands with Valsalva. Orbital varices range from hypointense to hyperintense on T1 sequences, appear hyperintense on T2 imaging, and demonstrate avid enhancement with gadolinium contrast (Black and Smith 2012) (Fig. 1).

Histopathology

On histopathologic examination, excised varices appear as dilated vascular channels lined by endothelial cells. The vessel walls are line with irregular, attenuated smooth muscle cells (Black and Smith 2012). There is thickening and fibrosis of the vessels walls, and these become lined with hemosiderin pigment as a result of chronic hemorrhage and fibrosis. Pathologic section may also demonstrate chronic infiltration of inflammatory cells as well as intraluminal calcifications consistent with phleboliths (Karcioglu 2014).

Management

Orbital varices are challenging to remove surgically and they are often monitored or managed conservatively. If orbital varices become symptomatic, the anterior portion may be resected or embolization may be attempted (Karcioglu 2010). Resection remains a challenge owing to the confined space of the orbit, proximity to vital structures, and risk of compartment syndrome from hemorrhage and requires an excellent understanding of the surgical anatomy, careful dissection, and hemostasis.

Alternatively, endovascular catheter embolization may be attempted prior to surgery or instead of surgery. Embolization may obviate the need for surgery or decrease the risk of bleeding intraoperatively but requires a skilled interventional radiologist who is familiar with the orbital vasculature. Percutaneous injection of n-butyl cyanoacrylate (NBCA) has also been reported as a preoperative measure to decrease bleeding from orbital varices (Karcioglu 2014).

Vascular System of Orbit

Elizabeth Marlow[1] and Gary Joseph Lelli[2]

[1]Weill Cornell Medical College, New York, NY, USA

[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Function

The ophthalmic artery is the primary source of blood supply to the orbit and is the first branch off the internal carotid artery within the skull. The branches of the ophthalmic artery can be divided into those that will supply the orbit and those supplying the globe.

Arterial Supply to the Globe

The central retinal artery is a branch off the posterior 1/3 of the ophthalmic artery which enters the dural sheath of the optic nerve 13 mm posterior to the globe. The central retinal artery supplies blood to the inner 2/3 of the retina and all the nerve fibers exiting the globe to deliver visual information to the thalamus.

The posterior ciliary arteries branch off the ophthalmic artery soon after the central retinal artery and produce the long posterior ciliary arteries that supply the anterior segment as well as the short posterior ciliary arteries that supply the choroid. There are 6–12 short posterior ciliary arteries that pierce the sclera to enter the globe around the exit site of the optic nerve; these supply the choroid from the posterior pole to the equator of the eye in addition to the ciliary processes. The short posterior ciliary arteries form an anastomotic network that provides the principle blood supply of the optic nerve head, known as the Circle of Zinn-Haller (Hayreh 2006).

There are two long posterior ciliary arteries in each eye that pierce the sclera posteriorly and course anteriorly between the sclera and choroid, each dividing into two branches, until they arrive at the ciliary muscle. There, they form an anastomotic circle around the circumference of the iris, known as the circulus arteriosus major, which connects via multiple branches to another arterial circle at the pupillary margin and also collateralizes with the vascular supply of the extraocular muscles. Thus, the long posterior ciliary arteries supply the choroid, ciliary body, iris.

Arterial supply to the extraocular muscles comes from the muscular branches of the ophthalmic artery, the lacrimal artery, and the infraorbital artery. The muscular artery divides into superior and inferior branches that subsequently give off the anterior ciliary arteries to supply the extraocular muscles. The superior branch supplies the levator palpebral muscle, superior rectus, superior oblique, and a portion of the lateral rectus. The inferior branch supplies the medial rectus, inferior rectus, and inferior oblique. The anterior ciliary arteries move anteriorly along the extraocular muscles to supply the rectus muscles, conjunctiva, and sclera. They then join the long posterior ciliary arteries in forming the major arterial circle of the ciliary body, the circulus arteriosus major. The superior, inferior, and medial extraocular muscles have two anterior ciliary arteries each, while the lateral rectus has only one.

The infraorbital artery is a branch off the maxillary artery that courses with the infraorbital nerve in the infraorbital groove before entering the infraorbital canal which exits onto the surface of the maxilla via the infraorbital foramen. While in the canal, the infraorbital artery gives off branches to supply the inferior rectus, inferior oblique, and the lacrimal sac.

The lacrimal artery commonly branches off the ophthalmic artery before entering the orbit. It joins the lacrimal nerve as it runs along the lateral wall of the orbit at the upper border of the lateral rectus to supply the lacrimal gland, eyelids, and conjunctiva. Along its course, it produces minor branches to supply the superior and lateral rectus muscles.

Arterial Supply to the Orbit

The arterial supply of the eyelids consists of anastomoses between the external carotid artery, which supplies the face, and the internal carotid artery via the ophthalmic artery. As previously mentioned, the lacrimal artery derives from the ophthalmic artery, and its terminal branches include the superior and inferior lateral palpebral arteries that supply the lateral upper and lower eyelids, respectively, as well as the conjunctiva (Foster et al. 2015). The terminal branches of the internal (medial) palpebral artery, also a branch off the ophthalmic artery, include the superior and inferior medial palpebral arteries that supply the lacrimal sac and medial eyelids. The medial and lateral palpebral arteries form anastomotic arches on both the upper and lower eyelid that lie either between the orbicularis oculi and the tarsi or within the tarsus. The upper eyelid has two such arches: one, known as the superior peripheral arterial arcade, is located peripherally at the margin of the tarsal plate within the superior tarsal muscle (Müller's muscle); the second, is the superior marginal arterial arcade that is located 3 mm from the free border of the eyelid. The lower eyelid has a single anastomotic arch, the inferior

marginal arterial arcade. Anastomoses also exist between the lower eyelid circulation and the transverse facial artery and its derivative, the angular artery, which are branches of the external carotid artery. The angular artery extends up to the lateral aspect of the nose and serves as an important landmark in dacryocystorhinostomy.

The supraorbital artery supplies the superior rectus and levator palpebral muscles, before passing though the supraorbital foramen to supply the eyebrow and forehead on the facial surface. The frontal artery leaves the orbit medially to supply the forehead and scalp, where it anastomoses with the terminal branches of the supraorbital artery.

Vascular supply to the sinuses includes the anterior ethmoidal artery, which supplies the superior oblique muscle, anterior and middle ethmoidal cells, frontal sinus, lateral wall nose, and nasal septum. The posterior ethmoidal artery passes through the posterior ethmoidal canal to supply the posterior ethmoidal cells, while the nasal artery supplies the superior lacrimal sac and nose.

Venous Drainage

The venous drainage of the eye consists of two routes classified by their anatomic location relative to the tarsus – pretarsal (superficial) veins drain into the internal and external jugular veins while the posttarsal (deep) veins drain into the cavernous sinus. The superior ophthalmic vein is the primary conduit for venous drainage from the orbit and originates in the superonasal quadrant (Black et al. 2012). The orbital veins are responsible for draining the choroid and include 4–8 vortex veins per eye that exit posterior to the equator with a distribution of 1–2 per quadrant. The 2–4 superior vortex veins merge into the superior ophthalmic vein that exits via the superior orbital fissure into the cavernous sinus. The inferior vortex veins merge to form the inferior ophthalmic vein and exit via the inferior orbital fissure.

The central retinal vein drains blood from the retinal capillaries and is relatively short, running through the optic nerve until about 10 mm posterior to the globe and empties into cavernous sinus, either directly or indirectly through the superior or inferior ophthalmic vein.

Clinical Relevance

The clinical significance of these vascular territories is highlighted during vaso-occlusive events. In particular, the central retinal artery and its branches do not supply the fovea, which is typically sustained by the choroid. In cases of central retinal artery occlusion, a "cherry red spot" is seen as the macula maintains choroidal perfusion amidst a pale, ischemic retina. In some individuals (approximately 20% of the population), a branch of the ciliary circulation known as the cilioretinal artery supplies the retina between the macula and the optic nerve, which allows for preserved central vision even in a central retinal artery occlusion. However, the cilioretinal artery itself is a branch of the short posterior ciliary arteries derived from the ophthalmic artery; therefore, if the cilioretinal artery were to become occluded, significant central vision acuity would be lost despite an intact peripheral visual field (Hayreh 2006). Similar to the central retinal artery, the central retinal vein can suffer from occlusive events.

In addition, the interplay between orbital and ocular vasculature is highlighted during strabismus surgery where detaching the extraocular muscles reduces blood supply to the anterior chamber. For this reason, it is generally preferred to operate on no more than two recti muscles to avoid anterior ischemic syndrome. Resecting or recessing the lateral rectus is generally less significant because of its single arterial contribution to the anterior chamber.

Vascular Tumors Disease of the Conjunctiva

Brent Betts
Department of Ophthalmology, Wake Forest Baptist Health, Winston-Salem, NC, USA

Synonyms

Acquired sessile hemangioma; Capillary hemangioma; Cavernous hemangioma; Glomangioma; Hemangiopericytoma; Kaposi sarcoma; Lymphangiectasia; Lymphangioma; Pyogenic granuloma; Racemose hemangioma; Varix

Definition

Benign or malignant proliferation of blood vessel endothelium that originates in either conjunctival epithelium or stroma.

Etiology

Most vascular tumors of the conjunctiva occur spontaneously (Shields et al. 2004). Kaposi sarcoma is associated with human herpesvirus 8 infection and almost exclusively seen in patients with acquired immune deficiency syndrome (Hiatt et al. 2008). Pyogenic granulomas are associated with infectious, inflammatory, or traumatic inciting events.

Clinical Presentation

Conjunctival vascular tumors are a heterogenous group of tumors with morphology dependent on the underlying cause of the tumor. The tumors can be divided into benign or malignant tumors.

A lymphangioma is a benign tumor. It can be diffused or circumscribed and generally presents as a soft, red mass with lymphatic vessels. It can present with focal or diffuse hemorrhage and can be confined to the conjunctiva or extend into orbit. Lymphangiomas usually present at birth and enlarge slowly. They are classically described as chocolate cysts (Shields et al. 2011a).

Lymphangiectasias presents as clear or blood-filled linear lymphatic channels. There generally is not a distinct mass.

A pyogenic granuloma is a slowly growing elevated, smooth, red vascular mass. It can be anywhere from sessile with a broad base to a pedunculated mass.

Capillary hemangiomas present in infancy. They are either diffuse or circumscribed with a pink to red appearance. They can enlarge over several months but usually regress without treatment.

A varix is a dilation of thin wall segments of a vein that is missing an elastic layer. It is similar to a lymphangioma in appearance.

Cavernous hemangiomas are red or blue, multiloculated lesions in conjunctival stroma. They can be small and circumscribed or large and diffuse. There is generally a solitary lesion. Diffuse hemangiomatosis of palpebral conjunctiva is indicative of orbital cavernous hemangioma (Shields et al. 2011a).

Racemose hemangioma is a prominent arteriovenous communication in the conjunctiva. The lesions are red and multilobular.

Acquired sessile hemangioma is a recently described sessile mass of curvilinear blood vessels with an associated feeding artery and draining vein. They can regress spontaneously (Shields et al. 2011b).

A glomangioma is a red-blue mass that originates from the glomus body. It is similar in appearance to lymphangioma lesions or cavernous hemangiomas.

Hemangiopericytomas are red conjunctival masses originating from conjunctival stroma. They have both benign and malignant cytological features.

Kaposi sarcoma is a malignant tumor associated with human herpesvirus 8 (HHV-8). It is classically seen in patients with AIDS. It presents as red, diffuse, or multifocal nodular lesions. Sometimes it may look like a subconjunctival hemorrhage.

Diagnosis

Diagnosis is mainly dependent upon clinical examination of the tumor, but definitive diagnosis requires pathologic tissue examination following biopsy.

Differential Diagnosis

Lymphangioma, lymphangiectasia, pyogenic granuloma, capillary hemangioma, Kaposi sarcoma, varix, cavernous hemangioma, racemose hemangioma, glomangioma, hemangiopericytoma, and acquired sessile hemangioma.

Prophylaxis

Prophylaxis is unclear for most vascular tumors. Eye protection can prevent trauma leading to development of pyogenic granulomas.

Therapy

Lymphangiomas are difficult to eradicate as both surgery and radiotherapy do not completely remove the mass.

Pyogenic granulomas can respond to topical corticosteroids, but some will still require surgical excision. Recurrent pyogenic granulomas can be treated with low-dose plaque radiotherapy (Shields et al. 2011a).

Capillary hemangiomas usually regress without treatment but can also be surgically resected. They regress in response to topical and systemic corticosteroids.

Varices are generally observed. There is a high risk of bleeding during surgical resection. If painful, cold compresses and aspirin can be used for pain relief.

Cavernous hemangiomas are treated definitely with surgical resection.

Hemangiopericytomas are managed by wide surgical resection with tumor-free margins.

Kaposi sarcoma is treated with cryotherapy and local or systemic chemotherapy. They have also been reported to be responsive to low-dose radiotherapy (Shields et al. 2011a).

Prognosis

All vascular conjunctival lesions are benign except for hemangiopericytomas and Kaposi sarcoma.

Epidemiology

These tumors are very uncommon, accounting for 4% of nonmelanocytic tumors of the conjunctiva (Shields et al. 2004).

Venography, in Orbital Evaluation

Elizabeth Marlow[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

In medical applications of magnetic resonance imaging (MRI), a strong, uniform magnetic field is applied to water-containing tissue in order to align all protons into an excited state and subsequently measure their variable relaxation rates distinguish tissue types on imaging. These basic MR principles are extended with newer pulse sequence techniques and contrast-enhancement to image arterial and venous blood flow.

Purpose

The purpose of magnetic resonance venography is to detail venous blood flow to assess for anomalous vessels, aneurysms, stenosis, or abnormal connections between the arterial and venous circulations.

Principle

In their natural state, the atomic protons of any given tissue exhibit random movement. A polarizing magnetic field delivered by surface coils brings all of the protons into an excited state with uniform alignment to the external magnetic field. When the magnetic field is removed, the protons relax from this induced excited state back toward equilibrium at variable rates dependent on the tissue type they compose, and in doing so emit radio frequencies that are recorded by a receiving coil. There are two forms of relaxation which create the T1- and T2-weighted imaging. The differences in proton relaxation rates create the distinction between different tissues on images. A variety of magnetic pulse sequences can be applied to highlight different tissue types. However, vessels are not clearly imaged in conventional MR techniques because the fast flowing blood does not generate adequate signal from the proton relaxation.

The application of exogenous contrast in conventional catheter angiography can be used to visualize the vasculature and remains the gold standard for imaging of vascular lesions (e.g., aneurysms, carotid-cavernous fistulas, arteriovenous malformations). In catheter angiography, vessels are visualized with the aid of contrast along with adjacent tissues. In digital subtraction angiography, pre- and post-contrast images are subtracted to show exclusively the contrast-filled vessels. However, injection of contrast into the venous system carries inherent risks that, although small, can be avoided with newer imaging modalities. Computed tomography venography (CTV) and magnetic resonance venography (MRV) are among the newer imaging modalities available to ophthalmologists that allow for visualization of orbital vasculature while exposing patients to lower risks of morbidity (Black et al. 2012).

Magnetic resonance angiography (MRA) allows visualization of arterial blood flow with or without contrast through a variety of techniques, and detailed information can also be extracted about the venous system using specialized computer software. In MRV, the excited tissue is located directly inferior to the plane being imaged; thus, the signal is collected from blood as it drains

away from the excited plane (Haacke et al. 1999). A similar technique is used in MRA where the information can be further processed to easily create flow-velocity maps.

Indication

MRA and MRV can be helpful in any case where a vascular pathology needs to be further characterized or excluded. The primary ophthalmic indication for MRV is to exclude dural venous sinus thrombosis in the setting of elevated intracranial pressure and papilledema. The combination of MRI and MRV has been shown to increase the sensitivity of radiographic diagnosis of cerebral sinovenous thrombosis in children to 100% (Jackson et al. 2011). CTV can also be applied for this purpose in individuals who cannot tolerate prolonged imaging. Superior ophthalmic vein thrombosis is also well imaged with MRV and frequently appears on axial sections as the only structure coursing diagonally across the superior orbit.

