Preface

Encompassed with comprehensive and focused information, accompanied by high-quality images, detailed tables, and graphics on all relevant ophthalmic topics, the *Encyclopedia of Ophthalmology* is a valuable resource for practicing ophthalmologists from the various ophthalmic subspecialties. This comprehensive source of ophthalmological expertise will also be of interest to optometrists, orthoptists, opticians, low vision specialists, researchers, residents, medical students, nurse practitioners, and all other eye care professionals who deal with the anatomy, physiology, and diseases of the eye.

The reader will benefit from the knowledge of leading experts in the rapidly changing field of ophthalmology with an easy reference, geared to provide detailed, timely, and relevant information about the rapid advances that continuously influence the field of ophthalmology. Intended as a user-friendly reference, available in hardcopy and electronic format and continuously updated. We hope that this encyclopedia facilitates easy reference and clinical use.

Acknowledgment

We would like to extend our thanks to the many authors who devoted an extensive amount of time in contributing to the development of this comprehensive coverage of current state-of-the-art knowledge in ophthalmology. We would also like to thank the consultants at Springer Nature for their commitment to publishing this book.

List of Topics

External Diseases and Cornea

Section Editor: *Shameema Sikder*

Fundamentals and Principles

Section Editor: *Bhavna P. Sheth*

Glaucoma

Section Editor: *George Spaeth*, *Jens Funk* and *Frances Meier-Gibbons*

Lens and Cataract

Section Editor: *Thomas Kohnen*

Neuro-Ophthalmology

Section Editor: ***Andrew G. Lee***

Optics Refraction and Contact Lenses

Section Editor: *Jens Bühren*

Orbit, Eyelids, and Lacrimal System

Section Editor: *Pete Setabutr*

Refractive Surgery

Section Editor: *Thomas Kohnen*

Retina

Section Editor: *Anat Loewenstein*, *Ursula Schmidt-Erfurth* and *Barbara Gold*

About the Editors

Ursula Schmidt-Erfurth Department of Ophthalmology and Optometry, Medical University Vienna, Vienna, Austria

Ursula Schmidt-Erfurth is Professor and Chair of the Department of Ophthalmology at the University Eye Hospital, Vienna, Austria, one of the largest academic institutions in ophthalmology in Europe. Professor Schmidt-Erfurth's clinical activities include surgical and medical retina. Her scientific research focuses on the development of novel diagnostic techniques, e.g., retinal imaging and novel treatment strategies such as intravitreal pharmacotherapy. She has founded the Vienna Study Center (VSC), which serves as the principal site for multicenter clinical trials, and the Vienna Reading Center (VRC), an independent institution for digital imaging performing image analysis for over 140 clinical sites worldwide. She is Head of the OPTIMA project, which is a continuation in the development of advanced image analysis (Christian Doppler Laboratory for Ophthalmic Image Analysis). Professor Schmidt-Erfurth is a member of many professional organizations, including the Association for Research in Vision and Ophthalmology (ARVO), Macula Society, Retina Society, Gonin Club, the European Academy of Ophthalmologists, and the American Academy of Ophthalmology. She currently serves as President of EURETINA (European Society of Retina Specialists), the largest community of retinologists worldwide. The author of over 260 original articles, Professor Schmidt-Erfurth is on the editorial board of the *British Journal of Ophthalmology* (BJO), the *Investigative Ophthalmology & Visual Science* (IOVS), and others. Professor Schmidt-Erfurth has received numerous grants and awards, among others the Research Award by the German

Ophthalmological Society, the Achievement Award of the American Academy of Ophthalmology, the Roger Johnson Award by the University of Washington, and the Donald Gass Award of the Retina Society. Since 2014, she holds an appointment as Adjunct Professor at Northwestern University, Feinberg School of Medicine, Chicago.

Thomas Kohnen M.D., Ph.D., FEBO is Professor and Chairman of the Department of Ophthalmology, Goethe-University, Frankfurt, which is one of the busiest teaching hospitals in Germany. He leads a team that helps over 35,000 patients annually and is highly active in teaching and research. He is Visiting Professor of Ophthalmology at the Cullen Eye Institute, Baylor College of Medicine, Houston, USA.

He originally studied medicine in Germany, Italy, India, and the USA before specializing in ophthalmology in 1989. After his residency, he was awarded a 2-year scholarship from the German Research Foundation to study at the Cullen Eye Institute in 1995/6 and gained an additional degree in Healthcare Management in 2006/7. During his career, he has worked both as a physician and as a scientist. This dual approach to the clinical and research aspect of the job is one he continues to be passionate about today.

A leading expert in the anterior segment, he specializes in cataract, IOL, refractive, and cornea surgery as well as treating glaucoma and retinal problems to increase optical quality. His research focuses on intraocular lenses, laser technology and cataract, and refractive and corneal surgery. He publishes and holds lectures worldwide regularly on these subjects.

He is Editor of the *Journal of Cataract and Refractive Surgery*, Associate Editor of *Der Ophthalmologe*, Focal Topic Editor of *Klinische Monatsblätter für Augenheilkunde*, Editorial Board Member of *Graefe's Archive for Clinical and Experimental Ophthalmology*, and frequently peer-reviews for top journals. He has received several awards including the AAO Lifetime Achievement Honor Award in 2002. Prof. Kohnen holds senior Board positions for a number of professional organizations including President and Treasurer of the DOG (Deutsche Ophthalmologische Gesellschaft) and is Past President of the DGII (Deutschsprachige Gesellschaft für

Intraokularlinsen-Implantation, interventionelle und refraktive Chirurgie). Elected Treasurer and Executive Board Member of the ESCRS (European Society of Cataract and Refractive Surgeons) and also the current Treasurer of the IIIC (International Intraocular Implant Club).

Research Funding: Abbott, Alcon, Hoya, Oculentis, Oculus, Schwind, Zeiss; Consultant or Advisory Board: Abbott, Alcon, Geuder, Oculus, Schwind, STAAR, TearLab, Thieme Compliance, Ziemer, Zeiss.

Aberrometry

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Wavefront measurement; Wavefront sensing

Definition

Method for measurement, visualization, and analysis of the wavefront error of the eye.

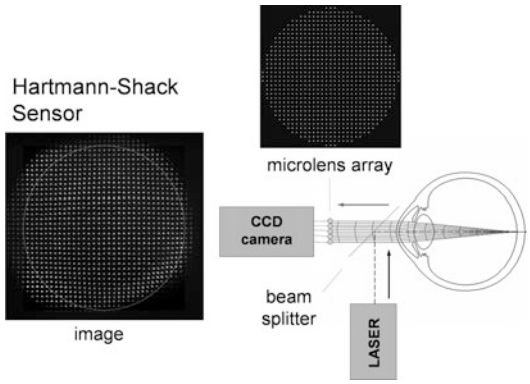
Purpose

Aberrometry is used to quantify and visualize the wavefront error (monochromatic aberrations) of the eye.

Principle

The common principle of aberrometry is the comparison of a test figure imaged by the eye with a reference figure. From the difference, the wavefront error can be computed. The most widespread used aberrometer is the *Hartmann-Shack*

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9



Aberrometry, Fig. 1 The principle of Hartmann-Shack Aberrometry

sensor (Liang et al. 1994). This system uses a laser beam that is reflected by the retina. The reflected light emerging from the eye is refracted into a spot pattern by a microlens array. The image of the spot pattern is caught by a CCD camera (Fig. 1). The deviation of the spots from a reference pattern is proportional to the wavefront deformation. The *aberrometer according to Tscherning* projects a spot matrix onto the fovea. The retinal image is documented by a CCD camera. Similar to Hartmann-Shack aberrometry, the wavefront error is calculated from the dislocation of the spots of the pattern. Ray tracing aberrometers apply a similar principle: a laser beam is projected onto the retina through different pupil locations sequentially. The deviation between measured and reference spot position is proportional to the slope of the wavefront in the pupil region represented by the ray. *Dynamic retinoscopy* uses – similar to retinoscopy – a light beam that is projected onto the retina. In contrast to conventional streak retinoscopy, the light beam is a laser beam that covers only a small pupil area. Thus, from local refraction data the entire wavefront error can be reconstructed.

For all aberrometers, the maximum pupil diameter for reconstruction is the pupil diameter at which the measurement was performed. While the wavefront error can be reconstructed mathematically for smaller pupils, a reconstruction for larger pupil diameters than the actual pupil diameter involves extrapolation and should be avoided.

Like all sensitive biometric measurements, aberrometry is subject to fluctuations due to tear film dynamics and microfluctuations of accommodation (Zhu et al. 2004; Montes-Mico 2007). Therefore, for clinical use it is recommended to calculate a mean value from several single measurements. For interpolation between the data points and for quantification of the wavefront error, typically Zernike polynomials are used (Thibos et al. 2002). The aberrometer software returns the Zernike coefficients as metrics of the wave aberration. From the Zernike coefficients, further image quality metrics and qualitative wavefront error representations like wavefront maps, point spread function, and convolution simulation images can be calculated.

Indication

Measurement of the entire optical properties of the eye, e.g., in preparation of wavefront-guided corneal laser refractive surgery and for the diagnostics of optical disturbances. Aberrometry is an important objective method for quantification of optical image quality for scientific purposes.

Contraindication

Aberrometric measurements are noninvasive. There are no contraindications.

Advantage/Disadvantage

In contrast to corneal topography, aberrometry allows measurements of the optical properties of the whole eye. Measurements could be taken easily without major discomfort for the patient. For maximum information, pupils need to be dilated. Aberrometry does not return valid results in case of optical media opacities (e.g., epithelial irregularities in dry eye, corneal scars, and cataract). Aberrometric measurements involving a Zernike reconstruction contain interpolated data. Modern devices combine a topographer and aberrometer within one unit. This combination allows the differentiation between corneal and lenticular origin of aberrations.

Absorption, Light, Spectra of Visual Pigments

Ido Perlman
Ruth and Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel

Definition

The first step of the visual process is the absorption of light by visual pigment molecules that are located in membranous disks of the outer segments in the rod and cone photoreceptors. Light absorption by the visual pigment molecules triggers a cascade of enzymatic reactions called "the phototransduction process" leading to changes in the electrical potential across the plasma membrane of the photoreceptors. Once light-induced electrical event occurs, the electrical activity is transmitted via chemical and electrical synapses to second-order (horizontal cells and bipolar cells) and then to third-order (amacrine cells and ganglion cells) retinal neurons. The ganglion cells transfer electrical activity to the brain via the optic pathways for further processing leading eventually to visual perception.

Light absorption by any medium follows a basic physical rule called the Beer-Lambert law and obeys the following relationship $I_\lambda = I_{0\lambda} * e^{-\alpha(\lambda)cl}$ where light transmission through the absorbing medium I_λ depends upon light intensity $I_{0\lambda}$ reaching the absorption medium, the absorption spectrum of the medium $\alpha(\lambda)$, the concentration c of the light-absorbing elements, and the length, l, of the light path through the medium. In the case of vision, the absorbing elements are the visual pigment molecules that are located in the outer segments of the photoreceptors. Therefore, the factors determining light absorption are the following: the intensity of light reaching the photoreceptors' outer segments (I_0), the concentration of the visual pigment molecules (c), the wavelength of light (λ), the length of the outer segments (l), and the absorption spectrum of the visual pigments (α).

The visual pigment molecules in the vertebrate retina, including human, are composed of two molecules, a protein and vitamin A derivative which in the case of mammals and humans is the 11-cis retinaldehyde (11-cis retinal). When a visual pigment molecule absorbs light, a chain of enzymatic reaction is triggered leading to an electrical signal, which starts the visual process, and the visual pigment molecule dissociate into its components; however, the chromophore 11-cis retinal is transformed into all-trans retinol. Regeneration of the visual pigment requires transformation of all-trans retinol to 11-cis retinal, a process occurring in cells of the retinal pigment epithelium.

A visual pigment is characterized by an absorption spectrum describing the probability of absorbance of monochromatic light that reaches it. The absorption spectrum reflects the interactions between 11-cis retinal and the specific protein. In the normal human retina, there are four types of photoreceptors that can be separated by the absorption spectrum of their visual pigments. Rod photoreceptors, determining vision in darkness and dim illumination, contain a visual pigment with absorption maximum at about 500 nm. Day vision depends upon three types of cone photoreceptors that differ in the absorption spectrum of their visual pigments, having absorption maxima around 450 nm, 530 nm, and 560 nm.

Disturbance in vision can reflect reduced absorption of light by the photoreceptors. According to the Beer-Lambert law, this can reflect (i) reduction in the light reaching the retina due to opaque ocular pathways (mature cataract, vitreous hemorrhage), (ii) abnormal absorption spectrum (mutation in the genes coding visual pigments), (iii) reduced concentration of visual pigment molecules (vitamin A deficiency), or (iv) shortening of outer segments (certain cases of RP).

Accommodating Intraocular Lens

Martin Baumeister[1] and Thomas Kohnen[2]

[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Accommodative intraocular lens

Definition

An accommodative IOL is an artificial intraocular lens which is designed to enable accommodation (a dynamic change in focus of the eye).

Indication

Accommodating IOLs are supposed to transform the movement of the ciliary muscle which occurs with an accommodative effort into a dynamic change of dioptric power of the eye. They are indicated to treat the loss of the ability to accommodate which occurs with advancing age (presbyopia).

Contraindications

Accommodative IOLs are not indicated in eyes with a weakened zonule and insufficient fixation of the crystalline lens capsule.

Techniques and Principles

All accommodating IOLs currently available are based on the principle of translation of the IOL optic. By means of a hinge or a similar mechanism in the IOL, haptic contraction of the ciliary muscle is expected to effect an anterior shift of the IOL optic

and thus increase the power of the eye. This allows only a limited range of accommodation which amounts to 0.5 up to 2.5 D for a shift of 1 mm dependent on the power of the IOL optic. Therefore, accommodative IOLs with two lens optics designed to move in opposite directions have recently been developed. A shift of the IOL optic in a dual-optic accommodative IOL can effect about 2.5–3.0 D of accommodation (McLeod et al. 2003).

Deformable IOLs which can change their surface curvature like the natural human lens could theoretically reach an accommodative amplitude of 4–7 D (Ho et al. 2001).

Outcome

Results with accommodative IOLs so far have been mixed. Clinical results indicate better uncorrected visual acuity in near and intermediate distances and a higher percentage of subjective spectacle independence with single-optic accommodative than with standard monofocal IOLs. Movement of the IOL optic after topical application of pilocarpine was significantly higher in several accommodative IOL models than in standard IOLs. Other objective measurement methods, however, failed to discover significant differences in change of focus of the eye (Findl and Leydolt 2007).

The first results with double-optic accommodating IOLs showed a subjective accommodative amplitude of about 3.2 D. Movement of the IOL optics could be shown with dynamic ultrasound biomicroscopy (Ossma et al. 2007).

Complications

Complications of the accommodative IOLs can arise from the behavior of the implant inside the capsular bag. The moveable haptics have in some cases led to dislocations of the IOL optic. Because of the smaller optic diameter and the ability to move inside the capsule, the barrier effect of the sharp optic edge could be weakened with ensuing posterior capsule opacification.

In summary, accommodative IOLs can provide an improvement in intermediate and near vision while avoiding the optical side effects associated with multifocal IOLs. The predictability of the results is, however, still limited (Baumeister and Kohnen 2008).

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Accommodation is a dynamic change in the dioptric power of the eye which is executed in order to focus on targets in different distances.

Mechanism

The accommodative mechanism in its entirety was first described by Helmholtz in 1855. This description is in all relevant aspects still valid. The accommodative apparatus of the eye consists of the ciliary muscle, the zonular fibers forming the suspensory apparatus of the crystalline lens, and the lens itself. According to Helmholtz, during accommodation (focus change far–near) the tension of the zonular fibers which hold the lens in is far-accommodated state decreases as an effect of the contraction of the ciliary muscle and the resulting decrease in size of the ring formed by the ciliary muscle. As a result, the shape of the lens changes under the influence of the elastic lens capsule as it proceeds to its mechanical resting state. This causes an increase in lens curvature and anteroposterior lens thickness and a decrease of the equatorial lens diameter. These changes contribute to an increase in the overall dioptric power of the eye.

During the change in focus from near to far (disaccommodation) this process is reversed: by relaxation of the ciliary muscle and the elastic fibers of the choroid the diameter of the ciliary ring increases and the lens is pulled into its unaccommodated state by the zonular fibers. This results in decrease of anterior and posterior lens curvature and lens thickness and consecutively decrease of dioptric power of the eye so that the eye is focused on far objects.

Presbyopia

With advancing age, humans and many other species lose the ability to accommodate. This phenomenon, called presbyopia ("old-sightedness") is the most widespread visual impairment and affects everyone who advances into a sufficiently high age without exception. The decrease of accommodative amplitude begins at an age of 10–12 years and continues until the complete loss of the ability to accommodate at about 50–55 years of age. Presbyopia has been attributed to hardening of the lens, changes in lens and zonular geometry, as well as aging of the ciliary muscle (Glasser et al. 2003).

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Accommodative excess; Accommodative spasm; Ciliary spasm; Focusing spasm; Spasm of accommodation

Definition

Accommodation is the adjustment of the eye for seeing objects at various distances accomplished by the ciliary muscle, which controls the lens of the eye and allows it to flatten or thicken, bringing images of objects into focus on the retina as needed. The circular ciliary muscle fibers affect the zonular fibers of the crystalline lens during accommodation.

When the ciliary muscle contracts, this releases tension on the lens caused by the zonules and causes the lens to become more spherical, adapting to shorter near range of focus. Accommodative spasm can result in ciliary muscle contraction and can be worsened by fatigue and strain.

Etiology

Functional accommodative disorders may be caused by trauma, eye-strain, or be nonorganic. Rarely true accommodative spasm can be organic.

Clinical Presentation

Functional accommodative disorders are characterized by intermittent attacks of accommodation, convergence, and miosis. Patients present with diplopia, from convergence spasm variable esotropia, blurred vision, miosis, pseudomyopia, headache, and facial pain localized in the eyes and may rarely complain of macropsia (in which the objects appear larger than their actual size). A characteristic of the blurred vision associated with this disorder is that it is often variable and worse toward the end of the day or after extensive near work.

Diagnostics

Patients may be diagnosed clinically by observation of the concomitant variable esotropia along with miosis that generally resolves when either eye is occluded with a patch. Clinical clues for diagnosis also includes bilateral variable abduction weakness with both eyes open but full abduction in each eye when opposite eye is patched and ductions are directly tested. Finally, retinoscopy and refraction with and without cycloplegia which establishes the presence of pseudomyopia.

Differential Diagnosis

Bilateral sixth nerve palsy, convergence excess, accommodative insufficiency, and esophoria.

Therapy

Functional accommodative spasm usually resolves spontaneously over time, and patients only require reassurance, typically. Psychiatric counseling may rarely be appropriate depending on etiology. With severe symptoms, treatment involves inhibiting the excessive accommodative tone with cycloplegic eye drops.

Definition and Medical Uses

Carbonic anhydrase inhibitor often used in treatment of glaucoma, altitude sickness, and epileptic seizures are the main story for the treatment of pseudotumour cerebri (idiopathic intracranial hypertension).

Use and Dose in Pseudotumor Cerebri

Carbonic anhydrase inhibitors are a first-line treatment and are believed to reduce the level of cerebrospinal fluid production as the mechanism at decreased intracranial pressure. A large multicenter trial, the idiopathic intracranial hypertension trial (IIHT), has supported the use of diet and acetazolamide in IIH. In adult patients, 500 mg twice per day is typically prescribed and advanced as required and tolerated by the patient. In young children, the recommended starting dose is typically 15 mg/kg per day up to 25 mg/kg per day with a maximum dose of 100 mg/kg per day or 2 g per day, but these higher doses are often not tolerated well.

Contraindication

Hyperchloremic acidosis, hypokalemia, hyponatremia, impaired kidney function, hypersensitivity to acetazolamide or less convincingly sulfonamides, and impairment of liver function are potential contraindications to the use of acetazolamide.

Adverse Reactions

The most common adverse effects are a metallic taste in the mouth particularly for carbonated beverages and peripheral paresthesias typically described as tingling in the hands and feet. These are generally however not dose-limiting side effects. Dizziness, light-headedness, increased urination, blurred vision, dry mouth, drowsiness, gastrointestinal upset, perioral and digital tingling, loss of appetite, metabolic acidosis, electrolyte imbalance, and nephrocalcinosis are less common. Rarely acetazolamide may cause potentially life-threatening anaphylactic reactions, Stevens-Johnson syndrome, or aplastic anemia.

Interactions

Acetazolamide increases the alkalinity of the urine and therefore can decrease excretion of other drugs (e.g., dextroamphetamine, anticholinergics, ephedrine, mexiletine, or quinidine). Increased urine alkalinity may also inhibit the conversion of methenamine to its active form formaldehyde. Acetazolamide can also potentiate salicylate toxicity by causing metabolic acidosis and enhancing the penetration of salicylate into tissues.

Achromatopsia (Rod Monochromatism), Gene Defects Causing

Joseph J. Carroll
Department of Ophthalmology, Eye Institute-Medical College of WI, Milwaukee, WI, USA

Synonyms

Rod monochromacy; Total color blindness

Definition

Autosomal recessive, congenital retinal disease characterized by severely reduced or completely absent color vision, photophobia, nystagmus, reduced visual acuity, and nondetectable cone electroretinograms.

Etiology

Congenital achromatopsia is caused by a disruption in the cone phototransduction cascade. Mutations in the genes encoding the α and β subunits of the cone cyclic nucleotide-gated channel (CNGA3 & CNGB3, respectively), the α subunit of cone transducin (GNAT2), and phosphodiesterase 6C (PDE6C) have been associated with the disease. Over 115 different mutations have been reported. These genes are expressed exclusively in the cone photoreceptor defects in them, which impair the cones' ability to hyperpolarize in response to light. There is phenotypic variability depending on the genotype, with novel high-resolution imaging tools being used to define the retinal phenotype on a cellular level.

Clinical Presentation

Individuals with rod monochromacy first present early in childhood with photophobia and nystagmus. Visual acuity is reduced (20/100–20/600) and visual fields may be normal or slightly constricted. Retina is normal in appearance on funduscopic examination. Retinal thinning in the macula may be present on optical coherence tomography. Eccentric fixation is also common. On the electroretinogram, cone (photopic) response is absent or significantly reduced while the rod (scotopic) response is normal or only mildly depressed.

Diagnosis

Clinical observation, electroretinography, and color vision testing are mandatory. Dark adaptometry, if available, can provide definitive diagnostic data. Pseudoisochromatic plates are of little value; rather color matching performance on an anomaloscope must be assessed. Fluorescein angiography and electroretinography can help differentiate these patients from those with cone or cone-rod dystrophies. Genetic testing should be considered, as mutations in *CNGA3*, *CNGB3*, *PDE6C*, and *GNAT2* have been associated with the disorder.

Differential Diagnosis

Differential diagnosis includes blue-cone monochromacy, cone monochromatism, cone dystrophies, and cerebral achromatopsia.

Therapy

Treatment of achromatopsia may include dark or special filter glasses or red-tinted contact lenses to reduce photophobia and potentially improve visual acuity, low vision aids (high-powered magnifiers), and occupational aids. Gene therapy has been used to restore cone function in mouse & dog models of the disease. Human trials are currently in preplanning stages.

Prognosis

Typically, congenital achromatopsia is a stationary condition.

Epidemiology

1:30,000, equal incidence in males and females.

Synonyms

Achromatic vision; Color blindness; Color vision deficiency; Daltonism; Dichromatic vision

Definition

Cerebral achromatopsia is a form of color blindness that results from cortical damage. It is characterized by severe or total color vision deficits. This loss may be complete or partial, and it may or may not be accompanied by other visual defects.

Etiology

Cerebral achromatopsia in contrast to retinal etiologies is due to brain disease. It can arise after meningitis, trauma, tumor, inflammation, or cerebral infarction. The underlying structural etiologies typically involve the lingual and fusiform gyri in the ventromedial aspect of the occipital lobe. Bilateral lesions are usually necessary for complete cerebral achromatopsia. Because the lingual and fusiform gyri border the lower lip of the calcarine sulcus, the homonymous hemianopsia when present typically involves the upper visual fields. If the lesion is more extensive and involves the upper lip of the calcarine sulcus, the scotoma will involve the lower visual fields as well. If the lesion is more widespread anteriorly within the fusiform gyrus, it may also lead to a prosopagnosia.

Clinical Presentation

Patients complain of monochromatic or washed out vision with or without the homonymous hemianopsia or cortical visual impairment.

Diagnostics

Diagnosis is based on medical history, color vision testing, electrophysiology, visual fields, psychophysical tests, and optical coherence tomography. Color vision tests include chairside testing (e.g., Ishihara or HRR color plates) or more extensive testing (e.g., the Farnsworth-Munsell 100-Hue Test, the Farnsworth D-15).

Differential Diagnosis

Congenital achromatopsia
Acquired retinopathy or optic neuropathy

Therapy

Treatment should be directed at the underlying etiology.

Acrylic Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Acrylic IOL; Polyacrylic IOL

Definition

Artificial lens made of transparent acrylic that is implanted in the eye and performs in focusing images. An acrylate polymer belongs to a group of polymers which could be referred to generally as plastics. They are noted for their transparency and resistance to breakage and elasticity.

Epidemiology

According to industry data worldwide, a number of implanted IOLs are estimated at between 6 and 10 million a year. Most of these IOLs are made of acrylic.

History

In 1949, Sir Harold Ridley implanted the first IOL in a human eye at St. Thomas' Hospital in London, UK. This was performed as an extracapsular surgery with a large incision size. With the development of phacoemulsification and smaller-incision surgery, the search for new foldable IOL materials led to the exploration of poly-hydroxyethyl methacrylic acid (poly-HEMA). In the 1980s, G.D. Barret developed the first hydrogel IOL (IOGEL PC-12), which was implanted in 1983 in Perth, Australia. These hydrogels were soft hydrophilic materials. Later on, hydrophobic acrylic IOLs were developed which represent the most common implanted foldable IOL today (Barrett et al. 1986; Kohnen and Koch 2009; Werner 2008).

Clinical Features

There are two different basic types of acrylic IOL:

- Hydrophilic
- Hydrophobic

The differences between these types are displayed in the entries "Hydrophilic acrylic intraocular lens" and "Hydrophobic acrylic intraocular lens"

Tests

During the decades, acrylic IOLs have undergone extensive research and testing in Europe, Asia, and the United States and have been proven safe for the treatment of cataracts and refractive errors.

Differential Diagnosis

See entries "▶ Hydrophilic" and "▶ Hydrophobic Acrylic Intraocular Lens."

Etiology

The term acrylic refers to the Latin word "acer" or Greek word "ákros" that means "sharp" due to the smell of acrylic acid.

Treatment

See also entries: "▶ Cataract Surgery" and "▶ Refractive Surgery" describing different IOL implantation techniques.

Actinic (Solar) Keratosis

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Senile keratosis; Solar keratoses

Definition

A premalignant cutaneous lesion (precursor form of cutaneous squamous cell carcinoma).

Basic Characteristics

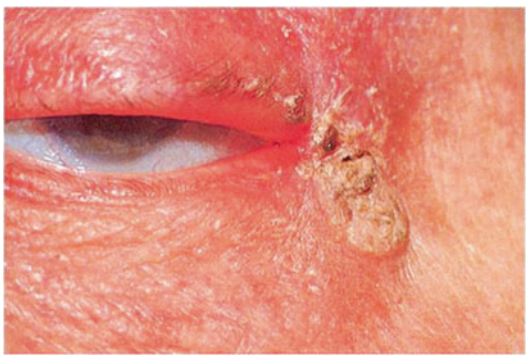
Actinic keratosis typically occurs in fair-skinned individuals, especially in the elderly, and affects face, hands, bald scalp, and eyelids (areas with chronic ultraviolet exposure). Individuals who are immunosuppressed are also at higher risk.

Some authors consider these lesions to be precancerous and others consider them to be a squamous cell carcinoma confined to the lower portion of the epidermis (incipient intraepidermal squamous cell carcinoma) (Albert and Jakobiec 2008; Shields and Shields 2008).

Usually it presents as multiple, erythematous, scaly plaques on sun-exposed skin (Fig. 1). They may range from millimeters up to 1 cm in size. Frequently keratosis, or an elevated white flaky crust, is seen on the surface and a nodular, horny, or warty configuration can be present.

A skin biopsy is indicated to confirm the diagnosis and to rule out invasive squamous cell carcinoma. Therefore, biopsies of suspected actinic keratosis should include the base of the lesion.

Treatment alternatives include surgical destruction and medical therapy. Excision, cryotherapy, curettage and electrosurgery, and laser surgery (CO_2 laser) are among surgical modalities. Medical therapy comprise fluorouracil (5-FU), imiquimod cream, topical diclofenac gel, photodynamic therapy (PDT), and chemical peeling. On the eyelid, these topical agents are not



Actinic (Solar) Keratosis, Fig. 1 Actinic ketatosis showing white scales near the medial canthus

usually applied because they can produce an intense inflammatory reaction and damage to the ocular surface (Albert and Jakobiec 2008; Shields and Shields 2008).

The prognosis is good, but early treatment should occur before the lesion develops into skin cancer (▶ squamous cell carcinoma). Follow-up of these lesions is necessary.

Actinic Cheilitis (AK on the Lips)

▶ Actinic Keratosis

Actinic Keratosis

Sojung Yi
Hospital and Health Care, School of Medicine and Health Sciences, George Washington University, Washington, DC, USA

Synonyms

Actinic cheilitis (AK on the lips); Senile hyperkeratosis; Senile keratosis; Solar keratosis

Definition

Actinic keratosis (AK) is a common skin lesion usually presenting as small, rough, scaly erythematous macules or papules on sun-exposed parts of the body. It is a precursor form of squamous cell carcinoma.

Etiology

AKs are caused by cumulative UV exposure, most commonly in the form of sunlight. UV rays induce mutation of the tumor-suppressor gene P53, and subsequent proliferation of the mutated atypical epidermal keratinocytes can develop into AK.

Clinical Presentation

AKs are small (usually 0.2–0.6 cm) and range in color from flesh colored or pink to slightly hyperpigmented (yellow brown). They are found frequently with a superimposed scale or hyperkeratosis that is rough upon touch and tender for the individual. AKs are found on sun-exposed parts of the body, commonly the face, forearms, dorsum of hands, eyelids, lower legs, and the balding scalp and tops of the ears. Multiple clinical and subclinical lesions may present in an area of sun-damaged skin, a concept known as "field cancerization."

Diagnosis

AKs that appear premalignant may be diagnosed by observation and palpation. A skin biopsy including the base of the lesion is recommended to confirm the diagnosis and to rule out invasive squamous or basal cell carcinoma.

Microscopy of AK lesions reveals atypical aggregates and pleomorphic keratinocytes in the basal cell layer that may extend to granular and cornified layers. Abnormal keratinocytes may cause parakeratosis of the overlying stratum corneum, leading to the signature "flag sign" of visible alternating orthohyperkeratosis above the spared epithelium.

A distinct margin also appears between the normal epidermis and the area of AK at lateral edges.

Differential Diagnosis

Squamous cell or basal cell carcinoma
Bowen disease
Seborrheic keratosis
Solar lentigines
Lentigo maligna
Nummular eczema
Lichenoid keratosis
Cutaneous lupus

Prophylaxis

Sunscreen applied properly and daily may protect against development of AK.

Therapy

Treatment options include surgical destruction and medical therapy.

Cryosurgery, excision, curettage, electrosurgery, and laser surgery (CO_2 laser) are possible surgical alternatives. Cryosurgery with liquid nitrogen is the most common method of treatment. It may be particularly superior for thicker lesions, but may leave scars.

Medical therapies include topical solutions such as fluorouracil (5-FU), imiquimod cream, or diclofenac gel, as well as chemical peeling or photodynamic therapy (PDT) with aminolevulinic acid and blue light. Transplant patients on immunosuppression therapy must take caution in using imiquimod cream due to its immunostimulatory properties. Routine follow-up skin examinations are necessary.

Prognosis

Prognosis of treated AK is excellent, if the lesion is treated early before developing into squamous cell carcinoma.

Epidemiology

AKs are so common that they account for more than 10% of visits to dermatologists. Individuals at higher risk of developing AKs include the elderly, those with lighter skin phototypes, and those with a history of chronic sun exposure.

Acute Angle Closure

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Primary angle closure; Pupillary block

Definition

Acute apposition of the peripheral iris to the trabecular meshwork resulting in reduced drainage of aqueous humor leading to a rise of intraocular pressure.

Etiology

Narrow occludable angles, often in hyperopic eyes with smaller than average anterior segment dimensions.

Prophylaxis

Prophylactic iridotomy or iridectomy in the fellow eye of a patient who has suffered acute angle closure, or in eyes with an occludable angle in gonioscopy.

Clinical Presentation

Patients may be asymptomatic or present with a unilateral attack of decreased vision, blurring, and pain, often occurring during dim illumination. Occasionally patients will present with nausea and vomiting.

Diagnostics

An affected eye may show conjunctival hyperemia, corneal edema, shallow anterior chamber, and a mid-dilated pupil in a slit lamp examination. Tonometry will show a high intraocular pressure. Gonioscopic examination reveals angle closure with iridocorneal contact.

Therapy

The definite management of acute angle-closure glaucoma is breaking the relative pupillary block with a laser iridotomy or a peripheral iridectomy. Medical therapy to lower the intraocular pressure serves in order to relieve the symptoms and to enable iridotomy or iridectomy.

Prognosis

Variable from complete recovery without optical disk or visual field damage to profound glaucomatous vision loss, depending on duration of pupillary block and rise of intraocular pressure. Following an episode of symptomatic angle closure, reports suggest that satisfactory intraocular pressure control can be achieved in 42–72% of cases with pupillary block alone. Once primary angle-closure glaucoma, defined as structural damage to the disk and a field defect, has developed, most cases (94–100%) will require further treatment to control intraocular pressure.

Epidemiology

The prevalence of pupillary block ranges from 0.04% in Europe and Australia to 1.37% in Asia.

Acute Hemorrhagic Conjunctivitis

Surajit Saha
Wilmer Eye Institute, The Johns Hopkins Hospital, Baltimore, MD, USA
Ophthalmic Consultants of Long Island Rockville Centre, New York, USA

Synonyms

Epidemic keratoconjunctivitis (EKC); Hemorrhagic viral keratoconjunctivitis

Definition

Self-limited, rapid onset viral conjunctivitis with subconjunctival hemorrhage

Etiology

Adenoviruses, *Enterovirus* type 70 (EV70), *Coxsackievirus* A type 24 variant (CA24v)

Clinical Presentation

Patients have subconjunctival hemorrhage that is either petechial or confluent. The latter can give a posttraumatic appearance. Hyperemia, papillary reaction, and follicles are generally noted in the palpebral conjunctiva. Some or all of the following may be present: rapid onset of eye discomfort, tearing, eyelid swelling, discharge, chemosis, preauricular adenopathy, superficial punctate keratitis, and photophobia. The discomfort is sometimes described as foreign body sensation. In rare cases, flare in the anterior chamber suggestive of mild iritis has been reported. Signs and symptoms can present in one eye or both. The condition can be part of a more generalized pharyngoconjunctival fever.

Diagnosis

Diagnosis is typically based on clinical findings. Immunochromatography and enzyme immunoassay can be done in 10 min and 70 min, respectively. The sensitivity of both tests is about 50% and the specificity is almost 100%. Polymerase chain reaction (PCR) can be used for identification and results are available within days. Cell culture isolation and the neutralization test (using antibody serum) are also options but can take weeks for results to become available.

Differential Diagnosis

Traumatic subconjunctival hemorrhage, herpes simplex virus, toxic conjunctivitis, Molluscum, pediculosis, gonococcus, bacterial conjunctivitis, allergic conjunctivitis, chlamydia

Therapy

This is a self-limited condition that typically resolves within 2 weeks, more or less. It is highly contagious and precautions should include handwashing and proper hygiene. Treatment is meant to address symptoms, e.g., artificial tears and cool compresses. If discharge is excessive or the condition becomes chronic, then conjunctival cultures are recommended to look for nonviral causes.

Prognosis

The disease often exhibits spontaneous resolution. A secondary bacterial infection is possible and should be treated accordingly.

Epidemiology

The condition was first reported in Ghana in 1969. The local population called it "Apollo" disease because it occurred around the same time as the Apollo mission's moon landing. Since then, outbreaks of AHC have been reported in both developing and developed countries, mostly in tropical and subtropical areas. Epidemics last several months and affected populations have been reported numbering 10,000–200,000.

Synonyms

Acute idiopathic blind spot enlargement

Definition

Symptomatic enlargement of the blind spot without commensurate optic disk edema, occurring in conjunction with presumed disease of the peripapillary retina (e.g., papilledma).

Etiology

This disorder may be triggered by a prodromal viral illness.

Clinical Presentation

Patients present with variable features including normal or decreased visual acuity, photopsia, and

abrupt onset of visual field defects (i.e., enlarged blind spot). Patients may present with a relative afferent pupillary defect. The most common presentation is in a young myopic female. The retina and optic nerve are normal initially but may show peripapillary retinal pigment epithelial changes later.

Diagnostics

Diagnosis is based on medical history, vision testing, visual field testing, fundoscopic exam, fluorescein angiography, optical coherence tomography (OCT) of the retina, or focal or multifocal electroretinography. Visual field testing shows enlarged blind spots, highly variable in terms of size, but which typically have steep margins. Fundoscopic exam is usually normal. Fluorescein angiography may show peripapillary hyperfluorescence from late RPE staining. Later fundus changes may occur, however multifocal electroretinography (MERG) might show depressed wave forms in the peripapillary retina.

Differential Diagnosis

Multiple evanescent white dot syndrome, acute zonal occult outer retinopathy, optic neuritis, migraine, papilledema, chiasmal lesion, optic nerve drusen, anterior ischemic optic neuropathy, benign intracranial hypertension, peripapillary coloboma, glaucoma, retrobulbar mass, inverted disk, juxtapapillary choroiditis, progressive myopia with a temporal crescent, inferior conus, adverse side effects of systemic drugs.

Therapy

No current treatment is known for this disorder.

Prognosis

Patients typically show spontaneous improvement of the enlarged blind spot within 3 months, but some patients have permanent visual symptoms.

Necrotizing viral retinitis

Definition

Necrotizing peripheral vaso-occlusive retinitis

Etiology

A rare, aggressive, and potentially devastating syndrome associated with human herpes viruses. The most common cause is varicella-zoster virus

(VZV), followed by herpes simplex virus (HSV-1, HSV-2), and rarely by cytomegalovirus (CMV) and Epstein-Barr virus. It usually occurs in healthy immunocompetent patients; however, HSV-1 acute retinal necrosis (ARN) was reported in patients with past or concurrent herpes encephalitis, and VZV and HSV-2 ARN were related to meningitis. Association between ARN and HLA-DQw7 (phenotype Bw62) and DR4 was found in Caucasian patients in the USA and with HLA-Aw33, HLA-B44, and HLA-DRw6 antigens in patients in Japan, suggesting a possible genetic contribution in some patients (Bodaghi and LeHoang 2009; Whitcup 2010).