In addition, orbital hemorrhages can be further characterized by MRA and MRV. In these cases, initial conventional CT or MRI may demonstrate a biconvex, well-defined, non-enhancing mass with increased density compared to the brain, which can be localized to the superior orbit in a subperiosteal hemorrhage, or can be more diffuse depending on the etiology. MR in particular can provide useful information about the age of the hemorrhage based on progressive decay of blood products. MRA and MRV are specifically helpful if there is concern for lesions with hemorrhagic potential (Black et al. 2012).

Contraindication

An individual patient may not be a good candidate for MRI if they have ferromagnetic implants in their body. The firmest contraindications include permanent pacemakers and pacing devices, nerve stimulators, cochlear implants, and certain aneurysm clips, but other types of implants may also be a relative contraindication (Levine et al. 2007). Moreover, in the event of orbital trauma, a CT scan is necessary to exclude the possibility of ferromagnetic foreign body prior to MRI.

Besides the technical constraints of MRI, the process of acquiring good quality, high-resolution MRIs requires a patient who is able to lie still for a prolonged period, often over 30 minutes. This may be impossible in medically unstable patients. The magnetic coil into which the person is inserted varies in size but is generally small, which can limit MRIs applicability in obese patients and require special planning for those with claustrophobia. Finally, MRI is considered safe in pregnant women, though the use of gadolinium-based (ferromagnetic) contrast is generally avoided (Webb and Thomsen 2013).

Advantage/Disadvantage

MRI is best applied for visualizing soft tissues and vasculature. Neurologic tissue is particularly well visualized, including the optic nerve and the brain. Innovations in surface coils, reduced signal-to-noise ratios, and fat-suppression on T1-weighted images have allowed steady improvements in orbital imaging. Pathology involving the bone – such as the cavernous sinus, orbital apex, and optic canal – produce relatively low signal on MRI and are generally better imaged with CT. Foreign bodies also typically produce poor signal on MRI, and given the risk of ferromagnetic material, are better examined with CT (Black et al. 2012).

Verisyse Iris-Supported Phakic Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Artisan iris-supported phakic intraocular lens; Iris-fixated phakic intraocular lens

Definition

A phakic IOL that is enclavated on the iris with specially designed "iris-claw" haptics.

Epidemiology

Before introduction of the latest phakic IOL model (AcrySof), the iris-supported phakic IOL models (Artisan/Verisyse and Artiflex/Veriflex) were the most frequently implanted anterior chamber phakic IOLs (Kohnen and Koch 2006).

History

The iris-claw phakic IOL was initially used in aphakic eyes after intracapsular cataract extraction. Starting in 1953, the first-generation models such as the Binkhorst lens and the Medallion lens were associated with cystoid macular edema, corneal decompensation, lens dislocation, uveitis, and glaucoma (Hardthen et al. 2003). In 1978, J. Worst designed the iris-claw or "lobster-claw" IOL, a coplanar one-piece PMMA IOL, which was enclavated in a fold of mid-peripheral iris stroma, a relatively immobile portion of the iris. Many surgeons have used the iris-claw lens after intracapsular cataract extraction or as secondary implantation in aphakia. In 1986, Fechner implanted the first sighted myopic phakic eye (Fechner and Alpor 1986). Follow-up of Fechner-Worst lens implantation showed good predictability but a progressive corneal endothelial cell loss. The currently available iris-claw model is basically the original IOL with few changes and with less likelihood of endothelial cell loss.

Clinical Features

The Verisyse/Artisan phakic IOL is made of a single-piece, non-foldable, ultraviolet light-absorbing PMMA material. It is available for the correction of myopia, hyperopia, and astigmatism, as well as for aphakia. The optic vaults approximately 0.87-mm anterior to the iris, allowing for an important clearance from both the anterior lens capsule and the corneal endothelium. The distance from the optic edge to the endothelium ranges from 1.5 to 2 mm depending on dioptric power, anterior chamber anatomy, and diameter of the optic. There are two models available to correct myopia: model 206 has a 5.0-mm optic with power ranging from −3 to −23.5 diopters (D) in 0.5-D increments and model 204 has a larger 6.0-mm optic and is

consequently limited to a smaller range of powers because of its greater proximity to the endothelium in the periphery of the IOL, −3 to −15.5 D in 0.5-D increments. For the correction of hyperopia, model 203 incorporates a 5-mm optic, and it is available in dioptric powers ranging from +1 to + 12 D in 0.5-D increments. Myopic lenses require more clearance than hyperopic due to thicker peripheral edges. The thickest part of the hyperopic IOL on the other hand is central, where the anterior chamber depth is greater. The toric model has a 5-mm optical zone and is available in powers ranging from +12 D to −23.5 D in 0.5-D increments, with additional cylinder from +1.0 D to +7.0 D, also in 0.5-D increments, and oriented either at 0° or at 90°. It has a fixed overall length of 8.5 mm (7.5 mm for pediatric implantations or small eyes), which is a great advantage to the surgeon who does not wish to deal with sizing measurements.

Tests

Anterior chamber depth for Artisan/Verisyse phakic IOL implantation must be at least 2.7 mm. Other inclusion criteria for phakic IOL implantation must be considered (see also "► phakic intraocular lens").

Differential Diagnosis

Other currently available types of phakic IOLs are anterior chamber angle (AcrySof) or posterior chamber (phakic refractive lens and implantable collamer lens) phakic IOLs.

Etiology

On the European market, this phakic IOL is distributed as ArtisanÒ (Ophtec B. V., Groningen, The Netherlands) and in the USA as VerisyseÒ (Abbott Laboratories, Abbott Park, Illinois, USA). The foldable model of the iris-claw lens is the Artiflex/Veriflex phakic IOL, which has a hydrophobic polysiloxane foldable design with a 6.0-mm optic.

Treatment

For Artisan/Verisyse implantation, retrobulbar or peribulbar anesthesia is recommended. A - two-plane, 5.2- or 6.2-mm posterior corneal incision is centered at 12 o'clock, and two vertical paracenteses directed to the enclavation area are performed at 2 and 10 o'clock. Alternatively, scleral incision may be used. Pupil should be constricted to protect the crystalline lens from contact with the phakic lens or instruments. After the anterior chamber is filled with viscoelastic material, the lens is introduced and rotated 90° into horizontal position. The lens is fixed with an enclavation needle that has a bent shaft and a bent tip that pushes the iris into both claws. Peripheral iridectomy should be performed to prevent pupillary block situation. Alternatively, Nd/YAG laser can be used preoperatively to create one or two small iridotomies 90° apart. The corneal wound is then sutured with five interrupted 10-0 nylon stitches, the scleral incision with one running suture (Güell et al. 2010).

Definition

Vernal conjunctivitis is a disease characterized by bilateral, recurrent inflammation of the conjunctiva that often has a seasonal incidence (Bonini et al. 2004). It is a member of a group of diseases that are all considered allergic conjunctivitis such as seasonal rhinoconjunctivitis and atopic keratoconjunctivitis (Bonini et al. 2004). It is more common in patients with an atopic background (Kumar 2009).

Etiology

The exact etiology of vernal conjunctivitis is unknown, but it is thought that the pathogenesis is multifactorial with immune, nervous, and endocrine systems all playing a role (Bonini et al. 2004). It is thought that IgE-mediated hypersensitivity and T helper cell type 2 (Th2)-mediated responses play major roles in pathogenesis (Kumar 2009). Patients often have a family history of other atopic diseases (Bonini et al. 2004).

Clinical Presentation

The most typical presentation of a patient with vernal conjunctivitis would include bilateral ocular itching and filamentous, sticky discharge (Gerstenblith et al. 2012). However, sometimes patients can initially present unilaterally. There is also often bilateral hyperemia, chemosis, photophobia, and lacrimation (Bonini et al. 2004).

The disease can present as a palpebral or limbal disease, but a range of mixed appearances also exists (De Smedt et al. 2013). The disease is often characterized by the appearance of giant papillae that create a cobblestone appearance at the upper tarsal conjunctiva or at the limbus (Gerstenblith et al. 2012). Aggregates of epithelial cells and eosinophils at the limbus known as Trantas dots are also often seen in the disease (Bonini et al. 2004). Subconjunctival fibrosis, symblepharon, and conjunctival keratinization can also occur in the disease (Bonini et al. 2004). The cornea can be damaged with a superficial keratopathy or the presence of corneal shield ulcers (Bonini et al. 2004).

Diagnosis

The diagnosis of vernal conjunctivitis is often made clinically based upon the epidemiology and clinical findings of the patient (Bonini et al. 2004). Currently, total and specific IgE determination and other skin tests are not useful as laboratory tests, because many patients with the disease will test negative on these tests (Bonini et al. 2004). Eosinophils found in conjunctival scrapings of patients can help support the diagnosis of vernal conjunctivitis (De Smedt et al. 2013).

Differential Diagnosis

The differential diagnosis includes:

- Atopic keratoconjunctivitis
- Seasonal allergic conjunctivitis
- Giant papillary conjunctivitis
- Bacterial conjunctivitis

Prophylaxis

Use a mast cell stabilizer and/or antihistamine 2–3 weeks prior to allergy season (Gerstenblith et al. 2012). Also, patients should avoid common

triggers such as sun, wind, and salt water and avoid contact with common allergens like plants (Kumar 2009).

Therapy

Treatment of vernal conjunctivitis is similar to that of other allergic conjunctivitis. Topical antihistamines and mast cell stabilizers are usually the first-line treatment (Bonini et al. 2004). Nonsteroidal anti-inflammatory drug topical agents have been shown to have a beneficial effect on the course of the disease (De Smedt et al. 2013). Topical corticosteroids are used in moderate to severe forms of the disease, but their use has to be carefully monitored due to potential long-term side effects such as glaucoma (De Smedt et al. 2013). Cyclosporin A can be used for severe disease when patients also have a shield ulcer (Gerstenblith et al. 2012). Surgical excision is sometimes utilized if the giant papillae cause corneal lesions (Kumar 2009).

Prognosis

Patients with vernal conjunctivitis often have spontaneous resolution of their disease after puberty (Bonini et al. 2004). However, a small percentage of patients can have permanent visual damage if they develop cataracts, glaucoma, or corneal ulcers as part of their disease (Bonini et al. 2004). Furthermore, if patients do have a chronic disease course, it can increase their risk for developing keratoconus (De Smedt et al. 2013). Negative prognostic signs include having larger papillae (Bonini et al. 2004).

Epidemiology

Vernal conjunctivitis mainly affects young patients in their first or second decade (De Smedt et al. 2013). It is more common in boys than girls (Bonini et al. 2004). The disease is rare in temperate regions; however, in areas such as Africa, Latin America, and Asia, it has a higher prevalence with some parts of Africa having a 4–5% population prevalence (De Smedt et al. 2013). Vernal conjunctivitis also has a seasonal variation with flare-ups often occurring during spring/summer months (De Smedt et al. 2013). However, the disease can be present year-round, and initial seasonal disease can become perennial (Bonini et al. 2004).

Verruca Vulgaris

Jeremiah Tao[1] and Betina Wachter[2]

[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Common wart; Verruca; Viral papilloma

Definition

Verruca vulgaris is a benign epithelial hyperplastic skin lesion thought to be caused by a viral infection.

Etiology

The human papilloma virus (HPV), is correlated to a DNA virus, verruca vulgaris. These lesions are spread by direct contact or autoinoculation and may occur anywhere on the skin, occasionally on the eyelid (Albert and Jakobiec 2008).

Clinical Presentation

Lesions appear elevated, multilobulated, grape-like, and with an irregular, hyperkeratotic, papillomatous surface. Lesions along the eyelid margin may induce a mild papillary conjunctivitis due to shedding of virus particles into the tear film. Patients also may develop a superficial punctuate keratitis and have pannus formation (Albert and Jakobiec 2008).

Diagnostics

Based on the typical appearance of clinical findings and may be confirmed by biopsy.

Differential Diagnosis

Differential diagnosis includes ▶ actinic keratosis, ▶ molluscum contagiosum, ▶ seborrheic keratosis, and ▶ squamous cell carcinoma.

Prophylaxis

Avoid contact.

Therapy

Observation is recommended if no ocular complications occur. Treatment, if necessary, includes topical agents, intralesional injections, systemic agents, cryotherapy, laser, electrodessication, and surgical excision (Nesi et al. 1998).

Prognosis

Recurrences are common. Spontaneous regression is also common. Rarely, squamous cell carcinoma may develop in verruca vulgaris, usually in immunocompromised patients (Albert and Jakobiec 2008).

Epidemiology

A peak incidence in late childhood and early adulthood.

Vertical Eyelid Splitting, for Anterior Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Definition

An anterior orbitotomy performed by creating a vertical incision through the eyelid margin to allow broader exposure to the anterio-medial orbit.

Indications

To obtain wider access to the superiormedial intraconal space for biopsy, lesion excision, or optic nerve fenestration.

Contraindication

Lesion deeper in the orbit or not able to be accessed via anterior orbitotomy. Any medical contraindication to surgery.

Techniques and Principles

This procedure is generally performed in the operating room under sedation or general anesthesia. An incision is marked vertically at the junction of the medial one-third and lateral two-thirds of the upper eyelid. The incision is made full thickness through the eyelid and requires proper realignment of the tarsal plate and anterior lamella in multiple layers at the close of the procedure (Nerad 2001; Levine 2003).

Outcome

Allows for wider exposure biopsy, lesion removal, foreign body removal, and orbital decompression as necessary.

Complications

Risks of the vertical eyelid splitting technique include risks associated with anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, ptosis, eyelid retraction, and need for additional procedures (Nerad 2001; Levine 2003).

Synonyms

Upgaze palsy

Definition

Vertical gaze palsy (VGP) is a conjugate gaze palsy that results in the inability to move both eyes in a single vertical direction (upgaze or downgaze or both). It usually occurs bilaterally; however, it is occasionally seen unilaterally (Rubin 2014).

Epidemiology

VGP can affect any age, either gender, and any racial group depending on underlying etiology.

History

One of the first clinical descriptions of VGP was published in 1964. In this case report, vertical gaze palsy was reported as a clinical manifestation of progressive supranuclear palsy (PSP) (Steele et al. 1964).

Clinical Features

Patients with VGP often track objects moving their head instead of the eyes, especially during a routine eye exam (Rubin 2014). The doll's head maneuver can be used to activate the vestibular ocular reflex to move the eyes vertically (up- and downgaze) if the lesion is supranuclear and the infranuclear pathways are intact.

Tests

Limited up and down eye movements during a routine eye exam can be used as an initial diagnosis. In addition, neuroimaging should be conducted to visualize the suspected midbrain lesion(s) or supranuclear lesion(s). Myasthenia gravis and thyroid ophthalmopathy can mimic VGP (Rubin 2014).

Differential Diagnosis

- Dilated pupil
- Vertical nystagmus during upward gaze

Etiology

Lesions in the midbrain (stroke or tumor) are causes of bilateral, symmetric VGP. Common locations of lesions include interstitial nucleus of Cajal and the rostral interstitial nucleus of the medial longitudinal fasciculus (Rubin 2014). The differential diagnosis for VGP includes stroke, tumor, demyelination, degeneration

(e.g., progressive supranuclear palsy), hydrocephalus, shunt failure, and other lesions of the thalamomesencephalic junction or dorsal midbrain (Benjamin 1999).

Treatment

Treatment should be directed to the underlying etiology (Rubin 2014).

Angiomatosis retinae; Cerebelloretinal hemangioblastomatosis; Familial cerebello-retinal angiomatosis; Hippel disease; Hippel–Lindau syndrome; HLS; Lindau disease or retinocerebellar angiomatosis; VHL; von Hippel–Lindau disease

Definition

von Hippel–Lindau disease (VHL) is a rare autosomal dominant condition that causes benign and malignant tumors and cysts in the central nervous system (CNS) as well as visceral organs. VHL results from a mutation in the VHL tumor suppressor gene on chromosome 3p25.3. One of the most common findings in VHL patients are

hemangioblastomas of the retina or optic nerve head. A hemangioblastoma is any case of angiomatosis, a proliferation of vascular endothelium, within the central nervous system. Retinal capillary hemangioblastomas are found in up to 70% of VHL patients by 60 years of age (Kreusel et al. 2006). This extremely high prevalence results in a high risk of vision loss starting at a young age and requires regular lifelong ophthalmic screening. Similarly, 60–84% of VHL patients develop hemangioblastomas of the brain or spinal cord. Other common tumors associated with VHL disease are pheochromocytoma, renal cell carcinoma, renal cysts, pancreatic cystadenoma, and pancreatic neuroendocrine tumors (Shuin et al. 2006).

Etiology

VHL is an autosomal dominant disorder caused by a mutation and loss of function of the VHL tumor suppressor gene located on chromosome 3p25–26. Over 1,500 mutations of this gene have been identified in patients with VHL. Approximately 20% of mutations are de novo, with the other 80% being inherited. Tumors form only in cells which have mutations in both copies of the VHL tumor suppressor gene (two-hit hypothesis). The loss of function of the VHL protein results in the cell's inability to break down hypoxia-inducible factors (HIFs) and other proteins. HIFs are the major transcription factors under hypoxic conditions and are usually degraded (ubiquitinated) under normoxic conditions. High levels of HIFs lead to the transcription of large amounts of vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and transforming growth factor alpha (TGF-α). These cytokines lead to the accelerated and abnormal proliferation of microvasculature known as angiomas. Within the CNS, focal collections of these angiomas are called hemangioblastomas (Dollfus et al. 2002; Shuin et al. 2006).

Clinical Presentation

The mean age at initial diagnosis of VHL disease is approximately 29 years. Retinal hemangioblastoma is the ophthalmological hallmark of VHL disease and is often the clinical sign that first leads to diagnosis. Retinal hemangioblastomas can develop from a very early age until around 30 years of life. After this age, the frequency gradually decreases. When caught early, the first clinical presentation is typically unilateral and often without symptoms. In later stages, about half of VHL patients with retinal manifestations develop bilateral disease. Juxtapapillary lesions can cause pseudopapilledema. Tractional retinal detachment is also a significant risk if hemangioblastomas are left untreated and may be the cause of presenting symptoms. Retinal hemangioblastomas can be detected by ophthalmoscopy, fluorescein angiography, or wide-field retinal imaging. Fluorescein angiography typically shows early leakage and hyperfluorescence. Macular edema caused by these growths can be identified on optical coherence tomography (OCT). Patients identified as high risk by genetic screening or family history should be seen by an ophthalmologist annually starting at preschool age (Shuin et al. 2006; Wong et al. 2007).

Hemangioblastomas may also present in other regions of the CNS. Excluding the retina, approximately 50% of VHL hemangioblastomas occur in the spinal cord, 40% in the cerebellum, and 10% in the brainstem. In these locations, symptoms can present as the result of compression of neural structures, bleeding, or paraneoplastic complications. In patients with VHL, routine screening of the neuroaxis via MRI is recommended starting after 10 years of age.

Diagnostics

Retinal hemangioblastomas can be diagnosed by ophthalmoscopy, fluorescein angiography, or wide-field retinal imaging. Fluorescein angiography

typically shows early leakage and hyperfluorescence. Macular edema caused by these growths can be identified on optical coherence tomography (OCT). For hemangioblastomas of the brain or spinal cord, gadolinium-enhanced magnetic resonance imaging (MRI) offers the best resolution. A family history of VHL disease should be sufficient for diagnosis; however, screening by southern blot and genetic sequencing may be necessary for many patients (Kreusel et al. 2006).

Differential Diagnosis

Coats disease, racemose hemangioma, retinal cavernous hemangioma, and retinal macroaneurysm can present similarly to retinal hemangioblastomas. However, a detailed family history and/or genetic screening are all that are needed to make an accurate diagnosis of retinal hemangioblastomas associated with VHL.

Prophylaxis

No method of prophylaxis has been identified.

Therapy

Multiple treatment modalities have been proposed for the management of retinal hemangioblastomas secondary to VHL disease. Depending on the location of the lesion being targeted and its associated findings, laser photocoagulation, cryotherapy, photodynamic therapy, surgical excision, enucleation, or very often just observation may be indicated. Laser photocoagulation has proven to be the most effective at controlling peripheral lesions. Anti-VEGF therapy has been proposed as an adjunct therapy to VHL management; however, small studies have suggested limited efficacy on the tumor itself, while reducing associated macular edema (Shuin et al. 2006).

Prognosis

The prognosis of VHL patients depends on the location and complications of the tumors. In one longitudinal study, visual acuity worse than 20/1,000 was reported in 20% of effected eyes by age 20 and 50% of effected eyes by age 30. Another study found that visual morbidity increases with the hemangioblastoma count. A large genetic study correlating genotype and phenotypes found that VHL patients with complete deletions of the VHL protein have the lowest prevalence of ocular disease and the most favorable visual outcomes (Shuin et al. 2006).

Epidemiology

VHL has been estimated to affect 1 in 36,000 births. In the USA and Europe, 70% of VHL patients develop retinal hemangioblastomas, while Japanese VHL patients have a significantly lower risk (<40%). Similarly, 60–84% of VHL patients develop hemangioblastomas elsewhere in the CNS. Approximately 50% of these occur in the spinal cord, 40% in the cerebellum, and 10% in the brainstem (Shuin et al. 2006).

Viscoelastic Agents

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Synonyms

Ophthalmic viscosurgical device (OVD)

Definition

Clear, soft substances with a texture ranging from honey to jam which have become essential to modern anterior segment surgery, consisting of any or a combination of the following substances: hydroxypropyl methylcellulose, sodium hyaluronate, and chondroitin sulfate. They aid surgery because they create space, protect the corneal endothelium and tamponnade structures (for example, they can be used to hold vitreous posterior). These agents flow easily when higher forces are applied to them but retain their original shape when a lower force is applied.

Vitrectomy

Armin Wolf[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians Universität München, München, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Anterior vitrectomy; Core vitrectomy; Pars plana vitrectomy

Definition

Surgical procedure to remove the vitreous or part thereof from the vitreous cave.

Epidemiology

Formerly related to a large variety of serious complications, vitrectomy – especially small gauge pars plana vitrectomy – has become a widely used technique for a large number of pathologies. To date approximately 200,000 vitrectomies are performed in the USA per year (Fabian and Moisseiev 2010; Recchia et al. 2010).

History

Up to the late 1960s, vitreous dissection was a general problem. Formerly, a vitrectomy was performed as so-called swap-vitrectomy. Here, the vitreous was soaked-up by the aid of a swap and cut thereafter using scissors. This was only possible during open-globe conditions.

Established as a single port 19 gauge procedure by Robert Machemer in 1969, it was then possible to extract vitreous in a closed system providing constant intraocular pressure. This procedure was

first used for vitreous hemorrhage. However, further technical improvement established vitrectomy as a widely used technique for a large variety of pathologies.

Clinical Features

Excision of the vitreous is usually performed using a specially designed cutter. This cutting tool usually consists of a tube with an oscillating knife. By applying suction, the vitreous is sucked into the tube and cut by the oscillating knife. Sizes of this so-called cutter may differ from 20 to 27 gauge.

The properties of a cutter are highly dependent suction, cutting rate, infusion, size, and design of the notch of the cutter.

Nowadays, there are different forms of vitrectomy. While in anterior vitrectomy, part of the anterior vitreous is removed mainly transpupillary, the access during pars plana vitrectomy is transcleral through pars plana. Core vitrectomy is a technique that refers to excision of only the central vitreous.

Tests

Efficacy of this surgical procedure has been demonstrated for a large number of pathologies.

Etiology

See history.

Treatment

Vitrectomy is performed in a large variety of pathologies ranging from posterior capsule rupture during cataract surgery to retinal detachment and macular surgery.

Vitreolysis, Enzymatic

William J. Wirostko
Eye Institute- Medical College of WI, Milwaukee, WI, USA

Definition

Process of manipulating the central vitreous collagen or cortical vitreous at the retinal interface with chemicals and enzymes rather than with mechanical instruments. Historically, enzymatic vitreolysis has been accomplished with chondroitinase, hyaluronidase, dispase, or plasmin.

Indication

The potential applications for enzymatic vitreolysis are numerous and include any condition that involves an abnormal vitreoretinal interface, with or without retinal traction. At present, no formal list of indications is available since enzymatic vitreolysis remains predominantly investigational. Nonetheless, enzymatic vitreolysis may be advantageous over mechanical vitrectomy whenever mechanical dissection is arduous or poses a risk to vital intraocular structures. Conditions that have been studied with enzymatic vitreolysis include advanced retinopathy of prematurity (stage 4 and stage 5), pediatric macular holes, diabetic macular edema,

and x-linked retinoschisis (Chen et al. 2008; Trese 2002; Wu et al. 2007).

Contraindication

Absolute contraindication for enzymatic vitreolysis includes a history of an allergic reaction to a specific enzyme. Additional contraindications will likely be forthcoming as future research indentifies which patients do not benefit from enzymatic vitreolysis.

Use and Dosage

Enzymatic vitreolysis is typically administered via an intravitreal injection. For eyes scheduled to undergo mechanical vitrectomy, the intravitreal injection of the enzyme is performed shortly before surgery.

Plasmin is usually given at doses between 0.4 IU and 2.0 IU, although amounts as large as 3 IU appear to be well tolerated. At these doses, intravitreal plasmin liquefies the vitreous and provides for easier peeling of cortical vitreous in conditions such as macular hole, diabetic retinopathy, x-linked retinoschisis, and retinopathy of prematurity. Enzymatic activity peaks within 15–30 min of the intravitreal injection, remains elevated for 1–2 h, and decreases to an undetectable level after several hours. Presently, intravitreal plasmin for intravitreal use is not commercially available and remains costly and time-consuming to obtain. Recombinant microplasminogen may soon be a reasonable substitute for autologous plasmin (Chen et al. 2008).

Hyaluronidase for intravitreal use also remains investigational. It recently underwent phase III testing as an adjunct for clearing vitreous hemorrhage, but failed to meet its efficacy end point in this study and did not receive FDA approval. It should be recognized that intravitreal hyaluronidase is distinctly different from the subcutaneous hyaluronidase, which is currently available as a spreading agent for anesthesia under the commercial name of Vitrase (ISTA Pharmaceuticals; Irvine, California).

Chondroitinase likewise remains investigational. It has been studied in phase I human trials, but no specific data is yet available.

Adverse Reactions

Since enzymatic vitreolysis is administered via an intravitreal injection, adverse reactions are similar to those for all intravitreal injection, including allergic reaction, cataract formation, endophthalmitis, vitreous hemorrhage, retinal tear, and retinal detachment. In addition, sterile inflammation with hypopyon has been described following hyaluronidase.

Interactions

No interaction has yet been described between these vitreolytic enzymes and any systemic medication. This may be due to the short duration of activity for these intraocular enzymes and the confinement of biological activity to the vitreous cavity following intravitreal injection.

Hyaloid

Definition

The vitreous is a transparent gel-like tissue that fills the posterior portion of the eye, extending from the posterior lens capsule to the internal limiting membrane of the retina. It occupies about four fifth of the eye, has a volume of about 4 ml, and weighs about 4 g.

Structure

The vitreous is a matrix of collagen filaments, hyaluronan acid, water, and rare cells called hyalocytes. Biochemically, the vitreous is about 99% water, 1.0% inorganic salts and organic lipids, and 0.1% soluble and insoluble proteins and hyaluronan acid. Collagen filaments form a framework to which hyaluronan acid binds. These hyaluronan acid molecules attract water, and together they act as spacers between adjacent collagen fibers. With age, the hyaluronan acid dissociates from the collagen filament framework. This results in more fibrous collagen filament aggregations and liquefaction of the vitreous.

Although the vitreous is continuous with all tissues it touches, it is only firmly attached in specific locations. Usual areas of attachment include the vitreous base, the margin of the optic nerve, the foveal and parafoveal areas of the macula, along major retinal vessels, and retinal tufts. The vitreous may also be more adherent to areas of lattice degeneration, areas of retinal degeneration remodeling, and some post-inflammatory lesions.

Function

The vitreous is a clear media that fills the eye and allows for light to pass through it to the retina. The vitreous also helps to modulate ocular development. During embryogenesis, the primary vitreous develops between the lens and optic cup and contains the hyaloid artery. The secondary avascular vitreous forms around the primary vitreous, creating the walls of the canal of Cloquet. A yet unknown stimulus signals for regression of the hyaloid artery around the third month post-conception, leading to the regression of the primary vitreous. The vitreous becomes more transparent, allowing for less light scatter as it enters the eye.

Clinical Relevance

Failure of regression of the primary vitreous can lead to several congenital anomalies, some that can dramatically affect on vision. These include persistent hyperplastic primary vitreous (PHPV) in which the primary vitreous and fetal vasculature fails to regress, a persistent opacity on the posterior lens capsule called a Mittendorf's dot, and a persistent vascular loop that extends into the vitreous from the optic nerve head called a Bergmeister's papilla.

A very common age-related change in the vitreous is a posterior vitreous detachment (PVD).

Liquefaction of the vitreous and collapse of the extracellular matrix of the vitreous lead to separation of the posterior vitreous base from the internal limiting membrane of the retina. Vitreous detachments can be localized, partial, or complete to the vitreous base. PVDs are more likely to occur as the eye ages. Eyes that are myopic or that have undergone cataract surgery have a greater occurrence of PVDs. Vitreous traction at areas of adhesion to the retina during a PVD can lead to retinal tears and retinal detachment.

Diseases associated with collagen disorders can have anomalous PVDs where liquefaction of the vitreous occurs without release of vitreoretinal adhesions. The resulting tractional forces can lead to large retinal tears and retinal detachments. Systemic diseases with collagen metabolism disorders where anomalous PVDs can occur include Marfan's, Sticklers, and Ehlers-Danlos syndromes.

Vitreoretinal adhesions to the retina can lead to the formation of macular edema as seen in vitreomacular traction syndrome and in patients with diabetes. With trauma, tractional forces by the vitreous on the retina can also result in macular hole formation retinal hemorrhages, or peripheral retinal tears and detachment. When the vitreous adheres to retinal blood vessels, as seen with neovascularization in proliferative diabetic retinopathy, vitreous hemorrhages can result.

There are many types of vitreous opacities. As the vitreous matrix collapses, bands of collagen form strands that can be seen as floaters. Inflammatory vitreous cells and vitreous cell collections called snowballs are common with pars planitis and posterior uveitis. Other opacities include calcium crystals called asteroid hyalosis, red blood cells, pigmentary cells, and tumor cells. Cysts may also form in the vitreous.

Vogt Lines, Keratoconus

Morgan Renner
Flaum Eye Institute, University of Rochester Medical Center, Rochester, NY, USA

Synonyms

Vogt striae

Definition

Fine vertical striations in Descemet's membrane and the posterior stroma that may be seen in the keratoconic cornea (Fig. 1).

Etiology

One of the classic clinical signs used to diagnose keratoconus that may be detected on slit-lamp examination of the cornea (other signs on slit-lamp examination include stromal thinning, corneal protrusion, Fleischer or iron ring, anterior stromal scars, and enlarged corneal nerves). Vogt lines or striae are fine lines running in a largely vertical direction in the deep stroma and Descemet's membrane that parallel the steepest axis of the cone and radiate from the center of the cone. Confocal microscopy suggests that these striae represent stress-related changes in the collagen lamellae (Hollingsworth and Efron 2005). These lines disappear transiently when intraocular pressure is raised by applying external pressure on the globe or by wearing a gas permeable rigid contact lens (Barbara 2012).

Occurrence

Of 1,209 patients with keratoconus enrolled at 16 sites across the United States between 1995 and 1996 in the Collaborative Longitudinal Evaluation of Keratoconus study, Vogt's striae were present unilaterally in 35% of the population and bilaterally in 30% of the population at baseline (Wagner et al. 2007).

Vortex (Hurricane) Keratopathy

Roomasa Channa
Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Cornea verticillata

Definition

Vortex keratopathy (VK) is an ocular condition characterized by whorl-like grayish, whitish, or golden-brown corneal epithelial deposits (Hollander and Aldave 2004). When the whorl pattern is highlighted with fluorescein, it is known as hurricane keratopathy (Dua and Gomes 2000).