Clinical Presentation

ARN was first described in 1971 by Akira Urayama and colleagues as a clinical syndrome consisting of acute unilateral panuveitis associated with retinal periarteritis progressing to diffuse necrotizing retinitis and, ultimately, rhegmatogenous retinal detachment. The authors suggested the term Kirisawa–Urayama uveitis in honor of their teacher Professor Naganori Kirisawa, who was then Professor of Ophthalmology at Tohoku University. The term "BARN," for bilateral ARN, was coined by Young and Bird in 1978. In 1994, the Executive Committee of the American Uveitis Society refined the definition of ARN based on clinical characteristics and disease course.

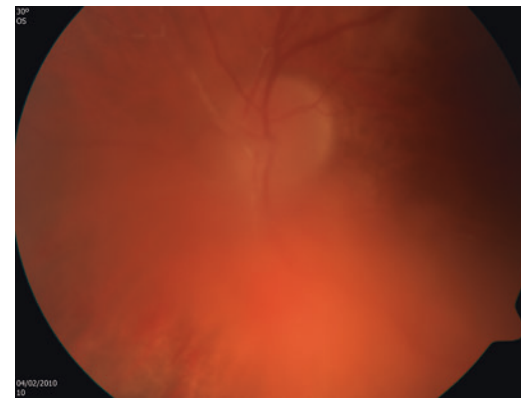
The most common complaints at presentation are red eye, blurred vision, photophobia, and ocular pain. Ocular examination findings may include episcleritis, scleritis, keratitis, and/or anterior chamber inflammation, which may be either non-granulomatous or granulomatous. Posterior segment findings include vitreous inflammation, patchy full-thickness necrotizing retinitis which may present as either confluent or multifocal patches of retinitis involving the peripheral retina, occlusive periarteritis and in some cases optic disk involvement may be seen.

The clinical diagnosis of ARN is based on the diagnostic criteria established by the American Uveitis Society, which consists of: (1) one or more discrete foci of peripheral retinal necrosis, (2) occlusive retinal vasculitis with arteriolar involvement, (3) prominent inflammation in the anterior and posterior chambers, (4) circumferential disease spread, and (5) rapid progression of disease in the absence of treatment.

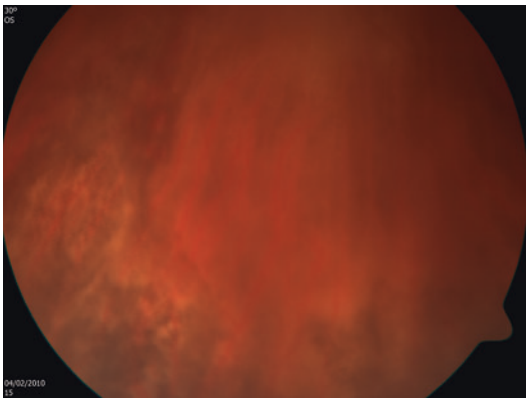
With prompt initiation of treatment, progression of the retinitis can usually be halted within 2–4 weeks. As the active retinal infection and inflammation resolve, affected areas develop pigmentary changes, retinal thinning, and atrophy, often producing a scalloped appearance at the junction of the involved and uninvolved retina. Vitreous organization and traction may progress during this phase, producing retinal breaks, retinal detachment, and proliferative vitreoretinopathy. Delayed complications of ARN may include chronic vitritis, macular edema, optic atrophy, epiretinal membrane formation, viral relapse with cessation of antiviral medication, and phthisis (Bodaghi and LeHoang 2009; Whitcup 2010).

Diagnostics

The diagnosis is based on clinical features of the disease and confirmed by demonstration of herpetic viral DNA in aqueous or vitreous samples by polymerase chain reaction (PCR) (Figs. 1 and 2) (Bodaghi and LeHoang 2009; Whitcup 2010).



Acute Retinal Necrosis (Necrotizing Herpetic Retinitis), Fig. 1 LE- inferior-nasal peripheral retinal necrosis with occlusive arterial vasculitis and severe vitritis, in a patient with a past history of HSV-1 encephalitis and a positive HSV-1 PCR result from vitreous sample



Acute Retinal Necrosis (Necrotizing Herpetic Retinitis), Fig. 2 LE- inferior-nasal peripheral retinal necrosis with occlusive arterial vasculitis and severe vitritis, in a patient with a past history of HSV-1 encephalitis and a positive HSV-1 PCR result from vitreous sample

Differential Diagnosis

- Cytomegalovirus retinitis may present similarly but be distinguished by mild inflammatory findings in the anterior chamber and vitreous, scattered hemorrhages, or granular lesions, and patients are often in an immunosuppressed state.
- Progressive outer retinal necrosis occurs in immunocompromised patients and characterized by extensive, rapidly progressing full-thickness necrosis of the retina involving initially the posterior pole, with little or no inflammatory component and spares the retinal vasculature.
- Other noninfectious diseases as Behcet's disease and intraocular tumors can present with retinitis that mimics ARN (Bodaghi and LeHoang 2009; Whitcup 2010).
- Nonviral infectious agents as *Toxoplasma gondii*, bacteria, or fungi.

Prophylaxis

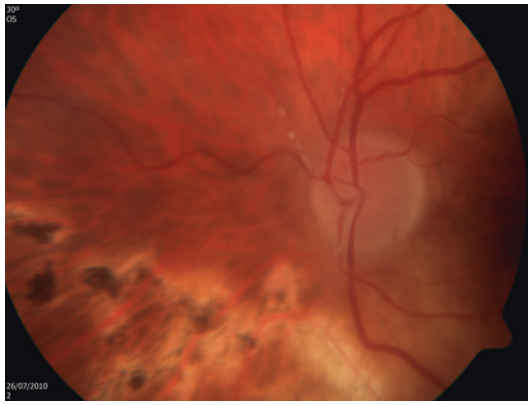
- Long-term antiviral therapy is the only possible way to avoid relapses.
- Prophylactic laser barricade applied posteriorly to necrotic areas has been suggested to reduce incidence of secondary retinal detachment.
- Early vitrectomy with intravitreal acyclovir lavage in addition to standard therapy has been suggested to reduce the rate of rhegmatogenous retinal detachment (Bodaghi and LeHoang 2009; Whitcup 2010; Wong et al. 2013).

Therapy

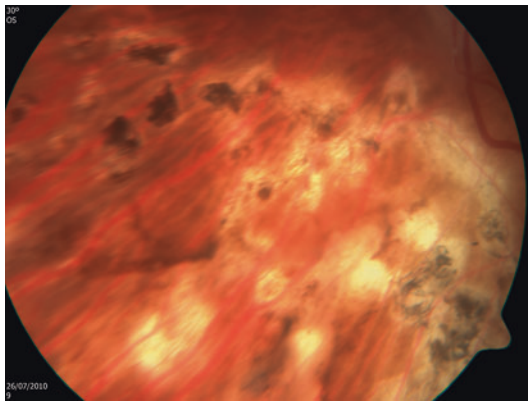
- The classical approach includes systemic intravenous acyclovir 10 mg/kg three times per day for 7–14 days, continued by oral acyclovir 800 mg five times a day for VZV-related ARN, or 400 mg five times a day for HSV-related ARN, for at least 6 weeks.
- An alternative treatment includes oral valacyclovir of 1 or 2 g three times per day for at least 6 weeks.
- For CMV-related ARN, an oral treatment with valganciclovir 900 mg twice per day for 3 weeks' induction and then 450 mg twice per day for maintenance. (In HIV patients prolonged therapy/prophylaxis until the CD4 count is repeated above 100 cells/μl for at least 6 months.)
- Oral corticosteroids (0.5–1 mg/kg/day), tapered along the course of antiviral therapy, are given in cases of significant inflammation or macula/optic nerve involvement (Figs. 3, 4, and 5).
- Intravitreal injections with ganciclovir (2 mg/0.1 ml) or foscarnet (2.4 mg/0.1 ml) may be given in patients resistant to or have contraindications to conventional therapy or as adjunctive with systemic treatment.
- Vitrectomy is done for rhegmatogenous retinal detachment, or in cases with poorly or non-responsive progressive retinal lesions and severe inflammation. Pars plana vitrectomy with endolaser and silicone oil tamponade has shown success in retinal reattachment and vision improvement (Bodaghi and LeHoang 2009; Whitcup 2010; Wong et al. 2013).

Prognosis

Visual prognosis depends mainly on the duration from disease onset to treatment.

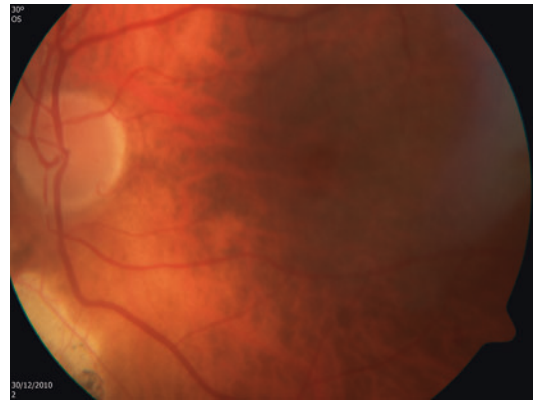


Acute Retinal Necrosis (Necrotizing Herpetic Retinitis), Fig. 3 LE- Post-systemic antiviral and corticosteroids treatment with application of laser photocoagulation posteriorly to necrotic areas. Vitritis and retinitis resolved and the macula is spared



Acute Retinal Necrosis (Necrotizing Herpetic Retinitis), Fig. 4 LE- Post-systemic antiviral and corticosteroids treatment with application of laser photocoagulation posteriorly to necrotic areas. Vitritis and retinitis resolved and the macula is spared

Generally, VZV–ARN patients tend to have more severe disease than HSV-ARN patients and often result in poorer visual prognosis. The onset of ARN syndrome is generally unilateral with contralateral eye involvement in approximately 2/3 of the cases, usually within 1–6 weeks from disease onset. Adequate antiviral therapy showed to reduce fellow-eye involvement to approximately 9%. Retinal detachment may develop in up to 75% of untreated infected eyes, but with proper treatment



Acute Retinal Necrosis (Necrotizing Herpetic Retinitis), Fig. 5 LE- Post-systemic antiviral and corticosteroids treatment with application of laser photocoagulation posteriorly to necrotic areas. Vitritis and retinitis resolved and the macula is spared

incidence is reduced to 20–52% of the cases (Bodaghi and LeHoang 2009; Whitcup 2010).

Epidemiology

ARN syndrome is rare; it was diagnosed in only 1.3% of 3,060 endogenous uveitis patients in Japan, and two national population-based studies in the United Kingdom reported its incidence to be approximately one case per 1.6–2.0 million population per year. There is no known association between gender, race or age, and the incidence of ARN. The mean onset age reported is in ascending order of HSV-2, HSV-1, and VZV–ARN syndrome (Bodaghi and LeHoang 2009; Whitcup 2010).

Acute Zonal Occult Outer Retinopathy (AZOOR)

Rohan J. Shah and Anita Agarwal
Vitreoretinal Diseases, Vanderbilt University School of Medicine, Vanderbilt Eye Institute, Nashville, TN, USA

Acute zonal occult outer retinopathy (AZOOR), initially described by Gass during the Donders' Lecture in 1993 (Gass 1993), is a syndrome characterized by sudden unilateral or bilateral zonal loss of outer retinal function corresponding to visual field defects, photopsias, variable or limited funduscopic changes, and electroretinogram (ERG) abnormalities. Vitreous inflammation can develop in those eyes that suffer higher degrees of visual field loss, and involvement of the fellow eye can occur weeks or even several years after initial presentation. Affected patients occasionally complain of an antecedent viral illness and their symptoms persist for approximately 4–6 months, after which the visual field loss often stabilizes or slightly improves (Gass et al. 2002). Late recurrences and progression have been described in some patients (Gass et al. 2002).

Since its initial description, features of AZOOR have been described in patients with multifocal choroiditis and panuveitis (MFC), punctate inner choroidopathy (PIC), multiple evanescent white dot syndrome (MEWDS), acute idiopathic blind spot enlargement syndrome (AIBSE), and acute macular neuroretinopathy (AMN), thus expanding the clinical spectrum of the syndrome to what Gass termed as AZOOR complex disorders (Gass et al. 2002; Gass 2003; Jampol and Wiredu 1995). Due to the variable presentation of AZOOR, its diagnosis can be confused with optic neuropathy and paraneoplastic, toxic, and autoimmune retinopathy. However, with the advent of new imaging modalities such as spectral-domain optical coherence tomography (SD-OCT) and fundus autofluorescence (FAF), our understanding of AZOOR has significantly expanded, thus improving diagnostic accuracy and analysis of treatment response.

Clinical Presentation

Most patients with AZOOR are young or middle-aged adults, myopic, generally healthy, and predominantly female. Compared to the general population, they or their first-degree relatives have a higher incidence of autoimmune disease(s) (Gass et al. 2002). AZOOR patients typically present with acute scotoma and photopsias corresponding to the zone of field loss. The photopsias can predate the scotoma or begin simultaneously with the field loss. They are more noticeable in bright lighting and daylight, in contrast to photopsias from vitreous degeneration, which are typically short lived and identified in dim lighting or at nighttime. Those patients with disabling photopsias sometimes present to the clinic wearing sunglasses. Photopsias are variably described as "fireworks, heat waves emanating from the road, microbes moving under a microscope, or moving colorful lights" (Gass 1993; Gass et al. 2002). Chronic photopsias can develop in patients who develop permanent fundus changes as a result of chronic photoreceptor destruction. During the evaluation, some patients complain of an antecedent viral illness or migraine type headaches prior to the onset of visual symptoms. On exam, those patients with larger scotomas or greater photoreceptor involvement can have vitreous cells. A small percentage of patients can have perivenous exudation or sheathing; however, a normal clinical exam is typical. Prior to accurate diagnosis of the condition, several patients undergo evaluation for functional vision loss or for neurological etiologies to explain the field loss.

Fundus Examination

The clinical spectrum of AZOOR is variable and can be unilateral or bilateral at initial presentation. Patients with bilateral involvement can have asymmetric clinical findings between eyes (Fig. 1). Fundus examination can reveal either a normal exam (Fig. 2a, b) suggesting an occult manifestation or demonstrate peripapillary, segmental, or diffuse pigment changes, representing overt manifestation of the syndrome. Some patients develop a yellow ring defining the border of the zone of involvement of the photoreceptors. A subset of patients can present with a gray-white ring demarcating the zone of visual field loss, which has been described as acute annular outer retinopathy (AAOR) and is likely a variant of AZOOR. Therefore, an eye with AZOOR can demonstrate a wide spectrum of fundus findings, which requires further testing including visual fields, fluorescein angiography (FA), FAF, SD-OCT, and ERG in making the diagnosis.

Visual Field

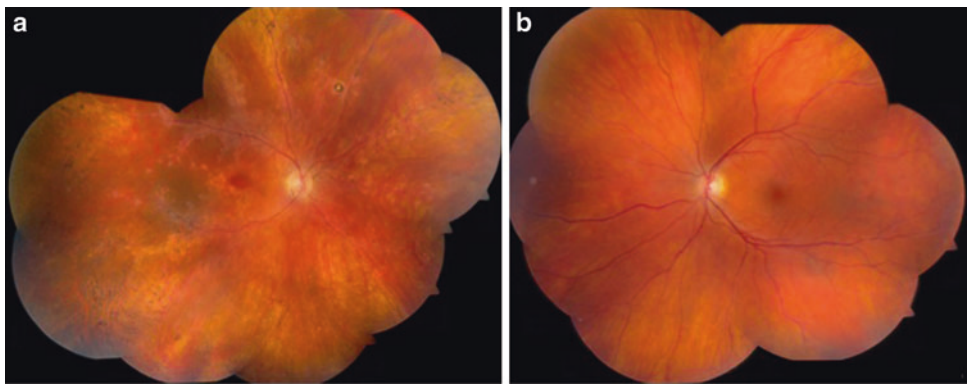
Visual field changes correspond to regions of photoreceptor involvement in AZOOR. Therefore, Goldmann visual field testing, which evaluates the entire visual field, is especially useful to confirm a diagnosis. Visual field changes are variable depending on where in the retina the photoreceptors are affected. The majority of cases involve the peripapillary region, which results in an enlarged blind spot or a scotoma emanating from the normal blind spot on visual field testing (Fig. 3a, b). Otherwise, the field loss can be peripheral or multifocal (Fig. 3c). Over time, the field loss can stabilize and even improve in a small subset of patients that are diagnosed in early stages of the disease and treated with corticosteroids and oral antiviral medications (Fig. 4). Therefore, follow-up visual field testing is beneficial for monitoring disease progression or stabilization.

Fluorescein Angiography

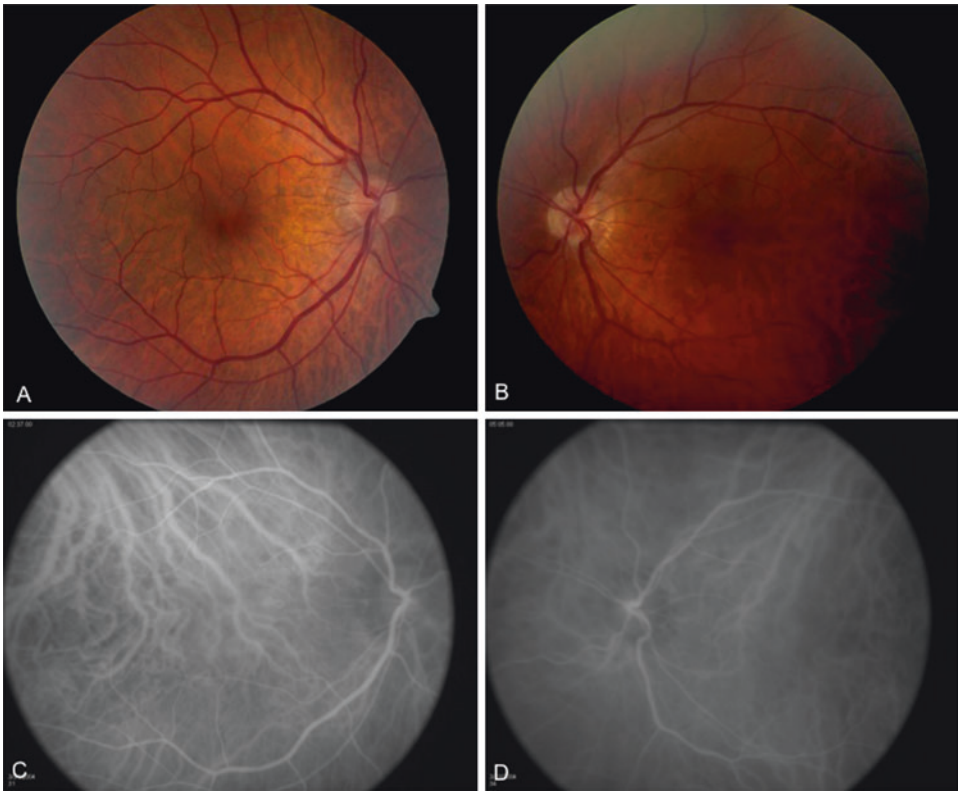
Fluorescein angiogram findings are generally normal in patients with early symptoms and minimal to no funduscopic changes (Figs. 5c and 7c). However, in chronic and more advanced cases, photoreceptor cell death can occur, which results in pigmentary changes at the level of the retinal pigment epithelium (RPE). This can result in RPE migration and a bone spicule appearance similar to retinitis pigmentosa in the later course of disease in some eyes. Angiography at this stage would reveal hyperfluorescence from window defects created by the zones of RPE degeneration (Figs. 6c, d and 7d).

Indocyanine Green Angiography

Indocyanine green angiography (ICG) findings have not been studied extensively in AZOOR. However, occult cases generally have normal



Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 1 Montage color fundus photographs of a patient with bilateral asymmetric AZOOR and an interval of 8 years between disease onset in the right eye versus left eye. (**a**) Right eye photos revealing diffuse atrophy and pigmentary changes and (**b**) left eye without significant fundus abnormalities despite symptoms of temporal field defect that progressed over 4 months and stabilized on immunosuppressive therapy



Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 2 Color fundus photographs of a patient with bilateral occult AZOOR with large temporal field defects in each eye, right eye affected 10 years prior to left. (**a**) Right and (**b**) left eyes demonstrate normal fundus appearance. ICG of (**c**) right and (**d**) left eyes reveals no abnormalities

ICG findings (Fig. 2c, d). In addition, late stage AZOOR lesions with pigment alterations and zones of RPE loss have shown hypofluorescence on ICG as a result of choriocapillaris atrophy within the corresponding region (Mrejen et al. 2014; Spaide 2004).

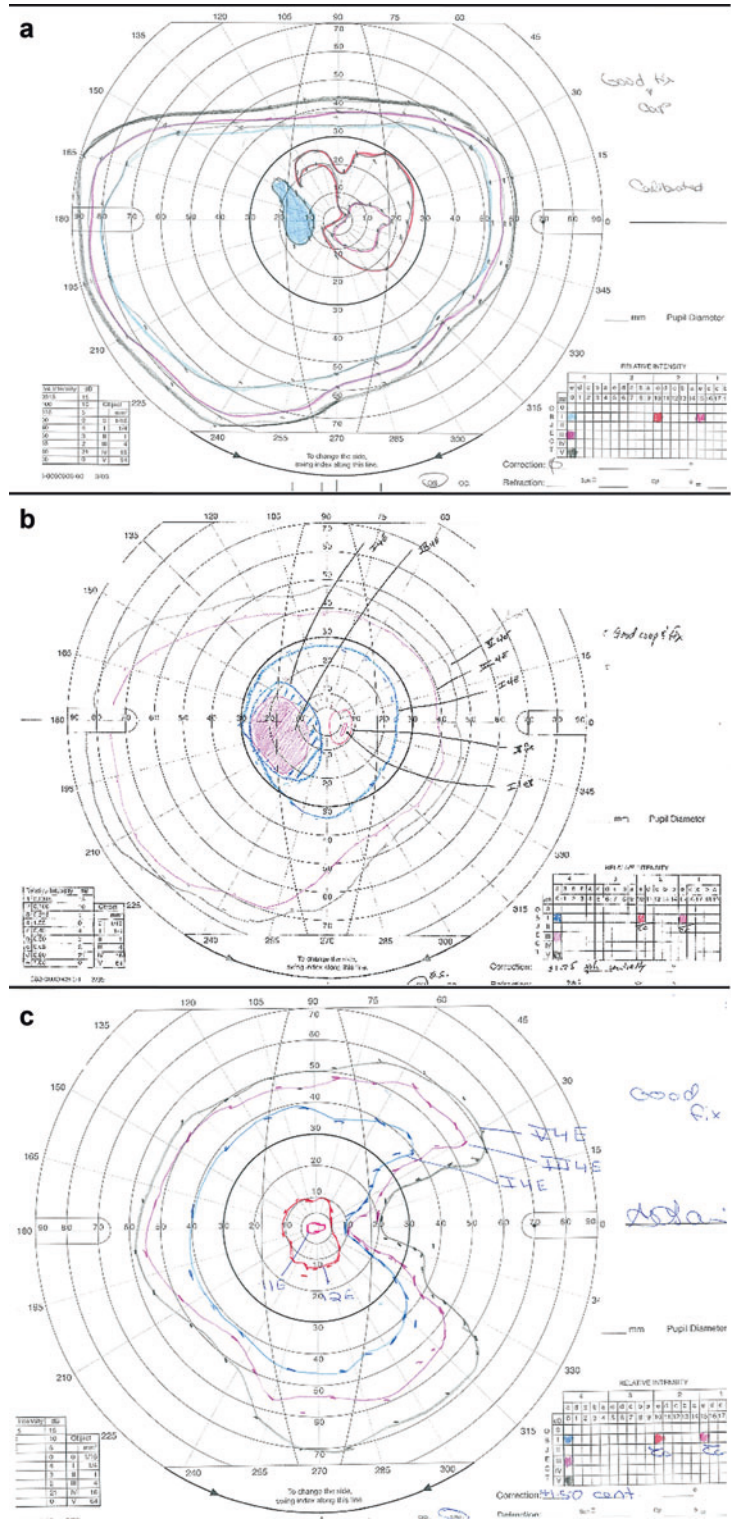
Fundus Autofluorescence

Autofluorescence imaging in AZOOR varies based on the type of presentation and degree of outer retinal disruption. Increased lipofuscin deposition within RPE cells that are metabolizing adjacent photoreceptor break down products results in hyperautofluorescence. With minimal photoreceptor damage, lipofuscin accumulation in underlying RPE cells is limited, and the region can be isofluorescent. On the contrary, in eyes with larger regions of photoreceptor damage, lipofuscin accumulation at the adjacent RPE cells increases, thus increasing FAF in corresponding regions (Fig. 6e, f). This can be seen in both occult and overt cases.

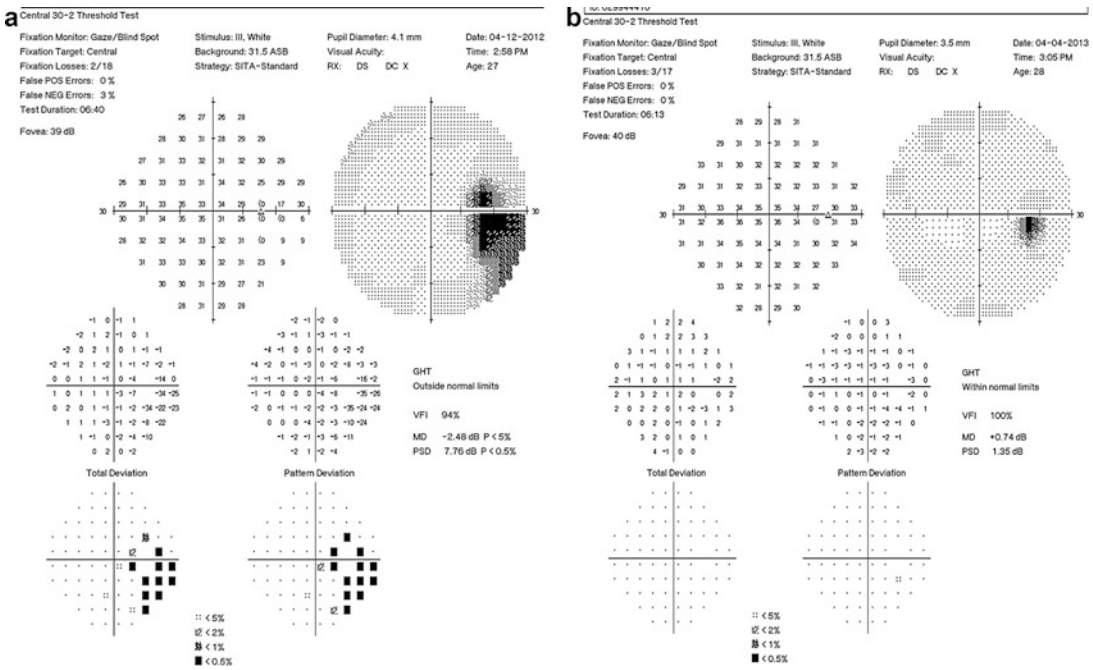
In a subset of AZOOR cases, hyperautofluorescence can be seen at the leading edge or "delineating line" of the lesion (Fig. 7f; Spaide 2004). With time, the FAF pattern within the delineating zone can become speckled and less prominent, which has been described in subacute lesions (Mrejen et al. 2014). Within this zone, increased autofluorescence can be found due to lipofuscin-laden RPE cells. Over time, the region turns hypoautofluorescent as a result of RPE cell apoptosis. As would be expected, these hypoautofluorescent regions correspond to hyperfluorescent zones on FA and ICG as described previously (Fig. 7d).

Optical Coherence Tomography

With recent advances in SD-OCT, imaging has been vital in identifying outer retinal disruption



Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 3 Goldmann visual fields of three different patients with AZOOR. All three (**a**–**c**) reveal enlarged blind spots and temporal field defects



Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 4 30-2 Humphrey visual field of a patient with occult unilateral AZOOR at (**a**) initial presentation revealing enlarged blind spot and (**b**) at 1 year revealing resolved visual field defect. This patient also recovered outer retinal SD-OCT features following treatment with systemic corticosteroids and acyclovir, as demonstrated in Fig. 8

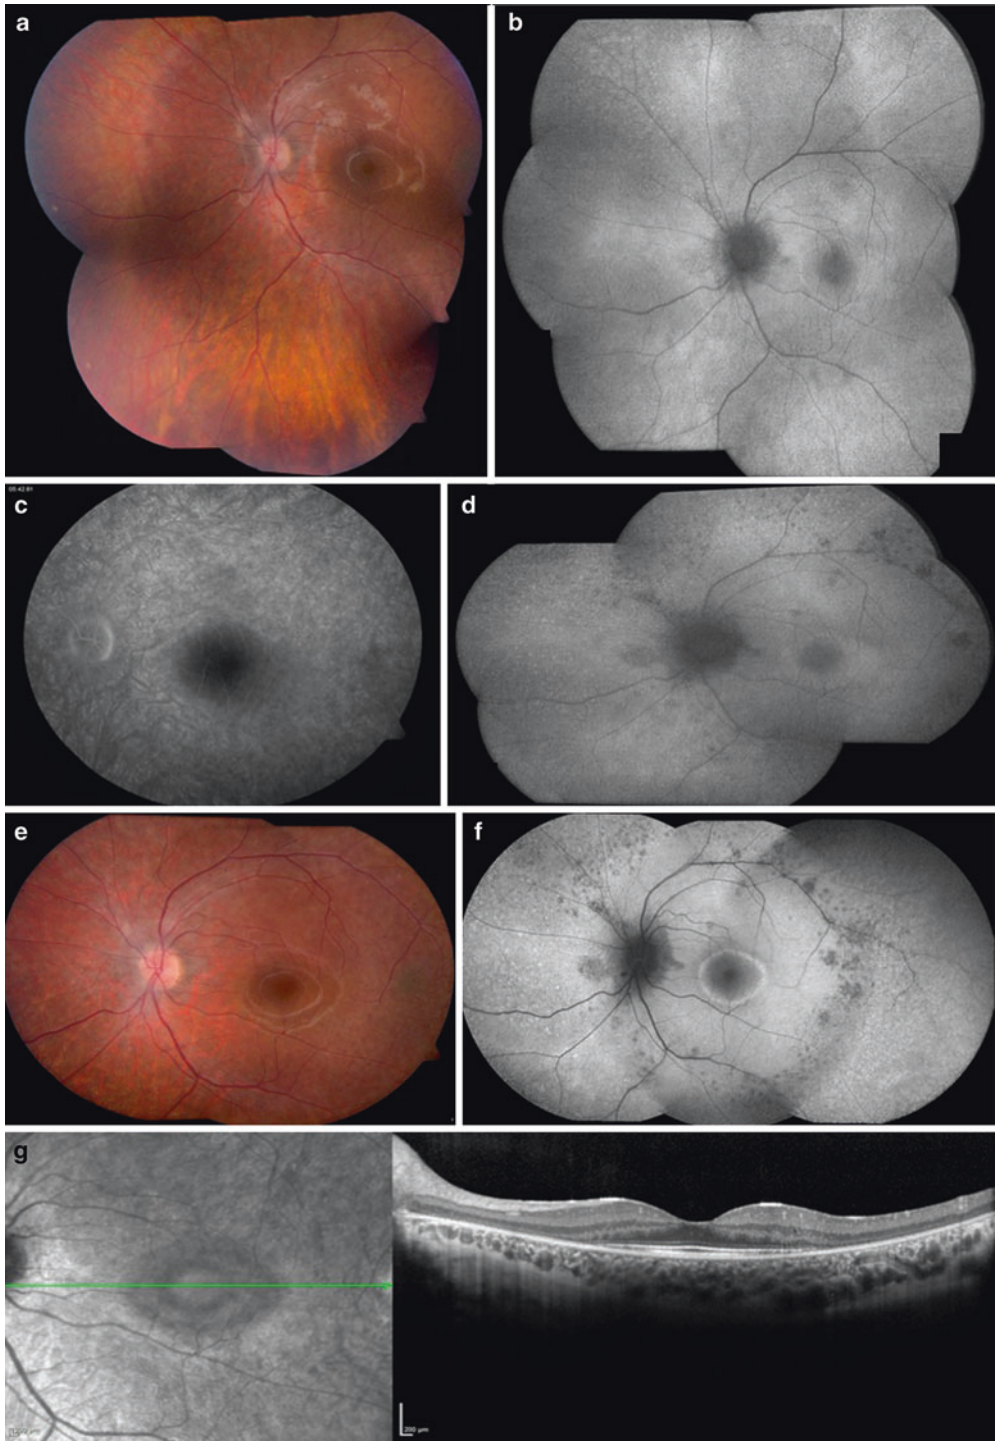
in AZOOR and AZOOR complex diseases. OCT scans corresponding to regions of visual field loss have revealed decreased ellipsoid zone and photoreceptor outer segment reflectivity, representing damage to outer segment cellular processes (Mrejen et al. 2014; Li and Kishi 2007; Spaide et al. 2008; Makino and Tampo 2013). Outer plexiform layer thickening with loss of the outer nuclear layer has also been described. In some patients that are treated early in the disease course, the outer retinal layers on SD-OCT can undergo reconstitution as the cells recover some or all function (Figs. 8 and 9). However, if actual receptor cell loss occurs, recovery of the outer retinal layers and visual field are unlikely (Fig. 10).

Electroretinogram

Electroretinogram (ERG) alterations depend on the degree of photoreceptor disruption. In eyes with unilateral or focal field loss, the ERG can be reduced compared to the normal fellow eye (Figs. 11 and 12). A subnormal ERG response can occur in eyes with extensive photoreceptor damage and visual field loss. The ERG alteration can be scotopic, photopic, or both depending on the region of photoreceptors affected by AZOOR. In bilateral cases, subnormal ERGs can be present in both eyes depending on the degree of outer retinal involvement. Asymmetric ERG responses between eyes, as described by Gass et al. and Jacobson et al., can be present, if the eyes have asymmetric manifestations of the disease (Gass et al. 2002; Jacobson 1996). Multifocal ERG tests cone function within the macula and can be valuable in identifying the location of visual field loss and degree of photoreceptor disruption. However, it may not be able to detect occult rod disruption outside the macula.

Pathogenesis

The exact etiology of AZOOR is unknown. However, Gass proposed a viral or other infectious



Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 5 (continued)

etiology for the syndrome (Gass 1993; Gass et al. 2002). Gass postulated that a virus or other infectious agent invades either at the ora serrata or the optic disc margin and propagates into the photoreceptor cells. These anatomical sites are the only two sites where the photoreceptors are not isolated from the systemic circulation by surrounding neuroepithelium. He hypothesized that, after invading the photoreceptors, cell to cell spread of this agent occurs without initially compromising photoreceptor function during an asymptomatic "preclinical phase." Later, in the "acute symptomatic phase," infected cell dysfunction is triggered by the host's immune response. Either a change in the antigenicity of the infective agent or a local autoimmune reaction to the receptors laden with this infective agent triggers photoreceptor dysfunction.

In a subset of AZOOR patients, this immune response results in impaired cell function that causes visual symptoms such as photopsias and visual field loss, but does not induce cell death. Long-term clinical or pathologic evidence of inflammation of the affected photoreceptor cell is absent in them. In others, the receptor cell bodies are destroyed, resulting in secondary RPE changes, bone spicule formation, and permanent visual field defects. Despite recovery of photoreceptors in some cases, retinal cell dysfunction likely persists in most eyes, thus explaining why photopsias can be chronic and visual field defects remain. Stabilization of visual fields and recovery of function typically occurs 6 months after the onset of symptoms; however, longer times to stabilization have been reported. Moreover, despite stabilization of the symptoms and visual field loss, disease recurrence and increased visual field loss can occur many months to years after the onset of symptoms in some.

In the other subset of patients, the immune response is strong enough to induce photoreceptor cell death. In these, vitreous inflammation, perivascular exudation, and optic disc edema can develop, likely as an epiphenomenon to the retinal receptor cell death. This inflammatory response becomes clinically evident in the weeks following the onset of symptoms and seems to vary depending on the degree of retinal involvement (Gass et al. 2002). Over time, in both occult and overt cases, retinal vascular narrowing, perivascular sheathing, and reactive changes to the RPE can develop. Impaired interaction of the microvilli between the photoreceptors and RPE causes migration of the RPE towards the inner retina resulting in a bone spicule appearance.

Autoimmunity

An autoimmune mechanism in the pathogenesis of AZOOR has been suggested, but the evidence is limited (Weleber et al. 2005; Heckenlively and Ferreyra 2008; Ara-Iwata et al. 1996). Anti-recoverin, anti-enolase, and other less common anti-retinal antibodies have been identified in individuals with cancer-associated retinopathy (CAR) and melanoma-associated retinopathy (MAR). In addition, these antibodies have been identified in cancer-free patients who have complained of photopsia, nyctalopia, and visual field loss. In a

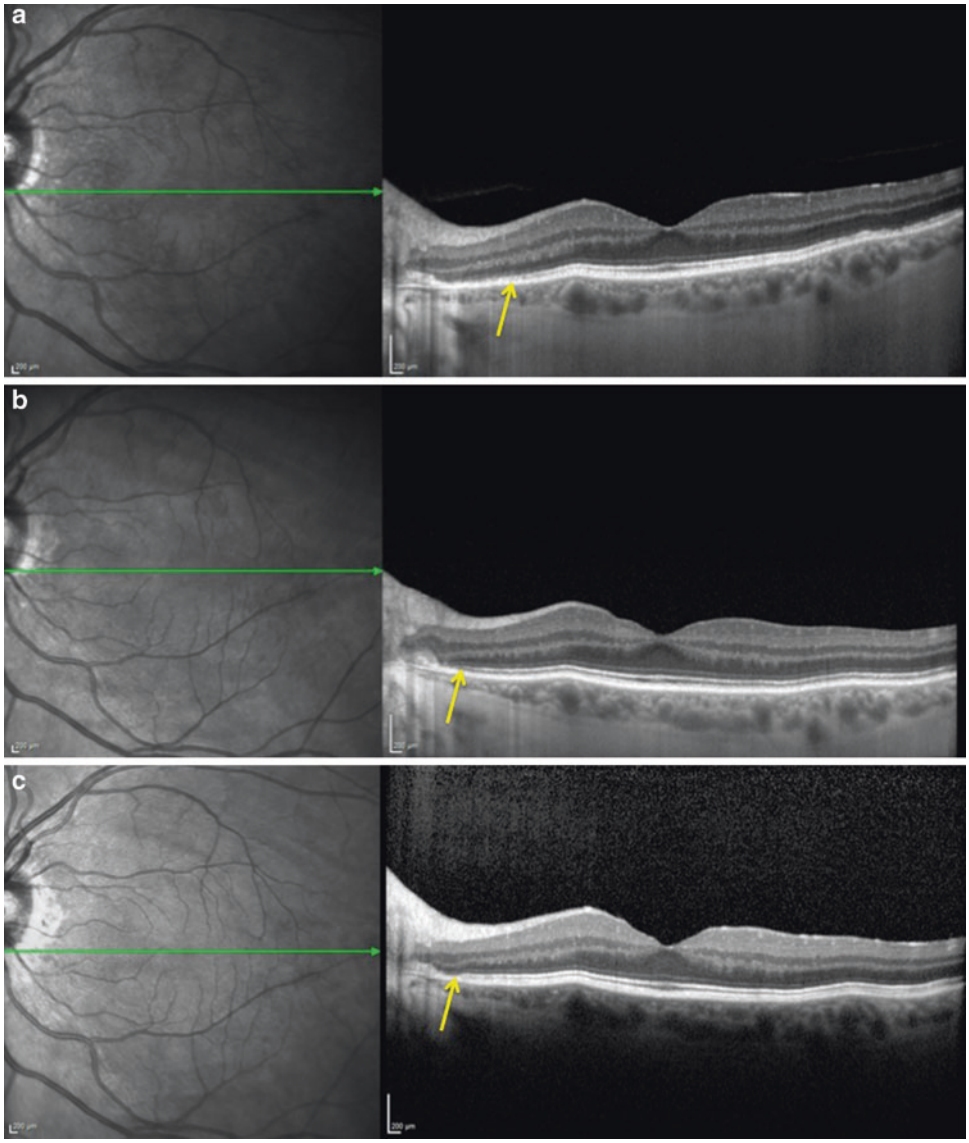
(**a**) Initial OCT with *white arrow* highlighting border where ellipsoid zone and outer segments are affected. On (**b**) 6 month follow-up, the SD-OCT reveals some recovery of ellipsoid zone as highlighted by *white arrow*. At (**c**) 1 year follow-up, SD-OCT reveals essentially recovered ellipsoid zone. Visual field improvement is highlighted in Fig. 4. There is a subtle change in the temporal juxtapapillary region highlighted in the infrared image corresponding to the OCT changes in (**a**) that normalized in (**c**)

subset of the reported cases, the clinical presentations and symptoms of patients were indistinguishable from those in AZOOR patients. Whether the circulating anti-retinal antibodies found in some patients are causative or an epiphenomenon is debatable. In fact, in a long-term follow-up study, there was a stronger association of autoimmune disease (28%) in AZOOR patients or their first-degree relative (Gass et al. 2002).