Etiology

Proliferating corneal epithelial cells migrate from the limbus toward the corneal center on a regular basis to replace terminally differentiated cells that are shed from the superficial layer. The cells follow a curvilinear track, leading to a vortex or whorl pattern in the cornea. Normally this path is not visible, but intracellular collection of substances like pigment, iron, drug metabolites, glycogen, and sphingolipid can highlight the vortex or whorl pattern leading to VK. This pattern on the corneal surface can also be seen when epithelial cell turnover is increased, e.g., in contact lens wearers and corneal graft recipients. In such situations, pattern is highlighted by fluorescein and is called "hurricane keratopathy." The proposed explanation for this phenomenon of being highlighted by fluorescein is that rapidly proliferating cells have poor intercellular adhesions allowing fluorescein to collect around and outline the cells (Dua and Gomes 2000).

A large number of medications are associated with VK including aminoquinolines (e.g., chloroquine, hydroxychloroquine), amiodarone, atovaquone, clofazimine, subconjunctival gentamicin, gold, ibuprofen, indomethacin, mepacrine, monobenzone, naproxen, perhexiline maleate, phenothiazines, suramin, tamoxifen, and tilorone hydrochloride (Hollander and Aldave 2004).

VK is also seen in Fabry's disease, an X-linked disorder leading to accumulation of glycosphingolipids within lysosomes due to deficiency of enzyme alpha galactosidase A. The VK pattern seen in Fabry's disease was first described by Francois in 1968 and noted to cause intralysosomal deposits, and the pattern was shown to be identical to the one associated with medication use (D'amico and Kenyon 1981; Dua et al. 1996; Hollander and Aldave 2004).

It is thought that the diverse medications and their metabolites enter lysosomes and bind with cellular lipids. The complexes, thus formed, tend to accumulate within the lysosomes. The whorl-like patterns are due to the centripetal migration of the limbal epithelial cells carrying these molecules (Hollander and Aldave 2004).

Occurrence

VK is seen in 69–100% of patients on 200–1,400 mg of amiodarone, is usually bilateral and symmetrical, and resolves within

3–20 months of cessation of drug. It is usually asymptomatic and its development is not an indication for discontinuing amiodarone treatment. Twenty-eight to 95% of patients on chloroquine and 1–28% on hydroxychloroquine develop verticillata (Hollander and Aldave 2004) When medications are stopped, VK fades away and resolves.

The whorl pattern in hurricane keratopathy persists for as long as there is stimulus for increased cell turnover. Once that stimulus is gone, the whorl pattern in the cornea resolves spontaneously (Dua and Gomes 2000).

VK is the most common ocular manifestation of Fabry's disease and occurs in 76.9% of females and 73.1% of males. As with medication use, VK is asymptomatic in Fabry's disease and its presence is not associated with more severe systemic disease (Sodi et al. 2007).

Classification

There is no specific classification for vortex VK. However, based on etiology, it can be classified as acquired or inherited.

[7]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[8]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Lateral medullary syndrome; Posterior inferior cerebellar artery syndrome

Definition

Wallenberg syndrome (WS) is a clinical brainstem syndrome that is typically due to an ischemic infarction of the lateral medulla, often associated with a vascular lesion of the posterior inferior cerebellar arteries (PICA) and/or vertebral arteries. Medullary structures affected include spinothalamic tracts, spinal nucleus/tract of trigeminal nerve, nucleus ambiguous, vestibular nuclei, and ascending/descending autonomic fibers (Horner syndrome) (Larner 2006; Siegel et al. 2006; Walsh and Hoyt's 2008).

Etiology

Although ischemia is the classic etiology of WS, tumor, demyelination, and trauma can produce

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

brainstem symptoms and signs of the WS (Walsh and Hoyt's 2008).

Clinical Presentation

Symptoms and signs of the WS include the classically described crossed signs of contralateral loss of pain and temperature in the body and ipsilateral face, loss of coordination, loss of gag reflex, hoarseness, dizziness, nausea, nystagmus, and difficulty with speech and swallowing. Lateropulsion (i.e., the sensation of being pulled toward one side, usually on the side of lesion) is often described. Uncontrollable hiccups may also be present, and problems with gait and balance coordination may also occur. Differences in heart rate and blood pressure from autonomic dysfunction may also be noted (Larner 2006; Siegel et al. 2006; Walsh and Hoyt's 2008).

Diagnosis

The diagnosis of WS is a clinical one supported by radiographic findings (e.g., computed tomography (CT) or magnetic resonance imaging (MRI)) (Brazis et al. 2007; Arora et al. 2011).

Differential Diagnosis

Horner syndrome
  Brainstem neoplasm

Therapy

Treatment is mainly supportive and directed at the etiology.

Prognosis

Prognosis depends upon the etiology and the size and location of brainstem lesion if damaged by stroke (Brazis et al. 2007; Arora et al. 2011).

Epidemiology

WS affects less than 200,000 people in the United States.

Wave Front Aberrometry

- ▶ Wave Front Analysis

Wave Front Analysis

Ron Gutmark
The Wilmer Eye Institute, The Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Aberrometry; Corneal aberrometry; Wave front aberrometry

Definition

Wave front analysis is a general descriptor for a number of methods used to quantify and analyze the optical quality of an optical system such as the eye.

Purpose

The goal of wave front analysis, as it relates to ophthalmology, is to analyze the optical quality of the eye. This information can then be used to guide treatment, for instance, with laser refractive surgery, assist in diagnosis of subjective visual quality complaints, or investigate the affects of various parameters on the quality of the optical system of the eye, for instance, in dry eye (Mello et al. 2012).

Principle

In the context of wave front analysis, the optical quality of an eye is measured as the degree to which the eye in question deviates from an ideal optical system. This deviation is often referred to as aberration or a wave front error. An aberrometer acquires this wave front error data and uses a mathematical equation to separate this wave front error into its component parts. In order to separate the wave front error into its component parts, mathematical analysis is undertaken, usually with polynomial equations such as the Zernike polynomial equation. Zernike polynomials deconstruct the wave front

error into different orders each representing a different type of aberration. For example, lower-order aberrations such as second-order aberrations include the familiar sphere and regular astigmatism errors. Higher-order aberrations include aberrations like coma and trefoil (third-order aberrations) or spherical aberration, secondary astigmatism, and tetrafoil (fourth-order aberrations) (Maeda 2009).

It is important to note that currently used aberrometers measure only monochromatic aberrations and do not address scatter, diffraction, and chromatic aberration (Zuberbuhler et al. 2013).

Indication

There are a number of applications for which wave front analysis has been employed. One of the most common and well-known applications for wave front technology is in guiding excimer laser ablation in refractive surgery. Wave front analysis has been used in this setting to both reduce preexisting aberrations as well as to avoid introducing new errors during ablation.

One important distinction to recognize in this area is the difference between wave front-guided and wave front-optimized treatments. Wave front-guided treatments rely on wave front measurements of the individual patients' higher-order aberrations to create a unique ablation profile for treatment of that particular patient's high- and low-order aberrations. Wave front-optimized treatments attempt to diminish aberrations by applying a precalculated aspheric treatment profile for a particular sphero-cylindrical refraction.

Other indications for wave front analysis include evaluating patients with keratoconus or pellucid marginal degeneration, cataracts and intraocular lenses as well as investigating tear film dynamics and the effects of ageing on the cornea (Maeda 2009; Mello et al. 2012).

Contraindications

There are no true contraindications to the use of wave front analysis, but there are certain limitations to the use of these technologies. Currently available wave front sensors are fairly accurate with low and moderate amounts of higher-order aberrations, but extreme levels of aberrations are not able to be measured accurately. Additionally, various factors related to the eye being evaluated may make measurements more or less accurate. For example, patients with dry eyes or poor tear films can have increased aberrations. The pupil size and presence of cataract can significantly alter measured aberrations. Multifocal intraocular lenses can also lead to errors in measurements of ocular aberrations (Mello et al. 2012).

Advantage/Disadvantage

The primary advantage of wave front technology lies in its ability to measure higher-order aberrations. These measurements can then be used to tailor refractive treatments in order to minimize the presence and effects of these aberrations on the patients' vision. This technology can also be used to evaluate the quality of the optical system in order to diagnose issues that may lead to poor image quality that could previously not be explained or detected (Oliveira et al. 2012).

Although wave front technology for refractive surgery can help in creating an optimal plan for treatment, at least in regard to certain optical aberrations, it does not predict healing responses and their effect on posttreatment aberrations. As mentioned previously, currently used wave front technology uses one wavelength of light to make measurements therefore and only evaluate monochromatic aberrations and do not address scatter, diffraction, and chromatic aberration. In addition, as mentioned above, there are certain aspects of the eyes being evaluated such as cataract, multifocal intraocular lenses, etc. that limit the accuracy of wave front analysis (Oliveira et al. 2012).

Wavefront-Guided Laser In Situ Keratomileusis

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Custom LASIK; Wavefront-guided LASIK; wg-LASIK

Basic Characteristics

Excimer laser keratorefractive surgery such as photorefractive keratectomy (PRK) or laser in situ keratomileusis (LASIK) successfully reduces sphero-cylindrical refractive errors, also known as lower-order aberrations (LOA). Wavefront-guided ablation profiles incorporate also the treatment of higher-order aberrations (HOA) which are present in the normal eye (Salmon and van de Pol 2006). Therefore, the treatment is not solely based on subjective refraction data but also on measurements obtained with a wavefront sensor (aberrometer). Subjective refraction values and HOA, often also corneal height data, are merged into an ablation profile that aims at reduction of both LOA and HOA. The first wg-LASIK treatment was performed by Seiler in 1999 (Seiler et al. 2000). Subsequently, numerous laser platforms for wavefront guided treatments including aberrometer and excimer laser became commercially available.

The benefit of wg-LASIK over conventional (sphero-cylindrical) LASIK is judged controversially. First-generation algorithms had a limited predictability of HOA reduction because induced HOA overrode the reduction effect (Kohnen et al. 2004; Bühren and Kohnen 2006). Later enhancements like improved eye trackers, faster excimer lasers, aspheric ablation profiles, and the use of femtosecond lasers for flap creation led to better results.

After one decade, the overall benefit of wg-LASIK is discussed controversially. On one hand, large studies showed (a moderate) superiority of wg-LASIK (Schallhorn et al. 2008), on the other hand, the effect of physiological HOA on retinal image quality is rather negligible (Yoon and Williams 2002), in particular in the context of HOA induction by the procedure itself.

Wavefront-guided ablations can also be performed with surface ablation techniques. Similar to wg-LASIK is topography-guided LASIK which is primarily used for secondary treatments of highly aberrated eyes, e.g., after decentration of the optical zone.

WEBINO

Definition

Wall-eyed bilateral internuclear ophthalmoplegia (WEBINO) is a disorder often characterized by primary gaze exotropia and a bilateral adduction

deficit with a dissociated, horizontal abducting-eye nystagmus in horizontal gaze.

Etiology

This disorder is typically caused by a lesion involving both medial longitudinal fasciculi (MLF). Breakdown of fusional mechanisms results in the concomitant exotropia (i.e., "wall eyed").

Occurrence

WEBINO occurs most frequently in patients with multiple sclerosis or brainstem strokes, but any lesion of bilateral MLF can produce a clinical WEBINO. Myasthenia gravis can also mimic WEBINO (i.e., "pseudo-INO").

Wegener Granulomatosis

Michael T. Yen[1] and Rehan Ahmed[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Greater Houston Eye Consultants, Houston, TX, USA

Definition

Wegener's granulomatosis (WG) is noninfectious systemic vasculitis that typically involves the respiratory tracts and kidneys (Pakrou et al. 2006). Orbital and ocular adnexal involvement occurs in up to 50% of patients and can include all ocular tissues (Pakrou et al. 2006; Perez et al. 2004).

Background

Scottish otolaryngologist Peter McBride (1854–1946) first described the condition in 1897, and it was later refined by Friedrich Wegener (1907–1990), a German pathologist in 1936 and 1939 (Bhatia et al. 2005). Classic and limited forms of WG have been recognized. Classic WG is a multisystem disorder that shows upper and lower respiratory tract granulomas, generalized vasculitis, and glomerulonephritis. The limited form does not always progress to generalized disease, often does not affect the kidneys, usually involves the head and neck, and is associated with a better prognosis. Orbital and adnexal manifestations can occur in either form.

Etiology/Pathophysiology

Wegener's granulomatosis (WG) results from the dual contributions of type II (cytotoxic) and Coombs hypersensitivity reactions giving rise to antibodies to neutrophil cytoplasmic antigens (ANCA) and type IV (cell-mediated) reaction leading to formation of giant cells and granulomas (Fechner et al. 2002). The disease involves small-sized, more often than medium-sized, blood vessels. Disease complications may result from focal vasculitis, granulomatous inflammation, vascular thrombosis, and hemorrhage, or due to chronic inflammation or ischemia (Perez et al. 2004). Orbital and adnexal disease accounts for a significant portion of ocular involvement. Orbital involvement may be due to either primary inflammation or result from contiguous extension of disease from adjacent paranasal sinuses or nasopharynx (Fechner et al. 2002).

Epidemiology

WG demonstrates a strong predominance for Caucasians, particularly those of northern European

ancestry, and affects males and females equally. The annual incidence is estimated to be approximately ten cases per million, and the mean age at diagnosis is 50 years. Orbital involvement occurs in up to 50% of patients (Perez et al. 2004).

Clinical Presentation

Ocular involvement in WG is reported to be the presenting feature in up to 15% of patients (Pakrou et al. 2006). Orbital disease usually manifests as proptosis, ocular pain, epiphora, or injection. Many patients may also develop diplopia, which may be due to the mass effect itself or vasculitis of vessels supplying the extraocular muscles (Fechner et al. 2002). The features of orbital disease are frequently bilateral and constitute a severe risk to useful vision, secondary to optic nerve compression or proptosis with associated exposure keratopathy. Orbital socket contracture is also a reported complication and represents proliferation of fibrous tissue replacing areas of acute inflammation and necrosis.

Diagnosis

The diagnosis of orbital WG depends on a combination of clinical and serological findings. However, given the overlap in presentation with other entities, biopsy remains indispensable. The histopathologic triad of granulomatous inflammation, tissue necrosis, and vasculitis is seen in less than 50% of orbital biopsies (Perez et al. 2004; Fechner et al. 2002).

ANCA is not recommended to be used alone in place of a biopsy because ANCA is positive in less than 70% of cases of limited WG. Positive ANCA may help in establishing the diagnosis in cases in which typical pathological features are lacking, and it has a value in following disease activity.

With respect to diagnostic imaging, although computed tomography can reveal sinus structure involvement and an orbital mass, MRI can depict granulomas and better delineate mucosal inflammation and ulceration in the sinuses, nasal cavity, and orbits.

Differential Diagnosis

Bacterial or fungal orbital inflammatory infiltration
Lymphoma of the orbit
Sarcoidosis
Graves orbitopathy
Idiopathic orbital inflammation (orbital pseudotumor)

Treatment

The gold standard treatment for WG and ANCA-associated vasculitis combines glucocorticoids and cyclophosphamide (Pakrou et al. 2006). In cases of limited WG, an alternative regimen of methotrexate and glucocorticoids may also be used. In general, appropriate treatment of the underlying disease is satisfactory in managing associated ocular problems. Surgical interventions in the management of WG are largely limited to those involved with obtaining tissue biopsies for pathological analysis. However, in cases of nasolacrimal duct obstruction, dacryocystorhinostomy can be effective.

Prognosis

Limited WG of the orbit is a rare disease but with overall good prognosis (Bhatia et al. 2005). In all cases of WG, early recognition and referral to a trained specialist, accompanied by prompt treatment and periodic follow-up, can significantly decrease the risk of visual impairment.

Synonyms

Mesodermal dysmorphodystrophy, congenital; Spherophakia-brachymorphia syndrome

Definition

Weill-Marchesani syndrome (WMS) is a rare inherited disorder of connective tissue first described by Weill in 1932 and further delineated by Marchesani in 1939 (Faivre et al. 2003). It is characterized by proportionate short stature, brachydactyly, joint stiffness, broad skull, heart defects, and characteristic eye abnormalities including shallow orbits, microspherophakia (small spherical lens), ectopia lentis (abnormal position of the lens), high myopia, and glaucoma.

Etiology

Weill-Marchesani syndrome is an inherited disorder of the connective tissue. Two modes of inheritance are predominant, the autosomal dominant (45%) and the autosomal recessive (39%), but there are also 16% of simplex cases (single occurrence in a family). For the autosomal recessive form, mutations in ADAMTS10 gene located on chromosome 19 (19p13.3-p13.2) have been shown (Tsilou and McDonald 2007). The product of the gene ADAMTS10 (disintegrin-like and metalloproteinase with thrombospondin type 1 motif) belongs to the ADAMTS family of proteins, believed to be anchored to the extracellular matrix. Mutations in FBN1 were found in a large family with autosomal dominant WMS.

Clinical Presentation

WMS usually presents in childhood with short stature and/or ocular problems. The mean age of recognition of an ocular problem is 7.5 years. Microspherophakia is the most important manifestation of WMS. Microspherophakia results in lenticular myopia, which is usually the first ophthalmological finding. Ectopia lentis usually results in downward displacement of the lens. Glaucoma is the most serious complication and results in most cases by pupillary block because of forward movement of the lens or by dislocation of the lens into the anterior chamber (Ritch et al. 2003). Chamber angle abnormalities have also been described. Biometry in eyes of patients with WMS shows thicker cornea, higher keratometry values with usually oblique astigmatism, shorter axial length, shallower anterior chamber, and thicker lens than age-matched normals.

Loss of vision occurs earlier in WMS and is more severe than in other lens dislocation syndromes. In some cases, lens dislocation and pupillary block appear after blunt trauma to the eye weakens the zonular fibers. Presenile vitreous liquefaction has been described in a large family with autosomal dominant WMS.

Proportional short stature is an essential part of the syndrome. An adult male with WMS is expected to achieve a height of 142–169 cm, while an adult female is expected to achieve a height of 130–157 cm. Digits are short (brachydactyly) and joints are stiff. Heart abnormalities are occasionally seen and include patent ductus arteriosus and pulmonary stenosis. Some of the WMS patients show mild to moderate mental retardation.

Diagnostics

Diagnostic criteria for WMS have not been formally established. The clinical diagnosis of WMS

is considered when the key findings of ocular abnormalities (microspherophakia and ectopia lentis), short stature, brachydactyly, joint stiffness, and heart defects (occasional) are observed. Establishing the diagnosis in a proband relies on clinical findings, but molecular genetic testing of the ADAMTS10 sequence variants can help confirm the diagnosis.

Differential Diagnosis

Ectopia lentis can also occur in Marfan syndrome, homocystinuria, sulfite oxidase deficiency, and hyperlysinemia. All, however, are clinically distinct from WMS. Simple dominant ectopia lentis, ectopia lentis and pupillae have ocular findings only, and glaucoma-lens ectopia-microspherophakia-stiffness-shortness (GEMSS) syndrome has features resembling WMS (WMS-like syndrome).

Prophylaxis

In an inherited disease, there is no primary prophylaxis available. In affected individuals periodic ophthalmic examinations for early detection and removal of an ectopic lens can help decrease the possibility of pupillary block and glaucoma. Airway management during general anesthesia can be difficult in persons with WMS because of the stiff joints, poorly aligned teeth, and maxillary hypoplasia. Patients with WMS should have a clinical cardiology evaluation including ECG and baseline echographic examination to rule out occasional heart defects.

Therapy

Correction of progressive high myopia to improve vision is the primary goal of treatment when WMS is detected in a young person. Implantation of phakic anterior chamber lenses to correct myopia is contraindicated. If the anterior chamber is very shallow, the lens rather thick and/or subluxated, and signs of imminent pupillary block or anterior synechia are present, laser or surgical iridectomy/iridotomy should be performed as prophylaxis of pupillary block glaucoma. Use of ophthalmic miotics and mydriatics should be avoided as they can induce pupillary block. If iridotomy/iridectomy fails to open the angle and appositional angle closure persists, argon laser peripheral iridoplasty (ALPI) might be successful. Surgery for ectopic lenses should not be delayed as patients may develop acute angle closure when the lens spontaneously or following minor ocular trauma luxates into the anterior chamber. Pars plana lensectomy or extraction of the lens via anterior approach including anterior vitrectomy should be performed (Harasymowycz and Wilson 2004). For an experienced surgeon, stabilization of the capsular bag using modified capsular tension rings may allow to implant a posterior chamber lens (Cionni et al. 2003).

Prognosis

Life expectancy is not limited by the disease. If angle-closure glaucoma is diagnosed early enough and treated adequately and the lens is removed if required, visual prognosis may only be limited by some degree of ametropic amblyopia. If angle closure is the presenting sign, urgent surgery may be required.

Epidemiology

The exact incidence of WMS is not known, but it is a rare disease. In 2003 Faivre et al. reviewed 128 cases from the literature.

Wies Repair

Ru-ik Chee[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Transverse tarsotomy; Two-snip procedure

Definition

The Wies repair is a surgical technique used in the repair of eyelid entropion that was initially described by Frederic Wies in 1954 (Wies 1954). It involves the creation of a full-thickness lower eyelid horizontal incision to negate upward movement of the preseptal orbicularis muscle over the tarsal plate, as well as the placement of horizontal mattress sutures that evert the eyelid margin.

Indication

The Wies repair is a relatively simple surgical procedure that has been shown to be relatively effective in cases of eyelid entropion. It has been described in the surgical repair of both involutional and cicatricial ectropion. The full-thickness lower eyelid horizontal incision leads to the development of fibrous scar tissue that acts as a barrier preventing the upward movement or overriding of the preseptal orbicularis muscle.

Contraindication

Contraindications to the Wies repair, which is usually performed under general anesthesia, are generally related to the general medical condition and operative risk of the patient. The Wies repair may be contraindicated in patients with concurrent uncontrolled medical conditions, systemic anticoagulation, or other conditions that interfere with appropriate positioning or safe management of the patient in the operating room. In such situations, simpler less invasive methods of eyelid malposition correction such as the Quickert procedure for entropion may be preferred, even if they may be associated with higher long-term recurrence.

Techniques and Principles

1. After skin preparation, infiltrate locally administered anesthetic agent subcutaneously and subconjunctivally along the inferior border of the tarsus.
2. Use a 15 blade to make a full-thickness incision through the middle lower eyelid at the level of the lower tarsus, approximately 2–3 mm below the lower eyelid margin. Utilize a corneal shield to protect the globe prior to performing the skin incision.
3. Starting from the conjunctival aspect of the lower eyelid margin, pass each arm of a 5–0 double-armed suture (e.g., Vicryl) full-thickness through the eyelid just inferior to the inferior margin of the full-thickness eyelid incision.
4. Pass each arm of the double-armed suture through the eyelid superior to the full-thickness incision in a partial thickness fashion, exiting the eyelid just inferior to the lash line.
5. Tie both ends of the double-armed suture together to complete the horizontal mattress suture.
6. Repeat steps 3–5 two to three more times to complete closure of the full-thickness eyelid incision.

The Wies procedure is also referred to as the two-snip procedure due to the nature in which the full-thickness eyelid incision may be made by extending a full-thickness stab wound with two scissor snips nasally and temporally.

Outcome

The Wies procedure is reported to have unsatisfactory surgical outcome rates as low as 11% (Lance and Wilkins 1991) and as high as 48% (Boboridis et al. 2000). The Wies repair alone does not address horizontal or vertical eyelid laxity and has been unfavorably compared to other procedures like the tarsal strip procedure that do so with higher reported surgical success rates. When combined with a lateral tarsal shortening procedure, surgical outcomes generally improved (Lance and Wilkins 1991). Nevertheless, in a direct comparison between procedures that did not involve horizontal shortening of the lower eyelid, the Wies repair was also found to be inferior to the Jones' retractor plication procedure (Boboridis et al. 2000).

The Wies repair has also been reported to be associated with higher rates of consecutive ectropion, which may be a result of cicatricial changes associated with the full-thickness eyelid incision inherent in the procedure (Baylis et al. 1977; Cheung and Sandramouli 2004). The process of cicatricial scarring is difficult to predict and is itself a known cause of eyelid entropion and ectropion.

Complications

Complications of the Wies repair include failure of entropion correction, recurrence, ectropion overcorrection, granuloma formation, infection, bleeding, and wound dehiscence. Careful burying of deep sutures while minimizing dead space aids in the reduction of suture granuloma formation and suture extrusion. Attention to appropriate surgical technique, good placement of sutures, and knot security maximizes the chances of surgical success. Avoidance of trauma in the postoperative period, good patient hygiene, and use of topical antibiotic ointment may also contribute to minimizing complications.

[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Junctional scotoma; Optic nerve decussation

Definition

The so-called Wilbrand knee is an anatomical term that describes decussating optic nerve fibers discovered by Hermann Wilbrand in 1904 (Wilbrand et al. 1904). He studied cadavers that had undergone enucleation prior to death and found inferonasal nerve fibers that looped into the contralateral optic nerve prior to traveling in the optic tract (Wilbrand et al. 1904). He believed these fibers would result in a pattern of vision loss seen with some parasellar lesions causing compression of the inferonasal optic nerve at its junction with the optic chiasm, namely, a central scotoma in the ipsilateral eye and a smaller superior temporal hemianopia in the contralateral eye (from involvement of the crossing inferonasal fibers) (Lee et al. 2006).

In 1997 JC Horton reported that the Wilbrand knee was actually an artifact of optic nerve atrophy after enucleation in monkeys (Horton 1997). He studied three postmortem human optic chiasms that had undergone monocular enucleation at time points of 5 months, 27 months, and 28 years prior to death and concluded the same was true for humans. It is now believed that shrinkage of the optic nerve in the enucleated eye causes the contralateral optic nerve to briefly enter the atrophic nerve resulting in a classic Wilbrand knee (Horton 1997).

In 2006 Lee et al. presented three cases of optic nerve lesions near the optic chiasm requiring resection. In all three cases, resection of the diseased optic nerve was performed without loss of vision in the contralateral eye, supporting the belief that Wilbrand knee is not found in normal human patients (Lee et al. 2006). Despite the anatomic controversy, the localizing value of the clinical visual field defect known as the junctional scotoma (ipsilateral nerve fiber layer defect or central scotoma and contralateral superotemporal visual field loss) is still localizing to the junction of the optic nerve and chiasm.

Hepatolenticular degeneration

Definition

Wilson disease is a genetic disorder of systemic copper accumulation. It is due to defective hepatic excretion and characterized by progressive neurologic disease, chronic liver disease, and ocular manifestations including Kayser-Fleischer rings and "sunflower" cataracts (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Etiology

Copper deposition in Wilson disease occurs due to decreased biliary copper excretion and diminished copper uptake into ceruloplasmin transport protein. An autosomal recessive mutation in *ATP7B* (13q14.3–q21.1), which codes for intrahepatocytic transport proteins necessary for ceruloplasmin copper uptake mechanism, is responsible for disease. Systemically, this process leads to development of liver failure and neurologic deficits as a result of copper accumulation in basal ganglia (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Clinical Presentation

The Kayser-Fleischer ring is a peripheral orange, brown, or green-brown discoloration due to gradual copper accumulation at the level of the Descemet membrane adjacent to the limbus. Approximately 95% of patients with neurologically symptomatic Wilson disease initially present with a Kayser-Fleischer ring in the peripheral cornea. This begins primarily in superior and inferior arcs which eventually coalesce to form a 360° green-brown zone of copper granule deposits in the Descemet membrane. Copper accumulation begins peripherally at Schwalbe's line and moves centrally. Slit-lamp biomicroscopy is used to identify these rings in most instances. Gonioscopy may be required to locate the ring in its early stage due to its primary peripheral location.

Copper accumulation within the lens capsule results in "sunflower" cataract, present in approximately one in five patients with neurologically symptomatic Wilson disease. This is characterized by multicolored central opacities with radiating spokes beneath the lens' anterior and posterior capsule. These cataracts occur in small portion of patients and do not impair vision. They may disappear within a few years of starting chelating therapy.

Systemically, patients may present with earlier symptom of jaundice indicating onset of liver disease. Basal ganglia dysfunction, behavioral disturbances, and nephrotic syndrome may manifest due to systemic copper toxicity (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Diagnosis

Diagnosis of Wilson disease is multifactorial and relies on the presence of characteristic clinical features and biochemical parameters. In a majority of patients, the presence of a Kayser-Fleischer ring and a low serum ceruloplasmin level (<200 mg/L) is sufficient to establish a diagnosis. In patients with neurological signs or symptoms, diagnosis can be made from the presence of

Kayser-Fleischer rings alone. Subsequent MRI scans may show lesions at sites compatible with the neurological features. Other biochemical findings include elevated basal 24-h urinary copper excretion and increased hepatic parenchymal copper concentration. In the absence of Kayser-Fleischer rings or neurologic dysfunction, a liver biopsy for quantitative copper measurement is necessary to establish diagnosis (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Differential Diagnosis

Corneal chalcosis (corneal copper deposition) may also occur due to intraocular foreign body, chronic copper poisoning, and multiple myeloma. Based on systemic presentation of Wilson disease, relevant neurologic and hepatic diagnoses should be considered such as cirrhosis, hepatitis, and neurodegenerative disease (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Prophylaxis

There are currently no methods of primary prophylaxis for Wilson disease. Genetic counseling is recommended for individuals with a family history of Wilson disease (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Therapy

Medical management of Wilson disease addresses systemic excess of copper through increased excretion and decreased absorption. Systemic copper removal is attained by D-penicillamine, a chelating agent. Zinc is administered to interfere with intestinal copper uptake and stabilize hepatic copper through the induction of metallothioneins. Patients are recommended to avoid foods with high copper content. Lifelong treatment is required to prevent further complications. Ocular examination can be utilized to assess the reduction of systemic copper levels (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Prognosis

Patient outcome in Wilson disease is optimized if treatment is started soon after disease is diagnosed. Failure to adhere to a consistent treatment regimen may result in loss of liver function and neurologic damage. Rapid hepatic decompensation may occur within three years and as early as eight months after treatment is stopped. Liver damage is usually refractory to reinstitution of chelation therapy. Affected patients require liver transplantation (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Epidemiology

Wilson disease occurs on average in 1 in 30,000 individuals, with a corresponding carrier frequency of 1 in 90. Prevalence is increased among Sardinian and Chinese populations (1 in 10,000). It is relatively infrequent in individuals of African descent (Yanoff and Duker 2009; Kanski and Bowling 2011; Krachmer et al. 2011).

Definition

Biological response of the cornea to (surgical) trauma.

Function

Surgical epithelial defects (induced by alcohol in LASEK, mechanical scrape in PRK, microkeratome or femtosecond laser application in LASIK and Epi-LASIK) lead to a release of cytokines from the injured epithelium. These cytokines and cytokines from the tear film induce apoptosis and necrosis of keratocytes in the anterior corneal stroma. Proinflammatory cytokines attract macrophages, T cells, and polymorphonuclear cells arriving via the limbal vessels and from the tear film. These cells clear cell debris. Remaining keratocytes from the deeper stroma are subsequently activated, proliferate, migrate, and repopulate the depleted stroma. Myofibroblasts derived form keratocytes responding to TGF ß play a role in stromal remodeling due to collagen and extracellular matrix formation. Myofibroblasts have a lower transparency than normal keratocytes due to a lower concentration of corneal crystallines in their cell body. Myofibroblasts play an important role in haze formation and regression. With the formation of a functional basement membrane myofibroblasts slowly disappear over months. Corneal wound healing processes are more pronounced after surface ablation as compared to LASIK because of the disruption of the epithelial basement membrane over the central cornea. In LASIK, wound healing processes are mainly limited to the cut margins and the corneal stroma adjacent to the flap interface. However, a significant decrease in keratocyte density in the flap and anterior subablation zone over the postoperative years has been observed after LASIK, but the clinical significance of this finding remains unclear. The decrease in keratocyte density may be associated with the trauma to stromal corneal nerves in LASIK surgery. Refractive regression, especially in higher levels of corrections, is more common and more pronounced after surface ablation than after LASIK. Refractive regression is associated with thickness changes in the cornea due to stromal remodeling and epithelial hyperplasia.

Clinical Relevance

Corneal wound healing after surgical trauma is aimed at restoring corneal hemostasis, barrier function, and corneal transparency. However, corneal wound healing processes are associated with refractive regression and haze formation, especially in surface ablation procedures.