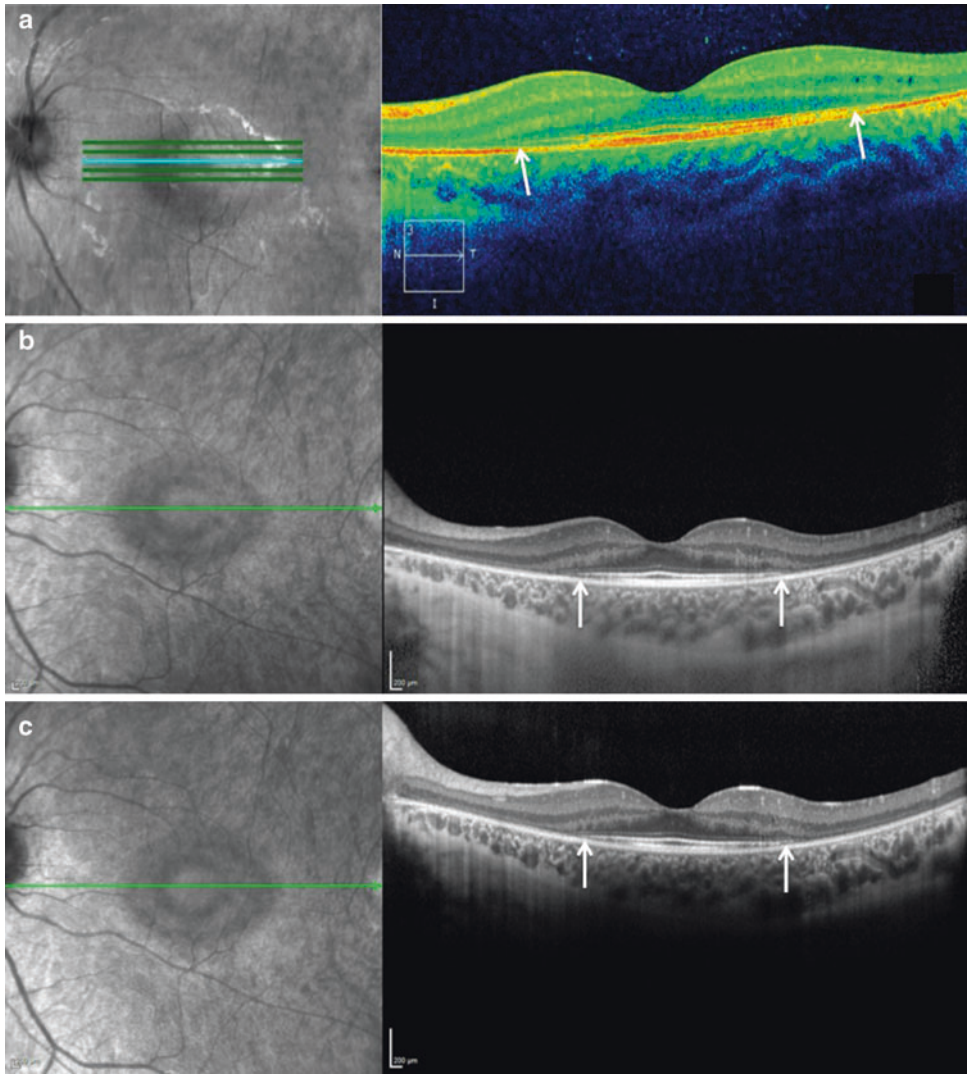


Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 9 SD-OCT images of a patient with unilateral occult AZOOR from (**a**) initial presentation through most recent follow-up over 2 years (**b**, **c**) revealing progressive improvement in ellipsoid zone as highlighted by *yellow arrow*

Despite this, presently, evidence against an autoimmune mechanism for AZOOR includes lack of consistent identification of anti-retinal antibodies in affected patients and inconsistent effectiveness of immunosuppression or corticosteroids in achieving disease stabilization (Gass 2003). However, a local inflammatory response without circulating systemic anti-retinal antibodies could still have a role in the pathogenesis of AZOOR.

Follow-Up and Clinical Course

The variable presentation of AZOOR creates a variable clinical course based on the initial presentation and subsequent changes. Affected eyes can present with either occult or overt disease, and due to its variable course, a subset of eyes with initial occult disease can develop clinical findings on exam if photoreceptor loss and RPE cell



Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 10 SD-OCT images of patient highlighted in Fig. 5. (**a**) Initial Zeiss SD-OCT revealing loss of ellipsoid zone with outer nuclear layer thinning nasal and temporal to foveal as highlighted by *white arrows*. Subsequent SD-OCT images over 2 years of follow-up (**b**, **c**) did not reveal any outer retinal recovery

migration occurs over time. In a long-term follow-up study of 51 patients, fundus examination was normal in 90% of patients at presentation and remained normal at follow-up in 52% of eyes (Gass et al. 2002). Visual acuity was 20/40 or better in 75% of patients and remained so in 68% on follow-up. Furthermore, two thirds of patients presented with unilateral involvement, and 75% had bilateral AZOOR at most recent follow-up. In this subset of patients, 72% demonstrated visual field stabilization within 6 months, and 24% showed mild improvement. It can be assumed that those eyes that recovered function did not undergo significant photoreceptor or outer nuclear layer loss. Interestingly, those eyes that presented with significant field loss and visual compromise did not regain function likely because of significant outer retinal cell death within close proximity to central fixation, thus limiting the potential for recovery.

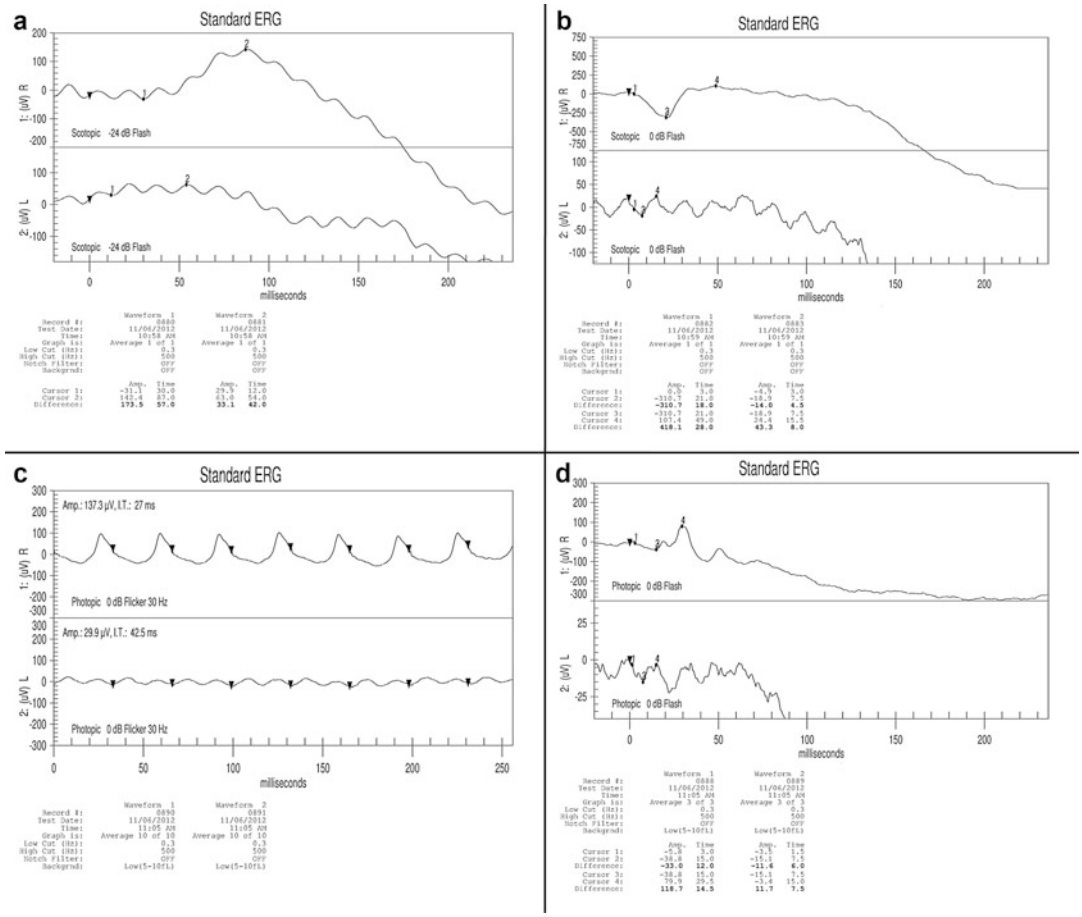
Normal exam of (**a**) right eye. Imaging of left eye including (**b**) fundus photograph and (**c**) FAF image revealing diffuse pigment changes and hypo AF with (**d**) severely depressed visual field on GVF exam

Treatment

There has been no definitive treatment that has been able to control the symptoms of AZOOR or induce stabilization or recovery of the visual field loss. However, given the presumed viral etiology and local inflammatory response, use of oral antiviral agents in conjunction with a tapering dose of oral corticosteroids for approximately 6 weeks has been utilized in those patients that present early in the disease course (Gass et al. 2002). Of those treated, a small subset achieved visual field and photoreceptor recovery and even improvement in photopsias. When symptoms persist and field loss progresses despite antiviral or corticosteroid treatment or when symptoms recur following corticosteroid tapering, use of periocular steroid treatment and immunosuppressive agents such as methotrexate, mycofenolate mofetil, and adalimumab can be implemented; however, the response is variable with some patients demonstrating stabilization of field loss and resolution of photopsias (Spaide et al. 2008; Neri et al. 2014).

AZOOR Complex Disorders

A small percentage of patients diagnosed with MFC, PIC, MEWDS, and AMN can present with photopsias and visual field loss similar to



Acute Zonal Occult Outer Retinopathy (AZOOR), Fig. 12 ERG of patient in Fig. 11 demonstrating depressed rod and cone responses of left eye compared to right eye on (**a**) scotopic −24 dB impulse (rods), (**b**) scotopic – 0 dB impulse (rods and cones), (**c**) 30 Hz flicker (cones), and (**d**) photopic impulse (cones)

symptoms of AZOOR (Gass 2003; Jampol and Wiredu 1995; Zweifel et al. 2009; Holz et al. 1994). Gass proposed that these disorders were part of a spectrum of a single disorder known as the "AZOOR complex"; however, controversy remains whether these disorders are necessarily related. Unless a definitive overt manifestation of AZOOR is present, differentiating the AZOOR Complex disorders from AZOOR based on imaging alone can be challenging (Mrejen et al. 2014). Furthermore, these disorders are classified based on clinical presentation rather than etiology. Until discrete etiologies of the individual disorders are understood, grouping them into AZOOR complex disorders may be easier as long as it is understood that they each have unique characteristics in addition to possessing the common features of field loss and photopsias (Zweifel et al. 2009; Holz et al. 1994; Taira et al. 2006).

Acute Annular Outer Retinopathy

In the few documented cases of AAOR, patients present with acute loss of visual field similar to AZOOR, but with a concurrent gray-white ring bordering the zone of field loss. The clinical spectrum (permanent versus variable pigmentary changes), fluorescence patterns on angiography, and response to corticosteroid therapy are variable.

This disease is believed to be a subset of AZOOR that is accompanied by field loss and clinical findings of retinal whitening at the border of the zone of field loss (annular type) or whitening of the entire zone (overt type) (Gass and Stern 1995; Fekrat et al. 2000; Cheung et al. 2002; Harino et al. 2004; Mitamura et al. 2005; Tang et al. 2008).

Definition

Adenoviral conjunctivitis is an inflammatory condition that affects the bulbar and palpebral conjunctiva as a result of an adenovirus infection.

Etiology

Adenoviruses, which are nonenveloped DNA viruses, are the most common cause of viral conjunctivitis. Of the 41 adenovirus serotypes, 19 can cause conjunctivitis. These infections are highly infectious, spreading via respiratory droplets or direct contact from fingers to the lids and conjunctival surface or in swimming pools. The incubation period is usually 5–12 days, and the clinical illness is present for 5–15 days. The two main infections of adenoviral conjunctivitis are:

Pharyngoconjunctival fever (PCF): Associated with systemic infection and is produced by adenovirus serotypes 3, 4, and 7.

Epidemic keratoconjunctivitis (EKC): The severest ocular disease. Adenovirus serotypes 8, 19, and 37 are the serotypes most commonly associated with EKC (Sambursky et al. 2006; Yanoff et al. 2009).

Clinical Presentation

It usually starts in one eye and spreads to the other several days later. It is frequently associated with exposure to an infected person or recent upper respiratory tract symptoms. Patients complain of a red eye, burning, or a foreign body sensation that is associated with a watery to mucous discharge and preauricular lymphadenopathy. Corneal subepithelial infiltrates may be present late in the course (Krachmer et al. 2011).

Pharyngoconjunctival Fever (PCF)

It is characterized by a combination of pharyngitis, fever, conjunctivitis, and adenopathy. Diarrhea or rhinitis might be present. The conjunctivitis is predominantly follicular with a scant watery discharge, hyperemia, and mild chemosis. PCF usually affects both eyes, with one eye generally affected more severely. In comparison with other types, PCF is more systemic with less corneal involvement (Yanoff et al. 2009; Sambursky et al. 2006).

Epidemic Keratoconjunctivitis (EKC)

The conjunctivitis is more severe than PCF. EKC produces a more follicular response of the conjunctiva with a watery discharge, hyperemia, chemosis, and ipsilateral preauricular lymphadenopathy. Subconjunctival hemorrhages, conjunctival membrane formation, and lid edema are common. Up to 50% of patients have only unilateral infection. One of the distinguishing features of EKC is corneal involvement. Focal epithelial keratitis may develop 1 week after the onset, characterized by central ulceration with gray-white dots, and they may persist for 2 weeks. Two weeks after the onset of symptoms, subepithelial infiltrates (SEI) can appear beneath the focal epithelial lesions (Sambursky et al. 2006; Yanoff et al. 2009).

Diagnosis

The diagnosis is usually made clinically, but confirmation of the disease by culture or polymerase chain reaction (PCR) is needed in certain situations. The clinical diagnosis of viral conjunctivitis can be based on the presence of acute conjunctivitis and one of the following features: follicles on the inferior tarsal conjunctiva, preauricular

lymphadenopathy, an associated upper respiratory infection, and a recent contact with a person with a red eye. If the diagnosis is not readily apparent, laboratory studies may be helpful in determining etiology (Sambursky et al. 2006; Krachmer et al. 2011).

Differential Diagnosis

Differential diagnosis includes other viral conjunctivitis, bacterial conjunctivitis, keratitis, allergic conjunctivitis, and toxic conjunctivitis.

Prophylaxis

It is very crucial to avoid personal contact. The patient is considered infectious until redness and tearing are gone; during this period, patients should minimize the risk of spreading the infection to others by washing their hands and avoiding sharing personal items. Cleaning the instruments that have been used during the examination is very important.

Therapy

Most cases of viral conjunctivitis resolve spontaneously, without sequelae, within days to weeks. Treatment is usually supportive with cold compresses and artificial tears. Pseudomembranes and membranes should be removed when detected. Topical corticosteroid might be used to reduce the inflammation, but these agents should be prescribed with caution. Topical corticosteroid could be used in cases with membranous or pseudomembranous conjunctivitis, iridocyclitis, severe keratitis, and persistent SEIs with visual loss (Yanoff et al. 2009; Krachmer et al. 2011).

Prognosis

Viral conjunctivitis is a self-limited process. The symptoms frequently get worse in the first 3–5 days, with very gradual resolution over the following 1–2 weeks. Some cases might develop corneal scar or symblepharon (Yanoff et al. 2009; Krachmer et al. 2011).

Epidemiology

The annual incidence of acute infectious conjunctivitis in primary care in the developed world has been estimated at 1.5–2%. Conjunctivitis accounts for 30% of all eye complaints in the USA. Of the infectious agents, viral conjunctivitis is most common, accounting for up to 50%.

Synonyms

Adie's pupil; Adie's tonic pupil; Holmes-Adie syndrome

Definition

A tonic pupil is typically dilated in the acute setting and the pupil that reacts slowly or not at all to light but shows a more definite tonic response to accommodation (i.e., light-near dissociation).

Etiology

The tonic pupil is caused by damage to the parasympathetic ciliary ganglion. The parasympathetic innervation to the iris and ciliary body travels with the third cranial nerve and synapses in the ciliary ganglion. This damage is usually due to inflammation from a viral or bacterial infection but can be due to trauma, orbital surgery, or rarely in association with systemic autonomic neuropathies (e.g., Ross syndrome). After the initial insult, reinnervation and upregulation of the postsynaptic receptors occurs, a process known as denervation supersensitivity. The number of axons that travel to the ciliary body is about 30 times the number that supplies the pupil. Due to aberrant reinnervation, fibers formerly supplying the ciliary body travel instead to the pupil.

Clinical Presentation

Patients may be asymptomatic or can present with a dilated and tonic pupil which responds poorly or does not constrict in response to light but reacts to near. There may be loss of deep tendon reflexes in the full Holmes-Adie syndrome.

Diagnostics

Diagnosis is made by clinical exam and topical confirmation with low-dose topical pilocarpine testing. Clinical exam will often show sector paresis of the iris sphincter or vermiform iris movements. Low-dose topical (1/8%) pilocarpine may constrict the tonic pupil due to cholinergic denervation supersensitivity. A normal pupil typically will not constrict with such a dilute dose of pilocarpine.

Differential Diagnosis

Traumatic iris damage, third cranial nerve palsy, pharmacological dilation, and iris rubeosis

Therapy

Prescription of asymmentric reading glasses can be used to correct for the accommodative visual impairment of the eyes. Pilocarpine low-dose

drops may be administered to constrict the affected pupil.

Prognosis

There is no mortality rate relating to the idiopathic tonic pupil (i.e., Adie's tonic pupil) but the systemic autonomic neuropathies (e.g., Ross syndrome) may have other potentially life-threatening parasympathetic problems (e.g., GI, cardiac, temperature regulation).

Epidemiology

Adie's tonic pupil most commonly affects younger women, with a 2.6:1 female preponderance. The mean age of the onset is 32 years. In 80% of cases, it only affects one eye but can become bilateral over time.

Adult-onset vitelliform macular dystrophy (AVMD); Gass disease; Pseudo-Best (disease); Pseudo-vitelliform (macular dystrophy)

Definition

Adult-onset foveomacular vitelliform dystrophy (AOFVD) is a macular dystrophy sharing phenotypic features with Best's disease, with onset in the adult age (between the fourth and sixth decades) (Gass 1974). Sharp distinction between AOFVD and pattern dystrophies may be difficult (Deutman et al. 2006).

Etiology

The mechanism underlying the physiopathology of AOFVD is still unknown, but it has been postulated that there is an abnormal accumulation of lipofuscin that may be caused by the increased workload of metabolism and phagocytosis on the RPE cells in conjunction with other disease-related factors (such as age, genetic predisposition, and environmental causes). As a result, the RPE layer is separated from the photoreceptor layer by hyperreflective material (Arnold et al. 2003). Mutations in the genes *BEST1* (11q12), *PRPH2* (6p21.1), or *IMPG1* (6q14.2-q15) (encoding bestrophin-1, peripherin and SPACR, respectively) have been found in some

individuals with AOFVD (Felbor et al. 1997; Allikmets et al. 1999; Kramer et al. 2000).

Clinical Presentation

The clinical onset is typically in the adult age, between the fourth and sixth decade of life (with a ratio M = F). In the early stages of AOFVD, patients are asymptomatic or have mild complaints of scotoma, visual blur, or metamorphopsia in one or both eyes (Gass 1974). On the other hand, significant visual impairment can result in patients with advanced stages or large atrophic lesions. Choroidal neovascularization (CNV) may develop in early as well as advanced stages.

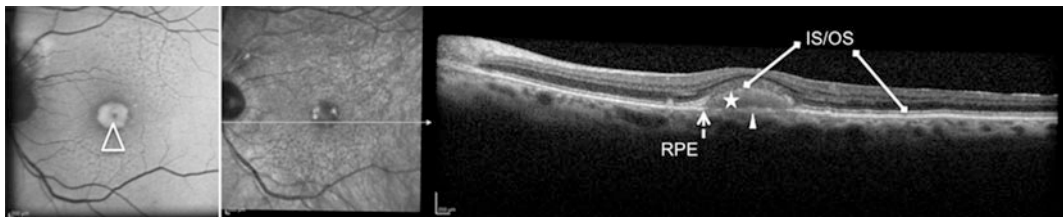
Different progressive stages can be defined on the basis of fundus examination, similarly to Best's disease or vitelliform macular dystrophy (Gass 1997; Querques et al. 2011). The vitelliform stage is characterized by a well-circumscribed, typically 0.5- to 1-disk-diameter, "egg-yolk" lesion (i.e., the yellow material) within the macula (Figs. 1 and 2a). The pseudohypopyon stage is characterized by the yellow material that accumulates inferiorly (Fig. 3) and is followed by partial reabsorption of the material (scrambled-egg lesion) in the vitelliruptive stage (Fig. 4). Development of macular atrophy or fibrosis characterizes the final stages of the disease (Fig. 2b). However, the disease is clinically heterogeneous and pleomorphic, with extreme variability in the size, shape, and distribution of the yellowish material. These stages do not always occur consecutively nor do they occur inevitably in all patients.

Diagnostics

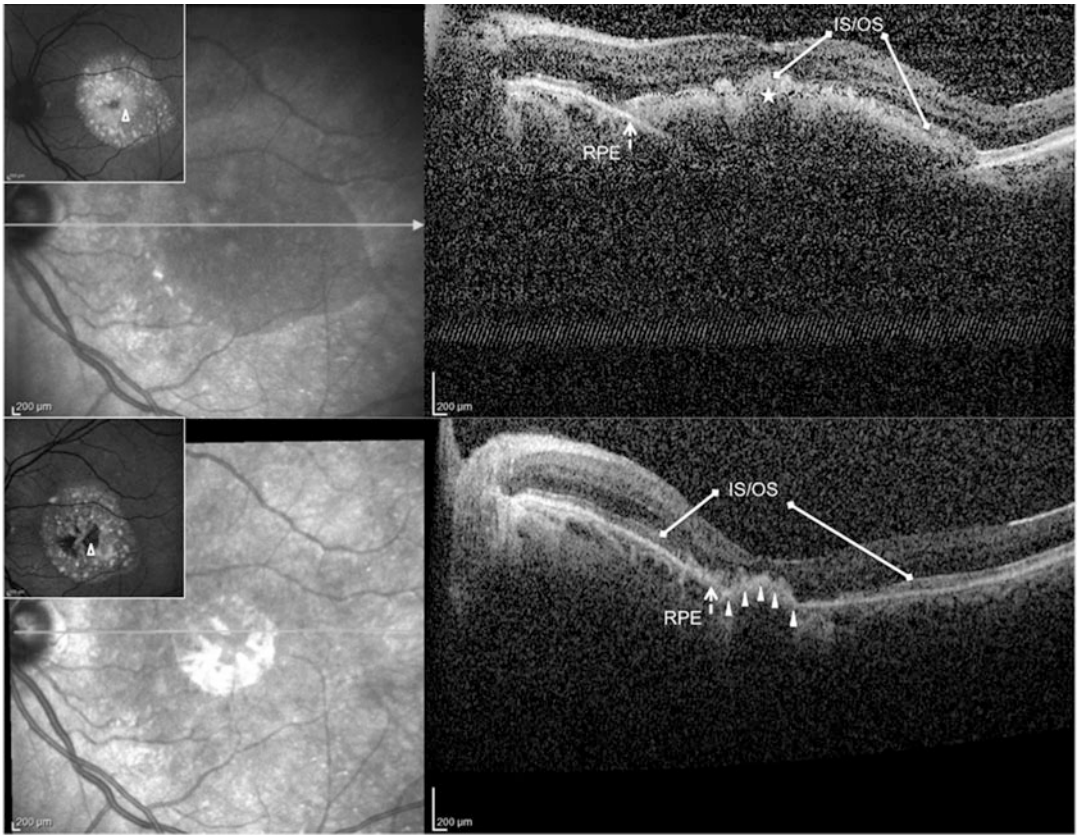
Multimodal imaging is particularly useful to make diagnosis of AOFVD. Fundus autofluorescence (FAF) and spectral-domain optical coherence tomography (SD-OCT) represent the main noninvasive imaging techniques to make the diagnosis and monitoring AOFVD (Querques et al. 2011).

In the vitelliform stage of the disease, FAF shows unilateral/bilateral and symmetric/asymmetric subretinal, oval or round, central intense hyperautofluorescence (Figs. 1 and 2a). In the pseudohypopyon stage, FAF shows loss of autofluorescence, particularly, in the upper part of the lesion in the pseudohypopyon stage (Fig. 3) and centrally with an increased amount of the autofluorescence at the outer border of the lesion in the vitelliruptive stage (Fig. 4). FAF shows central hypoautofluorescence in more advanced stage (Fig. 2b).

On SD-OCT, AOFVD is characterized by dynamic alternating phase of accumulation and reabsorption of hyperreflective material in the subretinal space, ending with atrophy or fibrosis. Alterations of the status of central photoreceptors,



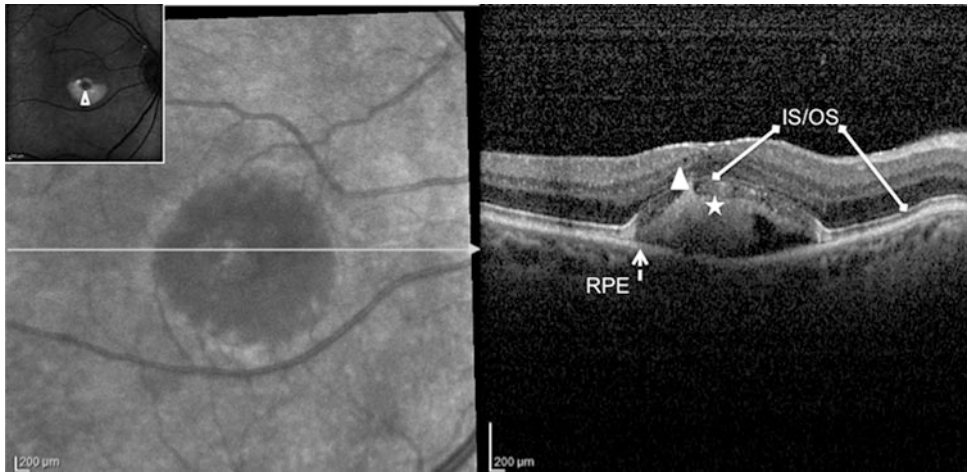
Adult-Onset Foveomacular Vitelliform Dystrophy, Fig. 1 Fundus autofluorescence (*FAF*) and spectral-domain optical coherence tomography (*SD-OCT*) in a patient with adult-onset foveomacular vitelliform dystrophy, presenting the vitelliform stage. FAF shows central hyperautofluorescence (*right panel*) (*open arrowhead*). SD-OCT showed the lesion as hyperreflective (*asterisk*), as well as hyperreflective drusen-like focal nodules (*solid arrowhead*) at the level of retinal pigment epithelium (*RPE*)/Bruch's membrane (*dotted arrows*) within the lesion area. Central interface of the inner and outer segments (*IS/OS*) of the photoreceptors appear "disrupted" (*left panel*) (Reprinted from Querques et al. (2011), with permission from Elsevier)



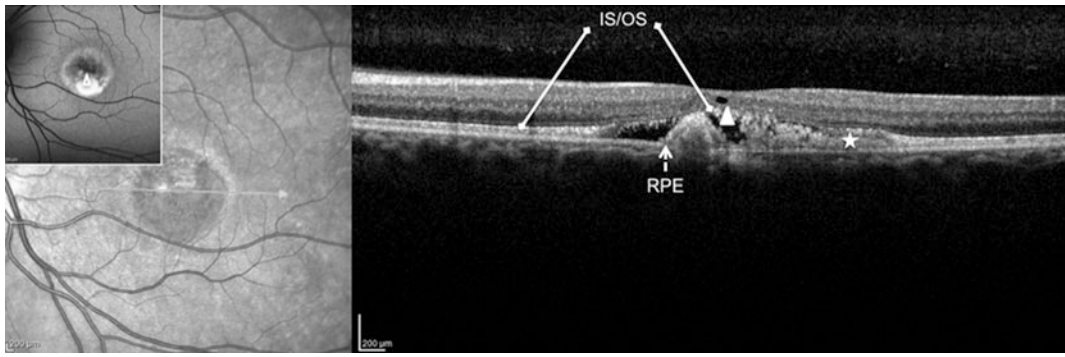
Adult-Onset Foveomacular Vitelliform Dystrophy, Fig. 2 Fundus autofluorescence (*FAF*) and spectral-domain optical coherence tomography (*SD-OCT*) in a patient with adult-onset foveomacular vitelliform dystrophy, presenting the vitelliform stage at baseline (**a**) and the atrophic stage 24 months later (last visit) (**b**). FAF showed central hyperautofluorescence at baseline (*top left*, *small panel*) (**a**) and central hypoautofluorescence at last visit (*bottom left*, *small panel*) (*open arrowhead*) (**b**). SD-OCT showed the lesion as hyperreflective at baseline (*top right panel*) (*asterisk*) (**a**). An atrophic lesion appeared at last visit (*bottom right panel*) (**b**); also, elevation of retinal pigment epithelium (*RPE*, *dotted arrow*) with hyperreflectivity inside (*solid arrowheads*) appeared within the lesion area. Central interface of the inner and outer segments (IS/OS) of the photoreceptors appeared "disrupted" at baseline (*top left panel*) (**a**) and "absent" at last visit (*bottom left panel*) (**b**). SD-OCT showed an overall decrease of lesion size (Reprinted from Querques et al. (2011), with permission from Elsevier)

degree of lesion reflectivity, presence of hyperreflective nodules at the level of RPE/Bruch's membrane, and elevation of RPE can be detected on SD-OCT (Table 1).

In the vitelliform stage, SD-OCT shows hyperreflective subretinal material, as well as hyperreflective drusen-like focal nodules at the level of RPE/Bruch's membrane within the lesion area. In this stage, the central interface of the inner and outer segments (IS/OS) of the photoreceptors may appear disrupted (Figs. 1 and 2a). In the pseudohypopyon stage, SD-OCT shows the lesion as hyperreflective in the inferior part and hyporeflective in the superior part. Central interface of IS/OS of the photoreceptors usually appears disrupted (Fig. 3). In the vitelliruptive stage, SD-OCT shows the lesion as mixed hyperreflective/hyporeflective; elevation of the RPE with hyperreflectivity inside the lesion area may be detected. Central interface of the IS/OS of the photoreceptors usually appears disrupted (Fig. 4). In the advanced



Adult-Onset Foveomacular Vitelliform Dystrophy, Fig. 3 Fundus autofluorescence (*FAF*) and spectral-domain optical coherence tomography (*SD-OCT*) in a patient with adult-onset foveomacular vitelliform dystrophy, presenting the pseudohypopyon stage. FAF shows central hyperautofluorescence (*small panel*) (*open arrowhead*). FAF also clearly shows the sedimentation of the hyperautofluorescence material. SD-OCT shows the lesion as mixed hyperreflective/hyporeflective (*right panel*) (*asterisk*). No hyperreflective drusen-like focal nodules at the level of retinal pigment epithelium (*RPE*)/Bruch membrane or RPE elevations (*dotted arrows*) were evident within the lesion area. Central interface of the inner and outer segments (*IS/OS*) of the photoreceptors appear "disrupted" (*right panel*) (Reprinted from Querques et al. (2011), with permission from Elsevier)



Adult-Onset Foveomacular Vitelliform Dystrophy, Fig. 4 Fundus autofluorescence (*FAF*) and spectral-domain optical coherence tomography (*SD-OCT*) in a patient with adult-onset foveomacular vitelliform dystrophy, presenting the vitelliruptive stage. FAF shows central hypoautofluorescence (*open arrowhead*) concentrically by hyperautofluorescence (*top left*, *small panel*). SD-OCT shows the lesion as mixed hyperreflective/hyporeflective (*right panel*) (*asterisk*); elevation of retinal pigment epithelium (*RPE*) with hyperreflectivity inside appeared within the lesion area (*dotted arrow*). Central interface of the inner and outer segments (*IS/OS*) of the photoreceptors appears "disrupted" (*left panel*). SD-OCT also reveals presence of retinal pseudocysts (*solid arrowhead*) (Reprinted from Querques et al. (2011), with permission from Elsevier)

uncomplicated stage, the central interface of IS/OS of the photoreceptors and the outer retinal layers are usually absent (Fig. 2b).

En face OCT imaging can help visualize the distribution of the vitelliform material in AOFVD (Fig. 5) (Puche et al. 2014).

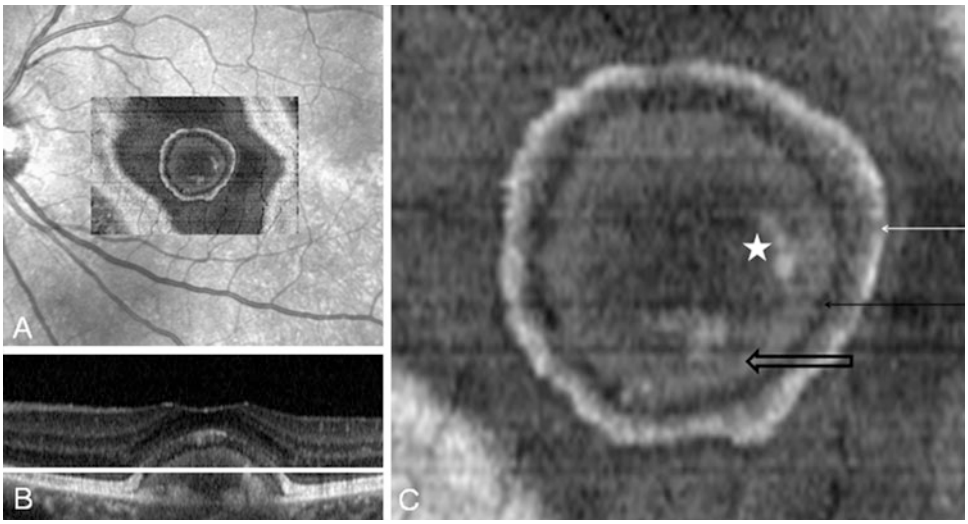
IS/OS: inner segment/outer segment; RPE:retinal pigment epithelium

Fluorescein angiography (FA) and indocyanine green angiography (ICGA) show a "blocking effect" in the vitelliform and the pseudohypopyon stages due to the accumulation of subretinal material. In the advanced stages of the disease, FA shows hyperfluorescence, which in the early phase is due to RPE defects and chorioretinal atrophy and in the late phase is due to material staining. FA and ICGA are particularly useful if there are signs of presumed CNV.

Differently from Best's disease, electrofunctional tests (both electrooculogram and electroretinogram) are typically normal.

Routine eye examinations, including ancillary exams, are recommended in patients with AOFVD, once or twice a year, to identify any possible complications. CNV is the most frequent complication of AOFVD, occurring with an estimated rate of 11.7% after a 6-year follow-up, and may develop in all stages of the disease. Sudden



Adult-Onset Foveomacular Vitelliform Dystrophy, Fig. 5 Photoreceptors' inner and outer segment (*IS/OS*) interface and interface of the material and photoreceptor in adult-onset foveomacular vitelliform dystrophy visualized by en face optical coherence tomography (*OCT*). Combined infrared reflectance and en face enhanced depth imaging (*EDI*) OCT images (**a**). Horizontal EDI-OCT B-scan (**b**) showed presence of hyperreflective vitelliform lesions between the IS/OS interface and the retinal pigment epithelium (*RPE*). The *dotted line* represents the section plane of the en face EDI-OCT. *En face* EDI-OCT imaging (*magnification*, **c**) showing from the periphery to the lesion centre: IS/OS of the photoreceptor layer, appearing as a hyperreflective ring (*white arrow*); interface of the material and photoreceptor appearing as a hyporeflective ring (*black arrow*); the vitelliform material (*black open arrow*) appearing as round hyperreflective lesion. At the centre of the vitelliform lesion, EDI-OCT shows clusters of intensely hyperreflective RPE elevations or bumps (*white star*) (With kind permission from Springer Graefe's Archive for Clinical and Experimental Ophthalmology, En face enhanced depth imaging optical coherence tomography features in adult onset foveomacular vitelliform dystrophy, 252, 2013, 555-62, Puche et al. (2014), Fig. 1)

drop in visual acuity, presence of hemorrhages or exudates on fundus examination, dye leakage on late FA phases, and hyperfluorescence of the lesion on early and late phases of ICGA are signs of CNV activity; OCT may show increase in foveal thickness.

Differential Diagnosis

Differential diagnosis of AOFVD includes Best's disease, which has typical childhood onset, and, depending on the different stages of the disease, CNV secondary to AMD. Central serous retinopathy and avascular pigment epithelial detachment should also be differentiated from AOFVD.

Therapy

At present, there is no effective therapy for AOVFD. In the absence of any CNV associated with AOFVD, there is no evidence to treat subretinal fluid with anti-VEGF intravitreal drug. Subretinal fluid seems due to debris (unphagocytosed photoreceptor OS) and lipofuscin accumulation in the subretinal space rather than exudative. Treatment of CNV associated with AOFVD by anti-VEGF drugs seems to reduce foveal thickness, but no visual improvement was reported (Mimoum et al. 2013).

Prognosis

The visual prognosis of AOFVD is relatively good in the majority of patients with AOFVD because the disease typically causes uncomplicated slow progressive vision loss. Nonetheless, severe visual lost may be observed.

Epidemiology

AOFVD is an uncommon disease; the exact prevalence is unknown.

Synonyms

Marcus Gunn pupil

Definition

The relative afferent pupillary defect (RAPD) is a clinical sign. The RAPD is caused by asymmetrical input to the Edinger-Westphal nuclei from the afferent limb of the visual pathway (e.g., retina, optic nerve, chiasm, optic tract, and pretectal neurons). Bilateral and symmetrical afferent system disorders (i.e., symmetric disease in both optic nerves) may not cause a detectable RAPD.

Etiology

Any lesion of the afferent visual pathway from the retina to the optic chiasm, optic tract, and pretectal neurons in the midbrain can result in an RAPD.

Diagnostics

The RAPD is diagnosed via the swinging flashlight test. In this test, a light is alternately shone into the left and right eyes. A normal response displays equal constriction of both pupils, regardless of which eye the light is shone in. A normal response indicates an intact direct and consensual pupillary light reflex. Observing pupil dilatation when the light is swung from the unaffected eye to the affected eye indicates an abnormal response and suggests a defect in the afferent limb of the pupillary light response pathway.

Therapy

Treatment should be directed toward the underlying cause for the RAPD.

Definition

Visual information is received by the eye and the signal is relayed by the retina, optic nerve, chiasm, optic tracts, lateral geniculate nucleus, and optic radiations to the striate cortex and extrastriate association cortices for final visual processing.

The eye is the primary sensory organ for vision. It is responsible for collecting and focusing light from the visual environment. Light first passes through the ocular media, consisting of the tear film, cornea, anterior chamber, lens, and the posterior-chamber vitreous. The tear-air interface and cornea have the power to focus light in a fixed manner. The ciliary muscles adjust the shape of the lens in order to dynamically focus light from varying distances upon the retina. Ultimately, the visual image is projected upside down and backward onto the retina.

In the retina, photoreceptors convert photons of light to an electrochemical signal that is relayed to retinal ganglion cells. To arrive at the photoreceptors, light must first pass through transparent inner layers of the neurosensory retina, comprised of the nerve fiber layer, ganglion cells, amacrine cells, and bipolar cells. The photoreceptors contain photopigment consisting of a membrane protein known as opsin and a chromophore molecule called 11-*cis*-retinal. As light reaches the photopigment, it causes a conformational change of 11-*cis*-retinal to all-*trans*-retinal. All-*trans*-retinal has a low binding affinity, so it detaches from the opsin molecule. The free opsin molecule then activates another membrane complex (the G-protein transducin), by replacing a guanosine diphosphate (GDP) molecule with a guanosine triphosphate (GTP) molecule. Activated G-protein transducin stimulates the enzyme phosphodiesterase (PDE), which hydrolyzes the cytoplasmic second messenger cyclic guanosine monophosphate (cGMP). Reduced levels of cGMP cause closure of membrane sodium channels, reducing the inward sodium current and hyperpolarizing the cell. Thus, the photoreceptor cell reduces its neurotransmitter output in response to absorption of light. This process is self-limited as the membrane complex transducin catalyzes GTP back to GDP, restoring the cell's tonic neurotransmitter release.

The excitatory "on" and "off" inputs to a ganglion cell are arranged to form an antagonistic center-surround receptive field. The action potential firing rate of an "on-center" ganglion cell is highest when a light stimulus is in the center of the receptive field with surrounding darkness. The action potential firing rate of "off-center" ganglion cells is highest when a light stimulus is in the peripheral receptive field, but not its center. When there is uniform illumination throughout a ganglion cell receptive field, the center and surround responses cancel each other and do not create an action potential.

Ganglion cell axons travel through the optic nerve and partially decussate in the chiasm, bringing together corresponding inputs from each eye. Some inputs follow pathways to mediate pupil light reflexes and circadian rhythms. The majority of inputs travel to the lateral geniculate nucleus. Different types of ganglion cells comprise separate pathways that are named for their targets in

the LGN of the thalamus. The three main types of ganglion cells are midget cells, which form the "P" (parvocellular) pathway; parasol cells, which form the "M" (magnocellular) pathway; and small bistratified ganglion cells, which form the "K" (koniocellular) pathway.

The chiasm is the site of decussation for axons from the optic nerve. This decussation serves to bring together information from the halves of each retina that view the same portion of the visual field. Axons from nasal ganglion cells cross and join axons from temporal ganglion cells from the contralateral eye. There is a greater number of crossed (53%) than uncrossed (47%) fibers.

Each optic tract contains axons from the ipsilateral temporal retina and the contralateral nasal retina. In the posterior tract, these axons fan out toward the LGN and interdigitate into its separate layers.

The number of cells in the LGN is large, with almost a 1:1 ratio to ganglion cell inputs. The hilum (central portion) of the LGN represents the macular vision. The superior visual field is represented in the lateral horn, and the inferior visual field is represented in the medial horn. The LGN is arranged in six neuronal layers, each with monocular inputs. Ganglion cell axons from the ipsilateral eye synapse in layers 2, 3, and 5. Axons from the contralateral eye synapse in layers 1, 4, and 6. Layers 1 and 2 contain the magnocellular layers which receive parasol ganglion cell inputs. Layers 3–6 contain parvocellular neurons and receive midget ganglion cell inputs. Scattered under each of the six major layers are the koniocellular cells.

The LGN is a relay station with dynamic control upon the amount and nature of information that is transmitted to the visual cortex. The pulvinar is another thalamic nucleus that forms a higher-order relay receiving descending cortical projections from both layers 5 and 6 of the visual cortex. The pulvinar nucleus is capable of modifying transmission in accord with requirements of selective visual attention.

The superior colliculi play a role in generating orienting eye and head movements to sudden visual stimuli. They are located in the dorsal midbrain within the tectal plate.

The pretectal nuclei receive a portion of fibers in the optic tract, which subserve the pupillary light reflex. There is consensual innervation to both pretectal nuclei, and each nucleus has dual connections to each Edinger-Westphal nucleus.

The suprachiasmatic nucleus (SCN) receives light information from a type of retinal ganglion cell that contains the photopigment melanopsin and demonstrates an intrinsic responsiveness to light. This allows the SCN to monitor ambient light levels reliably. The SCN communicates with the pineal gland, where melatonin secretion drives circadian rhythms.

Second-order neurons of the visual pathway form the optic radiations traveling from the LGN to the striate cortex in the occipital lobe. These neurons travel in two major groups: the temporal radiations termed Meyer's loop and the parietal radiations. Temporal radiations represent the contralateral homonymous superior field, and parietal radiations represent the contralateral homonymous inferior field.

The optic radiations arrive at the mesial surface of the occipital lobe, in the striate cortex. The parietal radiations synapse in the superior bank of calcarine cortex, while those from the temporal radiations arrive in the inferior bank. These axons make connections in cortical layer 4, which is termed the "stripe of Gennari." Macular projections make their synapses in the posterior pole of calcarine cortex. The macular representation is greatly magnified in the visual cortex retinotopic map; 2% of the visual field encompasses 60% of the striate cortex. This cortical magnification correlates to extremely high central acuity.

Synonyms

Age-related maculopathy (ARM); AMD; ARMD

Definition

Degenerative process of the choriocapillaris-retinal pigment epithelium (RPE) complex which leads to a significant loss in visual acuity.

Epidemiology

Age-related macular degeneration (AMD) is the leading cause of significant irreversible loss in visual acuity in people over 50 years old in developed countries. The prevalence increases with age, namely, from 1.6% in the age group 52–64 years to 28% in the age group 75–86 years. Pathologic features related to AMD may be found in the outer retina, retinal pigment epithelium (RPE), Bruch's membrane, and choriocapillaris. According to these abnormal findings, AMD may be classified as non-neovascular or neovascular, with a prevalence of 85–90% and 10–15%, respectively.

Histopathology and Clinical Features

Non-neovascular (Dry) AMD

The hallmark of the non-neovascular AMD is drusen. Other characteristic features are abnormalities of the RPE and choriocapillaris. The advanced form of this disease is geographic atrophy, characterized by atrophy of the outer layers of the retina and RPE with loss of choriocapillaris.

Drusen are small, yellowish white lesions located below the RPE. There are several types of drusen – hard, soft, basal laminar, and crystalline.

Hard Drusen

Hard drusen are smooth-surfaced, dome-shaped structures, located between the RPE and Bruch's membrane. They contain hyaline material, mucopolysaccharides, and lipids. These drusen are smaller than 50 mm in diameter. They are common in young adults and do not lead to macular degeneration.

Soft Drusen

Soft drusen are pale yellow lesions with poorly defined edges. They are a localized detachment of RPE with basal linear deposits (located external to the RPE, composed of an electron dense, lipid-rich material) or with basal laminar deposits (located between the plasma and the basement membranes of the RPE, composed of granular material with wide spaced collagen). They gradually enlarge to form a confluent drusen (contiguous boundaries between drusen). Soft drusen are classified into small (<63 μm), intermediate (63–125 μm), and large (>125 μm). The risk of progression from non-neovascular AMD to neovascular AMD increases with the size and the total area covered by drusen.

Basal Laminar Drusen

Basal laminar drusen are tiny and white, located between the plasma membrane and basement membrane of the RPE, mainly composed of collagen, laminin, and fibronectin.

Crystalline Drusen

Crystalline drusen are dehydrated soft drusen that may predispose to geographic atrophy.

Geographic Atrophy (GA)

GA is the advanced form of non-neovascular AMD, frequently associated with loss of central vision. GA is a well-demarcated area of decreased retinal thickness, which allows visualization of choroidal vessels. There is a loss of RPE cells in the area of atrophy with secondary loss of external neuro-retinal layers. The choriocapillaris may also be absent due to the RPE atrophy. GA typically develops in the eyes with drusen. As drusen fade, focal areas of atrophy may develop in their place; as they expand, GA is formed.

Differential Diagnosis

Differential diagnosis includes, from the most common to less frequent conditions, ▶ central serous chorioretinopathy (CSC), → pattern dystrophy, → cuticular drusen, and → drug toxicity (e.g., chloroquine toxicity.

Neovascular (Wet) AMD

Patients present with complains of sudden or gradual onset decrease in visual acuity, metamorphopsia, and central or paracentral scotomas.

The hallmark of the neovascular AMD is choroidal neovascularization (CNV).

The major clinical features include subretinal fluid (SRF), subretinal hemorrhage, sub-RPE fluid, sub-RPE hemorrhage, hard exudates, serous pigment epithelial detachment (PED), and fibrovascular PED. The overlying retina may show cystoid macular edema (CME).

Choroidal Neovascularization (CNV)

Any disturbance of Bruch's membrane can increase the likelihood that a break will occur, allowing choroidal vessels to grow into that place between the RPE and Bruch's membrane, between the retina and RPE, or a combination of both. Disciform scar represents the end stage of neovascular AMD.

The CNV may be visible as an area of grayish greenish color. Chronic neovascular AMD is characterized by subretinal fibrosis. The location of the CNV is divided into subfoveal (0 μm from foveal avascular zone (FAZ)), juxtafoveal (1–199 μm from FAZ), and extrafoveal (200–2,500 μm from FAZ).

The pathogenesis of CNV is not fully understood. It is generally agreed that angiogenic factors such as VEGF have a primary role in the initiation and growing of CNV.

Pigment Epithelial Detachment (PED)

PED is the result of a process by which the RPE separates from the underlying Bruch's membrane due to the presence of blood, serous exudate, drusen, or a neovascular membrane. PED appears as a smooth, dome-shaped subretinal elevation, with sharply demarcated. The pathogenesis of PED formation is incompletely understood, but most likely it involves penetration of CNV through Bruch's membrane into the sub-RPE space with secondary extravasation of fluid or blood and an increase in hydrostatic pressure that separates the RPE from the underlying Bruch's membrane. Hemorrhage or exudates

may or may not be presented, depending on the presence or absence of associated CNV.

Disciform Scar

An area of subretinal fibrosis or sub-RPE fibrosis. On examination it appears as dull, white fibrous tissue. It can present concomitantly with CNV or replace the latter over time. CNV is accompanied by fibroblasts, resulting thus in a fibrovascular complex that proliferates within the inner aspect of Bruch's membrane. This fibrovascular complex can disrupt and destroy the normal architecture of the choriocapillaris, Bruch's membrane, and the RPE. In addition, fibroglial and fibrovascular tissue can also disrupt and destroy the normal architecture of the photoreceptors and remaining outer retina. Ultimately, this process results in a disciform fibrovascular scar that replaces the normal architecture of the outer retina and leads to permanent loss of central vision.

Differential Diagnosis

Differential diagnosis includes, from the most common to less frequent pathologies, CNV caused by other conditions (i.e., ocular histoplasmosis syndrome, pathologic myopia, choroidal rupture, ▶ angioid streaks, or idiopathic), → polypoidal choroidal vasculopathy, and → choroidal tumors.

Genetics

AMD is a multifactorial disease; there are several known genes thought to be involved, including complement-related genes such as complement factor H, factor B, complement component 2, and complement C3. Other genetic factors that increase the risk for AMD include chromosome 10q26, inflammatory genes CXCR1 and TLR4, extracellular matrix fibulin, CST3, and MMP-9, and other genes that are involved include LPR6, VEGF, VLDRL, ACE, MnSOD, and EPHX1.

Risk Factors

- Age – the strongest risk factor.
- Race – Caucasian race is a risk factor.
- Heredity.
- Cigarette smoking.
- Possible risk factors include female gender, higher level of education, light iris color, hyperopic eyes, cardiovascular disease, hypertension, dyslipidemia, sunlight exposure, dietary fish intake, and alcohol consumption.
- Not associated with AMD – diabetes.

Imaging

Fluorescein Angiography (FA)

FA plays a critical role in the diagnosis and management of AMD. In the past FA was crucial in localizing and guiding both laser and photodynamic therapy (PDT). Nowadays, FA is useful in confirming the cause of exudative findings.

Patterns in non-neovascular AMD:

- Hard drusen appears as hyperfluorescent spots due to a transmission defect resulting from RPE thinning over the surface of the drusen. FA often reveals a greater number of hard drusen that can be seen clinically.
- Soft drusen form a shallow elevation of the RPE; thus during the early phase FA, there is a faint increasing hyperfluorescence of the drusen with no signs of leakage.
- Basal laminar drusen appears as a "starry sky," a multitude of tiny hyperfluorescent spots from multiple transmission defects.
- Focal hyperpigmentation appears as a blocked fluorescence on FA.
- GA does not hyperfluorescence in early phases due to loss of underlying choriocapillaris. In later phases there is a well-defined hyperfluorescence from staining of the exposed deep choroid.

Patterns in neovascular AMD:

- The angiographic appearance of CNV is governed by the density and maturity of the vessels and by the intervening tissue.
- Classic CNV is seen as a bright early hyperfluorescence lesion, almost immediate, and also has well-demarcated boundaries. This corresponds to a relatively acute growth of

vessels that break through Bruch's membrane and the RPE and then proliferative above the RPE in the subretinal space. There is prominent leakage and eventually the vessels and their borders become obscured by the leakage.

- Occult CNV is defined by a fibrovascular PED in which abnormal vessels remain beneath intact RPE. There are two types of occult CNV:
  - Fibrovascular RPE detachment is seen as a slowly increasing in fluorescence often in a heterogeneous manner. The dye retained in the fibrovascular PED and leakage from the fibrovascular PED can result in the appearance of hyperfluorescence inside the fibrovascular PED, subretinal space, or the retina.
  - In late leakage of undetermined source, there is no early hyperfluorescence, and during the late phase, there is generalized leakage beneath the RPE often either mild to moderate stippled fluorescence.
- Classic and occult CNV can occur in the same lesion. If the lesion is composed of 50% or more classic CNV, it is termed "predominantly classic"; if there is less than 50%, it is termed "minimally classic."

Indocyanine Green Angiography (ICGA)

ICGA is a useful technique for the diagnosis of AMD, especially in the presence of occult CNV. ICG allows better recognition of subtypes of occult CNV.

Patterns in ICGA:

- Serous PED – ICGA reveals a minimal blockage of normal choroidal vessels; thus a serous PED is hypofluorescent on ICG.
- Classic CNV has a similar appearance to that with FA, a bright early hyperfluorescence lesion.
- In occult CNV type 1, the ICGA reveals early vascular hyperfluorescence and late staining of the abnormal vessels.
- Occult CNV type 2 is associated with a serous PED of at least one disk diameter in size.
- Occult CNV is also subgrouped into two types, a solitary area of well-defined focal neovascularization (hot spot) and the other with a larger and delineated area of neovascularization (plaque).

Optical Coherence Tomography (OCT)

Provides cross-sectional retinal images that closely resemble to the histology. In non-neovascular AMD, OCT is able to track changes in drusen volume, morphology, and GA. In neovascular AMD, OCT can illustrate CNV, SRF, and CME. Qualitative and quantitative information provided by OCT are currently used in retreatment decisions:

Patterns in non-neovascular AMD:

- Drusen common pattern is convex and homogenous with internal reflectivity. The photoreceptor layer overlying drusen has shown to be significantly thinned.
- In GA there is an attenuation of the outer retina with loss of the external limiting membrane, the outer nuclear layer is thinned, and there is a posterior bowing of the outer plexiform layer. At the margin of atrophy, two kinds of patterns can be noted – smooth and irregular.

Patterns in neovascular AMD:

- Occult CNV appears as a localized fusiform PED which may be serous or fibrovascular in nature.
- Classic CNV can present as highly reflective fibrovascular tissue with irregular borders between the RPE and Bruch's membrane or above the RPE. It may also present as a localized serous or fibrovascular PED. Disruption of the photoreceptor layer or CME can be observed.
- In general, active CNV (of any type) is associated with the presence of fluid. The fluid can accumulate in the subretinal space, sub-RPE space, or between all layers of the inner retina.

Treatment

Neovascular AMD

Angiogenesis is characterized by a complex cascade of events. The first step in the cascade is vasodilation of existing vessels and increased vascular permeability. This is followed by degradation of the surrounding extracellular matrix, which facilitates migration and proliferation of endothelial cells. After endothelial cells proliferate, they join together to form a lumen, which becomes a new capillary. The vessels subsequently mature and undergo remodeling to form a stable vascular network. The successful execution of this cascade requires a carefully balanced interplay of growth-promoting and growth-inhibiting angiogenic factors. Identified activators of angiogenesis include vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF) families, transforming growth factor (TGF)-α and TGF-β, angiopoietin-l, and angiopoietin-2. Inhibitors of angiogenesis include thrombospondin, angiostatin, endostatin, and pigment epithelium-derived factor (PEDF). Most recent research has focused on VEGF.

VEGF is a homodimeric glycoprotein, which is a heparin-binding growth factor specific for vascular endothelial cells. It can induce angiogenesis, vascular permeability, and lymphangiogenesis. VEGF expression is increased in RPE cells during the early stages of AMD, suggesting that VEGF plays a role in the initiation of neovascularization rather than being secondary to it. In addition, high concentrations of VEGF have been observed in excised CNV from AMD patients as well as in vitreous samples from patients with CNV. There are four major VEGF isoforms: $VEGF_{121}$, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$. $VEGF_{165}$ is thought to be the most pathologic.

Anti-VEGF Therapies

Pegaptanib is an aptamer that binds human $VEGF_{165}$ with high affinity and specificity. Pegaptanib selectively binds to the heparin-binding domain of $VEGF_{165}$ and larger isoforms, preventing ligand-receptor binding. Unfortunately, patients in general still lost vision with pegaptanib therapy, and the use of this drug has dropped as newer anti-VEGF agents have been developed.

Bevacizumab (Avastin) is a full-length humanized murine monoclonal antibody directed against human VEGF-A. Bevacizumab was approved by FDA for the intravenous treatment of metastatic colon cancer; intravitreal injection of bevacizumab is an off-label use.

Ranibizumab (Lucentis) is a recombinantly produced, humanized, antibody (Fab) fragment that binds VEGF. Unlike pegaptanib, ranibizumab binds to and inhibits the biologic activity of all active forms of VEGF-A and their active degradation products.

Aflibercept (Eylea, VEGF Trap-eye) is a recombinant chimeric VEGF receptor fusion protein in which the binding domains of VEGF receptors 1 and 2 are combined with the Fc portion of IgG to create a stable, soluble, high-affinity inhibitor. Aflibercept is designed to inhibit all members of the VEGF family (VEGF-A, VEGF-B, VEGF-C, and VEGF-D) and placental growth factors (PIGF-1 and PIGF-2). Aflibercept binds VEGF-A with a higher affinity than any other anti-VEGF drug.

Additional anti-VEGF drugs are in development.

Regimens of treatment:

- Pro re nata (PRN) or "treat and observe": patients are treated with a loading dose of three monthly injections, followed by as-needed decision to treat. Decision to treat is based on the presence of worsening BCVA, clinical evidence of disease activity on fundoscopy, or OCT evidence of retinal thickening in the presence of intraretinal fluid or SRF.
- "Treat and extend": initially, patients are treated with a loading dose of three monthly injections, and then the interval between injections is gradually increased, until stabilization of the neovascular AMD is achieved. The "treat and extend" is a dosing regimen designed to resolve all the intraretinal fluid

and SRF and to keep the macula "dry" as long as possible with less injections and visits than the monthly dosing.
- Monthly injections: patients are treated with monthly injections, regardless of BCVA, fundoscopy findings, or OCT evidence of retinal thickening in the presence of intraretinal fluid or SRF.
- With aflibercept, patients are treated with a loading dose of three monthly injections and then once every 2 months.

Non-VEGF Pathways

Although anti-VEGF therapies have dramatically improved treatment outcome, many patients still fail to improve in visual acuity. There are other cellular pathways that mediate or modulate angiogenesis, such as angiogenic signaling, endothelial migration, vessel maturation, and fibrosis. Each of these mechanisms can be harnessed or blocked in order to improve the therapeutic effect. In the future, a combined approach targeting multiple pathways is likely to be available.

Laser Photocoagulation

At present, anti-VEGF therapy is the first-line treatment for all subtypes of subfoveal CNV secondary to AMD. In the past, laser photocoagulation based on FA location of the CNV was the therapy of choice for several categories of well-defined CNV. A significant loss in visual acuity occurred over time in most laser-treated eyes.

Photodynamic Therapy (PDT)

PDT is a two-step process that entails systemic administration of a photosensitizing drug followed by the application of light of a particular wavelength to the affected tissue to incite a localized photochemical reaction. This reaction generates reactive oxygen species that can lead to capillary endothelial cell damage and vessel thrombosis. The FDA approved PDT with verteporfin for the eyes with predominantly classic CNV. Although PDT is an improvement over subfoveal laser, on average, patients still lose visual acuity and have minimal visual gain with monotherapy. With the advent of pharmacotherapy, PDT use has dropped considerably.

Non-neovascular AMD

In the Age-Related Eye Disease Study (AREDS), participants were stratified into four categories:

1. No drusen or few small drusen.
2. Extensive small drusen, pigment abnormalities, or at least one intermediate druse in at least one eye.
3. Extensive intermediate drusen, large drusen, or noncentral GA in at least one eye.
4. Advanced AMD or vision loss due to non-advanced AMD in one eye.

Patients were treated with high dose of micronutrient supplements consisting of antioxidants and vitamins (500 mg vitamin C, 400 IU vitamin E, and 15 mg beta-carotene) and zinc (80 mg zinc oxide and 2 mg cupric oxide to prevent zinc-induced anemia).

According to this study, the combination of antioxidant vitamins and zinc was protective against the development of advanced AMD for categories 3 and 4. Patients in categories 1 and 2 had a very low risk to develop advanced AMD.

AREDS-2 studied the effect of adding lutein, zeaxanthin, and omega-3 to the original formula. The study showed that removing the beta-carotene and lowering the zinc did not have an effect on the progression rate. Lung cancer rates were higher in the beta-carotene group, mostly in former smokers who had stopped smoking more than a year before. Lutein and zeaxanthin would be appropriate substitutes for beta-carotene, and they did not cause any increase in the risk of lung cancer. The addition of omega-3 did not reduce the risk of progression. The results led to the recommendation that the AREDS formula be adjusted by the removal of beta-carotene and addition of lutein and zeaxanthin.

Synonyms

Visual agnosia; Visual form agnosia

Definition

A visual agnosia is the loss of ability to visually recognize formerly familiar objects, while there is no defect in vision nor is there any significant memory loss to account for the symptom. Two subtypes include apperceptive visual agnosia and associative visual agnosia. Patients with apperceptive visual agnosia display the ability to see contours and outlines when shown an object, but they experience difficulty if asked to categorize objects. Patients with associative visual agnosia experience difficulty when asked to name objects.

Etiology

Apperceptive visual agnosia is associated with damage to one hemisphere, specifically the posterior sections of the right hemisphere. Associative agnosia is associated with damage to both the right and left hemispheres at the occipitotemporal border.

Clinical Presentation

Patients with apperceptive visual agnosia are unable to distinguish visual shapes and have trouble recognizing visual stimuli and have difficulty with copying images. Patients with associative visual agnosia can describe visual scenes and objects but may fail to recognize them. These patients are typically still able to reproduce an image through copying.

Diagnostics

In order to assess a patient for agnosia, it must first be verified that the individual is not suffering from a loss of vision and that their language and cognitive functions are intact. Copying and matching tasks may help differentiate apperceptive agnosia (unable to match two stimuli that are identical in appearance) from associative agnosia

(unable to match different examples of the same stimuli).

Differential Diagnosis

Vision loss and cognitive degeneration.

Therapy

When possible, the underlying cause is treated (i.e., surgery for brain tumor). Patients with object agnosia may benefit from cognitive-perceptual rehabilitation. This therapy involves teaching the patient other ways to access information, bypassing the damaged pathways. This can include taking advantage of the patient's continued ability to recognize objects using alternate senses, such as taste, smell, touch, and hearing. Patients with visual agnosia often benefit from predictable environments and consistency in task stimuli.

Prognosis

Recovery may be influenced by the type, size, and location of the lesion causing the visual agnosia. Most recovery occurs within the first 3 months but may continue to a variable degree up to a year.

Definition

Neuro-ophthalmic problems are known to occur both in human immunodeficiency virus (HIV) infection and acquired immune deficiency syndrome (AIDS). Central nervous system (CNS) opportunistic infections and malignancies such as lymphoma are the major source of these AIDS-related manifestations, but some are the result of direct effect of HIV on the CNS. Neuro-ophthalmic signs may in fact be the initial manifestation of AIDS.

Optic neuropathy in patients with HIV/AIDS may result from inflammation, ischemia, infection, compression, infiltration, and increased

intracranial pressure (ICP). Inflammation results largely from opportunistic infections. However, the optic nerve may be a direct site of insult of the HIV virus. Primary HIV optic neuropathy however is a diagnosis of exclusion. It may present clinically as papillitis, retrobulbar optic neuritis, or neuroretinitis. Visual loss is variable. Early initiation of highly active antiretroviral therapy (HAART) has been shown to improve vision in some cases. Infectious optic neuropathy may be caused by cytomegalovirus (CMV), toxoplasmosis, herpes simplex virus (HSV) and herpes zoster virus (HZV), syphilis, tuberculosis, and *Cryptococcus neoformans*.

CMV can involve the optic nerve during advanced stages of CMV retinal disease, leading to severe vision loss. Furthermore, this infection carries a poor prognosis because of often irreversible necrosis of the optic disk. Treatment includes high doses of intravenous foscarnet and/or ganciclovir and also with oral valganciclovir.

Toxoplasma optic neuritis can present as papillitis, retrobulbar optic neuritis, and neuroretinitis often with retinochoroiditis.

HSV and HZV may produce acute retinal necrosis (ARN) and progressive outer retinal necrosis (PORN) in patients with AIDS. Disk edema, hyperemia, and atrophy may be seen. Intravenous acyclovir is the first line of treatment.

Syphilitic optic neuritis may present with papillitis, retrobulbar optic neuritis, neuroretinitis, and optic perineuritis. Visual outcomes with treatment remain variable.

Cryptococcus neoformans optic neuritis can produce papillitis, retrobulbar optic neuritis, and optic perineuritis. Prompt administration of intravenous amphotericin b and 5-flucytosine before permanent nerve damage develops may preserve vision, and serial spinal taps to reduce increased ICP may be necessary to treat cryptococcal papilledema.

Optic neuritis has also been reported with mycobacterium tuberculosis, histoplasmosis, hepatitis B, and *Bartonella henselae*. Papilledema may develop in AIDS patients from raised intracranial pressure from CNS infections or neoplastic processes. Optic nerve sheath fenestration has been used to preserve vision in cases of papilledema (e.g., cryptococcal meningitis).

Visual field defects in HIV may be due to optic neuropathy, and retrochiasmal pathways produce homonymous hemianopia and have resulted from toxoplasmosis, cryptococcosis, cerebral astrocytoma, neurosyphilis, tuberculosis, progressive multifocal leukoencephalopathy, and lymphoma. Cortical blindness and visuospatial abnormalities could result from involvement of the primary or association visual cortices.

Ocular dysmotility in HIV/AIDS can result from nuclear, supranuclear, or infranuclear lesions causing cranial nerve palsies, gaze palsies, internuclear ophthalmoplegia, and nystagmus. Rarely, these symptoms may be the presenting features of HIV/AIDS.

Chronic progressive external ophthalmoplegia-like syndromes may occur in patients with long-standing HIV infection, especially those who have received long-term treatment with HAART Sudhakar et al. (2012).

Pupillary abnormalities seen in HIV/AIDS include RAPD, light-near dissociation tonic pupil, iris abnormalities, and Horner syndrome.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Cerebral akinetopsia; Motion blindness

Definition

An inability to perceive motion in the visual field.

Etiology

Akinetopsia is caused by a lesion in area MT/V5 of the extrastriate cortex. It can also be caused as a side effect of certain antidepressants or due to damage by stroke or Alzheimer disease.

Clinical Presentation

Patients state that their worlds are devoid of or have impaired motion perception. They are able to see stationary objects but cannot perceive moving objects. Generally the faster an object moves, the more difficult it is to see. Visuomotor tasks such as reaching for objects and catching objects may also be disturbed. These patients typically maintain normal spatial acuity, flicker detection, stereopsis, and color vision.

Diagnostics

Basic visual functions should be tested before a patient's symptoms are ascribed to akinetopsia. An examination of visual acuity, spatial contrast sensitivity, and visual fields may be done. General intellect may be measured using the Wechsler Adult Intelligence Scale-Revised (WAIS-III). Testing of motion perception may be done using random dot cinematograms (RDCs). RDCs present a motion signal against a spatially random background and can be designed to test different aspects of motion perception. This is currently generally available only in research settings. It may also be possible to assess motion vision by observing smooth pursuit or optokinetic eye movements.

Differential Diagnosis

Vision loss, cognitive degeneration.

Therapy

There is currently no effective treatment or cure for akinetopsia. In cases of akinetopsia caused as a side effect of antidepressants, vision returns to normal after discontinuation of the drug.

Albinism

Gad Dotan
Department of Ophthalmology, Sourasky Tel Aviv Medical Center, Tel Aviv, Israel

Synonyms

Ocular hypopigmentation; Nystagmus

Definition

Albinism is a genetic impairment of melanin production (melanogenesis) characterized by congenital hypopigmentation of the eyes, skin, and hair (oculocutaneous albinism, OCA) or of the eyes alone (ocular albinism, OA). The inheritance pattern of these conditions is different. OCA has an autosomal recessive transmission, whereas OA is X-linked recessive.

Etiology

In albinism there is complete or partial deficiency of melanin, which is responsible for the natural pigmentation of the skin, hair, and eyes. Melanin is normally produced in the melanosome, an intracellular organelle of melanocytes, which are derived from two embryonic tissues: the neural crest and optic cup. Melanocytes originating from the neural crest are present in the skin (epidermal-dermal junction), hair follicles, and eyes (choroid and iris stroma), whereas melanocytes of the retinal pigment epithelium are derived from the neuroectoderm of the optic cup. Melanin is produced from the amino acid tyrosine. The most important step in this conversion is catalyzed by the enzyme tyrosinase.

Clinical Presentation

The external features of albinism are readily noticeable and include: white skin, white hair, and pink-blue eyes. Ocular features include absence of pigment in the uveal tract and retinal pigment epithelium causing iris transillumination defects and prominence of choroidal vessels, macular hypoplasia, optic nerve hypoplasia, and abnormal retino-cortical projections characterized by increased decussation of optic nerve fibers in the optic chiasm. Reduced visual acuity, nystagmus, photophobia, strabismus, and high astigmatic refractive errors are typically present.

Oculocutaneous Albinism

OCA is characterized by inherited hypopigmentation of the skin, hair, and eyes with an estimated inheritance frequency of 1:28,000 affecting both Caucasians and Blacks. It is classified into three subtypes, designated as OCA 1, OCA 2, and OCA 3. The inheritance pattern of all three subtypes is autosomal recessive.

OCA 1 (OMIM #203100) is tyrosinase-negative OCA. It is caused by a homozygous or compound heterozygous mutation in the tyrosinase gene (*TYR*) on chromosome 11q14. It is divided into two subtypes: OCA 1A (classic tyrosinase-negative OCA) in which there is complete absence of tyrosinase activity and OCA 1B in which there is some degree of residual tyrosinase activity. Patients with OCA 1A have no

capability of producing any melanin during their lifetime or following sun exposure, whereas patients with OCA 1B have no skin, hair, and eye pigmentation at birth, but they can produce some melanin later on in life, causing their skin and hair to mildly darken with age. They can also mildly tan on sun exposure.

OCA 2 (**OMIM** #**203200**) is tyrosinase-positive OCA. This subtype is caused by mutations of the P gene, mapped to chromosome 15q11. This is the most common type of OCA and it has a wide range of phenotypic expression. Although complete absence of melanin pigment is usually present in birth, most patients with OCA 2 acquire small amounts of pigment with age. In Caucasians the skin is typically white and does not tan on sun exposure, the hair is blonde, and the eyes are pink-blue with iris transillumination defects, depending on the degree of iris pigmentation. In Blacks the skin is creamy-white and does not tan and the eyes are blue-gray. Individuals with OCA 2 have the same ocular features of OCA 1, including reduced visual acuity and nystagmus; however, they are typically less severe.

OCA 3 (**OMIM** #**203290**) is caused by homozygous or compound heterozygous mutation in tyrosinase-related protein-1 (*TYRP1*) gene on chromosome 9p23. When first found in Southern African Blacks, it was named "rufous (red) oculocutaneous albinism (ROCA)," because it is characterized by bright copper-red coloration of the skin and hair and dilution of the color of the iris. This subtype is present only in Africans or African American individuals, and some of them do not have the classic features of albinism, such as iris translucency or foveal hypoplasia.

Oculocutaneous Albinism Associated with Systemic Disease

Hermansky-Pudlak syndrome 1 (**HPS1**, **OMIM** #**203300**) is a rare autosomal recessive disorder, caused by homozygous or compound heterozygous mutation in the *HPS1* gene on chromosome 10q24. This syndrome is characterized by the triad of OCA, bleeding, and lysosomal ceroid storage resulting from defects of multiple cytoplasmic organelles: melanosomes, platelet-dense granules, and lysosomes. This syndrome occurs primarily in Puerto Rican individuals, where the estimated frequency of the gene defect is 1:1800. The clinical features of HPS1 include the typical ocular manifestations of OCA accompanied by bleeding diathesis and easy bruisability caused by defective platelet function without a reduction in their counts. The skin is creamy white with some tanning possible on sun exposure. Freckles in sun-exposed areas and pigmented nevi are frequently found. Interstitial pulmonary fibrosis and renal failure are commonly present as a result of the lysosomal storage dysfunction. **Hermansky-Pudlak syndrome 2** (**HPS2**, **OMIM** #**608233**), which includes immunodeficiency in its phenotype, is caused by mutation in the *AP3B1* gene on chromosome 5q14. Other **Hermansky-Pudlak syndromes** (**HPS3 to HPS9**) caused by different gene mutations and a similar phenotypic expression to HPS1 have been found in recent years.

Chediak-Higashi syndrome (**OMIM** #**214500**) is caused by homozygous or compound heterozygous mutation in the lysosomal trafficking regulator *(LYST)* gene on chromosome 1q42. It is characterized by hypopigmentation of the hair and eyes (partial albinism) and increased susceptibility to infection and lymphoreticular malignancies. Large eosinophilic, peroxidase-positive inclusion bodies are present in leukocytes, and neutropenia is frequent. Death often occurs before the age of 7 years.

Ocular Albinism

Ocular albinism type 1 (**OMIM** #**300500**) is the most common form of ocular albinism, caused by a mutation in the *GPR143* gene, mapped to chromosome Xp22. Affected Caucasian males have the ocular features of albinism, including decreased visual acuity, nystagmus, iris hypopigmentation, and macular hypoplasia, with a normally pigmented skin and hair. In contrast to Caucasians, affected Black males can have brown irides with little or no translucency and varying

degrees of fundus hypopigmentation, the so-called nonalbinotic fundus. Heterozygote carrier females usually have punctate iris translucency and a mottled pattern of fundus pigmentation as a result of X chromosome inactivation (lyonization). It is thought that the OA1 protein has a regulatory role in distributing melanosomes between microtubule- and actin-based cytoskeletal elements and its deficiency results in formation of giant macromelanosomes in ocular and skin melanocytes.

Lab Diagnostics

Prenatal diagnosis of albinism is possible.

The degree of tyrosinase activity in hair bulb culture differentiates between OCA 1 (tyrosinase negative) and OCA 2 (tyrosinase positive).

In recent years, optical coherence tomography has been found to be useful for demonstrating foveal hypoplasia in patients with albinism (Izquierdo et al. 2007). Visual evoked potential (VEP) in albinism is typically asymmetric (Russell-Eggitt et al. 1990). Monocular flash stimulation elicits a greater response in the contralateral occipital cortex because 90% of optic nerve fibers cross in the optic chiasm to reach the opposite lateral geniculate nucleus and visual cortex. The asymmetrical VEP and normal Electroretinography (ERG) recorded in infants and young children with albinism permits distinction of this disease from other conditions with whom they may be confused by a clinical examination only, including congenital cone dysfunction and infantile nystagmus syndrome.

Management

Efforts in albinism are made to improve vision with appropriate refractive correction and low-vision aids. Tinted lenses can provide relief from photophobia and glare, and protection from ultraviolet light exposure is also important. Strabismus surgery can be performed when strabismus causes a significant concern (Wright and Strube 2012).

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Alexander's Law states that nystagmus is often increased with the eyes directed toward the fast-phase direction (e.g., downbeat nystagmus is worse in downgaze) compared to the slow-phase direction. This phenomenon occurs frequently in individuals who have an acute peripheral or central vestibular lesion.

It has been proposed that Alexander's Law is an attempt made by the nervous system to

compensate for vestibular lesions that occurs via two different mechanisms. First, there is a gaze-independent component, which is influenced by the vestibulo-ocular reflex. The second component is a gaze-dependent nystagmus which is from unilateral inhibition on the neural integrator. On physical exam, this phenomenon can be reduced by visual fixation.

Synonyms

Disconnection syndrome; Pure alexia; Pure word blindness; Word blindness

Definition

Alexia without agraphia is an acquired inability to comprehend written language as a consequence of brain damage. It is a disorder of written language. A specialized variety of aphasia, this term alexia without agraphia refers to a specific disability in reading where the ability to write is preserved. There may be intact auditory and verbal aspects of language but there is a loss of efficient reading despite adequate visual acuity. It was first described by Dejerine in a patient with an associated incomplete right homonymous hemianopia from a lesion of the left fusiform and lingual gyri. The left angular gyrus stores the visual representation of words (needed for reading and writing), and a disconnection of the visual inputs crossing in the splenium of the corpus callosum of one hemisphere (typically the intact right occipital lobe) from the left angular gyrus could disrupt reading but leave writing intact.