Xanthelasma, Dyslipoproteinemia

Maria J. Suarez
Ocular Pathology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Planar xanthoma

Definition

Xanthelasmas are single or multiple soft, flat or slightly elevated, yellowish plaques on the eyelids or in the periorbital skin, particularly, near the inner canthi (Weedon 2010; Eagle 2011).

Histologically, xanthelasmas are characterized by sheets of foamy, lipid-laden histiocytes within the upper dermis, often around blood vessels as well as the pilosebaceous follicles (Weedon 2010) (Fig. 1).

Etiology

Although abnormal lipid metabolism has been described to play an important role in the development of xanthelasmas, approximately 50% of cases have normal lipids (Rohrich et al. 2002; Weedon 2010; Eagle 2011). The pathogenesis remains unclear; apoprotein abnormalities and vascular permeability impairment have been documented as contributing factors (Weedon 2010).

Clinical Presentation

Typically, xanthelasmas present as yellow, soft macules or slightly elevated plaques on the medial aspect of the upper and lower eyelids (Fig. 2).

In children, the presence of corneal arcus as well as extensor tendon xanthomas, and associated xanthelasmas, is always a sign of hyperlipoproteinemia (Rohrich et al. 2002).

Xanthelasma, Dyslipoproteinemia, Fig. 2 Xanthelasmas in the nasal aspect of upper and lower lids

Diagnosis

In general, xanthelasmas are diagnosed clinically and its presence may be an important factor of underlying systemic disease (Rohrich et al. 2002; Weedon 2010; Eagle 2011). If they present before age 40, association with familial dyslipoproteinemia including type IIa, IIb, and even type III needs to be considered, and a lipid profile is recommended (Rohrich et al. 2002).

Differential Diagnosis

Other systemic conditions such as cirrhosis, hypothyroidism, and nephrotic syndrome need to be also considered as part of the differential diagnosis for typical lesions (Rohrich et al. 2002; Weedon 2010; Eagle 2011).

More severe xanthogranulomatous disorders such as necrobiotic granuloma, orbital xanthogranuloma with adult onset, and Erdheim-Chester present with atypical indurated xanthelasma-like lesions (Rohrich et al. 2002; Eagle 2011). Lipoid proteinosis, a very rare autosomal recessive disorder which is characterized by perivascular deposits of hyaline, may present as well, with very similar atypical lesions along the lid margin (Rohrich et al. 2002).

Prophylaxis

No definitive alternatives to prevent the development of xanthelasma have been described yet. However, dietary restriction of fat has been associated with xanthelasma regression (Rohrich et al. 2002). As before, treatment of the underlying disease may also cause regression of the lesion as seen when hormone replacement therapy is given such as in hypothyroidism (Caplan and Curtis 1961; Rohrich et al. 2002).

Therapy

In general, xanthelasma represents a cosmetic concern and very rarely may obstruct visual axis due to its size (Rohrich et al. 2002). A variety of therapeutic options are considered in order to ameliorate the appearance of the eyelid including surgical excision; ablation with laser such as carbon dioxide, argon, and erbium-yttrium-argon-garnet (YAG); pulsed dye; peeling of the lesions with trichloroacetic acid; and also giving therapeutic agents for the underlying medical condition (Caplan and Curtis 1961; Mendelson and Masson 1976; Rohrich et al. 2002).

Prognosis

Overall, xanthelasma represents a benign condition which commonly recurs, regardless of the type of treatment (Rohrich et al. 2002; Weedon 2010; Eagle 2011). Mendelson and Masson (1976) previously found 40% recurrence rate after primary excision and 60% recurrence rate after secondary excision, having the highest incidence of recurrence, 26%, within the first year. They did also highlight three scenarios in which surgical excision is less likely to prevent lesion recurrence: patients with defined familiar hyperlipoproteinemia, involvement of all four eyelids, and more than one recurrence (Mendelson and Masson 1976; Rohrich et al. 2002).

Epidemiology

Xanthelasma is the most common cutaneous xanthoma (Weedon 2010) In general, most of the patients are in the fifth or sixth decade of life with an incidence of 1.1% in women and 0.3% in men (Caplan and Curtis 1961; Rohrich et al. 2002). Patients with a history of familial hypercholesterolemia may develop these lesions at a younger age (Caplan and Curtis 1961; Rohrich et al. 2002; Weedon 2010).

Xanthomas

Sherveen Salek
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Xanthelasma; Xanthelasma palpebrarum

Definition

Xanthomas are sharply demarcated, yellow-colored lesions in the connective tissue of skin, tendons, or fascia that are formed by foam cells. In the eyelids, they appear most commonly near the medial canthus.

Etiology

Xanthomas develop through increased local extravasation of lipids through the vascular wall into the surrounding interstitial space. Local macrophages and monocytes phagocytose the lipid particles, mostly low-density lipoprotein (LDL) complexes, through LDL receptors. LDLs undergo intracellular oxidation, which gives rise to foam cells.

Clinical Presentation

Xanthelasma typically present in middle age during the fifth and sixth decades of life. The lesions are typically painless and do not affect vision.

Diagnosis

Eyelid xanthomas are diagnosed clinically based on the presence of yellow-colored, demarcated plaques near the medial canthus. Biopsy is typically not warranted for diagnosis, and histology demonstrates foam cells in the middle and superficial layers of the dermis in a perivascular and

periadnexal distribution. Lipid profiles will be abnormal in approximately one-half of patients.

Differential Diagnosis

There are several benign and malignant lesions to consider in the differential for xanthomas of the eyelid.

Benign lesions: chalazion, hordeolum, molluscum contagiosum.

Malignant lesions: basal cell carcinoma, squamous cell carcinoma, sebaceous carcinoma, keratoacanthoma.

Prophylaxis

Pharmacologic control of serum cholesterol does not appear to affect the clinical course and outcomes of xanthomas, despite the association of these lesions with serum lipid profile.

Therapy

The literature has described several treatment options for xanthomas of the eyelid. These include surgical resection; ablation with various lasers such as Nd:YAG, erbium YAG, and CO_2; and trichloroacetic acid (TCA) peels. Each method is associated with its own set of drawbacks. Surgical resection is limited by scar and ectropion formation. Pigmentation and scarring can complicate chemical treatment with TCA, and laser treatment is mostly beneficial early-stage lesions. All treatment modalities have a high rate of recurrence, especially when multiple eyelids are involved.

Prognosis

Removal of eyelid xanthomas is complicated by a high rate of recurrence. Their presence can also be associated with the presence of xanthomas elsewhere on the body. As for association with systemic disease, a prospective cohort study in *BMJ* with data from the Copenhagen City Heart Study found an increased risk for myocardial infarction, ischemic heart disease, and early mortality. This effect was independent of the presence of an abnormal lipid profile. However, other studies have disagreed, and the link between xanthomas and cardiovascular disease remains inconclusive.

Epidemiology

Xanthomas of the eyelid occur in both men and women, with increasing prevalence in middle age.

Xeroderma Pigmentosum

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Definition

First described in 1874 by Hebra and Kaposi, xeroderma pigmentosum is a rare autosomal

recessive disorder with a genetic defect in the deoxyribonucleic acid (DNA) repair system that results in an early susceptibility to developing malignancies in sun-exposed skin and ocular structures. Clinically, xeroderma pigmentosum is characterized by extreme sensitivity to sunlight, photophobia, and pigmentary skin changes. Ocular findings are most prevalent in sun-exposed areas and can include ectropion, symblepharon, pterygium, conjunctivitis, conjunctival nevi, extreme dry eye, and corneal ulcers and opacification. Benign lid papillomas, corneal dysplasias, and ocular neoplasms such as squamous cell carcinoma, basal cell carcinoma, and melanomas are also much more frequent.

Neurological changes are found in 14–40% of patients with xeroderma pigmentosum. Motor impairment, peripheral neuropathy, and mental retardation have been reported and are thought to be secondary to increased neurodegeneration from DNA damage. Patients also have an increased risk of oral mucosa cancers and internal organ neoplasms including leukemia and central nervous system neoplasms.

Etiology

The nucleotide excision repair (NER) pathway of DNA repair for ultraviolet (UV)-light-induced DNA damage is a multi-step process that involves damage recognition, localized opening of the DNA double helix around the area of injury, excision of damaged DNA, and DNA-repair synthesis to replace removed DNA. Genetic mutations in genes involved in the nucleotide excision repair (NER) pathway of DNA repair that characterize xeroderma pigmentosum result in failure to remove UV-light-induced DNA damage, and mutations are replicated in the genome. These changes can result in the transformation of normal cells to malignant cells.

Clinical Presentation

Hypersensitivity to sunlight presents at a very early age. Serious sunburns can occur after very minimal sunlight exposure and persist for weeks. Significant pigmentary changes occur in light-exposed skin. Erythema, pigmentary changes, scabbing, and scarring occur due to cellular hypersensitivity to UV radiation. Precancerous lesions, actinic keratoses, and malignant skin tumors develop in childhood and adolescences.

About 12–50% of patients with xeroderma pigmentosum have visual impairment due to ocular changes. Ocular tissues with direct light exposure including the eyelids, conjunctiva, and cornea are most affected. More than 80% of patients will have benign and/or malignant lesions on the eyelids including hyperpigmented lesions, basal cell carcinomas, or squamous cell carcinomas. Other ocular findings include keratitis, band keratopathy, pterygium, and corneal scarring, ulceration, neovascularization, and perforation. Malignant neoplasms of the ocular surface can also occur, including squamous cell carcinoma, basal cell carcinoma, and melanomas. Patients usually have extreme photophobia.

Diagnosis

Diagnosis can be confirmed by molecular analysis by performing DNA-repair tests after UV exposure on a skin biopsy. DNA sequencing can also be done to determine specific mutations in the DNA-repair genes.

Differential Diagnosis

Xeroderma pigmentosum must be distinguished from other DNA-repair deficiency syndromes such as Cockayne syndrome and trichothiodystrophy that also present with extreme light sensitivity and autosomal recessive inheritance. Cockayne syndrome has characteristic neurological symptoms with distinct facies and weight loss. Trichothiodystrophy is characterized by dwarfism, brittle short hair, and ichthyoses.

Prophylaxis

Prenatal diagnosis by analyzing amniotic cells is possible.

Therapy

The main therapy for xeroderma pigmentosum is prevention by absolute avoidance of sunlight and other UV light exposure. Use of sun block and UV-blocking clothing, hats, and eyewear is recommended. Patients may benefit from switching day-night cycles. Close monitoring by dermatologist, ophthalmologists, and dentists for early identification and removal of neoplasms is necessary.

Prognosis

Prognosis is poor. Patients with xeroderma pigmentosum have a 1,000 times higher risk of tumor incidence. About two-thirds of patients die before reaching adulthood due to metastatic disease.

Epidemiology

Xeroderma pigmentosum is a rare autosomal recessive disorder that occurs equally in males and females. Prevalence is higher with consanguinity. Incidence is estimated at 1:250,000 live births in Europe and North America and 1:40,000 live births in Japan.

Xerophthalmia

Sana Idrees
The George Washington University, Washington, DC, USA

Synonyms

Vitamin A deficiency

Definition

Xerophthalmia refers to the spectrum of ocular disease caused by vitamin A deficiency, and it is a late manifestation of severe deficiency of this nutrient.

Etiology

Vitamin A is a fat-soluble vitamin that is involved in corneal metabolism. Additionally, specific retinol-binding proteins are present in the epithelium, keratocytes, and endothelium of the cornea. The mechanism by which xerophthalmia develops is unclear, but the role of vitamin A deficiency in xerophthalmia is clear. The liver is able to store a 1–2-year supply of vitamin A under normal conditions. When vitamin A intake exceeds 300–1200 mg/day of retinol or an equivalent, the liver lays down stores of the vitamin. However, when intake falls before this level, the stores are depleted in order to maintain serum retinol levels above 0.7 mmol/L (Paranjpe et al. 2011). Vitamin A can be found in animal and dairy products, usually in the form of retinyl palmitate. Carotene is a naturally occurring precursor to vitamin A, which is produced by plants. The most important of the carotenoids is beta-carotene, which is found is dark-green leafy vegetables and some colored fruits (Kent and Jakobiec 2008).

Lack of vitamin A may be secondary to malnutrition, malabsorption, and chronic alcoholism. Infants are at increased risk for xerophthalmia if

their mothers are malnourished and by coexisting diarrhea or measles (Kanski and Bowling 2011). Systemic diseases associated with vitamin A deficiency affect its absorption or metabolism, including sprue, Crohn's disease, cystic fibrosis, abetalipoproteinemia, and pancreatic insufficiency. Surgical procedures, such as jejunoileal bypass, can be causes of vitamin A deficiency and eventual xerophthalmia (Kent and Jakobiec 2008). Measles (rubeola virus) is closely associated with vitamin A deficiency. Xerophthalmia secondary to measles keratoconjunctivitis was a significant issue until the mid-twentieth century in Europe and continues to be a devastating disease in developing countries (Paranjpe et al. 2011).

Deficiencies of fats or proteins involved in the metabolism of carotene and vitamin A can lead to xerophthalmia as well, but they tend to play a minor role. Vitamin A deficiency usually occurs in conjunction with generalized protein-energy malnutrition (PEM), which has raised uncertainty as to which factor is more significant in corneal disease. The malabsorption seen in PEM may cause reduced retinol levels directly and by impairment in beta-carotene conversion. Reduced protein synthesis prevents vitamin A release from the liver. Therapy with high doses of vitamin A has been shown to stimulate healing in cases of xerophthalmia despite the presence of severe PEM, which would support the significance for vitamin A as a factor in corneal disease (Paranjpe et al. 2011).

Clinical Presentation

Xerophthalmia causes changes in mucosal surfaces throughout the body, including the eye. Other organ systems affected include the epithelium of the lungs and the intestine, which undergo keratinizing metaplasia (Paranjpe et al. 2011). Xerophthalmia may present with night blindness (nyctalopia), ocular discomfort, and vision loss. Children with vitamin A deficiency are likely suffering from systemic illnesses, including diarrhea, respiratory illness, and measles (Vaddavalli et al. 2011). A grading scheme has been devised to classify different stages of the disease. The WHO grading scheme remains the standard for assessment for xerophthalmia (Kanski and Bowling 2011).

XN: night blindness
X1A: conjunctival xerosis
X1B: Bitot's spots
*X*2: corneal xerosis
X3A: corneal ulceration, less than one-third
X3B: corneal ulceration, more than one-third
XS: corneal scar
XF: xerophthalmic fundus

Night Blindness (XN)

Night blindness is one of the earliest symptoms of xerophthalmia. Mild cases of nyctalopia or night blindness may only be apparent after photic stress. Histologically, photoreceptor degeneration may be observed in the outer segment (Kent and Jakobiec 2008). Retinol is essential for the production of rhodopsin, a visual pigment produced by the rod photoreceptors. All patients respond rapidly to therapy with vitamin A, typically within 48 h (Paranjpe et al. 2011).

Conjunctival Xerosis (X1A) and Bitot's Spots (X1B)

Xerosis is characterized by dryness of the conjunctiva, particularly of the interpalpebral zone. Histologically, xerosis results in loss of goblet cells, squamous metaplasia, and keratinization (Kanski and Bowling 2011). Though histologic evidence of xerosis is present throughout the conjunctiva in the early stages of the disease, it is typically only clinically apparent in the temporal conjunctiva. The nasal and inferior conjunctivas are next to show clinical evidence. The superior conjunctiva shows clinical evidence in the later stages of the disease (Paranjpe et al. 2011). Conjunctival xerosis signifies mild disease, but corneal xerosis implies more severe deficiency (Vaddavalli et al. 2011). Once excised, if an adequate diet is maintained, the lesions do not recur (Paranjpe et al. 2011).

Bitot's spots appear as triangular patches of foamy keratinized epithelium in the interpalpebral zone (Kanski and Bowling 2011). Histologically, they are seen as tangles of keratin with saprophytic bacteria and occasionally fungi. The

material can easily be scraped off, but the base remains xerotic and the spot tends to recur within a few days. It may involve the cornea and the conjunctiva and can be quite extensive. Bitot's spots were first observed as dry scaly patches on the bulb of the eye. They were seen in association with nyctalopia and lackluster corneas. However, Bitot's spots have been observed in isolation and been nonresponsive to vitamin A therapy, suggesting that they may not be associated with vitamin A deficiency. *Corynebacterium xerosis* has been identified in Bitot's spots, and it has been suggested that it may be responsible for their typical foamy appearance (Paranjpe et al. 2011).