Etiology

The most common cause of this syndrome is ischemic or thromboembolic disease; however, it had also been reported with transtentorial herniation and intra- or extraaxial left occipital region neoplasms (e.g., primary or metastatic tumor, cerebral abscess, demyelinating plaque, vascular malformation, traumatic shear hemorrhage, etc.). Of note it had been also reported with carbon monoxide poisoning and in migraine. Theoretically, any process that affects the splenium of the corpus callosum and related white matter tracts can result in this disconnection syndrome:

- In the case of damage to the left visual cortex and the splenium, words perceived in the right visual cortex are unable to cross over to the language areas in the left angular gyrus and patients will have diminished ability to read.
- Thus, the clinical syndrome of alexia without agraphia is typically due to combined lesions of left occipital lobe and splenium of the corpus callosum and is often caused by ischemic lesions in the distribution of the left posterior cerebral artery.

Clinical Presentation

The key clinical feature is the dissociation between the inability to read and normal writing performance. Patients can write fluently and spontaneously, but typically cannot read what they have written. The disease has a wide range of difference in the clinical presentation which ranges from the milder form in which reading is slow and effortful to the complete lack of reading ability. Words may be read one letter at a time, creating a characteristic "word length effect" with prolonged naming latencies with increasing numbers the number of letters in the word being read. This is referred to as letter-by-letter reading, or spelling dyslexia. On the other hand, in the severe form (global alexia), patients cannot read words or letters or even musical notations or map symbols (i.e., visuographemic alexia).

The ability to name objects may be preserved, and patients with the pure syndrome can recognize objects by using other modalities (e.g., auditory, taste, smell, or even by touch or texture). Spelling and spelling comprehension are typically normal. Theoretically writing should be normal or nearly so; however, subtle defects can usually present (e.g., letters are too large or too widely spaced, an absence or misuse of punctuation, misplaced or inappropriate use of capitals, letters dropped or reduplicated). The syndrome can be seen with acalculia as well.

Pure alexia is often part of a triad: right homonymous visual field defect (from left occipital involvement) and there may be color anomia (impaired naming of colors) or right hemiachromatopsia. Rarely, pure alexia can occur without the hemianopia.

To summarize the clinical criteria for the diagnosis of pure alexia:

1. Severe disturbance of reading comprehension (alexia).
2. Intact and correct writing.
3. Normal oral spelling.
4. Right homonymous hemianopia.
5. Color anomia or hemidyschromatopsia.
6. Verbal amnesia may or may not be present.

Diagnostics

The diagnosis is based on physical examination and detailed language and mental state examination. The laboratory tests required depend on the underlying pathophysiology. Neuroimaging is required to localize and diagnose the cause. Contrast-enhanced cranial CT and MRI are the mainstays of neuroimaging. Neuropsychological testing and speech therapy evaluation may be helpful.

Differential Diagnosis

1. Alexia with agraphia
2. Paralaxia
3. Visual agnosia
4. Amnesia
5. Global aphasia
6. Conduction aphasia
7. Expressive aphasia
8. Receptive aphasia
9. Pure word deafness
10. Thalamic aphasias
11. Subcortical aphasias
12. Transcortical aphasias
13. Right hemisphere language disorders

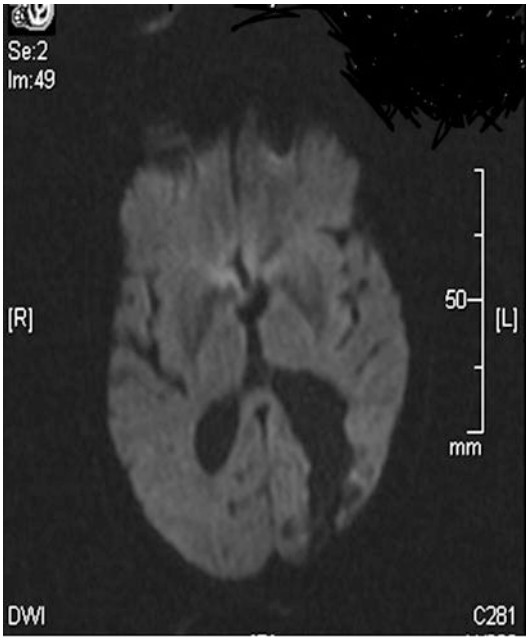
Prophylaxis

NA

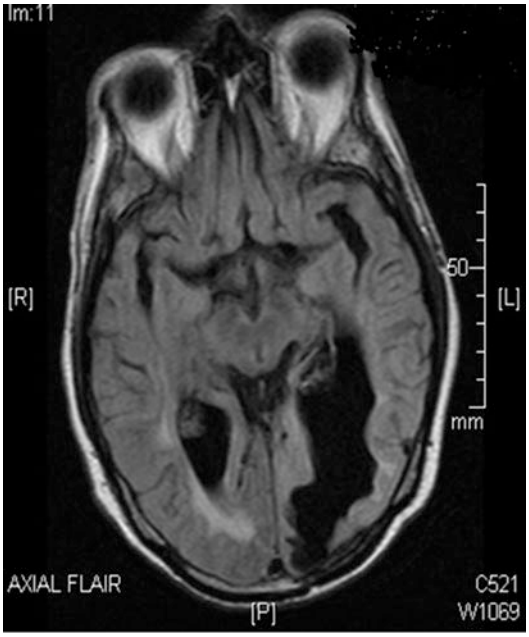
Therapy

The treatment of a patient with depends on the cause of the alexia, without agraphia, e.g., acute stroke, tumor, or infections. Speech and language therapy is the mainstay of care for patients with alexia, without agraphia.

The use of remediation program consists of training by head turning to compensate for a right homonymous hemianopia visual field defect, letter-by-letter reading out loud, practice in naming objects, and drill with flash cards. Speech and language therapy may improve clinical outcome, and psychological support is



Alexia, Without Agraphia, Fig. 1 Cranial diffusion weighted imaging (DWI)



Alexia, Without Agraphia, Fig. 3 T2-fluid attenuation inversion recovery (FLAIR) sequence axial MRI (Figure 3) show an area of encephalomalacia in the left occipital cortex corresponding to the clinical symptoms of alexia without agraphia in a patient with a right complete homonymous hemianopsia after remote occipital stroke

Allergic Conjunctivitis

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Conjunctivitis; Eye allergies; Ocular allergies; Perennial allergic conjunctivitis; "Pink eye"; Seasonal allergic conjunctivitis

Definition

Inflammation of the conjunctiva due to allergic exacerbation (Bielory and Friedlaender 2008)

Etiology

Allergic conjunctivitis is caused by external allergens that come into contact with the eye (Haq et al. 2012). Allergens can include environmental exposure or medications applied directly to the eye. Examples include pollen, dusts, molds, spores, animal dander, cosmetics, industrial chemicals, eye drops (e.g., artificial tears), glaucoma drops, and ointments.

Allergic conjunctivitis can present acutely, seasonally, or perennially.

Acute presentations are triggered by a transient presentation of an allergen, e.g., animal dander. Symptoms tend to resolve within 24 h of allergen removal (Bielory and Friedlaender 2008).

Seasonal forms tend to coincide with pollen seasons varying with geography. Seasonal conjunctivitis is the most common type and typically occurs during the spring and summer months, with increased levels of airborne environmental allergens.

Perennial allergic conjunctivitis tends to display mild, chronic symptoms that are linked to long-standing allergens, such as animal dander, dust, or molds.

Clinical Presentation

Common presentations are sudden onset of itchy eyes and eyelids, foreign body sensation, watery/mucoid discharge, glassy chemosis, burning, and hyperemia (Haq et al. 2012). Symptoms tend to be bilateral and are not accompanied by pain. It is also often seen as a triad of conjunctivitis, rhinitis, and wheezing (Bielory and Friedlaender 2008). Visual acuity, pupil response, and intraocular pressure remain typically unaffected. Acute viral or bacterial conjunctivitis may present with similar symptoms, however, with more profuse and purulent discharge.

Patients with allergic conjunctivitis may have history of asthma, eczema, or allergies.

Diagnostics (Lab Diagnostics)

Allergic conjunctivitis is a clinical diagnosis. Blood tests or skin tests are not required unless needed in some patients.

Differential Diagnosis

Differential diagnosis includes infectious conjunctivitis, blepharitis, dry eye, microbial keratitis, iritis, and acute glaucoma.

Prophylaxis

Avoidance of known environmental or medical allergens helps to prevent symptom onset (Ono and Abelson 2005).

Patients experiencing frequent attacks (more than 2 days per month) may require prophylactic therapy with topical medicine containing both antihistamine and mast cell stabilizer properties. Efficacy should be assessed after 2 weeks of therapy.

For seasonal/perennial allergic conjunctivitis, prophylactic treatment 2–4 weeks before expected onset of symptoms is recommended.

Therapy

Acute Allergic Conjunctivitis

1. Allergen avoidance.
2. Cold compress to reduce mild symptoms.
3. Treatment if necessary. Combination therapy has been found to be effective in reducing symptoms (Ono and Abelson 2005).

Topical antihistamines are recommended to reduce symptoms of itchiness and watering. Examples include levocabastine, emedastine, and olopatadine

Oral antihistamines are recommended if symptoms persist. However, topical agents are preferred due to fast-acting and fewer side effects.

Examples include fexofenadine, loratadine, and cetirizine.

Vasoconstrictors reduce redness and edema; however, regular use for more than 2 weeks can lead to rebound hyperemia. Short-term or episodic treatment is recommended. Examples include naphazoline-pheniramine and naphazoline-antazoline.

Mast cell stabilizers reduce inflammatory response from mast cells. The effects of these medications last longer than antihistamines. Examples include lodoxamide and nedocromil.

Seasonal/Perennial Allergic Conjunctivitis

1. Prophylactic treatment for expected symptom onset
2. Similar treatment as acute allergic conjunctivitis

Additional therapies for refractive conjunctivitis include immunotherapy, corticosteroids, and topical NSAIDs (e.g., ketorolac). Corticosteroids and topical NSAIDS should be monitored and used only when other medication trials have failed to produce results.

Prognosis

Allergen avoidance provides excellent prognosis for acute allergic conjunctivitis (Ono and Abelson 2005).

Recurrence of seasonal allergic conjunctivitis symptoms occurs annually, though symptom severity may decline after age 50.

Epidemiology

Allergic conjunctivitis affects about 20% of the population annually (Bielory and Friedlaender 2008). Allergic conjunctivitis typically appears in young adults with average age of onset at 20 years. Roughly half of patients also have a personal or family history of allergies, such as asthma, eczema, or allergic rhinitis.

Allograft Rejection

► Subepithelial Graft Rejection

Alport Disease/Syndrome, Renal

Kelly Bui[1] and SriniVas Sadda[2]
[1]Eye Associates Northwest, PC, Seattle, WA, USA
[2]Department of Ophthalmology, Doheny Eye Institute, University of California, Los Angeles, CA, USA

Definition

Oculo-auditory-renal syndrome comprising of glomerulonephritis, sensorineural hearing loss, and ocular findings.

Etiology

Alport syndrome results from a genetic mutation in one of three genes, COL4A3, COL4A4, or COL4A5 encoding for the collagen α3α4α5(IV) found in the basement membranes of the eye (cornea, lens, retina/RPE), cochlea, and glomerulus. Most commonly, the inheritance pattern is X-linked dominant (Xq22.3; COL4A5), although autosomal recessive and rarely autosomal dominant inheritance has been described.

Clinical Presentation

Classic Alport syndrome generally presents in childhood with hematuria, followed by proteinuria, hypertension, and progressive renal failure warranting a need for hemodialysis and eventually renal transplantation in the third decade of life. Ocular findings generally appear in adolescence and often coincide with the onset of high-tone sensorineural hearing loss and renal failure. Classic ocular findings include posterior polymorphous corneal dystrophy (less common), anterior lenticonus, and fleck retinopathy (e.g., dot-and-fleck retinopathy) found in the macula and midperipheral retina. Other ocular findings that have been described include juvenile arcus, microcornea, spherophakia, cataract (anterior polar due to lens capsule rupture), bulls-eye maculopathy, giant macular hole, temporal macular thinning (Ahmed et al. 2013), and vitelliform maculopathy (Fawzi et al. 2009). These ocular findings are similar in the XLD and AR forms of Alport, whereas typically only fleck retinopathy and cataract are found in the AD form. ERG and EOG are typically normal even in the presence of fleck retinopathy (Jeffrey et al. 1994). Subnormal ERGs have been reported in patients undergoing long-term dialysis, and it is unclear whether the subnormal ERG is due to renal disease, long-term hemodialysis, or the RPE basement membrane dysfunction from Alport syndrome. Reported VEP results are variable, ranging from normal to reduced amplitude and increased latency, with subnormal VEP generally found among those with renal dysfunction. The whitish-yellow flecks have been reported in both the superficial and deep layers of the retina. Histopathologic study of normal retina shows that the α3(IV), α4(IV), and α5(IV) collagen chains are present in both the ILM and the RPE basement membrane, even though the ILM is not a true basement membrane. Optical coherence tomography of flecks localizes to the ILM/RNFL layer, rather than the RPE/Bruchs membrane. Segmentation analysis in one study showed that there was thinning of both the ILM/RNFL and RPE basement membrane (Savige et al. 2010). The localization of the flecks to the superficial retinal layers and the often normal ERG and EOG have led some to postulate that perhaps the fleck retinopathy arises from dysfunction of the Mueller cells.

Diagnostics

Clinical suspicion for Alport syndrome should be confirmed with a tissue biopsy, either of the skin or kidney. Diagnosis is based on histologic evidence of abnormalities in the expression of

α3(IV), α4(IV), and α5(IV) collagen in the basement membrane of the epidermis of the skin or the glomerulus of the kidney. Demonstration of lamellation of the glomerulus basement membrane is also diagnostic. It has been recommended that genetic testing be reserved for prenatal screening, when biopsy of the skin or kidney is nondiagnostic or when mode of inheritance needs to be determined.

Differential Diagnosis

Other syndromes involving renal disease and retinopathy includes:

Type II membranoproliferative glomerulonephritis – the retinopathy found in this disease manifests as drusen-like deposits rather than flecks.

Alstrom disease – there is early, severe vision loss in this disease with fundus findings more similar to retinitis pigmentosa rather than fleck retinopathy.

Bardet-Biedl complex disorders – pigmentary retinopathy is found in this syndrome along with systemic manifestations of short stature, obesity, diabetes mellitus, developmental delay, polydactyly, and renal disease.

Senior-Loken syndrome – retinitis pigmentosa in conjunction with familial juvenile nephronophthisis.

Other syndromes involving deafness and retinopathy includes:

Usher syndrome – retinitis pigmentosa with sensorineural hearing loss.

Alstrom disease – pigmentary retinopathy with sensorineural hearing loss, renal insufficiency, short stature, dilated cardiomyopathy, and diabetes mellitus.

Cockayne syndrome – genetic defect in DNA repair leads to this syndrome consisting of pigmentary retinopathy, sensorineural hearing loss, short stature, premature aging, developmental delay, and microcephaly.

Refsum disease – hereditary neuro-cutaneous syndrome arising from defect in peroxisomal enzyme leading to phytanic acid accumulation. Signs include retinitis pigmentosa, anosmia, peripheral polyneuropathy, cerebellar ataxia, and ichthyosis.

Other fleck retinopathies that need to be distinguished from that found in Alport syndrome include Stargardt, fleck retinopathy of Tandoori, retinitis punctata albescens, fundus albipunctatus, and vitamin A deficiency.

Prophylaxis

Genetic counseling and examination of family members should be performed.

Therapy

Treatments for anterior lenticonus and cataract formation include correction of refractive error and lens replacement. The dot-fleck retinopathy is generally asymptomatic. Angiotensin-converting enzyme inhibitors and ARB are used to treat proteinuria and delay the onset of renal failure. Eventually, renal transplantation will be warranted.

Prognosis

Vision generally remains unaffected with dot-fleck retinopathy. Mortality arises from complications relating to kidney disease.

Epidemiology

The prevalence of Alport syndrome has been estimated at 1:50,000 live births. There is no gender predilection, but males are often more severely affected than females. The most common inheritance pattern is XLD (80%), followed by AR (15%) and then AD (5%). Ocular manifestations such as dot-and-fleck retinopathy occur in 85% males with XLAS, and anterior lenticonus occurs in 25% males with the XLAS

(Colville and Savige 1997). PPMD is a rare but well-described ocular finding.

Definition

Alström syndrome (AS) is a poorly understood, rare autosomal recessive syndrome that includes congenital retinal dystrophy leading to blindness, hearing impairment, metabolic syndrome, and other systemic manifestations.

Etiology

Alström syndrome is an autosomal recessive multisystem disorder due to mutations in the *ALMS1* gene. This gene is located on the short arm of chromosome 2 (2p13) and contains 23 exons. The protein is 4,169 amino acids in length and contains a large tandem-repeat domain that makes up about 40% of the entire protein (Hearn et al. 2002). It is ubiquitously expressed and appears to be necessary for function of ciliated cells. Mutations commonly occur in exons 8, 10, and 16, and different mutations appear to cause variable degrees of severity of disease.

Clinical Presentation

The ocular manifestations of AS include severely impaired vision, nystagmus, and photodysphoria by age 15 months. Unfortunately, ultimate vision will likely be at the light perception level by age 15 years. Anterior exam may demonstrate posterior subcapsular cataract. Examination of the fundus early on in the disease course typically reveals narrowing of the retinal vasculature. Later, optic nerve pallor and atrophy of the retinal pigment epithelium with increased visibility of choroidal vessels will be seen. The visual fields are generally constricted, and electrophysiologic testing will show progressive cone-rod dystrophy by early childhood (Russell-Eggitt et al. 1998; Malm et al. 2008). Optical coherence tomography of patients with AS demonstrates retinal immaturity and mild changes early, with progressive loss of retinal pigment epithelium and photoreceptors as the disease progresses (Vingolo et al. 2010).

Systemic manifestations of AS involve multiple organ systems (Russell-Eggitt et al. 1998; Marshall et al. 2005). Almost all individuals with AS will have metabolic syndrome – obesity, type II diabetes mellitus with hyperinsulinemia, and hypertriglyceridemia. Obesity is typically present by early childhood and may be exacerbated by the lack of physical activity due to vision and hearing loss. The insulin resistance may ultimately require insulin to control the hyperglycemia. Growth may be accelerated early, but

ultimate adult height will be below the 5th percentile. Affected individuals have wide, thick, and flat feet and short, stubby fingers but no poly/syndactyly as seen in Bardet-Biedl syndrome. Acanthosis nigricans can be present. Sensorineural hearing loss occurs frequently, often complicated by chronic otitis media. Developmental milestones may be delayed because of the sensory deficits that accompany this disease.

Individuals with AS commonly have dilated cardiomyopathy and congestive heart failure. This can occur abruptly during infancy, prior to the other symptoms of AS. These individuals typically survive and may have an interval of normal cardiac function, but then suddenly have a recurrence of heart failure in adolescence or adulthood. Others develop heart failure for the first time as adolescents or adults. Chronic bronchitis or frequent episodes of bronchopneumonia also occur. Hepatic dysfunction begins as silent elevation of liver enzymes and steatosis. This progresses to inflammatory infiltration, to fibrosis, and ultimately to cirrhosis. Hypogonadotropic hypogonadism can be present, with male patients demonstrating small external genitalia and testicular atrophy. Females with AS may present with pubertal delay and signs of hyperandrogenism. No individuals with AS are known to have reproduced. Patients with AS may also have urologic disturbances and progressive renal dysfunction. Renal failure is another common cause of mortality.

Diagnostics

Diagnosis can be made based on the clinical presentation. Diagnostic criteria vary according to age, but generally include poor vision with nystagmus or photophobia, abnormal electrophysiology, obesity, type II diabetes mellitus, and dilated cardiomyopathy or congestive heart failure. A family history may be present. Genetic testing by sequencing the *ALMS1* gene can be positive in up to 70% of cases.

Differential Diagnosis

In infants and children presenting with poor vision and associated nystagmus/photophobia, the differential diagnosis includes Bardet-Biedl syndrome (BBS), congential achromatopsia, Leber's congenital amaurosis (LCA), and Alport syndrome. The following features help distinguish AS from these conditions.

Bardet-Biedl Syndrome (*BBS*): Individuals with BBS have a similar clinical picture to AS, including vision loss, short stature, obesity, type II diabetes mellitus, and renal disease. Patients with BBS typically have mental retardation and poly/syndactyly, which are not features of AS. Their vision loss is generally not as severe as in AS. Moreover, dilated cardiomyopathy and sensorineural hearing loss are generally not features of BBS.

Congenital Achromatopsia/Rod Monochromatism: Congenital achromatopsia is a generally stationary retinal disorder with loss of cones but relatively normal rod function. Thus, visual acuity will be diminished but generally does not decrease past the 20/200 level. Clinical exam may show minimal retinal abnormalities. The electroretinogram will exhibit nearly absent cone response but nearly normal rod response. The systemic findings of AS such as obesity, metabolic syndrome, and cardiomyopathy are not characteristic of congenital achromatopsia.

Leber's Congenital Amaurosis: Leber's congenital amaurosis is a multigenic disease. The clinical exam in LCA is variable. Similar to AS, patients with LCA will have profound vision loss. They may also exhibit oculo-digital behavior. The electroretinogram will show extinguished photopic and scotopic response. Systemic features of AS are not characteristic of LCA.

Alport Syndrome: Alport syndrome is an oculo-auditory-renal syndrome comprised of glomerulonephritis, sensorineural hearing loss, and ocular findings. The ocular findings generally include posterior polymorphous corneal dystrophy and fleck retinopathy. Electroretinogram is generally normal. Alport syndrome does not have the systemic finding of metabolic syndrome, and the vision loss generally appears later than in Alström syndrome.

Prophylaxis

Genetic counseling and examination of family members should be performed.

Therapy

Ocular: Monitoring and supportive therapy, including low vision aids, is recommended.

Systemic: Management of systemic manifestations includes control of blood glucose and triglyceride levels. Individuals with AS should be monitored by appropriate subspecialists, including endocrinology, cardiology, gastroenterology, and nephrology. Genetic counseling for the patient and family members should be initiated.

Prognosis

Unfortunately, ocular prognosis is poor. Patients typically have progressive retinal degeneration with visual acuity decreasing to the light perception range by the teenage years. Mortality is frequently due to complications of cardiomyopathy and renal failure. Organ transplantation for end-stage disease of a single organ is hampered by the systemic nature of this disease.

Epidemiology

- No gender predilection.
- <1:100,000.
- Only about 300 cases have been reported.

Synonyms

Hertwig-Magendie sign; Magendie-Hertwig sign; Skew deviation

Definition

Skew deviation is an acquired vertical strabismus with hypertropia (upward deviation of the eye) in one or both eyes. Skew deviation may be classified into three categories. Type 1 (utricle) skew deviation involves unequal (with different amplitudes) upward deviation of both eyes. Type 2 skew deviation (one eye is hypertropic and the fellow eye remains in primary position) is commonly seen in patients with Wallenberg syndrome, which involves infarction of the dorsolateral medulla oblongata. The excyclotropia of the ipsilateral eye is associated hypertropia of the contralateral eye. Type 3 skew deviation results from damage to the superior portion of the brainstem, such as the pons or medulla. Type 3 skew involves contralateral hypertropia in one eye and ipsilateral hypotropia (downward deviation of the eye) in the other eye.

Etiology

The causes of skew deviation include lesions to the brainstem or cerebellum or damage of the prenuclear vestibular input to the ocular motor nuclei. The most common events which result in skew deviation are brainstem or cerebellar stroke, demyelination, tumor, and head trauma.

Clinical Presentation

Patients with skew deviation typically complain of binocular vertical diplopia but may have other symptoms related to other posterior fossa signs.

Diagnostics

The diagnosis of skew deviation includes a complete eye exam to exclude alternative causes of the vertical deviation (e.g., extraocular muscle, myasthenia gravis). The vertical deviation in skew deviation typically does not localize to any one muscle or nerve innervation and due to otolith innervation. One method for differentiating isolated fourth nerve palsy from skew deviation is testing for torsion. In an ipsilateral fourth nerve palsy, ipsilateral excyclotorsion would be expected, but in skew, there might be bilateral torsion toward the hypotropic eye or other combinations of torsion that do not match for a fourth nerve palsy alone. Another method to potentially differentiate skew deviation from other causes of vertical strabismus is to perform an upright-supine test of the alignment. Patients who have skew deviation instead of another form of vertical strabismus (e.g., fourth nerve palsy) typically report and improvement of symptoms and reduction of the hypertropia when they change position from upright to supine position.

Differential Diagnosis

Other considerations in vertical strabismus include ocular motor cranial neuropathy, neuromuscular disorders, restrictive, and decompensated fusional disorders.

Therapy

Treatment should be directed at the underlying etiology. Patching, prism, or strabismus surgery can be offered as potential treatments.

Prognosis

Depends on the underlying etiology.

Epidemiology

Skew deviation may occur in individuals of any age or gender, but it is most commonly seen in older individuals with a history of vascular problems because ischemia is a common cause of skew deviation.

Synonyms

Superior or inferior altitudinal visual field defects

Definition

An altitudinal visual field defect is a condition in which there is defect in the superior or inferior portion of the visual field that respects the horizontal midline. The altitudinal defect can be unilateral or bilateral. The most common cause of this type of nerve fiber layer visual field defect in adults is glaucoma, but any process that damages the retinal nerve fiber layer can produce an altitudinal visual field defect including retinal vascular damage (e.g., branch retinal artery occlusion), nonarteritic and arteritic anterior ischemic optic neuropathy, optic disk drusen, papilledema, and other lesions producing optic nerve damage. Rarely juxtaposed homonymous quadrantanopic or hemianopic visual field defects can mimic bilateral altitudinal visual field loss. The optic nerve in altitudinal visual field loss may show sector or diffuse edema, be normal, or show optic atrophy. Disk drusen, glaucomatous cupping, optic atrophy, papilledema, or anterior optic neuropathies typically are clinically distinguishable by history or exam.

Amaurosis Fugax

Anat Kesler
Neurology, Neuro-Ophthalmology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Synonyms

Transient monocular visual loss

Definition

Amaurosis fugax (from the Greek *amauros*, meaning dark or *obscure*, and *fugax*, meaning fleeting) is a subtype of transient monocular visual loss attributed to ischemia or vascular insufficiency. Typically, patients describe a painless, diminished, or absent vision in one eye that lasts few minutes, followed by complete recovery. Patients often depict the loss of vision as a shade or curtain that obscures vision in one eye; vision loss may be altitudinal, central, or peripheral (1990).

Most episodes of transient monocular visual loss last 2–20 min and then resolve spontaneously. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) found that the duration of the episodes ranged from 15 s to 23 h, with a median duration of 4 min (Ritter and Tyrrell 2013).

Rarely, patients with amaurosis fugax will complain of transient monocular blindness after exposure to bright light, these patients presenting an inability of borderline ocular circulation to sustain the increased retinal metabolic activity associated with exposure to bright light.

Etiology:

(a) Thromboembolic: some of the events are considered to be due to emboli reaching ophthalmic circulation from ipsilateral common carotid artery and its branches.
(b) Hemodynamic: occurring less frequently, when visual loss is precipitated by change in posture, exercise, or exposure to bright light, and it is most likely due to retinal vascular insufficiency.
(c) Idiopathic: some patients with monocular transient visual loss have no demonstrable ocular or systemic explanation for their symptoms; in some cases the mechanism may be vasospastic.

Diagnostic evaluation: ophthalmic examination, laboratory studies (complete blood count, sedimentation rate screening for hyperlipidemia diabetes, in younger patients search for thrombophilia), and duplex carotid for estimation of the degree of internal carotid stenosis. If the results of duplex are normal, computerized tomography or magnetic resonance imaging is recommended to provide evidence of clinically silent cerebral embolism. The risk of stroke in patients with amaurosis fugax is lower than that associated with hemispheric TIA (2% vs. 8%) (1991).

Treatment: if not contraindicated, antiplatelet therapy with aspirin 81–325 mg should be instituted in all patients with amaurosis fugax to reduce the risk of stroke; often, an aspirin-dipyridamole combination is prescribed, although the addition of dipyridamole is controversial.

Because the risk of stroke after amaurosis fugax is lower than that after hemispheric stroke, the guidelines for management of high-grade >70% internal carotid stenosis differ slightly between these two groups, tending to favor medical therapy for patients with isolated transient monocular visual loss. However, other factors have been used to stratify stroke risk in patients with amaurosis fugax, including male sex, age over 75 years or older, previous history of hemispheric stroke intermittent claudications, and stenosis of 80–94%. Patients with none or only one of these risk factors had a very low 3-year risk of ipsilateral stroke; for patients with three or more risk factors, the stroke risk is increasing to 24.2%. Surgical management – carotid endarterectomy – may have benefit for patients with amaurosis fugax who have three or more risk factors for stroke (Benavente et al. 2001).

Ametropia: Definition

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

Introduction

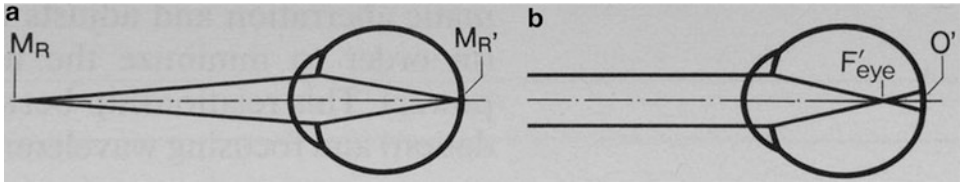
An eye is defined as ametropic if its far point does not lie at infinity. An (infinitely) far object point is then no longer imaged as a point on the retina. If the cornea and the crystalline lens have spherical surfaces, identical optical conditions are present in all meridian planes, and the eye is spherically ametropic.

If, however, the refracted rays only converge in two meridian planes (principal meridians) perpendicular to each other, the eye is termed astigmatically ametropic.

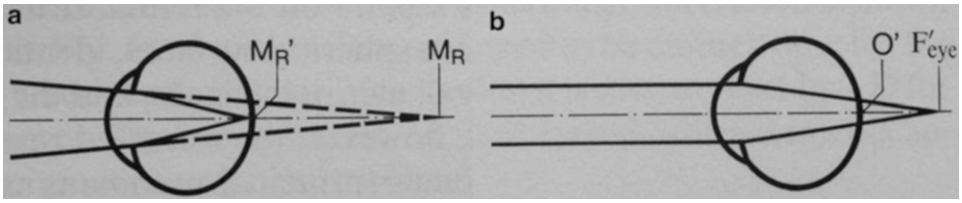
Kinds of Ametropia

Myopia: An eye is defined as myopic if its far point is located at a real finite distance in front of it. Far point refraction is negative: $K < 0$. The myopic eye usually has an overall length which is too long in comparison with the refractive power of the average emmetropic eye (axial myopia). Occasionally, it has a refractive power F_R which is too high in relation to the overall length of the standard eye (refractive myopia). The image-side focal point F'_{eye} of the eye with static accommodations lies inside the eye in front of the retina and an (infinitely) distant object is unsharply imaged in circles of confusion on the retina. As the near point of a myopic eye is also real in front of the eye, the accommodation range is real (Fig. 1).

Hypermetropia: An eye is termed hypermetropic if its far point is virtual behind it. Far point refraction is positive: $K > 0$. The overall length of the hypermetropic eye is usually too short in relation to the refractive power of the average emmetropic eye (axial hypermetropia). Occasionally the refractive power F_R is too low in relation to the overall length of the average emmetropic eye (refractive hypermetropia). The focal point F′eye of the eye with static



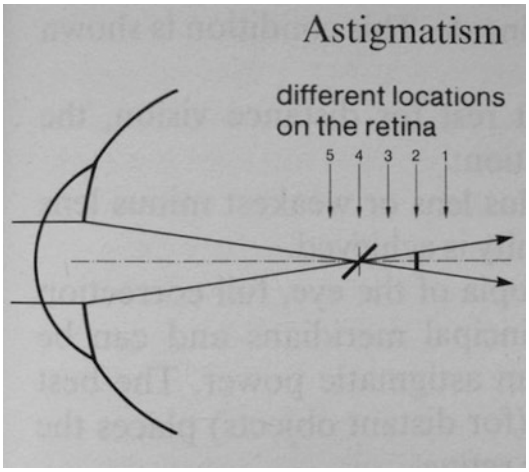
Ametropia: Definition, Fig. 1 Myopic eye (**a**) far point (**b**) focal point



Ametropia: Definition, Fig. 2 Hypermetropic eye (**a**) far point (**b**) focal point

accommodation lies behind the retina, and a (infinitely) distant object is unsharply imaged in circles of confusion on the retina. The location of the near point is dependent on the maximum amplitude of accommodation of the eye. If the latter is smaller than the far point refraction ($\Delta A_{max} < K$), the near point is virtual, and a virtual accommodation range also results. For $\Delta A_{max} = K$ the near point lies at infinity, and for $\Delta A_{max} > K$, the near point is real in front of the eye, with the result that part of the accommodation range is real. Appropriate accommodation increases the visual acuity of a hypermetropic eye, as the focal point then comes closer to the retina (Fig. 2).

Astigmatism: An astigmatically ametropic eye has two different far point locations for the two principal meridians with the refractive powers F_{RI} an F_{RII}. The (first) principal meridian with the higher refractive power F_{RI} is frequently almost vertical. This is astigmatism with the rule (astigmatismus rectus). If the principal meridian with the higher refractive power is almost horizontal, astigmatism against the rule (astigmatismus inversus) is present. In all other directions of the principal meridians, the astigmatism is called oblique astigmatism (astigmatismus obliquus). Each principal meridian itself can be emmetropic, myopic, or hypermetropic, with a line resulting as the image of an (infinitely) distant object. Further designation of the astigmatism is therefore dependent on the position of the two focal lines relative to the retina. Corneal and lenticular astigmatism exist (with corneal astigmatism occurring more frequently). Both together (but not by simple addition) give the total astigmatism. The difference between the total astigmatism and the corneal astigmatism is sometimes called the residual or physiological astigmatism (Fig. 3).



Ametropia: Definition, Fig. 3 Designation of the astigmatism. (*1*) Compound myopic astigmatism. (*2*) Simple myopic astigmatism (astigmatismus myopicus simplex). (*3*) Mixed astigmatism (astigmatismus mixtus). (*4*) Simple hypermetropic astigmatism (astigmatismus hyperopicus simplex). (*5*) Compound hypermetropic astigmatism (astigmatismus hyperopicus compositus)

Synonyms

Purtscher's like retinopathy

Definition

Purtscher's retinopathy is an occlusive microvasculopathy which was first described in 1910 by Otmar Purtscher. The estimated incidence is 0.24 persons per million per year (Ashish and Martin 2006; Retina and Vitreous 2014–2015).

Etiology

Purtscher's retinopathy generally occurs as a result of cranial trauma or thoracic compression. When the etiology is nontraumatic, it is referred to as Purtscher-like retinopathy. Common causes of Purtscher-like retinopathy include acute pancreatitis, renal failure, amniotic fluid emboli, and autoimmune disease (Ashish and Martin 2006).

It is hypothesized to be caused by complement activation which causes granulocyte aggregation and leukoembolism. This process in turn occludes small arterioles such as those found in the peripapillary retina.

Clinical Presentation

Fundoscopic findings include Purtscher flecken (which consists of multiple areas of retinal whitening in the superficial aspect of the inner retina, between the arterioles and venules), cotton-wool spots, retinal hemorrhages (usually flame shaped), and optic disc edema, occasionally accompanied with afferent pupillary defect. The retinal whitening may extend to the edge of an adjacent venule but a clear zone usually exists between the affected retina and an adjacent arteriole. If the retinal whitening encircles the fovea, then a pseudo-cherry-red spot may be seen. These fundus abnormalities are usually confined to the posterior pole.

Without treatment, the above findings may resolve spontaneously within 1–3 months and maybe replaced by mottling of the retinal pigment epithelium, temporal disc pallor, and attenuation or sheathing of the retinal vessels (Ashish and Martin 2006; Retina and Vitreous 2014–2015).

Diagnosis

The diagnosis of these retinopathies is based on clinical findings and supported by fluorescein angiography. Patients usually present with sudden vision loss of variable severity in one or both eyes, hours up to days following the onset of the associated illness. Loss of vision may be accompanied by visual field loss such as central or paracentral scotoma. Peripheral visual function is usually preserved.

Fluorescein angiography (FA) findings include non-perfusion of the smaller retinal arterioles or capillaries, late leakage from the retinal vessels in areas of ischemia, and leakage from the optic nerve (Ashish and Martin 2006; Retina and Vitreous 2014–2015).

Differential Diagnosis

The differential diagnosis includes branch or central retinal artery occlusion, commotio retinae,

and fat embolism (Retina and Vitreous 2014–2015).

Therapy

There are no definite guidelines upon treatment for this condition. One should approach and treat the precipitating illness. Notable improvement of visual outcomes has been reported using high-dose intravenous steroids (Ashish and Martin 2006).

Amniotic Membrane Graft

► Amniotic Membrane Transplantation Nonpharmacotherapy

Amniotic Membrane Transplantation Nonpharmacotherapy

Alan Fremder Utria
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Amnion graft; Amnion transplantation; Amniotic membrane graft

Definition

Amniotic membrane transplantation (AMT) is the use of the innermost layer of the fetal amniotic sac as a graft in ocular surface surgery. The amniotic membrane (AM), also known as the amnion, is comprised of epithelium, basal lamina, and stromal matrix. It is avascular and does not trigger a clinically relevant immunologic response when transplanted. Amniotic membranes are obtained through elective cesarean section and preserved in either a dry or a wet form for later use.

Indication

Indications for the use of amniotic membrane transplantation can be divided into two categories: conjunctival surface reconstruction and corneal surface reconstruction. Defects in the conjunctival tissue most commonly arise from the surgical treatment of a variety of pathological processes, including ocular surface squamous neoplasia, pterygium, symblepharon release, and conjunctivochalasis. To repair these conjunctival defects, first the diseased conjunctiva is removed, and then AM is grafted to provide a suitable scaffold for epithelial proliferation and differentiation. AMT can be used similarly for defects in the cornea. Examples of pathologic conditions that result in corneal defects either directly or indirectly through the treatment of the condition are band keratopathy, bullous keratopathy, tumor excision, and non-healing stromal ulcers. When used to reconstruct the cornea, AM serves the same purpose as when used to reconstruct the conjunctiva, namely, providing a scaffold for corneal epithelium growth. AMT use is also indicated for corneal perforations due to trauma, acute chemical, and thermal burns, as well as for acute Steven-Johnson syndrome (SJS). Ocular surface damage can be quite extensive in cases of thermal/chemical burns and SJS, but as long as there is not a total limbal stem cell deficiency, AMT can prevent scarring, minimize symblepharon formation, and reduce limbal stromal infiltration.

Contraindication

Amniotic membrane transplantation serves as a substrate for limbal epithelial stem cell and

conjunctival epithelial stem cell growth to heal the defect. As the success of the transplant is reliant on the recipient's ability to provide epithelial and mesenchymal cells, amniotic membrane cannot be used in conditions where the limbal and conjunctival epithelial stem cells have been compromised or are absent. Amniotic membrane transplantation can therefore not be used in cases of severe aqueous tear deficiency, diffuse keratinization, absence of blinking in severe neurotropic state, or stromal ischemia.

Techniques and Principles

Amniotic membranes are obtained though elective cesarean section and preserved in either a dry or wet form. All prospective donors are screened for communicable diseases such as HIV, hepatitis, and syphilis. The tissue is cleaned in a mixture of antibiotics and cut into appropriate sizes; a single donor may provide sufficient tissue for 25–50 transplants. The amniotic membrane is then either cryopreserved or freeze dried to produce the wet and dry forms, respectively, which can be used for transplant.