Nasally situated spots have been identified as more reliable indicators of active vitamin A deficiency, and they are always less prominent than temporal spots. Additionally, age is a more significant indicator of deficiency. In children under the age of 6 years, 97% of the lesions resolve rapidly. However, individuals over the age of 10 years are unresponsive in 60% of cases. Dryness of the conjunctiva should always be considered significant in children (Paranjpe et al. 2011).

Corneal Xerosis (X2)

The cornea may exhibit a lusterless appearance due to secondary xerosis. Vitamin A deficiency has been found to reduce aqueous tear production, and the loss of goblet cells leads to localized drying of the epithelium. Superficial punctate epithelial erosions may develop in xerophthalmia, initially seen inferonasally and later spreading to affect the entire corneal epithelium (Paranjpe et al. 2011). Bilateral punctate corneal epithelial erosions in the interpalpebral zone may progress to larger epithelial defects (Kanski and Bowling 2011). Occasionally, water-repellant microcysts that do not stain with fluorescein are observed. However, these changes are reversible with vitamin A therapy. Keratinization of the corneal epithelium may occur, causing the epithelium to take on a peau d'orange appearance. Pooling of fluorescein dye between keratinized epithelial plaques may give the epithelium a tree bark appearance (Paranjpe et al. 2011).

Corneal Ulceration and Keratomalacia (X3A/X3B)

Uncomplicated ulcers may develop in xerophthalmia, which typically have sharp margins. Rupture of subepithelial bullae may cause superficial ulcers of varying depths, which tend to form in the lower half of the cornea. Superficial ulcers tend to heal with minimal scarring (Paranjpe et al. 2011). Severe lesions may develop sterile corneal melting by liquefactive necrosis known as keratomalacia, which can lead to perforation of the cornea (Kanski and Bowling 2011). Secondary infection may develop and often leads to permanent blindness (Vaddavalli et al. 2011). The ulcers are typically gray or yellow in color and vary in size from 2 mm to involvement of the entire cornea. They may appear elevated, but collapse to reveal stromal loss with sharp boundaries following treatment. Deep stromal loss produces descemetoceles, which rupture easily under pressure. Rupture frequently results in scarring and formation of anterior staphylomata (Paranjpe et al. 2011).

Retinopathy

Xerophthalmia may also cause retinopathy characterized by yellowish peripheral dots with irregular borders. Retinopathy typically occurs in advanced cases, and it is associated with decreased electroretinogram amplitude (Kanski and Bowling 2011).

Diagnosis

The diagnosis of xerophthalmia is clinical and does not require any additional workup. When the diagnosis is in doubt, cytology of the superficial layers of the conjunctival epithelium may reveal loss of goblet cells and keratinization of epithelial cells (Prajna and Rajamani 2013). Dark adaptation, electroretinographic findings, and visual fields are all abnormal in early cases manifesting as night blindness (Vaddavalli et al. 2011).

Differential Diagnosis

The differential diagnosis for xerophthalmia includes Sjögren's syndrome, age-related

hyposecretion, lacrimal tissue destruction or obstruction, chemical ocular trauma, neurologic lesions with sensory or motor reflex loss, meibomian gland dysfunction, lagophthalmos, contact lens wear, and environmental conditions leading to dry eye (Kanski and Bowling 2011).

Prophylaxis

Improving vitamin A status of all deficient individuals, particularly children, could prevent one to three million deaths annually. The cost of vitamin A supplementation for 2 days costs approximately 10 cents per child. Measles immunization can prevent infection, which is a known risk factor for vitamin A deficiency (Paranjpe et al. 2011).

Therapy

The diagnosis of xerophthalmia should be treated promptly with massive supplementation of vitamin A. The development of keratomalacia indicates very severe vitamin A deficiency, and it should be treated as a medical emergency due to the associated risk of death, particularly in infants. Systemic treatment involves oral (oil-based 200,000 IU) or intramuscular (aqueous-based 100,000 IU) supplementation of vitamin A -(Kanski and Bowling 2011). Standard dosing by the World Health Organization varies with age. In children over 12 months of age and all women of childbearing age, oral therapy is preferred, which can be administered as 110 mg retinol palmitate or 66 mg retinol acetate (200,000 IU) given immediately and again the following day. Another dose should be given 2 weeks later to boost liver reserves of the vitamin (Paranjpe et al. 2011).

If parenteral replacement is indicated, such as in cases of severe anorexia, edematous malnutrition, septic shock, or inability to take oral supplementation, 55 mg of water-miscible retinol palmitate can replace the first dose. One-half the dosage is indicated in children aged 6–12 months. In children younger than 6 months, one-quarter of the dosage is appropriate. Multivitamin supplements and dietary sources of vitamin A should also be administered. Protein-deficient individuals should receive adequate treatment for PEM, and vitamin A supplementation should continue every 1–2 weeks until PEM correction is achieved (Paranjpe et al. 2011).

Women of reproductive age with night blindness or Bitot's spots should be treated with 5,000–10,000 IU daily for 4 weeks. Alternatively, a weekly dose of 25,000 IU may be administered. However, supplementation should be avoided in pregnancy to prevent teratogenesis. Instead, the mother should be given 400,000 IU at childbirth to increase the level of vitamin A provided to her infant via breast milk. Children at high risk should receive repeat dosing every 4–6 months. A priming dose given 1 week before the full dose can extend the protection provided (Paranjpe et al. 2011).

Local treatment involves aggressive lubrication. Topical retinoic acid may be used to promote healing, but it does not provide adequate treatment without systemic supplements. Corneal perforations should be addressed surgically with primary corneal grafting or amniotic membrane transplantation (Kanski and Bowling 2011).

Prognosis

Night blindness typically responds well to treatment with vitamin A supplementation (Kent and Jakobiec 2008). Prompt treatment of a corneal ulcer or keratomalacia involving less than one-third of the corneal surface often restores vision given the visual axis is usually unaffected. Treatment in cases of more extensive corneal involvement may prevent globe rupture and preserve useful vision in the contralateral eye (Paranjpe et al. 2011). However, the presence of keratomalacia indicates severe deficiency and a poor prognosis. More than 50% of children with xerophthalmia die due to poor nutritional status and susceptibility to disease (Vaddavalli et al. 2011).

Epidemiology

An estimated 140 million children worldwide are vitamin A deficient, second only to protein-calorie

malnutrition in prevalence. Of these children, 4.4 million are xerophthalmic. Approximately 250,000–500,000 xerophthalmic children become blind each year, and up to half of them will die within a year of losing their vision. Young infants depend upon the vitamin A supplied by their mother's milk, which decreases over time. Thus, children between 6 months and 3 years of age are most at risk of blinding corneal disease (X2, X3). It is estimated that 7.2 million pregnant women is vitamin A deficient and 13.5 million have reduced vitamin A levels. Over 6 million pregnant women develop night blindness, particularly during their third trimester when maternal and fetal demands are greatest. Older children, between 3 and 6 years of age, are more at risk of conjunctival disease, due to nutritional deficiencies. Xerophthalmia is particularly prevalent in Southeast Asia where rice is a staple food. Areas of endemic xerophthalmia have a diet deficient in preformed vitamin sources, such as milk, eggs, and meats, and provitamin sources are relied on more heavily (Paranjpe et al. 2011). Malnourished children with low vitamin A levels often become xerophthalmic after contracting measles (Vaddavalli et al. 2011). Though xerophthalmia largely affects impoverished individuals in developing countries, it can occur occasionally in developed nations as well. It has been observed in food faddists, psychiatric patients, and chronic alcoholics (Paranjpe et al. 2011).

Xerosis

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Conjunctival xerosis

Definition

Xerosis refers to the extreme ocular dryness and keratinization that occurs in eyes with severe conjunctival cicatrization (Kanski and Bowling 2011).

Etiology

Xerosis may occur secondary to keratoconjunctivitis sicca, ocular pemphigoid, trachoma, measles, vitamin A deficiency, exposure proptosis, chemical burns, and Stevens-Johnson syndrome (Yanoff and Sassani 2015).

Clinical Presentation

Patients may present asymptomatic with xerosis or with symptoms such as redness, dryness, itching, foreign body sensation, and pain (Khurana 2008). Severe damage may result in ulceration.

Diagnosis

The diagnosis of dry eye and xerosis is made primarily by patient history and physical exam.

Excessive reflex tearing and sensation of itching, burning, redness, and irritation are helpful in determining if a patient has experienced dry eye (Gupta et al. 2006). Ocular staining with agents such as lissamine green may be used to determine extent of dryness and possible corneal damage. Further, testing can include a Schirmer's tear test and tear film break-up time.

Patients with vitamin A deficiency may present with Bitot's spots, which are superficial keratin accumulations on the conjunctiva (Shukla and Behari 1979).

Histologically, the epithelium undergoes epidermidalization with keratin formation, and the underlying subepithelial tissue frequently shows cicatrization (Yanoff and Sassani 2015).

Differential Diagnosis

Deficient lid closure, vitamin A deficiency, congenital tear reduction, Sjogren syndrome, medication side effect.

Prophylaxis

If nutrient related, vitamin A supplementation may benefit patients (Kiegman et al. 2011). Avoiding triggers (medications) as well aids in preventing xerosis. Tear preparations may help patients as well as prevent xerosis.

Therapy

Treatment of xerosis involves treating the initial cause of the dry eyes. Symptomatic treatment may involve artificial tear preparations (0.7% methyl cellulose or 0.3% hyperomellose or polyvinyl alcohol) (Khurana, 2008).

Prognosis

Prognosis is positive for patients who continue with medical management and follow-up to limit progression of corneal and conjunctival disease secondary to dry eye and xerosis (Khurana 2008). Lack of care from dry eye may result in ulceration and ocular damage.

Epidemiology

Xerosis may affect patients of all ages and genders. It has been found to be associated with patients with vitamin A deficiency (Kiegman et al. 2011).

Synonyms

Medial canthoplasty; Medial epicanthoplasty; Y-V medial canthoplasty

Definition

Generally speaking, Y-V-plasty is a reconstructive surgical technique which can be utilized for the modification of contracted scars. In the realm of ophthalmic plastic surgery, it can be used more specifically for the repair of telecanthus and epicanthus associated with the blepharophimosis syndrome.

Indication

Y-V plasty is indicated in the surgical correction of mild/moderate telecanthus and epicanthus in blepharophimosis syndrome. The technique may be combined with other techniques such as local transposition flaps (as in the Mustarde modification) and transnasal wiring if more severe telecanthus and epicanthus exist.

Contraindications

An alternative or combined approach may be required in addition to Y-V-plasty if there is a significant degree of epicanthus and/or telecanthus.

Techniques and Principles

A horizontally oriented Y shaped incision is made at the medial canthus, with the base of the Y positioned at the desired new position of the medial canthus. The skin flaps are elevated to allow mobilization. Subcutaneous tissue is often

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

thickened and can be conservatively thinned to create the appearance of the medial canthal depression. Depending on the severity of the telecanthus, the surgeon can access and tighten the anterior limb of the medial canthal tendon during surgery. If desired, the anterior limb of the medial canthal tendon is disinserted from the periosteum, advanced medially, and reattached to more medially positioned periosteum. This results in medialization of the medial canthus and reduction of telecanthus. The skin is closed with suture of the surgeon's choice. The technique may be combined with other techniques such as local transposition flaps (as in the Mustarde modification) and transnasal wiring if more severe telecanthus and epicanthus exist.

Outcome

The net effect of the Y-V-plasty in the medial canthus is recruitment of tissue in the vertical plane perpendicular to the medial canthal tendon and shortening of tissue in the horizontal plane parallel to the medial canthal tendon. This results in improvement of telecanthus and epicanthus with V-shaped surgical scar at the medial canthus.

Complications

Flap necrosis and poor wound healing may result, particularly if excess tension on the wound exists. Use of the Y-V-plasty technique alone in severe telecanthus may result in recurrent telecanthus and phimosis of the medial canthus if significant postoperative tension is present.

Zernike Coefficients

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Wavefront aberration coefficients

Definition

A Zernike coefficient is the coefficient that represents each Zernike polynomial in the wavefront function (Zernike reconstruction).

Basic Characteristics

The reconstruction of the human eye's wavefront with Zernike polynomials is widely accepted both in physiological optics and clinical practice (Thibos et al. 2002). Zernike polynomials are a set of orthogonal functions over the unit circle, each polynomial describing a certain surface shape. Irregular surface shapes such as the ocular wavefront or the corneal surface can be reconstructed efficiently by creating a summary function of Zernike polynomials. The addition of a set of polynomials creates a new surface. The dominance of each polynomial in the summary function is indicated by a coefficient – the Zernike coefficient – that weights the polynomial within the function. The more the coefficient is different from Zero, the more the shape of the wavefront is dominated by the certain polynomial. The full set of Zernike coefficients equals a numerical representation of the reconstructed wavefront, comparable to the CMYK or RGB representation of a color. Zernike coefficients are only valid over a given pupil diameter (PD). For other PDs than the given, the coefficients need to be recalculated. While down-scaling to a smaller PD can be achieved mathematically, an up-scaling to a larger PD involves extrapolation and leads to probably invalid results.

Zernike coefficients are numerical values, typically with the unit micrometers [μm]. The sign can be positive or negative. Change of sign of rotationally symmetric polynomials results in a

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

flip along the frontal plane, change of sign of cosine phase polynomials results in a flip along the horizontal plane, and change of sign of sine phase polynomials results in a flip along the vertical plane. The nomenclature for Zernike coefficients equals the nomenclature for Zernike polynomials with the letter C instead of Z. In clinical practice, C and Z are often used synonymously. Also for Zernike coefficients, a double (C_n^m) or single index scheme can be used (C_n). Coefficients of the same order or homologous coefficients can be condensed to root mean square (RMS) values that quantitatively describe the wavefront aberration. RMS values cannot be negative.

The contribution of each Zernike mode to visual function remains to be determined. Each mode tends to interact with the other modes in the wavefront function; therefore it is difficult to define critical values for each coefficient (Applegate et al. 2002). From Zernike coefficients, the point spread function (PSF) and modulation transfer function (MTF) and corresponding image quality metrics can be computed using Fourier transformation.

Zernike coefficients represent the basis data generated by wavefront sensors. They can be used for further computations such as wavefront maps, RMS values, image quality metrics, and construction of wavefront-guided ablation profiles.

Synonyms

Rotational advancement flap; Transposition flap

Definition

Z-plasty is a reconstructive surgical technique utilizing transposition flaps to release tension and contracture of scars and to redirect scars into more favorable orientations.

Indication

Z-plasty has extensive applications in plastic and reconstructive surgery of the face and eyelids. Broadly speaking, however, it can be utilized to achieve several basic outcomes: release of and lengthening of a contracted scar, reorienting a scar to fall within relaxed skin tension lines, and dispersion of a scar. More specifically, the technique can be utilized for: revision of facial scars; surgical modification of eyelid scars, for example, scars resulting in cicatricial ectropion; management of epicanthal folds and telecanthus, for example, in blepharophimosis syndrome; and correction of symblepharon.

Contraindications

Large scars may limit the ability to achieve tension-free closure which can result in flap necrosis and contraction.

Techniques and Principles

The classic z-plasty technique is comprised of three incisions of equal length. The central incision lies in the long axis of the scar parallel to the plane of tension. This incision becomes the central arm of the Z. The second and third incisions are made at opposite ends of the central incision and at an angle of 60° to the central incision and become the arms of the Z. Modifications exist where the angles utilized are more or less than 60°; however, the classic Z-plasty utilizes 60° angles as described. The three incisions are of equal length and the result is two equilateral triangle shaped flaps that are mirror images. Undermining of the flaps with scissors is performed until the scar contracture bands are lysed and the flaps are able to be transposed without tension. The tips of the flaps are then transposed. Multiple deep-buried absorbing sutures are placed to reduce tension and the skin is then closed.

Outcome

Z-plasty results in reorientation, lengthening, and dispersion of a scar; reduction in scar contracture and tension; and a z-shaped surgical scar as a final result.