The goal of amniotic membrane transplantation is to reconstruct the ocular surface, reduce inflammation, and promote epithelialization. Depending on the indication, the amniotic membrane can be used as either a patch or as a graft. When used as a patch, the amniotic membrane is temporarily placed over the defect on the surface of the eye and acts as a protective bandage. The patch is secured with the epithelial side up, and it acts as a barrier to the chemical constituents in the tear film. The patch also reduces inflammation through its anti-inflammatory properties. The patch is eventually removed or falls off. When used as a graft, the amniotic membrane is cut to match the defect and is fixed in place with the epithelial side up. This technique enables the amniotic membrane to act as a pseudo-basement membrane, which allows the recipients' own epithelial cells to migrate over the graft leading to faster healing. The graft becomes integrated with the host tissue and is therefore permanent.

Outcome

The outcomes of AMT differ depending on the underlying condition for which it is being used and the degree of inflammation. Most uses of AMT have demonstrated positive outcomes; however, outcomes from its use in conditions such as bullous keratopathy still remain controversial.

Complications

The most serious complications associated with amniotic membrane transplantation are failure to obtain the desired results or recurrence of the original defect requiring subsequent transplantation. The membrane may also become loose and fall out, although this can be avoided by suturing it in place or using a bandage contact lens. AMT may result in corneal calcification, which can impair vision. It is also possible that the subepithelial layer of the membrane persists, resulting in some opacification of the visual fields. Complications associated with the surgery itself include infection, suture granuloma, hematoma, and sterile hypopyon.

Amorphous Corneal Dystrophy, Posterior Disease

Allen O. Eghrari
Johns Hopkins University, School of Medicine, Baltimore, MD, USA
Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Posterior amorphous corneal dystrophy

Definition

Posterior amorphous corneal dystrophy (PACD) is a rare, hereditary condition of the posterior stroma resulting in sheetlike opacity, corneal flattening, and thinning of the cornea.

Etiology

PACD has been identified in several families worldwide with a hereditary distribution consistent with autosomal dominant inheritance. Linkage and haplotype analyses have identified a locus at 12q21.33 in a single family with PACD; mutations in candidate genes KERA, LUM, DCN, and EPYC at this locus have been ruled out. Posterior stromal opacity is secondary to disorganization of stromal fibrils; histological studies have shown no evidence of deposition with hematoxylin-eosin, Masson trichrome, or Alcian blue stains. Electron microscopy has shown amorphous extracellular material between stromal lamellae in the anterior cornea, although its visual significance is unclear.

Clinical Presentation

Patients present with bilateral, symmetric corneal opacification affecting the posterior cornea at the level of or slightly anterior to Descemet's membrane. These focal opacities are gray-white and sheetlike in appearance. Areas of clear cornea are interspersed between opacities, which are present paracentrally or peripherally; visual acuity is therefore generally well maintained. Corneal thickness was approximately 453 μm and average corneal curvature 39.1 diopters in the largest series of 20 affected individuals in a single pedigree. Iris abnormalities are variably present and include corectopia, coloboma, iridocorneal adhesions, and iris atrophy. Endothelium is inconsistently affected, ranging from focal attenuation to normal configuration. Secondary glaucoma may occur.

Diagnosis

The diagnosis of PACD is made clinically with slit-lamp biomicroscopy and can be confirmed with an autosomal dominant pattern of inheritance. Histological examination of corneal buttons submitted during penetrating keratoplasty may be used to confirm clinical findings. No genetic testing is yet available for diagnostic purposes.

Differential Diagnosis

Posterior polymorphous corneal dystrophy (PPCD) is also a posterior corneal dystrophy that can result in epithelialization of the corneal endothelium.

Prophylaxis

There is no known method of prophylaxis at this time.

Therapy

Patients with advanced disease limiting visual acuity may benefit from corneal transplantation. The choice of deep anterior lamellar keratoplasty or penetrating keratoplasty varies based on the distribution of opacities through the stroma and the extent to which Descemet's membrane is affected. Therapy must also be directed toward secondary features such as maintenance of adequate intraocular pressure and correction of refractive error.

Prognosis

Corneal endothelium typically remains intact centrally and patients maintain good vision.

Epidemiology

Rare; prevalence is unknown. PACD has been reported in several families throughout the world, mostly in North America and Europe.

(ABLC); Deoxycholate Amphotericin (D-AmB); Liposomal Amphotericin B (L-AmB)

Definition

Amphotericin B (AmB) is a heptaene polyene antifungal originally discovered as a metabolite of *Streptomyces nodosus*. AmB is a poorly water-soluble compound and has been combined with deoxycholate or placed in liposomes to improve its bioavailability.

AmB is effective against most *Aspergillus* species including *A. fumigatus*, *A. flavus*, and *A. niger*, while *A. Terreus*, *A. nidulans*, *A. ustus*, and *A. glaucus* can show resistance to AmB. This antifungal medication acts by binding to ergosterol, a sterol component of the cell membrane of susceptible fungi. This leads to the formation of transmembrane channels and subsequent ion leakage. Another possible mechanism of action of AmB is through lipoperoxidation of the cell membrane resulting in oxidative damage to the cell.

AmB binds to plasma protein and distributes into the reticuloendothelial tissues and the kidney. Following intravenous infusion of 1 mg/kg of D-AmB, a peak plasma concentration of 2–4 μg/mL is achieved with a half-life of 24–48 h. The recommended dosing regimen of D-AmB associated with minimum risk of systemic toxicity is 0.25–1 mg/kg/day given through a slow intravenous infusion over 2–6 h. In cases of invasive aspergillosis, a salvage therapy is recommended using lipid formulation of AmB. The recommended dose for ABLC and ABCD is 5 mg/kg/day and 3–4 mg/kg/day, respectively, while L-AMB is approved at a dosage of 3–5 mg/kg/day. In animal experiments with endotoxin-induced uveitis, systemic administration of AmB provides intraocular concentrations ranging from 0.47 μg/mL for D-AmB to 0.16 μg/mL for the lipid formulation of AmB.

Due to the low concentration of intraocular AmB obtained following systemic administration, intravitreal injections of (non-liposomal) AmB at doses of 5–10 μg with or without vitrectomy are the treatment of choice in fungal endophthalmitis with vitreous involvement. Intravitreal AmB is used as adjunctive therapy along with systemic antifungal agents in patients who have sight-threatening endophthalmitis caused by *Aspergillus* species. Following intravitreal administration, the half-life of AmB is 7–14 days, reduced to two days in vitrectomized eyes.

Adverse reactions against AmB include infusion-related reactions such as fever, rigors, chills, myalgias, arthralgias, nausea, vomiting, headaches, and bronchospasm. The therapeutic doses of AmB for aspergillosis can induce hepatotoxicity and nephrotoxicity; the latter occurs especially in the presence of concomitant nephrotoxic agents such as cyclosporine and tacrolimus. The risk of renal failure secondary to AmB is also more common in patients with background renal impairment and also patients suffering from diabetes mellitus.

Intravitreal injection of AmB at doses higher than the recommended dose has been reported to cause retinal toxicity, retinal detachment, and cataract although retinal toxicity has been documented even with intravitreal injections of 1 μg.

Even now, most of the information regarding the effectiveness and treatment outcome of AmB in *Aspergillus* endophthalmitis comes from case reports and series. Favorable response to intravitreal injection of AmB has been observed in some case reports of patients with *Aspergillus* endophthalmitis. However, poor visual outcome can still occur despite repeated intravitreal AmB injection combined with vitrectomy.

[2]Department of Ophthalmology, Oculoplastic and Orbital Institute, Tel Aviv University, Tel Aviv, Israel
[3]Department of Ophthalmology, Tel Aviv Medical Center (Ichilov) and Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Definition

Amyloidosis encompasses a spectrum of disorders characterized by the abnormal deposition of insoluble protein aggregates. Amyloidosis can affect any organ and may be a localized or systemic disease. Ocular amyloidosis includes the orbit, extraocular muscles, conjunctiva, cornea, iris, trabecular meshwork, lens, vitreous, retina, and choroid. Ocular amyloidosis is a rare cause of vitreous haze and should be included in the differential diagnosis of vitreous opacification. The incidence of vitreous opacities in amyloidosis varies from 5.4% to 35%.

Vitreous amyloidosis manifests as "lacy," "cobweb-like," "sheet-like," or "stringy" veils of gray or yellowish-white material in the vitreous. It is frequently visually significant. Most cases show an initial retinal tuft adjacent to retinal vessels followed by secondary vitreous involvement. Bilateral disease is typical, but unilateral or highly asymmetric presentations exist. Symptoms include floaters, blurry vision, or glare, although patients may be asymptomatic. Displacement of a vitreous veil into the visual axis may manifest an acute decrease in visual acuity. Vitreous amyloidosis frequently arises in the setting of neuropathic heredofamilial systemic disease and is often accompanied by multiple organ involvement. Mutations in transport protein transthyretin (TTR), also known as prealbumin, are responsible for the majority of cases. Amyloidosis involving the vitreous has rarely been observed in nonfamilial cases. Differential diagnosis includes asteroid hyalosis and chronic (dehemoglobinized) vitreous hemorrhage. Diagnosis is made by a diagnostic vitrectomy with vitreous biopsy. The gold standard is Congo red staining which demonstrates apple-green birefringence when viewed through crossed polarimetric filters. In patients with visually significant vitreous amyloidosis, vitrectomy has been used with satisfactory results. Recurrence is common in the presence of systemic disease. Glaucoma may develop concurrently with vitreous amyloidosis or follow an independent time course. Filtering surgery may be indicated at the time of vitrectomy or at any time postoperatively. Direct seeding of the trabecular meshwork during surgery has been theorized as a possible mechanism for elevation in intraocular pressure. Based on the theory that the retinal pigment epithelium (RPE) is responsible for production of amyloidogenic transthyretin, panretinal photocoagulation (PRP) is being investigated as a possible therapy for recurrence of vitreous amyloidosis deposits. Most cases of vitreous amyloidosis are part of systemic amyloidosis. A therapy for systemic amyloidosis is needed. The treatment is typically managed by a rheumatologist. Conventional treatment includes prednisone and melphalan. Other agents include dexamethasone, thalidomide, etanercept, glycosaminoglycan analogues, and various types of targeted immunotherapy.

Analgesic Rebound Headache

Andrew G. Lee[1,2,3,4,5], Khurrum Khan[4], Sumayya J. Almarzouqi[1] and Michael L. Morgan[1,6]

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Drug-induced headache; Medication misuse headache; Medication overuse headache; Rebound headache

Definition

Analgesic rebound headache may be caused by any medications used to treat headache including triptans, ergotamines, opioids, and other analgesics. Analgesic rebound headache typically results from the chronic overuse of analgesics for headache relief and is defined as a headache that has started or has worsened from the use of analgesic medications. This condition is primarily seen in individuals who have a chronic headache disorder, such as migraine, and take analgesics for pain relief more than two to three times per week for a period of more than 3 consecutive months. Analgesic rebound headache may even interfere with the proper treatment of an underlying chronic headache disorder.

Etiology

The exact mechanism for analgesic rebound headaches is not understood. There are a number of factors that may contribute, including sensitization to the medication, genetics, biological influences, and psychological factors. It is important to note that while the overuse of analgesics to reduce headache can cause analgesic rebound headache, the overuse of analgesics for other causes has not been shown to cause headache. Further study is needed to clarify the exact mechanism and identify the specific drug components that trigger this condition. It is often difficult to determine which medications are strictly causative because patients are usually taking more than one medication at a time.

Clinical Presentation

The classic presentation of this disease is a patient who complains of chronic headaches and daily analgesic use. Often, the headaches may seem either caused by or exacerbated by the use of analgesics.

Diagnostics

The diagnosis of analgesic rebound headache is made on a clinical basis and no laboratory examination is necessary. It is important to rule out any organic alternative causes of primary and secondary headache prior to making the diagnosis of analgesic rebound headache.

Differential Diagnosis

When formulating a differential for these patients, one should consider any cause of primary or

secondary chronic headache. Among the primary causes of headache to rule out are chronic tension headache, chronic migraine headache, hemicrania continua, and new daily persistent headache. Some of the secondary causes of chronic headache to rule out include thrombosis of the venous sinuses and giant cell arteritis.

Prophylaxis

Any individual who has a chronic headache condition should be assumed to be at risk for developing analgesic rebound headache. In order to prevent this condition from occurring, medication should be aimed at controlling their underlying disease. Anticonvulsants, antidepressants, antihypertensives, and antihistamines may all be considered. In addition, there are some general strategies that may be employed. A headache diary may be kept in order to identify and avoid any headache triggering factors. Individuals should refrain from taking analgesics more than two times a week, follow a structured sleeping schedule, avoid skipping meals, become physically active, reduce stress, and quit smoking.

Therapy

The first step in the approach of the patient with analgesic rebound headaches is to quickly stop the medication that is suspected to have been overused. Upon stopping the offending medication, withdrawal symptoms may occur. These can last for up to 10 days and may include anxiety, headache, nausea, vomiting, tachycardia, hypotension, and changes in sleep patterns. It is important to educate patients who have rebound headaches that the overuse of medication is what is triggering their headaches and to encourage them to minimize the analgesic medication they have been using to less than 2 days per week or avoid it altogether. A prophylactic medication may be used for patients who have underlying causes of chronic headache, such as migraine, to prevent a flare-up of headaches following withdrawal from analgesics. After the patient has been instructed to discontinue usage of the offending medication, it is critical to follow up with them in order to see if they have actually been compliant and if there have been any new headache occurrences.

Prognosis

Withdrawal therapy has been shown to reduce headache days by 50% and success rates between 60% and 70% have been reported. Patients have the highest risk of relapse during the first year of withdrawal therapy. The risk of relapse has been determined to be dependent upon two main factors: the etiology of the primary headache and the type of medication that was overused. Patients with primarily tension-type headaches have a higher risk of relapse than patients with chronic migraine headache, and patients who overuse analgesics have a higher risk of relapse than those who overuse other medications. Factors such as the duration of analgesic overuse, the duration of analgesic rebound headache, and the use of prophylactic treatment were not shown to have a significant impact on relapse rate.

Epidemiology

Analgesic rebound headache is a growing problem because there is an increasing amount of people that overuse analgesic medications. Studies show that up to 4% of the population engages in analgesic overuse, and between 2% and 5% of the population have chronic headache. Analgesic rebound headache has a prevalence of 1% in the total population and is seen more commonly in women than in men. General risk factors for developing analgesic rebound headache include migraine headache, chronic tension-type headache, chronic headache, and low socioeconomic status. Of the different types of chronic headache associated with analgesic rebound headache, migraine is the most frequent one.

Anatomic Reattachment Surgery, for Retinal Detachment

Sibel Kadayıfçılar and Bora Eldem
Department of Ophthalmology, Hacettepe University School of Medicine, Ankara, Turkey

Definition

It is a surgical procedure to reattach separated neurosensory retina back to the retinal pigment epithelium anatomically. The aim is to close each retinal break. For permanent closure of the breaks, elimination of vitreoretinal traction is mostly necessary.

Indications

Rhegmatogenous retinal detachment, tractional retinal detachment.

Pneumatic retinopexy: Retinal detachment with superior retinal break(s) extending less than 3 clock hours of retina

Scleral buckling: Rhegmatogenous retinal detachment, retinal detachment due to dialysis

Pars plana vitrectomy: Tractional retinal detachment, detachments with significant vitreous opacities, grade C–D proliferative vitreoretinopathy (PVR), macular hole retinal detachment, detachments due to giant retinal tears with PVR, thin sclera

Contraindications

Pneumatic retinopexy: Break(s) in the inferior 4-clock-hours, grade C or D PVR, lattice degeneration, uncontrolled glaucoma, uncooperative patient for head positioning, media opacities preventing complete peripheral retinal assessment

Scleral buckling: Grade D PVR, significant vitreous opacity preventing complete examination of the peripheral retina, sickle cell anemia, significantly posterior breaks, extremely thin sclera

Pars plana vitrectomy: Relatively simple phakic retinal detachment, inferior retinal dialysis

Techniques and Principles

Principles of reattachment surgery for retinal detachment are closure of the break(s), relief of traction, alteration of fluid currents and retinopexy (Williamson 2008). To attain these goals, various techniques can be applied:

Pneumatic retinopexy: Minimally invasive technique involving injection of gas (0.4–0.6 ml sulfur hexafluoride, SF_6, or 0.3–0.4 ml perfluoropropane, C_3F_8) into the vitreous cavity, retinopexy with cryotherapy at the same session, or laser photocoagulation 1–2 days later and head positioning to enable the gas bubble to oppose the break(s). A limbal paracentesis is generally performed before the injection of gas. If there is bullous retinal detachment near an attached macula, to prevent iatrogenic macular detachment, steamroller maneuver of gas is recommended before cryotherapy.

Scleral buckling: Traditionally the gold standard treatment for uncomplicated rhegmatogenous retinal detachment. The purpose is to indent the sclera toward the retina beneath the retinal break to limit the rate of fluid flow to the subretinal space and close the break(s) and to relieve vitreoretinal traction. To seal the break(s), cryotherapy or laser photocoagulation is employed.

The technique involves local or general anesthesia. Depending on the size of the planned buckle, after partial or complete circumferential limbal peritomy, two to four rectus muscles are slung with traction sutures, and sclera is examined for ectatic areas. Whole peripheral retina is examined with indentation and retinal breaks are marked on the sclera. Subretinal fluid may be drained at this stage. Cryotherapy or transscleral diode laser is applied around the edges of the break(s). Appropriate explant and if necessary encircling band are placed and sutured to the sclera. If necessary, air or gas is injected for internal tamponade. Ends of the encircling band are fastened to each other with a Watzke sleeve. Optic nerve head perfusion and position of the buckle are checked, traction sutures are removed, and the peritomy is closed (Sullivan 2013).

Materials that have been used for scleral buckling include fascia lata, human donor sclera, gelatin, hydrogel implants, silicone sponges, solid silicone tires, and bands. The last three are the most preferred materials currently. Selection of the scleral buckling element depends on number, location, orientation, and size of the break(s) and presence of vitreoretinal degeneration. Guidelines for selection can be summarized as follows (Rizzo et al. 2012):

Radial segmental buckling: A single retinal break, an atrophic hole, a flap tear, a large horseshoe tear, two breaks at different quadrants, posterior breaks with or without lattice degeneration

Circumferential segmental buckling: Multiple adjacent retinal breaks, retinal breaks with limited lattice degeneration, anterior retinal breaks, or retinal dialysis

Encircling buckling: Multiple retinal breaks at multiple quadrants, multiple retinal breaks with extensive lattice degeneration, absence of recognized breaks, total chronic detachment with fibrosis

Many surgeons supplement the segmental buckle, either radial or circumferential, with an encircling band.

Pars plana vitrectomy: First reserved for complex retinal detachments with vitreous pathologies, however with developments in sutureless small gauge and wide-field imaging techniques recently became the preferred method even for simple detachments

Standard technique involves creation of three ports through the pars plana, insertion of infusion cannula, core vitrectomy, detachment of posterior vitreous if not already present, peripheral vitrectomy with low suction and higher cutting speed, injection of perfluorocarbon liquid if the detachment is bullous, identifying each break with indentation, internal drainage of subretinal fluid from the original break via fluid-air exchange, retinopexy with endolaser or cryotherapy, air-gas exchange, and closure of the ports. In complex cases silicone oil may be used as the tamponade. Some surgeons add encircling buckle in the presence of widespread peripheral pathology.

Selection of a specific reattachment procedure depends on the type and location of retinal breaks, amount of vitreoretinal traction, and the lens status. All procedures can be used alone, consecutively or in combination.

Outcome

Primary success rate for pneumatic retinopexy was reported to be 74.4%, which increased to 96.1 with further operations (Chan et al. 2008). Ideal case selection and complete peripheral retinopexy for 360° increase the success rate to 97%. Scleral buckling is successful in 74–91% of the cases after a single operation. With further surgeries the ratio increases to 95%. With vitrectomy primary anatomic success is reported to be 74–92.9%. With additional surgeries this ratio increases to nearly 100%. In the scleral buckling versus primary vitrectomy study involving 681 patients, primary reattachment in phakic patients was similar, 73.7% with scleral buckling and 74.9% with vitrectomy, but in aphakic/pseudophakic patients vitrectomy was superior: 60.1% primary reattachment with scleral buckling and 79.5% with vitrectomy (Heimann et al. 2007). Best corrected visual acuity improvement was significantly marked in phakic cases with scleral buckling.

Causes of failure with these procedures are due to missed breaks, new breaks, reopening of a retinal break, inadequate buckle, misplaced buckle, fishmouthing, and most importantly PVR.

Complications

- Scleral rupture/perforation
- Rectus muscle rupture
- Damage to the vortex veins
- Intraocular hemorrhage
- Retinal incarceration
- Retinal perforation
- Iatrogenic retinal breaks
- Subretinal gas
- Fish egging of air or gas
- Trapped air or gas
- Fishmouthing
- Increased intraocular pressure
- Central retinal artery occlusion
- Lid swelling and/or chemosis postoperatively
- Ptosis
- Persistent retinal detachment/recurrence
- Symblepharon
- Anterior segment ischemia/necrosis
- Ciliochoroidal detachment (pre-, intra-, postoperatively)
- Persistent subretinal fluid
- Muscular imbalance/diplopia
- Cystoid macular edema
- Macular hole
- Changes in the refractive error
- Extrusion/infection of buckling material
- Band migration
- Endophthalmitis
- Epiretinal membrane
- Cataract
- PVR
- Phthisis bulbi

Synonyms

15 mg anecortave acetate depot suspension; Anecortave; Retaane

Definition

Anecortave acetate (Retaane, Alcon, Inc.) is an angiostatic cortisone derived from cortisol which has been chemically modified to eliminate all glucocorticoid activity, thereby reducing ocular side effects such as glaucoma and cataracts (Tombran-Tink and Banrstable 2006). Due to lack of efficacy in a phase III clinical study of *age-related macular degeneration (AMD)*, it is no longer manufactured (Albert et al. 2008).

Indication

Although there are currently no official indications for anecortave acetate, it has been used successfully to treat *choroidal neovascularization* (CNV) secondary to AMD and primary open angle glaucoma. In addition, it has been studied as a potential prophylaxis for the progress of dry AMD to wet AMD (Roy et al. 2007).

Contraindication

There are no reported contraindications for anecortave acetate.

Use and Dosage

Though no longer available, anecortave acetate was originally manufactured as a 15 mg (0.5 ml of 30 mg/ml) and 30 mg dose (0.5 ml of 60 mg/ml). It is administered as a single posterior juxtascleral injections at 6 month intervals.

Adverse Reactions

Most adverse reactions associated with anecortave acetate result from the procedure itself. Reported ocular adverse events are cataract, decreased visual acuity, ptosis, eye pain, visual abnormalities, and *subconjunctival hemorrhage*.

Interactions

There are no reported interactions for anecortave acetate.

Anesthesia (Anesthetics), Local

Arti Panchal
Department of Anesthesiology, Medical College of Wisconsin, Milwaukee, WI, USA

Synonyms

Regional anesthesia

Definition

Local anesthesia for ophthalmic procedures refers to the administration of anesthetic agents either topically, intraocularly, or by injection.

Indication

Anesthesia for ophthalmic procedures is indicated to provide analgesia (pain relief) with or without

akinesia (elimination of extraocular motility). The route of administration depends on several factors, including surgeon and patient preference, patient's ability to follow commands, type and length of procedure, and amount of akinesia desired.

Topical anesthesia provides anesthesia of the conjunctiva, cornea, and anterior sclera. Topical anesthesia does not provide any akinesia. Topical anesthesia can be used for short duration procedures such as cataract surgeries. Advantages of topical anesthesia include quick visual recovery, avoidance of injection anesthesia, and lack of need to hold anticoagulation or antiplatelet therapy. Disadvantages may include patient discomfort with intraocular manipulation or pressure fluctuations and eye movements during surgery.

Intraocular anesthesia may be used as an adjunct to topical anesthesia during cataract surgeries, as it provides anesthesia for the intraocular structures such as the iris, as well as reduces the sensation of pressure fluctuations in the anterior chamber.

Injection anesthesia can be delivered by parabulbar, peribulbar, or retrobulbar routes and provides anesthesia to the ocular surface and intraocular structures. Injection anesthesia also allows for a decrease or elimination of the extraocular movements and thus is suitable for patients who are not able to follow commands, for surgeries that require extensive intraocular manipulation, or for lengthy procedures. Injection anesthesia requires that placement of a patch on the eye in the immediate postoperative period. Patients on anticoagulation or antiplatelet therapy may need there therapy discontinued to decrease the risk of a retrobulbar hemorrhage. Parabulbar injections are placed using a subtenon's incision, while peribulbar injections are generally delivered through the skin and orbicularis muscle. Retrobulbar anesthesia consists of placing the anesthetic agent more posterior than a peribulbar injection, into the intraconal region. A properly placed retrobulbar injection provides the most amount of akinesia.

Contraindication

Anesthetic agents are contraindicated in patients with known hypersensitivity to those agents. Contraindications to topical and injection anesthesia also include a perforating or penetrating globe injury.

Use and Dosage

Topical anesthesia can be achieved using solution or gel formulations of anesthetic agents, such as tetracaine, proparacaine, or lidocaine, directly on the surface of the eye. Topical agents include tetracaine (0.5%) and proparacaine (0.5%) drops or lidocaine gel (2%) or Akten TM 3.5% lidocaine gel. Agents used for injection anesthesia, such as lidocaine (1–4%), may also be used topically.

Intraocular anesthesia can be administered by injecting 0.1–0.5 ml of preservative free lidocaine (1%) into the anterior chamber using a paracentesis port.

Injection anesthesia can be administered using lidocaine (1% or 2%) with or without bupivacaine (0.75%). A total volume of 3–5 ml is generally used. Hyaluronidase can be used in conjunction with either of these two agents to facilitate the diffusion of the anesthetic agents through the orbital tissues.

Adverse Reactions

General:

Allergy to anesthetic agent

Topical anesthesia:

Superficial punctate keratopathy

Intraocular anesthesia:
Corneal edema (when anesthetic agents with preservatives are injected intraocularly)
Injection anesthesia:

Retrobulbar hemorrhage
Scleral perforation

Optic nerve or extraocular muscle damage
Oculocardiac reflex
Intravascular injection with CNS affects
Brain stem anesthesia

Interactions

Although drug interactions have been reported with local anesthetics, given the route of administration for ophthalmic cases and the small doses used, the incidence is rare. Adverse reactions are as noted above.

Anesthesia, Cataract

Armin Wolf
Department of Ophthalmology, Ludwig-Maximilians Universität München, München, Germany

Synonyms

Cryoanalgesia; No-anesthesia cataract surgery

Definition

Cataract surgery without the use of anesthetics

Indication

Reserved to very experienced surgeons and moderate cataract in patients with good compliance and contraindication for topical anesthesia.

Contraindication

Mature cataract, expected complications during cataract surgery

Techniques and Principles

A few authors have described this technique. No-anesthesia cataract surgery can only be performed in selected patients (Shah 2010). During surgery, grasping the conjunctiva or sclera with toothed forceps should be avoided. By using clear-cornea incision, there is no need for cautery. Microscope luminance and the power used for phacoemulsification has to be kept as low as possible to avoid heating of the phaco tip.

Although not fully understood, this technique seems to be possible due to anatomic variations of corneal sensitivity: (Nouvellon et al. 2010) in the upper peripheral cornea, there is less density of inervational network and there are more free nerve endings in the horizontal than in the vertical one. As corneal sensitivity is declining by the age, this technique seems to work better in patients >60 years. In addition, there is a number of factors that have influenced on corneal sensitivity such as UV radiation, race, and corneal thickness.

Other no-anesthetic cataract surgery techniques use additionally chilled agents such as cooled eye pads or chilled viscoelastic material.

Outcome

According to a prospective study of Agarwal and colleagues, patients' pain is not differing form topical anesthesia (Pandey et al. 2001). However this study also showed that even though pain score was comparable in both groups the patient's as well as the surgeon's discomfort was higher in the no-anesthesia group of patients.

Complications

There is no study on specific complications using this technique. However, it seems clear that in

case of complications management thereof is difficult.

Aneurysm Retinal Arterial

Maurizio Battaglia Parodi
Department of Ophthalmology, University Vita-Salute, IRCCS San Raffaele Hospital, Milan, Italy

Definition

Retinal arterial macroaneurysm (RAM) is an acquired saccular or fusiform dilation of the arterioles of the retina. RAM typically develops within the first three orders of arteriolar bifurcations, especially at the site of an arteriolar bifurcation or at an arteriovenous crossing. The most commonly reported site for RAM is the superotemporal quadrant with involvement of the superotemporal artery, but also the nasal arteries can be affected, and less commonly the cilioretinal arteries or the optic nerve head vessels can even be involved.

Etiology

RAM is strongly associated with systemic hypertension and atherosclerosis. However, the exact pathophysiological mechanisms leading to the RAM development is not understood yet (Abdel-Khalek and Richardson 1986; Rabb et al. 1988; Brown et al. 1994). The most common hypothesis suggests that arteriosclerosis could lead to progressive fibrotic degeneration of the vessel wall. The consequent decrease in wall elasticity in combination with the elevated luminal pressure could result in the development of an arterial aneurysmal dilation. An alternative hypothesis is that emboli or even intra-arterial thrombosis could determine mechanical damages of the endothelium or the adventitial which predisposes the vessel to aneurysm formation.

Clinical Presentation

The diagnosis of RAM can be occasionally made on routine examination in cases of asymptomatic RAM, but can also be related to the occurrence of a sudden and painless loss of vision. The clinical picture may vary according to the stage of the disease. Classical appearance of RAM is characterized by the detection of a round-oval dilation along the course of a major retinal arteriole. RAM can be asymptomatic, without exudative manifestations, or can also be associated with extensive preretinal, intraretinal, subretinal, and sub-internal limiting membrane hemorrhages (Abdel-Khalek and Richardson 1986; Rabb et al. 1988; Brown et al. 1994). Moreover, other exudative manifestations can be visible, including neurosensory detachment, intraretinal cysts, and hard lipid exudates in a circinate pattern (Battaglia Parodi et al. 2011). The identification of macular intraretinal fluid can originate from RAM apparently located far away from the fovea, and the detection of fluid turns out to be easier using optical coherence tomography techniques. Pulsations of the aneurysm can be appreciated in 10% of cases (Rabb et al. 1988).

Natural History

The clinical aspect of RAM may remain unchanged for many years, but in the long run,

RAM eventually undergoes toward a progressive fibrotic involution. Thus, natural history may vary from the spontaneous obliteration of the lesion to a number of vision threatening complications, including subretinal, preretinal, or vitreous hemorrhages, macular edema, serous macular detachment, macular deposition of hard exudates, epiretinal membrane, macular hole, and branch retinal vein occlusion.

Diagnostics

In many cases, the simple biomicroscopic examination allows the direct identification of RAM. Ophthalmoscopy can clearly reveal a focal saccular or fusiform dilation of the artery affected. Nevertheless, a precise diagnosis may be difficult if secondary exudative manifestations are present or when preretinal, retinal, or subretinal hemorrhages cover the vessel anomaly. In those cases, angiography is indicated. Fluorescein angiography typically identifies that RAM as a round hyperfluorescent lesion along the course of a retinal artery, showing rapid filling of the lesion, and dye leakage throughout the study. When a thick hemorrhage is present, an area of blocked fluorescence around the aneurysm is observed. Indocyanine green angiography may reveal particularly useful in the identification of RAM in cases associated with thick hemorrhage, correctly guiding the laser treatment application. It is noteworthy that a dye leakage can be found even using indocyanine green angiography, revealing the damage to the artery wall.

OCT may unveil the presence of exudative manifestations, including blood, intraretinal cysts, neurosensory detachment, and at times small intraretinal breaks which are detectable on the external surface of neurosensory detachment.

Differential Diagnosis

Many conditions should be differentiated from RAM, including traumatic hemorrhage, branch retinal vein occlusion, idiopathic parafoveal telangiectasia, Leber's miliary aneurysm retinopathy, Coats' disease, radiation retinopathy, von Hippel-Lindau disease, capillary hemangioma, cavernous hemangioma, arteriovenous malformation, diabetic retinopathy, and exudative age-related macular degeneration.

Therapy

Treatment of RAM is controversial. At present there is no general consensus about the indications to the treatment of RAM. Spontaneous obliteration of RAM may occur over the follow-up, but the long persistence of blood or subretinal fluid may lead to progressive photoreceptor damage with consequent visual impairment. More specifically, long-standing subretinal hemorrhage beneath the fovea leads to a progressively impaired visual function. Treatment is generally indicated for symptomatic RAM, which is associated with exudative manifestations involving the fovea (Battaglia Parodi et al. 2011). The most commonly employed approach is direct or indirect laser photocoagulation with visible end point. Conventional laser treatment is generally affective in achieving the obliteration of RAM and the resolution of the exudative manifestations. Nevertheless, several complications may be associated with visible laser photocoagulation for any macular lesion, including enlargement of laser scar, choroidal neovascularization, and subretinal fibrosis. In addition to these complications, arteriolar obliteration, increased retinal exudation, and scarring, with possible retinal traction, have also been explicitly reported as potential sequelae of the conventional laser photocoagulation of RAM.

A different approach can be pursued with the use of subthreshold laser treatment, which minimizes the negative aspects of conventional photocoagulation by reducing the duration of laser exposure and by using a subvisible clinical end point. Subthreshold laser treatment can reach the same anatomical and functional outcomes obtained with conventional laser treatment, but generally requires more time to take affect (Battaglia Parodi et al. 2012).

Laser hyaloidotomy using neodymium-YAG, argon, or krypton lasers for the successful management of subhyaloid hemorrhage has been

reported, even though there is the risk of damage to the macula. In the setting of vitreous hemorrhage, or when the laser fails to induce blood evacuation into the vitreous cavity or the blood pocket is too close to the macula, vitreous surgery may be performed. Submacular hemorrhage can be surgically removed with the help of recombinant tissue plasminogen activator or with a combined approach with pneumatic displacement.

Intravitreal injection of anti-VEGF molecules can accelerate the progressive involution of the RAM, with faster resolution of the exudative manifestations.

Epidemiology

RAM usually develops in patients between 60 and 80 years of age, with higher prevalence in the female gender. Although usually singular and unilateral, RAM can be bilateral in 10% of cases and can also present with multiple aneurysms along the same vessel or on multiple vessels in 20% of cases. Systemic hypertension is the most commonly associated risk factor. Up to 75% of patients have a history of systemic hypertension and clinical or ophthalmoscopic evidence of arteriosclerosis (Rabb et al. 1988). Other risk factors reported in the literature include elevated lipid levels and systemic vasculitis such as polyarteritis nodosa, sarcoidosis, diabetes, rheumatoid arthritis, and Raynaud's phenomenon.

Definition

An aneurysm is classically an abnormal area of dilation in the wall of an artery (but also can affect veins and the heart). A true aneurysm involves all three layers at an antery.

Etiology

There are a number of factors that impact the likelihood of having an aneurysm including trauma, family history of aneurysms, smoking, hypertension, atherosclerosis, syphilis, older age, and genetic conditions that weaken the connective tissue wall of the artery. Examples of genetic conditions that predispose to aneurysm are Marfan syndrome and Ehlers-Danlos syndrome. Aneurysms may be placed into the following categories: aortic aneurysms, brain aneurysms, or peripheral aneurysms. This section will mostly focus on cerebral aneurysms that may present with visual defects.

Cerebral Aneurysms

An intracranial aneurysm can affect any part of the cerebral circulation but typically occurs at the bifurcations. An aneurysm can rapidly expand and rupture producing an intracranial hemorrhage.

Clinical Presentation

The clinical presentation may vary based on the location of the aneurysm and whether or not a rupture has occurred. Patients who have an unruptured cerebral aneurysm may remain asymptomatic until the aneurysm expands to a very large size, impinges on an adjacent structure, causing focal neurologic or stroke-like signs, or ruptures.

Posterior Communicating Artery Aneurysms

Aneurysms at this location may cause an ipsilateral oculomotor nerve palsy because of the close proximity of the posterior communicating artery to the oculomotor nerve in the subarachnoid space. Basilar tip aneurysms might also cause third nerve palsy.

Internal Carotid Artery Aneurysms

Aneurysms at this location may cause compression in the cavernous sinus of ocular motor cranial nerves, or suprasellar lesions may cause compression of the optic nerve or optic chiasm, leading to visual acuity or visual field defects.

Anterior Cerebral Artery Aneurysms

Aneurysms at this location may cause compression of the optic chiasm or the optic nerve, depending on the direction in which the aneurysm extends.

Diagnostics

The usual method utilized to diagnose an aneurysm is neuroimaging. Cranial CT or MRI may be used for screening but in general angiography of some type is necessary for the evaluation of intracranial aneurysms. CT angiography (CTA) and MR angiography (MRA) are less invasive but less sensitive for the detection of aneurysm than standard catheter digital subtraction angiography (DSA).

Differential Diagnosis

On the differential for brain aneurysm are acute stroke, arteriovenous malformation, cerebral hemorrhage, cluster headache, hydrocephalus, and fibromuscular dysplasia.

Prophylaxis

Prophylactic measures are centered on reducing risk factors for developing an aneurysm by lifestyle alterations. Smoking cessation, adoption of a healthy diet, physical activity, and hypertension or hyperlipidemia control are the major methods to reduce risk.

Therapy

Aneurysms may be treated with either surgery, endovascular technique or medical management. Small asymptomatic or incidentally found aneurysms may not require treatment. Symptomatic, larger, or radiographically enlarging aneurysms may require endovascular therapy or surgical clipping depending on clinical circumstance.

Prognosis

The prognosis for patients who have an aneurysm depends on a number of factors and widely varies. Location of the aneurysm, whether or not the aneurysm has ruptured, and whether or not surgery or endovascular therapy is required are important prognostic factors.

Epidemiology

Cerebral aneurysms have an incidence of 2–5%, and up to 1.9% of these patients can experience rupture.

Synonyms

Fibrous papule

Definition

Angiofibromas are tiny, smooth-surfaced papules that are found on the body. They are most commonly seen on the nose and the medial portions of the cheeks, but they may also be present on the chin, forehead, and eyelids. These papules are fibrous tissue composed of collagen and vascular elements of the skin and can vary in appearance, from red or flesh colored on light skin, to reddish brown and dark brown on more highly pigmented skin. While a single angiofibroma is most likely benign, the presence of multiple angiofibromas on the body may suggest that there is an underlying medical condition such as tuberous sclerosis ("adenoma sebaceum") Birt-Hogg-Dube syndrome, or multiple endocrine neoplasia type 1.

A majority of patients with tuberous sclerosis have multiple angiofibromas, which can range anywhere from as few as three to hundreds. Angiofibromas may occasionally be confused for basal cell carcinomas. In order to rule out the aforementioned diseases and determine the type of angiofibroma that is present, biopsy is typically needed. Treatment of an angiofibroma is centered on the lesion's destruction. Shave excision, dermabrasion, electrodessication and curettage, and laser therapy are some of the conventional options that are available for treatment. Recently, it was discovered that topical rapamycin can cause regression of facial angiofibromas and can lead to better cosmetic outcomes as well. After treatment, recurrence of the lesion is not uncommon. Of note, angiofibromas can be highly proliferative during puberty in both males and females. For this reason, if a child has an angiofibroma, treatment may be performed prior to pubertal age in order to prevent further growth from occurring.

Angiography, Fluorescein

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Definition

Sodium fluorescein (molecular weight 376 Da) is an orange-red crystalline hydrocarbon that can absorb photons of light in the blue wavelength (465–490 nm) of light and subsequently emit them in the yellow-green wavelength (520–530 nm) of light (Gass 1997; Johnson et al. 2006) (Fig. 1).

Indication

Sodium fluorescein is used primarily as an intravenous diagnostic agent during ocular angiography to diagnose and treat ocular diseases affecting the retina and choroid. During ocular angiography, it effectively demonstrates the retinal circulation based on its ability to bind serum proteins and remain in the intravascular space following intravenous injection. It can also be used as a topical solution to identify epithelial defects on the corneal surface.

Contraindication

The main contraindication to the use of sodium fluorescein is a history of a severe allergic or anaphylactic reaction to fluorescein. It should be used with caution in patients with severe liver or kidney dysfunction, as its rate of drug clearance may be reduced.

Use and Dosage

During fluorescein angiography, sodium fluorescein is given intravenously as either 3 mL of a 25% concentration or 5 mL of a 10% concentration in a sterile aqueous solution immediately prior to obtaining photographs. For topical use, sodium fluorescein is administered as a 0.25% solution.

Adverse Reactions

Sodium fluorescein is a relatively safe drug but does cause a transient yellowing of the skin and conjunctiva for up to 12 h in all patients. It also produces a transient orange-yellow discoloration of the urine for up to 36 h in all patients. Less common systemic side effects include nausea, vomiting, and vasovagal reactions, which occur in up to 10% of patients. These symptoms can be mitigated in some patients by injecting the intravenous dye very slowly. If sodium fluorescein extravasates into surrounding dermal tissue during intravenous injection, it can produce a local inflammatory reaction which can rarely lead to tissue necrosis. Urticarial reactions occur in approximately 1% of the patients, with less than 1 in every 100,000 patients developing frank anaphylaxis or shock.

Angiography, Fluorescein, Fig. 1 Fluorescein angiography of the ocular fundus

Interactions

Major interactions between sodium fluorescein and other systemic medications are rare. However, free circulating levels of sodium fluorescein may be effectively increased for patients in a protein deficient state.

Synonyms

Knapp streaks or Knapp striae

Definition

Angioid streaks (AS) are irregular radiating jagged lines extending from the peripapillary area into the periphery with an ophthalmoscopic similarity to blood vessels. They result from breaks in calcified Bruch's membrane and may appear in numbers with atrophy in the surrounding area. Fifty percent of patients have associated systemic disorders that include pseudoxanthoma elasticum (PXE), osteitis deformans (Paget's disease), and various blood dyscrasias such as sickle cell anemia, fibrodysplasia hyperelastica (Ehlers-Danlos syndrome), and senile elastosis of the skin. Angioid streaks may lead to the development of choroidal neovascularization (CNV) and macular degeneration (Piro et al. 1983), which can cause severe vision loss.

Disease

Angioid streaks were first described by Doyne in a case presentation to the Ophthalmologic Society of the United Kingdom (Doyne 1889). In 1892, Knapp coined the term angioid streak. Kofler, in 1916, stated that the main changes were at the level of Bruch's membrane (Knapp 1892; Kofler 1917). Anatomopathological correlations by Bock in 1938 and Hagedoorn in 1939 in patients with pseudoxanthoma elasticum confirmed that the angioid streaks represent linear breaks in Bruch's membrane.

Etiology

Histopathologic studies of eyes with AS have shown linear partial breaks of the thickened and calcified Bruch's membrane. Subsequently, a full-thickness defect of Bruch's membrane may occur, followed by atrophy of the surrounding tissues or fibrovascular tissue ingrowth from the choroid. However, the reason why Bruch's membrane becomes calcified spontaneously or otherwise fragile and predisposed to developing cracks is unknown (Doyne 1889). A primary abnormality in the fibers of Bruch's membrane has been suggested to induce a tendency for metal salt deposits (Klein 1947). Significant deposition of calcium, not iron, at Bruch's membrane has been identified in immunohistochemistry and electron microscopy in sickle cell anemia (Jampol et al. 1987). Immunohistochemistry of CNV with AS has also shown calcium deposits in Bruch's membrane (Kazato et al. 2010). Abnormal calcification of elastic tissue is seen in other parts of the body in patients with pseudoxanthoma elasticum, as well as with Paget's disease, sickle hemoglobinopathies, and other systemic disorders (Piro et al. 1983).

Predisposition to AS is often idiopathic or associated with systemic conditions such as PXE, Paget's disease, sickle cell anemia, and Ehlers-Danlos syndrome.

Clinical Presentation

Typically, linear irregular streaks radiate outward from a peripapillary ring to the periphery on ophthalmoscopy. The streaks can be wide or narrow, tapering to a point within a few millimeters of the disk, and can vary in number. They lie deeper than the retinal vessels and have a cracked line appearance. The color of the angioid streaks can range from red to dark brown and generally depends on the pigmentation of the fundus and on the degree of overlying atrophy of the retinal pigment epithelium (RPE). They are almost always bilateral. AS may increase in length and width over time but do not regress. Spontaneous atrophy develops in the vicinity of the AS.

Other associated findings include *peau d'orange* changes, peripheral focal lesions (salmon spots), hemorrhages with or without scarring, and disk drusen that may classically precede the appearance of the streaks (Gass 1997). The peau d'orange term describes the fine, relatively symmetrical, widespread drusen-like, flat, yellowish, and occasionally confluent lesions at the level of the RPE. The mottled fundus appearance is most distinct in the area temporal to the macula but extends throughout the posterior pole and sometimes up to the equator. Visual acuity is not affected by peau d'orange even when the fovea is involved. When identified in an individual, siblings and parents should be investigated for the presence of peau d'orange even in the absence of angioid streaks.

Punctate or reticular macular pigment dystrophies may appear over time. "Comets" are multiple, small, subretinal white crystalline bodies, sometimes associated with a tail of RPE atrophy pointing toward the optic disk. Such comets are located in the fundus mid-periphery or juxtapapillary and are considered highly suggestive for PXE.

Other retinal changes follow focal or blot hemorrhages: salmon patches (typically the healing of subretinal hemorrhage), black dots (the result of metaplasia of the pigment epithelium), and "pearls" (deep white or yellow-white foci 150–300 μ in size, either resulting from subretinal or sub-RPE hemorrhage or from the spontaneous healing of a focal disciform scar). Occasionally, subretinal hemorrhages in the periphery, near the ora serrata, may evolve into discoid metaplasia of the RPE simulating disciform degeneration.

Although the exact prevalence is unknown, AS seem to appear more frequently in white people compared with Asians and black people (Dhermy 1987; Mansour et al. 1993) and can manifest at various ages depending on associated conditions.

Associated systemic disorders were found in half of the cases of angioid streaks using a diagnostic survey (Clarkson and Altman 1982). By far, the most common is PXE (Grönblad-Strandberg syndrome), followed by Paget's disease and sickle hemoglobinopathies. Many other conditions have been reported (Clarkson and Altman 1982) (Table 1).

PXE is a rare autosomal recessive inherited multisystem disease, with mutations in the ABC transporter gene *ABCC6* on chromosome 16 encoding for cellular transport protein, which are responsible for the disease. The basic defect in PXE may be glycosaminoglycans and glycoproteins attached to elastic fibers that cause abnormal collagen synthesis.

PXE affects 1 in 25,000–100,000 people. Angioid streaks are present in approximately 85% of patients with PXE with a variable phenotype (Knapp 1892; Ellabban et al. 2012). They may already be seen in young adults and develop in almost all patients with time (Georgalas et al. 2009). Other ocular associations more commonly noted in cases associated with PXE include

Angioid Streaks, Table 1 Common systemic conditions associated with angioid streaks

Finding	%
PXE	30–50
Paget's disease	10
Hemoglobinopathy	6
Idiopathic	50

optic disk drusen, salmon spots, and peau d'orange.

Paget's disease is a chronic, progressive, sometimes hereditary connective tissue disorder that involves the collagen matrix of the bone. The most significant mutation identified is in the nuclear factor B signaling pathway. In advanced Paget's disease, angioid streaks develop in 10–15% of patients. The incidence is greater in those patients with early onset of symptoms, skull involvement, and an active systemic disease as demonstrated by markedly elevated serum alkaline phosphatase and urinary hydroxyproline.

Angioid streaks appear in 1–20% of patients with any of the hemoglobinopathies, with the incidence increasing with age. The incidence is not related to the degree or stage of proliferative sickle cell retinopathy. Complications, such as CNV or macular degeneration, are uncommon.

Angioid streaks have been found in patients with the Ehlers-Danlos syndrome – a rare autosomal dominant connective tissue disorder with hyperextensible skin and hyperflexible joints caused by an abnormality in the synthesis and metabolism of collagen. Senile elastosis with angioid streaks is considered rare. The other systemic conditions described probably represent coincidental findings.

Diagnosis

Most patients with angioid streaks are asymptomatic unless the macula is involved. Thus, the initial diagnosis is often made on routine ophthalmoscopic examination. In at risk families, a screening examination will reveal characteristic features of AS. However, decrease of vision due to a subretinal hemorrhage after a mild head or eye contusion occurs in up to 15% of patients with AS. The most common and significant complication of AS is the development of CNV.

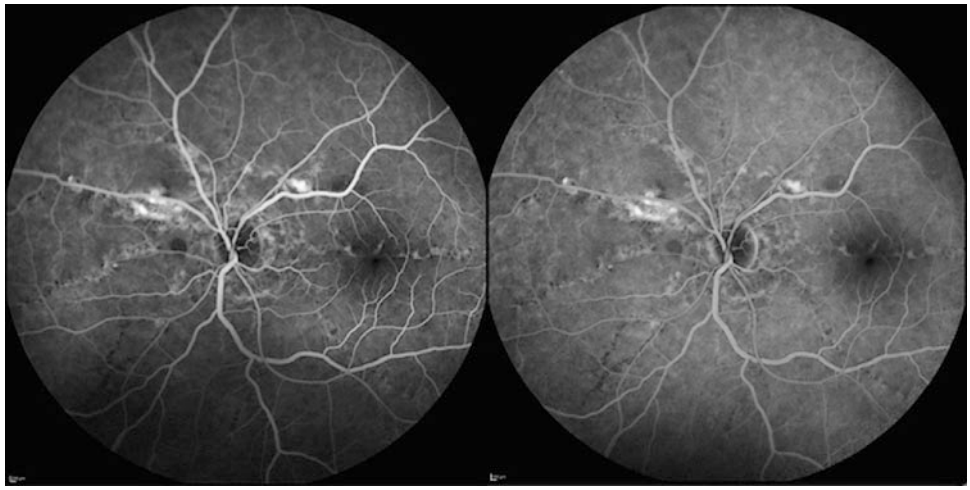
The initial diagnosis of AS requires a diagnostic workup for a systemic disease in the patient but also in the family. PXE has an autosomal recessive inheritance, whereas Ehlers-Danlos syndrome and Paget's disease are autosomal dominant. Senile elastosis, sickle cell disease, facial angiomatosis, and neurofibromatosis also have familial occurrence.

Diagnostic Tests

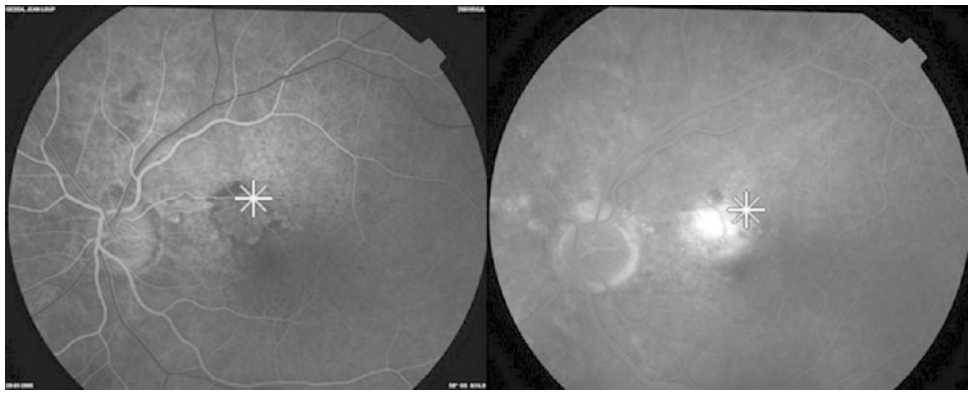
The diagnosis is usually made by clinical examination alone. Fluorescein angiography (FA) confirms or ascertains the diagnosis when the clinical findings are subtle or uncertain. In addition, FA is a critical tool as part of the evaluation in any patient with angioid streaks and visual symptoms to identify associated CNV, which would warrant therapy. Occasionally, FA findings may reveal a streak under CNV that is not clinically observed. Angioid streaks appear irregularly hyperfluorescent on FA due to overlying RPE atrophy with mottled edges from RPE clumping (Fig. 1). The choroidal neovascular membrane usually arising from the border of a macular streak will show a characteristic increase in size and intensity of fluorescence with angiography progression of pre-epithelial CNV, for example, located between the RPE and the photoreceptor the layer (Fig. 2; Nakagawa et al. 2013). Fundus autofluorescence, which is considered to reflect the RPE metabolic activity, varies in relation with the severity of atrophy.

On indocyanine green angiography, angioid streaks are hyperfluorescent on early-phase angiograms (Fig. 3). On late frames, the streaks located at the posterior pole are hyperfluorescent, while those eccentric demonstrate a normal fluorescence. The peau d'orange, rarely visible on FA, stains in a speckled pattern mainly temporal of the macula.

Spectral-domain optical coherence tomography (OCT), which allows for quasi-histologic assessment of the posterior ocular fundus in vivo, has been used to study PXE-related features. Angioid streaks have consistently been found to be associated with breaks in Bruch's membrane, providing the clinical direct evidence of the underlying pathology of AS (Finger et al. 2010). The calcification of Bruch's membrane may induce an increased reflectivity (Fig. 4). Disruption and undulation (inward and outward deformation) of Bruch's membrane on



Angioid Streaks, Fig. 1 Fluorescein angiography of LE with angioid streaks. Early and late phase showed an early central zone of hypofluorescence due to a break in Bruch's membrane, causing a separation of the choriocapillaris. Adjacent light-colored areas were hyperfluorescent, possibly due to abnormal retinal pigment



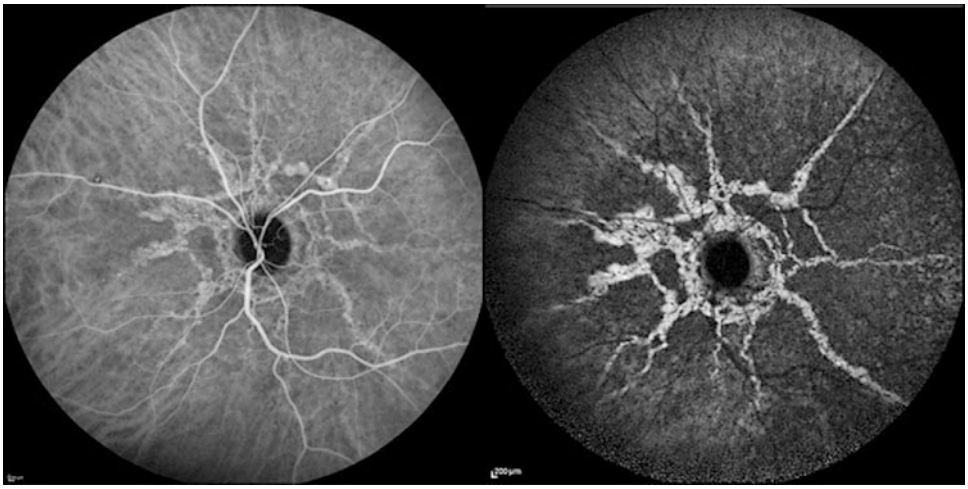
Angioid Streaks, Fig. 2 The left eye at baseline. Early and late phase of fluorescein angiography showed leakage from active subfoveal choroidal neovascularization secondary to angioid streak

OCT are much more frequent in eyes of older PXE patients than in eyes of AMD patients (Connor et al. 1961), adding a clue to differentiate between those two causes for CNV. The transition from calcified to uncalcified retinal areas correlates well with peau d'orange changes (Fig. 5; Finger et al. 2010). Comet tails, which are difficult to record due to their localization, may show hyporeflective spaces in the outer neurosensory retina with a slightly hyperreflective inner lining and focal debris-like deposits just above the RPE level (Finger et al. 2010). Mean subfoveal choroidal thickness is reduced (Gliem et al. 2014).

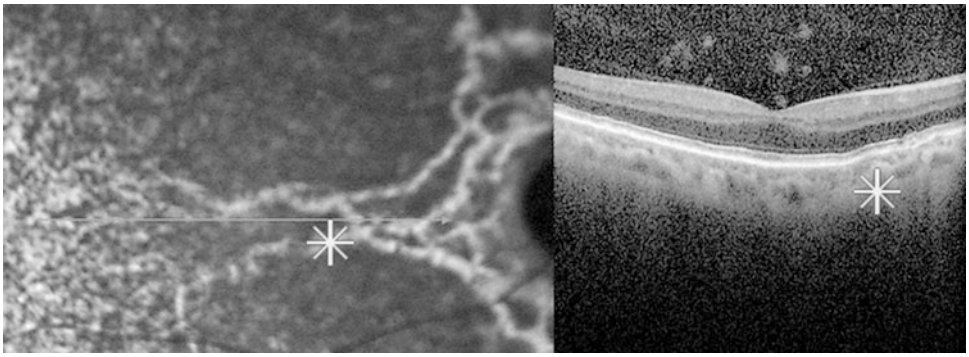
Secondary Complications

AS can cause subretinal hemorrhages from choroidal fibrovascular ingrowth that may spread toward the macula. These hemorrhages can resolve spontaneously. In addition, extensive calcification of Bruch's membrane and AS may progress to severe CNV and disciform scarring.

An estimated 72–86% of patients with AS have CNV at presentation (Connor et al. 1961; Mansour et al. 1988). A British study reported AS-associated CNV affecting mostly young or middle-aged individuals and occurring at an incidence of 0.057 per 100,000 people (Abdelkader



Angioid Streaks, Fig. 3 ICG angiography frames of the left eye. Angioid streaks are hyperfluorescent on early- and late-phase ICG angiogram



Angioid Streaks, Fig. 4 Optical coherence tomography of the left eye. *Asterisks* indicate corresponding angioid streaks on indocyanine green angiogram and on spectral-domain optical coherence tomography. Increased reflectivity is seen within the outer zone of retinal pigment epithelium-Bruch's membrane complex and disruption in the photoreceptor layer

et al. 2013). Pre-epithelial CNV usually occurs on the borders of the streaks in the posterior pole. Occasionally, eccentric CNV may remain unnoticed because of the low impact on visual function. CNV leads to subretinal hemorrhage and exudation and results in the formation of a fibrovascular scar. Overall, classic CNV appears to have a worse spontaneous prognosis with regard to visual function compared to sub-epithelial CNV that is rare in AS (Nakagawa et al. 2013). CNV can be recurrent and lead to progressive visual loss, especially in middle-aged active patients.

Recently, polypoidal choroidal vasculopathy (PCV) was also described in eyes with angioid streaks (Nakagawa et al. 2013). In contrast to classic CNV, these polyps are not located next to the angioid streak. PCV may occur as an initial vascular change or secondary to CNV.

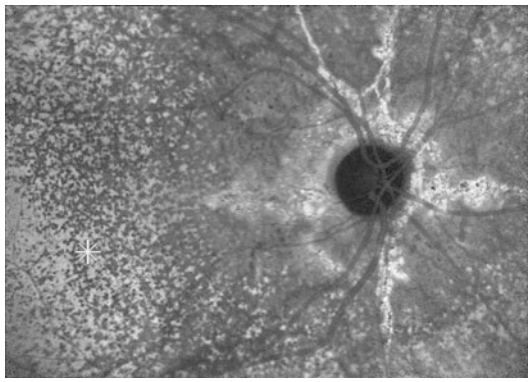
Differential Diagnosis

For differential diagnosis, consider exudative age-related macular degeneration (AMD), choroidal rupture and choroidal folds, toxoplasmosis,

histoplasmosis, retinal vasculitis, myopia and lacquer cracks, choroidal sclerosis, and traumatic subretinal hemorrhage.

Prophylaxis

Initially, patients are mostly asymptomatic and should be advised to wear safety glasses and to avoid contact sports, which could increase the potential risk of subretinal hemorrhage even from relatively mild ocular contusion. Prophylactic photocoagulation treatment of the AS should not be performed as it may induce CNV. Genetic counseling should be considered in some cases.



Angioid Streaks, Fig. 5 Asterisk in ICG angiography indicates the area of peau d'orange, which is characterized by *small dark spots* on a whitish or opaque background (calcified and noncalcified Bruch's membrane)

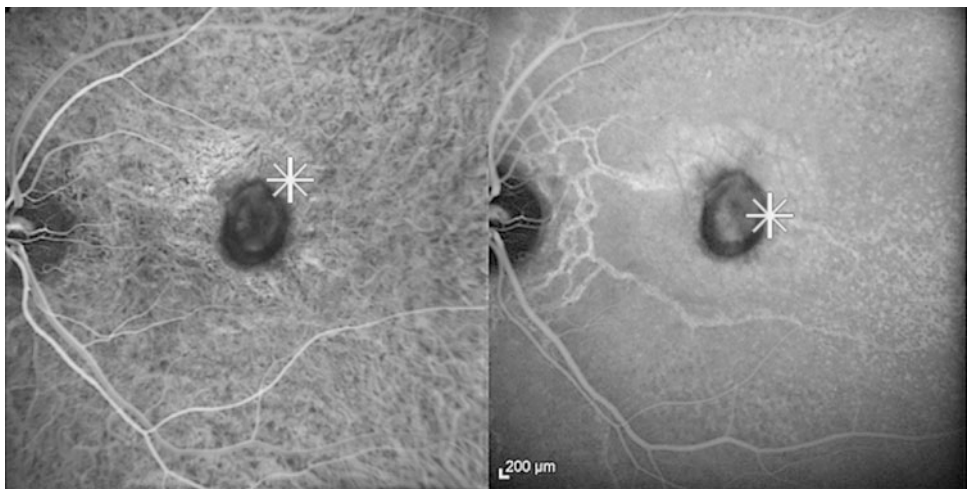
Prognosis

The visual prognosis of eyes harboring angioid streaks depends on the ingrowth of choroidal neovascularization. Subsequent macular degeneration can cause devastating visual loss, especially when bilateral, often leading to visual acuity of 20/200 or worse. Vital prognosis depends on the associated systemic diseases that may be life threatening.

Treatment

Historically, CNV associated with AS has been successively treated with laser photocoagulation, photodynamic therapy with verteporfin, or surgery in short term; however, all developed disappointing functional and long-term results (Pece et al. 1997; Roth et al. 2001).

Recently, some studies have shown the benefits of intravitreal injections of anti-vascular



Angioid Streaks, Fig. 6 At 12-month follow-up after four injections of ranibizumab, indocyanine green angiography confirmed resolution of choroidal neovascularization activity despite persistence of a well-defined, inactive neovascular network, indicated with *asterisk*

endothelial growth factor (VEGF) in small series using bevacizumab (Bhatnagar et al. 2007; Myung et al. 2010). A large retrospective case series showed stabilization of visual acuity using ranibizumab (Mimoun et al. 2010). Ranibizumab is another anti-VEGF agent approved by the FDA for the treatment of all types of CNV due to AMD.

Due to the multiple breaks in Bruch's membrane, CNV may persist, compelling continuous and frequent follow-up of both eyes both during and after treatment periods. Figure 6 demonstrates a case of CNV treated repeatedly with ranibizumab, resulting in an inactive neovascular network after 12 months. Currently, treatment is aimed at slowing the progression of vision loss and recurrence of CNV.

Definition

An angioma is a benign tumor composed of cells of the vascular or lymphatic system. Angiomas can be various in shapes and sizes and present in individuals as they age. The presence of an angioma does not necessarily indicate an underlying disorder. The presence of multiple angiomas, however, is highly suspicious for a systemic disease process. Angiomas can develop on any part of the body, but they are commonly seen close to the skin surface and may cause skin discoloration or nodules. Angiomas can be classified into two groups: hemangiomas if they are derived from cells of the vascular system and lymphangiomas if they are derived from cells of the lymphatic system. The majority of angiomas are harmless and may be left untreated unless they are causing damage to the adjacent tissue. However, retinal angiomas may be a cause for concern because they can involve prominent arterioles or venules of the eye and might suggest von Hippel-Lindau disease.

Angiomatosis is a benign medical condition in which there are multiple angiomas throughout the body, on the skin, or internal organs. One of the notable risks that come with multiple angiomas is that they may rupture and cause internal bleeding. Angiomatosis is associated with a number of diseases, including Von Hippel-Landau disease, bacillary angiomatosis, Klippel-Trenaunay-Weber syndrome, and Sturge-Weber syndrome. Retinal angiomatosis is the most common presenting feature of von Hippel-Lindau disease. Angiomatosis may also be acquired as a result of Bartonella infection, which typically occurs in immunodeficient individuals. This condition is known as bacillary angiomatosis.

Angle Closure

Cornelia Hirn
Eye Clinic, City Hospital Triemli, Zurich, Switzerland

Synonyms

Closed angle

Definition

Angle closure is defined by iridotrabecular contact, followed by reduced outflow of aqueous humor through the anterior chamber angle. Angle closure can occur due to reversible apposition of the peripheral iris to the trabecular meshwork (*acute angle closure*) or due to irreversible peripheral anterior synechiae (PAS) (chronic angle closure). The term *angle-closure glaucoma* is used if glaucomatous optic neuropathy (GON) is present.

Etiology

Angle closure is caused either by anterior ("pulling") or posterior ("pushing") mechanisms, eventually leading to iridotrabecular contact.

In posterior "pushing" mechanisms, the iris is pushed forward from behind due to obstruction of aqueous flow at different anatomical locations: at the level of the pupil with absolute or relative pupillary block (*primary angle closure*, *acute angle closure*), at the level of the iris and ciliary body (*plateau iris configuration*, *plateau iris syndrome*), at the level of the lens (*phacomorphic glaucoma*, *lens-induced angle-closure glaucoma*), or posterior to the lens inducing forward movement of the lens-iris diaphragm (*aqueous misdirection*, *malignant glaucoma*, *uveal effusion*, retinal gas or oil tamponade, tumors, contracture of retrolenticular tissue in *retinopathy of prematurity* and *persistent hyperplastic primary vitreous*). Two or more mechanisms may coexist, although one is usually predominant.

In anterior ("pulling") mechanism, the iris is pulled forward into contact with the trabecular meshwork, either by consolidation of inflammatory products in the anterior chamber angle (*uveitic glaucoma*) or by contracture of membranes in the anterior chamber. Such membranes can be neovascular (in proliferative vitreoretinopathy, *central retinal vein occlusion*, *carotid occlusive disease*, *ocular ischemia*, or chronic retinal detachment), endothelial (in *ICE syndrome* or *posterior polymorphous dystrophy)*, or epithelial (after penetrating trauma or surgery).

The term primary refers to a condition where an anatomic predisposition without any further pathology leads to obstruction of aqueous flow and subsequent angle closure; the term secondary is used if an underlying pathologic cause for obstruction can be identified.

Chronic angle closure may develop after acute angle closure in which synechial closure persists. It may also develop when the anterior chamber angle closes gradually and intraocular pressure (IOP) rises slowly. In such cases, the term creeping angle closure may be used. In chronic or creeping angle closure, slowly, peripheral anterior synechiae advance circumferentially. Multiple "pushing" mechanisms may be involved, including pupillary block, iris changes, and plateau iris configuration.

Clinical Presentation

Most angle closures occur asymptomatically.

A shallow anterior chamber may be a hint at an occludable (or narrow) anterior chamber angle with possible angle closure either primarily in predisposed eyes (*angle-closure suspect*) or secondary to other pathologies.

Manifest angle closure can present as *acute angle closure* with excessive rise in IOP and severe symptoms, like decreased vision, halos, pain in the eye, headache, nausea, and vomiting, or as subacute or intermittent angle closure with mild recurrent symptoms like painless blurry vision. Thus, the sensitivity and specificity of symptoms for identifying angle closure are rather poor.

Signs of previous attacks include a permanently fixed and dilated pupil, sector iris atrophy,

pigmentary dusting of the corneal endothelium, anterior subcapsular lens opacities (so-called glaukomflecken), PAS, and manifest GON.

In chronic or creeping angle closure, PAS cause chronic but modest, asymptomatic elevation of IOP and eventually progressive GON with corresponding visual field defects.

Diagnosis

Angle closure is diagnosed on *gonioscopy*, preferably by indentational gonioscopy, to distinguish between appositional angle closure and PAS. *Ultrasound of the anterior segment* may reveal underlying structural changes of the peripheral iris or ciliary body. Biomicroscopy with accurate assessment of the anterior chamber as well as the posterior segment is mandatory in classifying the various forms of angle closure and angle-closure glaucoma.

Previous ocular and medical history, family history, as well as subjective symptoms should be inquired, and IOP measurements, visual field examination, retinal nerve fiber layer, and optic disk imaging should be performed to assess the stage of disease.

Differential Diagnosis

Shallow anterior chamber without angle closure

Therapy

Treatment varies depending on the etiology of angle closure and the clinical presentation (*acute angle closure*).

In intermittent and chronic angle closure, a laser iridotomy may be the treatment of choice to relieve a pupillary block component and to reduce the risk of further permanent synechiae. In some cases, the disease may nevertheless progress, and the long-term use of topical hypotensive medication or even filtering surgery may be indicated to lower IOP. In *secondary angle-closure glaucoma*, the underlying pathology should be eliminated.

Prognosis

Prognosis depends on the etiology of angle closure and the presence or absence of subsequent damage like GON.

Epidemiology

The prevalence for primary angle closure in populations older than age 40 varies depending on the ethnicity and is highest in Inuit, followed by East Asians and Japanese. Chronic angle closure is more common in black populations.

Angle Closure Secondary to Uveal Effusion

Cornelia Hirn
Eye Clinic, City Hospital Triemli, Zurich, Switzerland

Synonyms

Secondary angle closure glaucoma and uveal effusion

Definition

Uveal effusion is defined by escape of fluid to the choroid and to the potential space between choroid and sclera. This fluid accumulation and forward bowing of the choroid causes a mass effect, resulting in anterior displacement of the lens-iris diaphragm. Eventually, the anterior chamber is flattened and angle closure occurs due to iris apposition to the trabecular meshwork.

Etiology

Uveal effusion is not one clinical entity, but due to a variety of causes.

Idiopathic uveal effusion syndrome is a rare condition with spontaneous choroidal detachment typically in healthy middle-aged men, presumably due to a congenital scleral anomality with abnormal uveoscleral protein transport.

Uveal effusion may also occur secondary to impair of the venous or transscleral outflow. This includes uveal effusion due to inflammation in posterior *scleritis, posterior uveitis,* or in HIV, as well as uveal effusion due to congestion or increased choroidal venous pressure as seen in *nanophthalmos*, after scleral buckling procedures (especially encircling bands), after panretinal laser coagulation, but also in case of *central retinal vein occlusion* and arteriovenous communication.

Uveal effusion is also seen secondary to choroidal tumors. In rare cases, bilateral uveal effusion has been described after systemic medication with either Topiramate or Acetazolamide.

Irrespective of the underlying pathology, uveal effusion is associated with swelling of the ciliary body and anterior rotation of the ciliary body, and subsequent anterior displacement of the lens-iris diaphragm, resulting in anterior chamber flattening and appositional angle closure. Reduced outflow of aqueous results in elevated intraocular pressure (IOP); depending on how long the iridotrabecular contact persists, subsequent glaucomatous damage of the optic nerve head may be seen.

Clinical presentation

One or both eyes may be affected.

A shallow anterior chamber is present, and *angle closure* is verified on gonioscopy.

IOP is elevated; depending on the level of increase, pain, red eye, and blurry vision may be present.

A choroidal thickening and elevation of various degrees is present; often the ora serrata can be visualized without indentation.

A serous retinal detachment with shifting fluid is not uncommon; involvement of the fovea is the main cause of vision loss.

Diagnosis

Angle closure is diagnosed on *gonioscopy*

A significant difference in anterior chamber depth is suggestive of *secondary angle closure glaucoma*.

Ultrasound of the anterior segment may reveal ciliary body swelling and anterior rotation of the ciliary body.

B-scan *ultrasound biomicroscopy* reveals a smooth, convex, elevated membrane limited in the equatorial region by vortex veins and anteriorly by the scleral spur, usually thicker and less mobile than retina.

Tonometry reveals elevated IOP.

Biomicroscopy with accurate assessment of the anterior chamber as well as the posterior

segment is mandatory to identify the underlying cause of uveal effusion.

Refraction and axial length should be measured in patients with suspected idiopathic uveal effusion syndrome or nanophthalmos.

Previous ocular and medical history should be inquired.

Differential Diagnosis

For differential diagnosis of angle closure glaucoma, consider any secondary angle closure with elevated IOP, either neovascular glaucoma, *uveitic glaucoma*, *lens-induced angle closure*, and angle closure due to aqueous misdirection (*malignant glaucoma*).

Choroidal melanoma, multifocal atypical *central serous retinopathy*, and *Vogt-Koyanagi-Harada* disease can also produce choroidal elevation.

Prophylaxis

No prophylaxis is known for angle closure glaucoma secondary to idiopathic uveal effusion.

Therapy

Treatment is on the one hand directed at lowering IOP directly, but on the other hand the underlying mechanism causing uveal effusion should be targeted.

Beside topical hypotensive medication to lower IOP, cycloplegic agents can help deepen the anterior chamber by relaxing the ciliary body. To prevent peripheral anterior synechiae (PAS) in shallow anterior chamber, topical steroids should be administered.

Depending on the underlying cause of uveal effusion, anti-inflammatory therapy may be necessary, as well as drainage of suprachoroidal fluid, or surgical revision of a preceding scleral buckling procedure. In idiopathic uveal effusion, lamellar sclerectomy or sclerostomy may be necessary.

As angle closure secondary to uveal effusion is not associated with a pupillary block mechanism, an iridotomy is not indicated.

Prognosis

Prognosis depends on the etiology of uveal effusion. In most cases, angle closure resolves under correct treatment.

Epidemiology

Idiopathic uveal effusion is usually seen in middle-aged men.

Angle Recession Glaucoma

Christoph Kniestedt[1] and Marc Töteberg-Harms[2]
[1]TAZZ Talacker Augenzentrum Zurich, Zürich, Switzerland
[2]Department of Ophthalmology, University Hospital Zurich, Zürich, Switzerland

Synonyms

Postcontusion glaucoma

Definition

Angle recession glaucoma is a chronic secondary open-angle glaucoma due to a blunt ocular trauma (Blanton 1964; Kaufman and Tolpin 1974; Stamper et al. 2009).

Etiology

Blunt ocular trauma may cause a tear in the ciliary muscle (angle recession). The angle recession itself is not the cause of the glaucoma. It is rather an indicator of previous trauma to the eye resulting in a chronic pressure rise (Blanton 1964; Kaufman and Tolpin 1974; Stamper et al. 2009). Eyes with an underlying tendency for primary open-angle glaucoma are more likely to develop chronic angle recession glaucoma (Stamper et al. 2009).

Clinical Presentation

The onset of a chronic, initially mild to moderate elevation of intraocular pressure might be delayed for months to years (Blanton 1964; Kaufman and Tolpin 1974; Stamper et al. 2009). Chronic angle recession and primary open-angle glaucoma show similar clinical course and treatment (Blanton 1964; Kaufman and Tolpin 1974; Stamper et al. 2009).

Diagnosis

Angle recession is diagnosed by gonioscopy and/or ultrasound biomicroscopy (UBM) (Stamper et al. 2009):

Angle Recession Glaucoma, Fig. 1 On gonioscopical examination an irregular widening of the ciliary band is visible. Sometimes carefully gonioscopy and comparison of both eyes is necessary to detect the changes

- Angle recess might be gonioscopically visible as an irregular widening of the ciliary band (Fig. 1).
- Posterior attachment of the iris root.
- Deep anterior chamber (deeper than in the fellow eye).
- Visible glistening scleral spur (Stamper et al. 2009).
- Torn or absent iris processes.
- Posterior anterior synechiae (PAS) at the border of recession and normal iris root.
- Increased visibility and width of the scleral spur.

However, postcontusion glaucoma may present with variable gonioscopic findings from severe-angle recession to very mild or even absent anatomical abnormalities (Blanton 1964; Kaufman and Tolpin 1974; Stamper et al. 2009).

Differential Diagnosis

Primary open-angle glaucoma, steroid-response glaucoma.

Prophylaxis

Since late onset of pressure rise is possible even years or decades after the initial injury, annual checkups are advisable (Blanton 1964; Kaufman and Tolpin 1974; Stamper et al. 2009).

Therapy

Local antiglaucomatous drugs are the first-line therapeutical regimen (Stamper et al. 2009). Laser trabeculoplasty is often disappointing and of limited use (Stamper et al. 2009). Filtration surgery is an alternative when medical therapy fails (Stamper et al. 2009).

Prognosis

Similar to open-angle glaucoma.

Epidemiology

The risk of developing angle recession glaucoma is 2–10% in eyes after blunt trauma (Blanton 1964; Kaufman and Tolpin 1974; Stamper et al. 2009).

Angle-Closure Glaucoma

Cornelia Hirn
Eye Clinic, City Hospital Triemli, Zurich, Switzerland

Synonyms

Narrow-angle glaucoma

Definition

The term angle-closure glaucoma defines a condition in which elevated intraocular pressure (IOP) due to ▶ angle closure has caused glaucomatous optic neuropathy (GON) and corresponding ▶ visual field defects, although elevation of IOP or peripheral anterior synechiae (PAS) may be absent at the time of initial examination.

Etiology

Primary angle closure occurs in predisposed but otherwise normal eyes, whereas secondary angle closure is due to an identifiable underlying pathology (▶ primary angle closure and angle-closure glaucoma, secondary angle-closure glaucoma).

Irrespective of primary or secondary, ▶ angle closure is caused either by anterior ("pulling") or posterior ("pushing") mechanisms, both of which eventually leading to iridotrabecular contact either due to transient apposition of the iris to the trabecular meshwork or due to irreversible PAS (▶ angle-closure suspect).

In either mechanism, outflow of aqueous humor through the anterior chamber angle is reduced, resulting in acute, intermittent or chronic, moderate to excessive, elevation of IOP, thus eventually causing angle-closure glaucoma characterized by GON and corresponding visual field defects.

Besides the above-described mechanism of direct obstruction, often with rapidly developing PAS, aqueous outflow may also be impaired by irreversible degeneration and damage of the trabecular meshwork during phases of raised IOP.

PAS in chronic angle closure may develop after an acute attack in which synechial closure persists, or may also develop when the chamber angle closes gradually with slow formation of PAS, which advance circumferentially. In such creeping ▶ angle closure, multiple mechanisms are suspected to be involved, including pupillary block and ▶ plateau iris.

Clinical Presentation

Most angle closures occur asymptomatic.

A shallow anterior chamber may be a hint at a narrow anterior chamber angle with possible angle closure. Asymmetry of anterior chamber depth is typical in secondary angle-closure glaucomas. Peripheral anterior synechiae are usually present.