Complications

Flap necrosis and poor wound healing may result, particularly if excess tension on the flaps exists.

Zygomatic Bone

B. Ranjodh Singh[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Cheekbone; Malar bone

Definition

The zygomatic bone articulates with the sphenoid bone, maxilla, frontal bone, and temporal bone to form the lateral wall of the floor of the orbit, part of the temporal and infratemporal fossa, and the prominence of the cheek.

Structure

The anatomy of the zygomatic bone is composed of two surfaces, four processes, and four borders.

The malar surface of the zygomatic bone is perforated near its center, which gives rise to the zygomaticofacial foramen. Slightly below this foramen is an elevation, which serves as the origin to the zygomaticus. At the center of the temporal surface of the zygomatic bone is the zygomaticotemporal foramen. The medial part of the temporal surface articulates with the maxilla, while the lateral upper part forms the anterior boundary of the temporal fossa and the lateral lower part forms the boundary of the infratemporal fossa.

The frontosphenoidal process of the zygomatic bone articulates with the zygomatic process of the frontal bone. Approximately 11 mm below the zygomaticofrontal suture and 2 mm behind the lateral orbital rim is the Whitnall's tubercle, which is the site of attachment for the lateral canthal tendon that provides the eyelid contour. The orbital process forms part of the floor of the lateral wall of the orbit by articulating with the orbital surface of the maxilla and the greater wing of the sphenoid. On the floor of the lateral wall of the orbit is the zygomatico-orbital foramen, which is a set of two canals. One of these canals opens on the temporal surface, making up the zygomaticotemporal foramen, and the second of these canals opens on the malar surface, making up the zygomaticofacial foramen. The maxillary process articulates with the maxilla, the temporal process with the zygomatic process of the temporal bone.

The orbital border forms part of the orbital circumference. The maxillary border articulates with the maxilla, and near the orbital margin, it gives rise to the quadratus labii superioris. The temporal border is continuous with the temporal bone and the zygomatic arch. The zygomatic border is attached to the masseter.

Function

The zygomatic bone functions as an integral part that makes up several other important structures, including the zygomatico-orbital, zygomaticotemporal, and zygomaticofacial foramen which transmit respective branches of the maxillary nerve (V2) and vasculature. The zygomatic bone also forms the lateral wall of the floor of the orbit, part of the temporal and infratemporal fossa, and the prominence of the cheek.

Clinical Relevance

Zygomatic fractures are the second most common fractures of the facial bones, and as much as 5% of patients with zygomatic fractures have associated ophthalmic injury (Covington et al. 1994). Due to its prominence, the zygomatic bone is prone to fractures from direct trauma to the side of the face. Zygomatic fractures can involve the zygomaticofrontal, zygomaticomaxillary, and zygomatic arch, with fractures involving all three regions being the most common (Hwang and Kim 2011). Since the zygomatic bone contains both the zygomaticotemporal and zygomaticofacial foramen with their respective nerves, zygomatic fractures commonly lead to anesthesia of the cheek and side of forehead. The zygomatic bone also serves as the insertion for the masseter, and zygomatic fractures can therefore lead to difficulty with mastication. Zygomatic fractures can lead to binocular diplopia due to muscle entrapment in the orbital cavity or neuromuscular injury.

The zygomatic bone also serves as an important landmark for several surgeries, including maxillofacial and orbital procedures, which involve osteotomies across the zygomatic bone (Loukas et al. 2008). Vascular and neoplastic lesions at the skull base can be exposed through an orbitozygomatic osteotomy approach, which involves five cuts to free the orbitozygomatic bone in one piece above the zygomaticofacial foramen. Excision of infraorbital tumors as well as orbital decompression can also be achieved through transmaxillary surgical approaches to the orbit.

Zygomatic Complex Fracture

► Zygomatic-Maxillary Complex Fractures

Zygomatic-Maxillary Complex Fractures

Gary Joseph Lelli[1], Dara Liotta[2], Benjamin Levine[1] and Ashutosh Kacker[2]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Otorhinolaryngology, Weill College of Medicine of Cornell University, New York, NY, USA

Synonyms

Malar complex fracture; Maxillary complex fracture; Orbito-zygomatico-maxillary fracture; Tetrapod fracture; Trimalar fracture; Tripod fracture; Zygomatic complex fracture

Definition

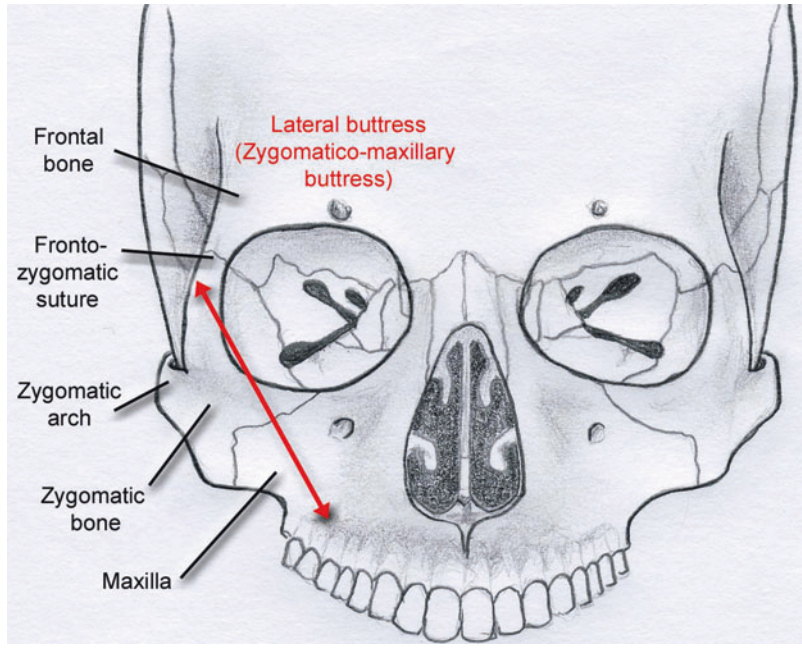
The most common zygomatico-maxillary complex (ZMC) fracture pattern involves fracture of the frontozygomatic suture (lateral orbital rim), the zygomatic arch, the lateral buttress (zygomatico-maxillary buttress), and the inferior orbital rim (Cummings 2005). The fractures through the lateral buttress and the inferior orbital rim are commonly connected by an anterior maxillary wall fracture. Although this represents the most common fracture pattern, significant variation exists. For example, the zygoma itself may be fractured into pieces and partial ZMC fractures, involving some, but not all of the fractures listed above, may occur (Figs. 1 and 2).

Etiology

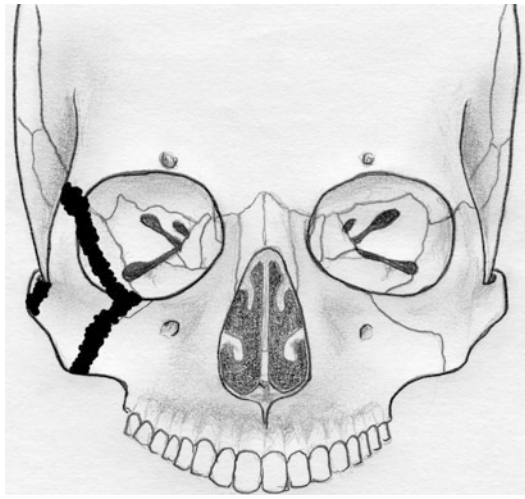
Motor vehicle accidents, interpersonal altercations, assaults, falls, and sports-related injuries.

Clinical Presentation

The zygomatic complex plays a key role in midfacial contour and protection of orbital contents and has many important relationships to surrounding soft tissue structures that influence the clinical signs of a ZMC fracture (Della Rocca et al. 2002). The masseter muscle attaches to the zygoma, and its unopposed force on the mobile bone fragment after ZMC fracture is responsible for the inferior displacement and medial rotation of the malar process. This displacement is appreciated clinically as flattening of the malar eminence. The temporalis muscle inserts on the coronoid process of the mandible and travels beneath the zygomatic arch to its attachment on the temporal bone superiorly. Depressed ZMC fractures can exert pressure on the temporalis muscle, causing trismus and severe pain with mastication. The lateral canthal tendon attaches to the inner aspect of the lateral orbital rim at Whitnall's tubercle. Inferior displacement of the zygoma after a fracture may result in displacement of the lateral canthus. Step-offs on the lateral or inferior orbital rims may often be palpated. Fractures may pass through, or close to, the infraorbital foramen, resulting in anesthesia of the infraorbital nerve distribution.



Zygomatic-Maxillary Complex Fractures, Fig. 1 Important anatomic correlates in ZMC fractures.



Zygomatic-Maxillary Complex Fractures, Fig. 2 Typical location of a ZMC fracture.

Significant facial edema is common, and it is important to investigate for additional maxillofacial injuries. The presence of diplopia or difficulty with eye movements may indicate extraocular muscle pathology (e.g., entrapment). Change in globe positioning, often in the form of enophthalmos, may occur.

Diagnostics

Facial fractures often occur as the result of significant trauma and evaluation should begin with airway control and homodynamic stabilization. Spinal cord injury should be ruled out. A thorough history and physical, including a complete head and neck, exam may then be performed. With any midfacial fracture, suspicion for CSF rhinorrhea and/or otorrhea should be high. ZMC fractures involve orbital wall fractures, and the eye must be completely evaluated (Holck and Ng 2006). Examination of dental occlusion is also important, as fractures can extend through the maxillary alveolus, resulting in malocclusion. Facial radiographs, particularly the submental vertex view, may suggest the diagnosis, but maxillofacial CT scan is considered the modality of choice for diagnosis of ZMC fractures.

Differential Diagnosis

Orbital floor (blowout) fracture, nasal bone fracture, naso-orbital-ethmoid fracture, LeFort fracture, and maxillary (Guerin) fracture.

Prophylaxis

The use of restraints, seat belts, and protective headgear can help prevent ZMC fractures.

Therapy

ZMC fractures in which the zygoma is nondisplaced and ophthalmologic examination is normal can be treated conservatively with analgesia, soft diet, and close follow-up. Indications for surgical reduction and fixation of a ZMC fracture are cosmetic deformity resulting from inferior and medial displacement of the zygoma, trismus, pain with chewing, enophthalmos, diplopia, or gaze restriction (Kelly et al. 2007). Stable surgical repair often requires fixation of at least two fracture sites, most commonly the frontozygomatic suture line and the zygomatico-maxillary buttress (Stewart 2005). Care must be taken to avoid postoperative enophthalmos, as reduction of the zygomatic fracture may accentuate an already-present orbital floor fracture, requiring orbital floor plating. Perioperative antibiotics should be considered in patients with facial fractures. Patients with ZMC fractures that are not displaced on initial presentation should be followed closely to assure that the fracture does not become displaced with time.

Prognosis

Long-term prognosis after repair of ZMC fracture is excellent. Postoperative infection rates are low and generally resolve with oral antibiotics. Facial asymmetry necessitating revision surgery after initial repair occurs in 3–4% of patients.

Epidemiology

ZMC fractures are the second most common midface fracture, after nasal fractures. Eighty percent of ZMC fractures occur in males and 80% of ZMC fractures occur between the ages of 18–45, with peak incidence between 20 and 30 years of age. Assault is responsible for the majority of ZMC fractures (40%), followed by sports injuries, MVA, and falls.

Zygomaticofacial Canal

B. Ranjodh Singh[1] and Gary Joseph Lelli[2]
[1]Weill Cornell Medical College, New York, NY, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

The zygomaticofacial canal arises from the zygomatico-orbital foramen and transmits the

zygomaticofacial nerve, which supplies the malar surface.

Structure

The zygomaticofacial canal arises from the zygomatico-orbital foramen and plays a vital role in transmitting the zygomaticofacial nerve. The zygomatic nerve enters the orbit through the inferior orbital fissure and divides in the back of the orbital cavity into the zygomaticofacial and zygomaticotemporal nerves. The zygomaticofacial nerve courses, along the infero-lateral angle of the orbit, enter the zygomatico-orbital foramen and into the zygomaticofacial canal, which transmits the nerve through the zygomaticofacial foramen on the zygomatic bone. The zygomaticofacial nerve then perforates the orbicularis oculi and joins with the zygomatic branches of the facial nerve and with the inferior palpebral branches of the maxillary nerve to supply the malar surface, i.e., the skin on the prominence of the cheek.

Function

The zygomaticofacial canal functions as an intermediary between the zygomatico-orbital foramen and the zygomaticofacial foramen to transmit the zygomaticofacial nerve, which supplies the prominence of the cheek.

Clinical Relevance

The zygomaticofacial canal and foramen can be disrupted during zygomatic fractures, which are the second most common fractures of the facial bones (Covington et al. 1994). Due to its prominence, the zygomatic bone is prone to fractures from direct trauma to the side of the face. Zygomatic fractures can involve the zygomaticofrontal, zygomaticomaxillary, and zygomatic arch, with fractures involving all three regions being the most common (Hwang and Kim 2011). Since the zygomatic bone contains both the zygomaticotemporal and zygomaticofacial canals and foramen with their respective nerves, zygomatic fractures commonly lead to anesthesia of the cheek and side of forehead.

Surgeons operating in the maxillofacial and orbital regions should take great care not to injure the zygomaticofacial canal and foramen. External pin fixation is a commonly used technique for rigid fixation of bony fragments of zygomatic fractures. However, this procedure may cause midface paresthesia due to difficulty in identifying the zygomaticofacial canal and foramen, and inadvertent nerve damage. To avoid zygomaticofacial nerve damage, some surgeons have reported using open reduction and fixation with a miniplate, principally in the frontozygomatic suture (Kim et al. 2013).

Lastly, the zygomaticofacial canal and foramen also serve as important locations for local nerve blocks, which are important for operations in this region.

Definition

The zygomaticotemporal canal transmits the zygomaticotemporal nerve, which supplies the side of the forehead.

Structure

The zygomaticotemporal canal and foramen play a vital role in transmitting the zygomaticotemporal nerve. The zygomatic nerve enters the orbit through the inferior orbital fissure and divides in the back of the orbital cavity into the zygomaticofacial and zygomaticotemporal nerves. The zygomaticotemporal nerve courses, along the lateral wall of the orbit, receive a branch of communication from the lacrimal, and enter the zygomatico-orbital foramen and into the zygomaticofacial canal. While it was previously thought that the zygomatico-orbital foramen gave rise to both the zygomaticofacial and zygomaticotemporal canals, recent work has highlighted that the zygomaticotemporal canal arises from the zygomaticofacial canal (Kim et al. 2013). The zygomaticotemporal canal transmits the respective nerve to the temporal fossa through the zygomaticotemporal foramen. The zygomaticotemporal nerve ascends between the bone and temporalis muscle, perforates the temporal fascia approximately 2.5 cm above the zygomatic arch, and supplies the skin on the side of the forehead. As the zygomaticotemporal nerve pierces the temporal fascia, it gives off a branch that runs between the two layers of the fascia to the lateral angle of the orbit.

Function

The zygomaticotemporal canal functions as an intermediary between the zygomatico-orbital foramen and the zygomaticotemporal foramen to transmit the zygomaticotemporal nerve, which primarily supplies the side of the forehead.

Clinical Relevance

The zygomaticotemporal canal and foramen can be disrupted during zygomatic fractures, which are the second most common fractures of the facial bones. Due to its prominence, the zygomatic bone is prone to fractures from direct trauma to the side of the face. Zygomatic fractures can involve the zygomaticofrontal, zygomaticomaxillary, and zygomatic arch, with fractures involving all three regions being the most common. Since the zygomatic bone contains both the zygomaticotemporal and zygomaticofacial canals and foramen with their respective nerves, zygomatic fractures commonly lead to anesthesia of the cheek and side of the forehead.

Surgeons operating in the maxillofacial and orbital regions should take great care not to injure the zygomaticotemporal canal and foramen. For example, the zygomaticotemporal canal, foreman, and nerve may be injured during Gillies or Dingman reduction procedure for a zygomatic fracture, or during an endoscopic subperiosteal facelift (Hwang et al. 2004). The zygomaticotemporal nerve may also serve as a site of migraine genesis, and therefore surgical decompression of the temporalis muscle can aid in reducing migraines and their associated symptoms (Janis et al. 2010).