Despite the varying degree of clinical symptoms of acute elevation of IOP (▶ acute angle closure), patients with angle-closure glaucoma show GON and corresponding retinal nerve fiber layer and ▶ visual field defects.

Additionally, signs of previous acute angle-closure attacks, including a mid-dilated pupil, sector iris atrophy, pigmentary dusting of the corneal endothelium, and anterior subcapsular lens opacities (so-called glaukomflecken), may be present.

Diagnosis

▶ Angle closure is diagnosed on gonioscopy.

Dynamic gonioscopy enables to distinguish between appositional angle closure and PAS.

Tonometry usually reveals elevated IOP, although in some cases IOP may be within normal limits at the time of examination.

Biomicroscopy with accurate assessment of the anterior chamber is necessary for the classification of angle-closure glaucoma. A significant difference in anterior chamber depth is suggestive of ▶ secondary angle-closure glaucoma.

Assessment of the posterior segment is mandatory to detect glaucomatous changes of the optic nerve and retinal nerve fiber layer, as well as for the classification of angle closure secondary to mechanisms behind the iris/lens diaphragm.

Previous ocular and medical history, family history, as well as subjective symptoms should be inquired to exclude or confirm previous attacks of angle closure.

▶ Visual field examination, retinal nerve fiber layer assessment, and optic disk imaging should be performed to assess the stage of disease.

Differential Diagnosis

With respect to the treatment modalities, effort should be made to determine primary or secondary mechanisms of angle closure.

Consider neovascular glaucoma, ▶ uveitic glaucoma, ▶ lens-induced angle closure, and angle closure due to aqueous misdirection (▶ malignant glaucoma) or to choroidal pathologies (e.g., ▶ uveal effusion).

Also consider any ▶ secondary open-angle glaucoma with acute rise of IOP-like inflammatory, ▶ corticosteroid glaucoma, ▶ Posner-Schlossman syndrome, ▶ pseudoexfoliative glaucoma, ▶ pigmentary glaucoma, ▶ ghost cell glaucoma, phacolytic glaucoma, or open-angle glaucoma due to intraocular malignant tumors.

For differential diagnosis, also consider other causes for optic neuropathy like vascular (▶ anterior ischemic optic neuropathy) or compressive (▶ compressive optic neuropathy) mechanisms.

Prophylaxis

There is clear evidence for prophylactic treatment in fellow eyes of acute angle closure.

In intermittent and chronic angle closure, further angle closure should be avoided by reducing the risk of pupillary block.

Therapy

Therapy of angle-closure glaucoma depends on the etiology, clinical presentation, and stage of disease. In secondary angle-closure glaucoma, the underlying pathology has to be treated.

The aim of treatment is to prevent the further development of PAS and further glaucomatous damage due to elevated IOP. Medical treatment includes mild topical miotic agents, topical hypotensive medication like ▶ beta-blocker, ▶ alpha agonists, ▶ carbonic anhydrase inhibitors, and ▶ prostaglandin analogues.

Further treatment includes ▶ iridotomy (either laser or surgical) to relieve a pupillary block component and reduce the risk of further permanent synechiae. Despite a patent iridotomy, the disease may progress, and filtering surgery may be indicated to lower IOP.

Another approach is ▶ cataract surgery, especially in cases where a lens block mechanism is involved.

Prognosis

Angle-closure glaucoma accounts for 50% of all glaucoma blindness worldwide and is probably the most visually destructive form of glaucoma. Prognosis depends on the etiology, clinical manifestation, and stage of disease.

Prognosis for intermittent and chronic primary angle closure depends on the extent of optic nerve damage and subsequent IOP control.

Epidemiology

Prevalence of angle closure varies depending on the ethnicity and is highest in Inuit, followed by East Asians and Japanese. Chronic angle closure is more common in black populations.

Angle-Closure Suspect

Cornelia Hirn
Eye Clinic, City Hospital Triemli, Zurich, Switzerland

Synonyms

Anatomically narrow drainage angle; Narrow angle; Primary angle closure suspect

Definition

Angle closure suspects are individuals with two or more quadrants of appositional iridotrabecular contact on gonioscopy but without evidence of peripheral anterior synechiae (PAS), elevation of intraocular pressure (IOP), or glaucomatous optic neuropathy (GON).

Etiology

Typically in patients with small, "crowded" anterior segments, a shallow anterior chamber, and short axial lengths, this anatomic predisposition results in partial apposition of the iris to the trabecular meshwork. The risk of such iridotrabecular contact in an eye with a narrow anterior chamber increases when the angle between the iris and trabecular meshwork is

equal to or less than 20°. In contrast to ▶ acute angle closure, in angle closure suspects, iris apposition does not result in elevated IOP or any other clinical symptoms. Angle closure in predisposed subjects may be induced by various factors including drugs with sympathomimetic or parasympatholytic activity, pain, or emotional upset. (▶ mydriasis-induced secondary angle closure)

Clinical Presentation

By definition, angle closure suspects are clinically asymptomatic. A shallow anterior chamber may be a hint at a narrow anterior chamber angle with possible angle closure. On gonioscopy, two or more quadrants of appositional iridotrabecular contact are seen, but no PAS. IOP is within normal limits. No signs of GON as well as no signs of previous ▶ acute angle closure are to be found. No secondary causes for shallow anterior chamber or narrow anterior chamber angle are present.

Diagnosis

▶ Angle closure is diagnosed on gonioscopy.

By indentational gonioscopy, appositional angle closure can be confirmed, and PAS can be excluded. ▶ Ultrasound of the anterior segment may rule out other pathologies causing angle closure.

Biomicroscopy with accurate assessment of the anterior chamber as well as the posterior segment should be performed, and attention should be paid whether there are signs of previous attacks of ▶ acute angle closure.

A provocative test with mydriatics is not recommended as it provides little additional information. Even when negative, the potential for angle closure is not ruled out.

Differential Diagnosis

Previous attacks of ▶ acute angle closure, ▶ angle closure glaucoma, and narrow angle or angle closure secondary to other pathologies should be considered and ruled out.

Prophylaxis

Evidence for prophylactic treatment is ambivalent. In cases of two or more quadrants of iridotrabecular contact, prophylactic treatment may be considered. In the fellow eye of primary ▶ acute angle closure, prophylactic treatment is clearly indicated.

Angle closure suspects should be informed about the clinical signs of ▶ angle closure and advised to get immediate ophthalmic attention in case of symptoms.

Therapy

The aim of prophylactic treatment is to prevent ▶ acute angle closure as well as the development of PAS and chronic angle closure.

As angle closure suspects are asymptomatic, the risks of treatment are to be balanced against the perceived risk of progression to ▶ acute angle closure or chronic angle closure. If treatment seems indicated, a prophylactic laser ▶ iridotomy is the therapy of choice.

Prognosis

Only a small percentage of individuals with a narrow angle develop ▶ acute angle closure or ▶ angle closure glaucoma. No valid tests exist to predict which patients are likely to progress.

Epidemiology

Female gender, older age, and hyperopia are factors associated with shallower anterior chambers and may predispose for angle closure. Besides, relatives of subjects with ▶ angle closure glaucoma are at greater risk to develop ▶ angle closure, although estimates of risk vary greatly.

Aniridia, Traumatic

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Traumatic iris loss

Definition

Partial or total loss of iris tissue due to ocular trauma.

Etiology

Traumatic aniridia is the result in open globe injuries after extrusion of iris tissue through the wound. The loss of tissue itself is due to either direct mechanical force during the trauma or secondary due to ischemia and necrosis. Often, during primary reconstructive surgery in open globe injuries prolapsed necrotic iris tissue is removed. In rare cases of extreme blunt force trauma, a total iridodialysis may occur, even if there was no open globe injury.

Clinical Presentation

Segments of the iris or the total iris are missing giving views of the lens or posterior chamber and vitreous.

Diagnostics

If the cornea is clear, diagnosis of traumatic aniridia is straightforward. It may be difficult or impossible in cases of corneal edema, corneal scarring, hematocornea, or hyphema which are often present after severe ocular trauma. In those cases, ultrasonic examination of the anterior segment could be helpful.

Differential Diagnosis

Congenital aniridia.

Prophylaxis

Primary surgery of open globe trauma should be performed as early as possible. All manipulations (e.g., at the slit lamp) should be avoided and all exams which are not immediately necessary (e.g., CAT scans) should be postponed to prevent suprachoroidal hemorrhage with consecutive extrusion of intraocular tissue. During surgery, as much iris tissue should be preserved as possible (Kuhn 2008).

Therapy

If the patient suffers from light sensitivity, a soft iris print contact lens can be fitted. In case of partial iris loss, secondary surgery with iris sutures or artificial iris (iris prosthesis, IOL, iris ring) can improve function and cosmetics (Chung et al. 2009). In pesudophakic eyes, total or segmental aniridia implants or IOLs can be used.

Prognosis

Eyes with traumatic aniridia often have a significant comorbidity due to the trauma (damage of cornea, lens, retina, and optic nerve) which determines the outcome. Moreover, traumatic aniridia is often associated with glaucoma which may be difficult to treat.

Epidemiology

In a large retrospective series of cases of contusion and rupture of the globe, the incidence of traumatic aniridia was reported to be 1% (Viestenz and Küchle 2001).

Synonyms

Anisocoria; Horner syndrome; Miosis; Oculosympathetic paresis

Definition

Anisocoria refers to a difference in pupil size (typically > 0.4 mm) between the two eyes. Miosis refers to pupillary constriction and mydriasis to relative dilation. Horner syndrome (HS) is characterized by the clinical constellation of ipsilateral miosis, ptosis (and upside down ptosis), and variable facial or body anhidrosis resulting from oculosympathetic paresis (i.e., damage to the sympathetic nervous system supplying the pupil and eyelid).

Etiology

Causes of anisocoria resulting from an abnormally small pupil include:

I. Ocular disease
   1. Anterior uveitis (i.e., posterior synechiae)
   2. Prior ocular surgery (e.g., iris damage)
   3. Pseudoexfoliation syndrome
II. Pharmacologic miosis (e.g., pilocarpine eye drops or other miotics)
III. Horner syndrome (HS)
   1. First order
   2. Second order
   3. Third order

The ocular sympathetic pathway is a three-neuron arc. The first-order neurons lie in the ipsilateral posterolateral hypothalamus. Their axons travel ipsilaterally in the lateral tegmentum of the midbrain, pons, and medulla to the ciliospinal center of Budge in the intermediolateral cell column in the spinal cord at the C8, T1, and T2 levels. The second-order axons of the preganglionic neurons then exit via the dorsal roots at T1 and travel in the cervical sympathetic chain. This path brings them near the apical lung and the subclavian artery. They ascend in the sympathetic chain to synapse with the third-order postganglionic neurons in the superior cervical ganglion near the bifurcation of the carotid artery at C3–C4. The pupillary postganglionic fibers travel along the internal carotid artery while the vasomotor and sudomotor fibers follow the external carotid artery. After entering the cavernous sinus with the internal carotid, the pupillary postganglionic fibers join the abducens nerve for a short course and then enter the orbit with the ophthalmic branch of the trigeminal nerve. Running in the long ciliary nerves, these fibers innervate the iris dilator and Müller muscle of the superior lid.

The first-order neuron can be damaged by compression (e.g., tumors of the hypothalamus, skull base or spinal cord, Chiari malformation), ischemic disease (e.g., lateral medullary syndrome), and other central nervous system (CNS) diseases (e.g., infection, inflammation, infiltration, toxin, demyelinating disease, or trauma). The second-order neuron can be compressed as it travels over the lung apex by a neoplasm (e.g., Pancoast tumor of the lung), central venous catheterization, traumatic or surgical dissection of the neck, aortic aneurysm, a cervical rib, and birth trauma (e.g., brachial plexus injury). In infants and children, a neuroblastoma of the sympathetic chain or any compressive lesion in the neck or upper chest can lead to HS. Possible damage to the third-order neuron includes dissection of the carotid artery (spontaneously or related to trauma), carotid-cavernous fistula, cluster or migraine headache, and mass lesions causing damage at the cavernous sinus or posterior orbit.

Clinical Presentation

HS presents with anisocoria and an ipsilateral miotic pupil, mild (less than 1–2 mm) ptosis, upside down ptosis (lower lid retractor), and possible facial or hemibody anhidrosis depending on the site of the lesion. The anisocoria in HS is more notable in darkness. In addition, there is typically a lag in the dilation of the involved pupil in HS (i.e., dilation lag) that can be detected by observing the anisocoria in the dark for 5–10 s and demonstrating a greater anisocoria initially that improves over time. Other evidence of sympathetic denervation such as ptosis from loss of input to Müller muscle is typically present but may be absent in a significant minority of cases or might be masked by contralateral dermatochalasis. Other associated clinical "neighborhood signs" can help define the likely location of the lesion. Lateral medullary stroke (i.e., Wallenberg syndrome) often features HS with variable combinations of ipsilateral facial sensory loss, contralateral hemibody pain, and temperature loss, dysphagia, dysarthria, nystagmus, vertigo, ataxia, palatal myoclonus, and hiccoughs. Other patterns of weakness and sensory loss as well as cranial nerve deficits can point to lesions in the brainstem or spinal cord. An acute onset with neck pain can accompany a cervical dissection

of a carotid or vertebral artery, especially with stroke or transient ischemic attack symptoms. Involvement of the abducens nerve, potentially together with involvement of the oculomotor and trochlear nerves, can suggest a cavernous sinus or superior orbital fissure localization.

Diagnostics

A careful and complete history is necessary to firmly establish the time course of presentation as well as accompanying symptoms in the HS. One can often use old photographs, such as a driver's license or identification card, to determine whether deficits are longstanding or not.

Examining the pupils both in light and dark conditions to identify the abnormal side is the first step. More pronounced anisocoria in darkness indicates that miotic pupil has failed to dilate appropriately, and this finding suggests a HS lesion to that side.

Pharmacologic confirmation of HS is classically made by instillation of 2–4% cocaine eye drops into both eyes. Cocaine inhibits reuptake of norepinephrine at the junction. Dilation of the pupil is the normal physiological response to the accumulation of norepinephrine. An anisocoria of greater than 0.8 mm 30 min following instillation is highly suggestive of an HS. However, cocaine drops are difficult to obtain and require compliance with institutional and state regulations for controlled substances. After a positive cocaine test, instillation of 1% hydroxyamphetamine (Paredrine test) can localize the HS to a preganglionic or postganglionic lesion. This Paredrine test should be performed at least 24–48 h after the cocaine test. Hydroxyamphetamine promotes release of norepinephrine from the third-order neuron. Dilation of the pupil and resolution of the anisocoria after a positive prior cocaine test for HS confirms the integrity of the third-order fibers and indicates a first- or second-order lesion HS. Alternatively, topical apraclonidine can be used to diagnose an HS and is more readily available than topical cocaine or hydroxyamphetamine. Under normal conditions, it acts as a weak alpha-1 and a stronger alpha-2 adrenergic agonist. In a normal pupil, the alpha-2 effect dominates, and the pupil either does not react or at most constricts mildly. However, denervation of the iris dilator results in supersensitivity of the alpha-1 receptors which are upregulated. Thus, instillation of 0.5–1% apraclonidine results in mydriasis of the smaller pupil and often a reversal of the ptosis in HS. However, this supersensitivity may take up to 1 week to develop following sympathetic denervation, and if the patients clearly have an HS clinically, then imaging the sympathetic axis without topical testing might be indicated.

When the presentation is acute, head CT is mandatory to evaluate for stroke, particularly hemorrhage, and a concomitant head and neck CT and CT angiography (CTA) provides a rapid means of evaluation for arterial dissection that can be performed during the same session. The ordering physician must remember that both carotid and vertebral dissections typically occur in the neck and include the neck in the studies. Cerebral angiography, however, remains the gold standard for diagnosis of arterial dissection when CT angiography is not conclusive. In the nonurgent setting, MRI and MR angiography (MRA) of the head and neck (down to T2 in the chest) is probably a superior initial study for an unexplained HS. As noted above, in children and infants, neuroblastoma of the sympathetic chain is a concern. Imaging of the entire ocular sympathetic axis can be combined with laboratory evaluation of urine and/or blood for elevated catecholamines (e.g., homovanillic acid and vanillylmandelic acid).

Differential Diagnosis

1. Anisocoria with a large pupil
2. Adie pupil
3. Physiologic anisocoria
4. Third nerve palsy
5. Adhesions of the iris

6. Phamacologic mydriasis
7. Pharmacologic miosis

Prophylaxis

Not applicable

Therapy

Treatment should be directed toward the underlying etiology. The ptosis of HS may be treated surgically once the etiology is confirmed and treated.

Prognosis

The prognosis for Horner syndrome depends on its etiology.

Synonyms

Adie syndrome; Adie's tonic pupil; Holmes-Adie syndrome; Little old Adie's pupil

Definition

The Adie tonic pupil (ATP) is characterized acutely by a dilated ipsilateral pupil with an impaired light reaction. Over time the pupil becomes smaller (i.e., "little old Adie") and develops a tonic near reaction (light-near dissociation). ATP is caused by damage to the parasympathetic innervation to the eye at the level of the ciliary ganglion or postganglionic fibers.

Etiology

ATP is caused by damage to the parasympathetic innervation to the iris and ciliary body at the

ciliary ganglion or postganglionic nerves. Initially, the pupil reacts poorly to both light and accommodation and thus can mimic a pharmacologically dilated pupil. Over the next few days to weeks after the acute denervation, however, postganglionic axons can regenerate, but some regeneration may occur aberrantly. Normally, there are up to 30 times more parasympathetic axons arising from the ciliary ganglion and destined for the ciliary body compared with the pupil. Thus, during aberrant regeneration, axons may accidentally reroute to the pupil rather than to their original destination in the ciliary body. The final result clinically is that the ATP may respond poorly to light but has a stronger and tonic reaction to accommodation (i.e., light-near dissociation). Although most cases of tonic pupils are idiopathic ATP, some tonic pupils are the result of inflammation, infection, or trauma (including surgical trauma) affecting the ciliary ganglion or postganglionic nerves. ATP is typically unilateral at onset, but up to 20% of cases become bilateral over time, and in one study, the annual rate bilateral involvement was 4%.

Clinical Presentation

The anisocoria of ATP is often discovered incidentally on routine exam or the pupil assymmetry may be noticed by the patient when looking in the mirror. Other times it is discovered by a friend or a family member of the patient. When symptomatic, there may be mild photophobia or difficulty reading (accommodation). ATP is usually painless, although some patients may complain of asthenopia (e.g., eye strain, "cramping sensation" in the affected eye secondary to spasm of the ciliary body ("ciliary cramps") or other reading difficulty). On exam, the affected pupil in the acute setting is larger, and the anisocoria is greater in the light. Over time the ATP develops the light-near dissociation, and slow re-dilation after constriction or after accomodation (i.e., "tonic" response). Tonic accommodation may also be present and can be described by patients as difficulty when changing fixation from a near to a distance visual target. Corneal sensation has been reported to be mildly depressed in some patients. On slit lamp examination, the pupil may be irregular, exhibiting sector or diffuse paresis or vermiform movements in the intact iris segments. In contrast to the third nerve palsy with pupil involvement, there should be no evidence for ptosis or extraocular motility deficit in ATP alone. The iris should be examined carefully for evidence of iris atrophy, synechiae, or sphincter tear that would suggest alternative diagnoses for the anisocoria.

Diagnostics

The distinguishing clinical features of ATP have been noted above. If decreased deep tendon reflexes are also present, ATP would then be a component of the full Holmes-Adie syndrome. Examining old photographs can help distinguish whether the anisocoria is old or new and the presence of a photographically documented and long standing ATP can often obviate the need for further testing. If the typical features of ATP are present and the findings are neurologically isolated then pharmacological testing is generally not necessary. However, in some cases there remains clinical uncertainty and in this setting, dilute 0.1% pilocarpine can be helpful in differentiating ATP from other etiologies of anisocoria. In ATP, cholinergic denervation supersensitivity leads to more constriction to dilute pilocarpine in comparison to the normal eye. This finding would support the diagnosis of ATP over iris sphincter abnormality, an atonic pupil (no iris tone), or pharmacologic mydriasis. The ATP can be distinguished from the pupil involved third nerve palsy by the absence of ptosis or motility deficit and the sector nature of the iris paresis. It should be kept in mind that only 80% of patients with ATP demonstrate cholinergic supersensitivity (false negative) and that this same supersensitivity reaction can also be noted in patients with CN III preganglionic lesions (false positive). The dilute topical pilocarpine should be applied to both eyes, as some patients, particularly those with normal but lightly pigmented irises, may respond to dilute pilocarpine. In addition, the fellow eye serves as a control to insure that the pilocarpine is

working and that it is not inadvertently undiluted (e.g., 1% pilocarpine).

Differential Diagnosis

ATP produces anisocoria that is typically worse in the light compared with the dark. The differential diagnosis of anisocoria greater in the light includes pharmacologic mydriasis, iris abnormality (e.g., iris atrophy, synechiae, atonic pupils, surgical trauma), or third nerve palsy with pupil involvement.

Tonic pupils can occur after local orbital syndromes (e.g., infection, inflammation, neoplasm, trauma, orbital surgery) and in systemic autonomic neuropathies (e.g., Charcot-Marie-Tooth disease and Guillain-Barre Syndrome). Local anesthesia due to an inferior dental block or retrobulbar blocks or alcohol injection can produce a tonic pupil. Other less common causes of a tonic pupil include ischemia, toxicity (e.g., quinine and trichloroethylene), and as a paraneoplastic syndrome. Although ATP can be associated with decreased deep tendon reflexes (i.e., Holmes-Adie syndrome), typically ATP is otherwise neurologically isolated. In contrast, patients with ATP and other autonomic cardiac, sweating, or gastrointestinal symptoms or signs should be considered for further neurologic and systemic testing for diffuse dysautonomia (i.e., Ross syndrome).

Although the Argyll Robertson pupil (miotic pinpoint pupils with bilateral light-near dissociation) is classically described in syphilis, bilateral tonic pupils similar to ATP can also occur in syphilis. We recommend consideration for syphilis testing in non-isolated ATP or in bilateral cases of ATP. Although imaging is not typically needed for typical ATP, atypical cases or unexplained bilateral light-near dissociation (especially without the tonic near reaction) of the pupils might still need imaging (e.g., cranial MRI) directed at the dorsal midbrain.

Therapy

The majority of patients are asymptomatic and do not require treatment beyond simple reassurance of the benign nature of the finding. Some patients, however, may complain of reading difficulty secondary to accommodation paresis in the early denervation stage. Although this symptom usually resolves over time, asymmetric bifocal glasses (unilateral frosted or unequal power) may help improve reading while reinnervation occurs. Application of low-dose topical pilocarpine may also ease symptoms of anisocoria. A few of our patients have used PRN dosing of low-dose topical pilocarpine for cosmetic reasons and social occasions. However, this pharmacologic intervention may also induce ciliary spasm and myopia and should therefore be used with caution.

Prognosis

The majority of ATP are benign and only require reassurance and supportive care. Ross syndrome, however, should be referred for systemic and neurologic evaluation. Patients with positive syphilis serology should be treated with penicillin and undergo neurologic evaluation and cerebrospinal fluid evaluation.

Epidemiology

ATP occurs in about 0.2% of the population (2/1000 individuals). It is more common in females with a 2.6/1 ratio, and it has been found to appear in all ages.

Synonyms

Annular tendon; Circle of Zinn-Haller; Common tendinous ring

Definition

The annulus of Zinn is a dense, fibrous ring of connective tissue located at the apex of the orbit that is the origin of four of the six extraocular muscles – the superior rectus, inferior rectus, lateral rectus, and medial rectus. In addition to its relation to the extraocular muscles, the annulus of Zinn has important connections with some of the cranial nerves. The optic, oculomotor, and abducens nerves all pass through the annulus of Zinn, while the trochlear nerve travels just medial to the annulus of Zinn. The nasociliary nerve is the sole portion of the ophthalmic division of cranial nerve V which passes through the annulus of Zinn. Finally, the medial portion of the annulus of Zinn is fused to the optic nerve sheath. This may be the reason that there is pain during eye movements for individuals experiencing optic neuritis.

Anomalous Trichromats

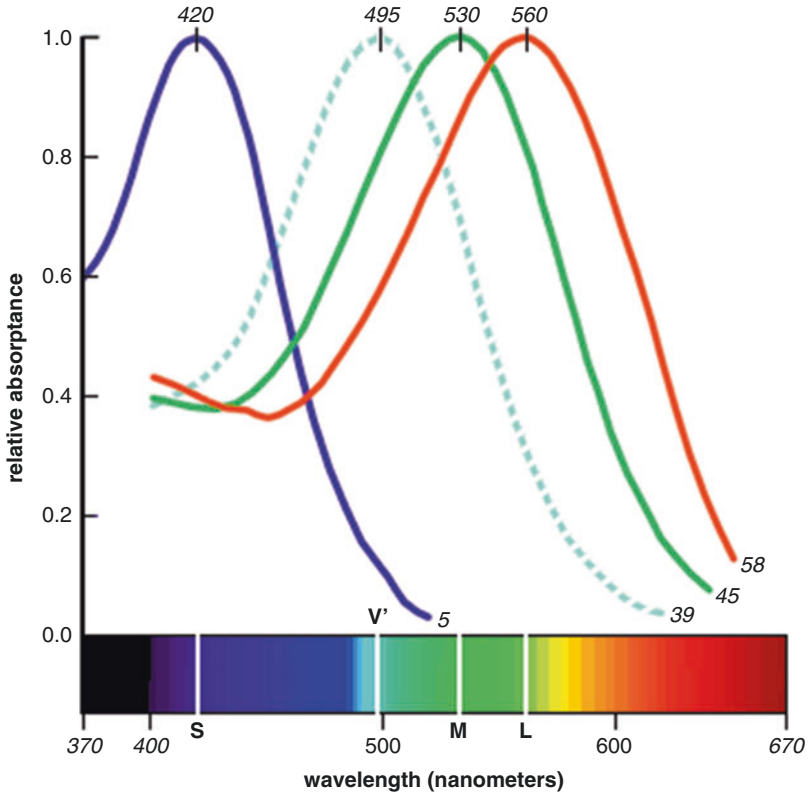
Naomi Fischer
Department of Ophthalmology, Tel Aviv Sourasky Medical Center, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Synonyms

Color "blindness"; Color vision deficiency

Definition

Anomalous trichromacy (a type of color vision deficiency) is an alteration in the spectral sensitivity of one of the three cone cell receptors in the retina



Anomalous Trichromats, Fig. 1 Human cone absortion cuves (normalized to equal peak absorptance (1.0) on a linear vertical scale; wavelength of peak absorptance in italics, number of photoreceptors measured for each curve at base of curve (Data from Dartnall et al. 1983; Bowmaker and Mollon 1983). (Bruce MacEvoy 2009)

that make up the color spectrum (Fig. 1) (Dartnall et al. 1983; ebook: Color blind essentials 2016).

Etiology

In the nineteenth century, Thomas Young and Hermann von Helmholtz theorized that human color vision is composed of a combination of three colors "trichromatic" (red, blue, and green). Color perception in the human eye is attributed to three different types of cone photoreceptor (opsin) cells. Gunner Svaetichin (1956) proved the existence of these cells and their sensitivity to different wavelength ranges (Svaetichin 1956). They contain a specific photopigment, which is most sensitive to a specific spectrum of light. The brain combines input from all the three cell types to interpret color. S-cones are sensitive to short wavelengths with normal peak absorption at approximately 420 nm (blue [tritan] light receptors). M-cones are sensitive to medium wavelengths and normally peak at about 540 nm (green [deutan] light receptors). L cones are sensitive to long-wavelength light and their normal peak is at about 560 nm (red [protan] light receptors). Anomalous trichromats have three types of cones, but one of the three types has a spectral sensitivity shifted from the normal cones (Sharpe and Gegenfurtner 2001; ebook: Color blind essentials 2016).

Nathan et al. (1986) isolated the genes encoding the S, M, and L-cone opsins (Nathan et al. 1986). Long-wavelength (L) and middle-wavelength (M) genes share over 98% nucleotide identity and are found on the X-chromosome at Xq28 (genetic designation OPN1LW and OPN1MW, respectively) with a normal variability in the number of these genes per chromosome. The gene for the short-wavelength (S) cone opsin shares only about 40% nucleotide similarity with the other opsin genes. It is found on chromosome 7 at 7q32 (OPN1SW) (Parker and Parker 2007).

Genetic causes of anomalous trichromacy are due to inherited mutations in these genes. Red and green visual anomalies (L and M opsins) are most common and are X-linked recessive. The L and M genes are adjacent to each other on the X-chromosome and as they are nearly identical, misalignment of these genes can occur between parent chromosomes leading to recombinant crossovers between the two genes. Protanomaly makes the L-cone more like the M-cone and deuteranomaly makes the M-cone more like the L-cone. With the absorption maxima of the cones shifting closer together, the ability to discern reds and greens decreases. Defects in the blue opsin (S) are inherited in an autosomal-dominant fashion and cause difficulty in distinguishing the blue-yellow spectrum, which is known as tritanomaly (Parker and Parker 2007).

Acquired causes of color vision deficiency are due to damage along the conducting paths of the optical system. Type 1 (red-green) mimics protanomaly due to more efficient short-wavelength processing and is associated with progressive cone dystrophy and retinal pigment epithelium dystrophies. Type 2 (red-green) resembles deuteranomaly but with a greater reduction in short-wavelength sensitivity and is associated with optic neuritis. Type 3a tritan type with increased efficiency to short wavelengths is found in central serous chorioretinopathy and age-related macular degeneration. Type 3b tritanomaly is found in rod and rod-cone dystrophies, retinal vascular disorders, peripheral retinal lesions, glaucoma, and autosomal-dominant optic atrophy (Birch 2001). Drugs including digoxin, ethambutol, chloroquine, hydroxychloroquine, phenytoin, and sildenafil can also cause color vision deficits as well as toxins such as lead, alcohol, and tobacco.

Clinical Presentation

Anomalous trichromacy presents as a smaller color spectrum.

Protanomaly presents as "red weakness" in terms of color power (saturation/depth of color) and brightness and red is perceived as much darker.

Deuteranomaly presents as "green weakness."

In both protanomaly and deuteranomaly, the main axis of colors of confusion is the same: red, orange, yellow green, and brown. However, the colors of the confusion for blue-purple hues are perceived very differently between the groups. Protanomaly defects may see violet shades as blue as the red component is weakened (colorvisiontesting.com).

Tritanomaly presents as a difficulty in distinguishing between yellow and blue.

Diagnosis

There is a range of color blindness tests in diagnosis of color vision deficiency. Seebeck developed color matching without the use of color naming in 1837 in which sample color was matched to more than 300 colored papers. This was the basis for the Holmgren wool test (1877) in which skeins of colored wool are matched (ebook: Color blind essentials 2016).

Modern color vision deficiency testing:

- **Anomaloscope**: This is based on the Rayleigh match in which a mixture of red and green light sources has to be matched with a yellow light source. It is probably the most precise commercially available diagnostic test. This enables discovery of red-green color deficiency. Some anomaloscopes also include the Moreland match (blue-green), which tests for tritan defects. People with protan defects use more red as opposed to deuteranomaly where more green is used for matching.

The International Commission on Illumination defined a color space chromaticity diagram in 1931(CIE31), which is the basis for many of the currently employed color vision tests. A graph was compiled based on subjects matching a test light color source to three adjustable light sources

(red, green, and blue). Confusion lines defined the colors that were hard to differentiate by color-blind people, with the copunctal points being where they converged (Smith and Guild 1931–32; CIE 1932).

- **Pseudoisochromatic plates**: The first published plates were by J. Spelling, which were a predecessor to the most famous type of color-blind test plates, the Ishihara plate test (Ishihara 1917). Patterns of differently colored dots, which correspond to colors of confusion, are used to differentiate color deficiencies. Types of plates include vanishing design where only people with good color vision can see the design, transformation design where color-blind people see a different sign to normal color vision, and hidden digit design where only color-blind people see the design and classification design which differentiates deutan from protan defects. Ishihara plates only differentiate red-green vision deficiencies. The 24 HRR (Hardy et al. 1954) plates also include tritan defects (Hardy et al. 1954).
- **Arrangement tests**: These also are base on copunctal points and dynamic test-colored disks or plates have to be arranged in the correct order. These tests include the Farnsworth D-15 arrangement test, Farnsworth-Munsell 100 hue test, and Lanthony desaturated D-15 test.
- **Lanterns**: These are most often used as vocational tests and were introduced by railway companies to establish whether employees could distinguish signals. These include Holmes-Wright, Farnsworth (Falant), Beyne lantern, Giles-Archer, and Eldridge-Green lanterns.
- **Computer-based testing**:
- **Genetic testing** (in parallel to physical testing).

Differential Diagnosis

- Dichromacy (one cone type missing)
- Monochromacy (two cone types missing)
- Complete achromatopsia (rod "monochromacy") – all cone types missing
- Cerebral achromatopsia/dyschromatopsia
- Disorders of the ocular media
- Macular detachment
- Cone dystrophies/degeneration
- Macular dystrophies/degeneration
- Vascular and hematologic diseases
- Glaucoma and optic nerve disease (e.g., autosomal-dominant optic atrophy)
- Diseases of the central nervous system (e.g., multiple sclerosis) and other organs (e.g., diabetes mellitus)
- Toxic agents and drugs (see list under "Etiology")

Prophylaxis

There is currently no prophylaxis for anomalous trichromacy. With improving genetic testing, identification of mutated genes may be possible.

Therapy

There is presently no cure for color-blind people. Neitz et al. have shown genetic therapy with subretinal injection of the missing genes in monkeys to improve color vision (Neitz and Neitz 2011).

Colored filters (lenses, glasses, or tools such as the Seekey) are available and are used over one eye to improve distinguishing between colors. There is also a range of computer-based tools available in aiding color-deficient people.

If the cause of color deficiency is acquired, then the underlying disease should be targeted appropriately or the offending drug/toxic agent removed.

Prognosis

Hereditary abnormal trichromacy is a stable condition.

Epidemiology

Color vision deficiency is a very common condition affecting approximately 8% of men and 0.5% of women. It is most common in people of European descent. Deuteranomaly is the most common affecting 4.63% men and 0.36% females. Protanomaly affects 1.08% males and 0.03% females (male predominance due to x-linked recessive inheritance). Tritanomaly is autosomal dominant and so is found equally in men and women (ebook: Color blind essentials 2016).

Anophthalmic Socket

Robert J. Peralta[1], Gary Joseph Lelli[2] and Christopher Zoumalan[3]
[1]Department of Ophthalmology and Visual Sciences, University of Wisconsin Hospital and Clinics, Madison, WI, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[3]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA

Definition

The absence of the globe and ocular tissue from the orbit.

Etiology

The majority of cases of anophthalmos are seen following evisceration or enucleation. Congenital anophthalmos is rare and due to the arrest of embryogenesis during formation of the optic vesicle. A genetic, infectious, or toxic etiology may be identified. Recent studies point to the role of SOX2 haploinsufficiency, as this variant was found in up to 10% of patients with anophthalmos or severe microphthalmia.

Clinical Presentation

Disfigurement may result from the volume deficit. An orbital implant is typically placed at the time of evisceration or enucleation. An ocular prosthesis is fitted subsequently. In the absence of an implant (or with placement of an undersized implant), postenucleation/evisceration socket syndrome (PESS) may result, manifest as enophthalmos, deep upper eyelid sulcus, ptosis,

lower lid laxity, ectropion or entropion, and shallowing of the inferior fornix.

Differential Diagnosis

Microphthalmos

Therapy

Eyelid Malposition

The volume deficit should first be corrected with an orbital implant (if none present) or an orbital floor implant (if an undersized intraconal implant is present). Depending on the degree of residual lower lid laxity and involvement of the medial or lateral canthus, a lateral tarsal strip or fascial sling is usually sufficient. Upper lid ptosis may then be addressed.

Socket Contracture

The socket is particularly susceptible following trauma, recurrent inflammation due to an inadequate prosthesis, or radiotherapy. Please refer to the entry on *Socket Contracture* for more information on this topic.

Orbital Implants

The goal of the implant is to replace the volume deficit, maximize motility, provide comfort, be aesthetically acceptable, and cause few complications. Numerous options are available, but there is no consensus regarding the ideal implant. The surgeon must first select the appropriate size and then consider whether the implant should be porous or nonporous, spherical or nonspherical, wrapped or unwrapped, and directly or indirectly coupled. Extraocular muscles were previously sutured over the implant but are now more commonly sutured directly to the implant itself or its overlying wrapping material. Tenon's capsule and conjunctiva are closed over the amalgam. A conformer is placed until an ocular prosthesis can be fit. Please refer to the entry on *Orbital Implants* for further information on this topic.

Congenital Anophthalmos

Treatment is directed toward the first stimulating growth of the orbit and adnexal soft tissues and then providing orbital volume replacement and soft tissue reconstruction. Progressively larger acrylic conformers are used to expand the socket. Spherical orbital implants, dermis fat grafts, and other socket/orbital expanders are then used for reconstruction. More recently, the use of injectable self-inflating hydrogel expanders has been proposed as a safer, less-invasive alternative in orbital reconstructive surgery.

If unilateral, ensuring the health and protection of the seeing eye with routine examinations is imperative. If bilateral, psychosocial support and early interaction with the appropriate agencies is essential in optimizing development, genetic counseling may be helpful in assessing the potential risk in future children.

Practice Patterns

Su and Yen (2004) surveyed members of the American Society of Ophthalmic Plastic and Reconstructive Surgery (ASOPRS) regarding their practice patterns after enucleation and evisceration. The porous polyethylene implant was used most frequently after both enucleation (42.7%) and evisceration (42.3%), followed by the porous hydroxyapatite implant (27.3 and 25.9%) and nonporous implants (19.9 and 25.7%). The majority of surgeons (59.8%) do not to wrap their implants. For those who do, human donor sclera was most commonly used (25.2%), followed by polyglycolic acid mesh (7.2%). Implant pegs were used in only 8.1% of cases. The most common complications included pyogenic granuloma (13.7%), exposure (5.7%), and discharge (5.7%).

Anterior Basement Membrane Dystrophy

► Map-Dot-Fingerprint Dystrophy (Epithelial/Anterior Membrane Dystrophy)

Anterior Capsule

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The anterior capsule is the anterior part of the membranous structure which envelopes the crystalline lens (lens capsule).

Anatomy

The lens capsule encloses the lens material (lens fibers). With a thickness of 3–5 µm at the posterior pole, 5 µm at the anterior pole, 11 µm at the lens equator, and 25–30 µm in the anterior mid-periphery, it is the thickest basement membrane of the body and consists mainly of collagen type IV.

Importance for Cataract Surgery

In extracapsular cataract surgery techniques such as phacoemulsification, the anterior capsule needs to be opened to allow for extraction or emulsification/aspiration of lens material and subsequent implantation of an artificial intraocular lens. While there are different methods for opening the capsule, the most preferable way is the continuous curvilinear capsulorrhexis (CCC) which minimizes the risk of radial tears in the lens capsule.

The inside of the anterior capsule is sometimes polished during cataract surgery to remove lens epithelium and lower the incidence of capsular fibrosis.

Anterior Capsule Opacification (ACO)

► Capsular Bag Opacification

Anterior Capsulorhexis

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Capsulorrhexis; Continuous curvilinear capsulorhexis (CCC)

Definition

The capsulorhexis (greek rhexis: to break) is a technique of anterior capsulotomy. The capsulorhexis delineates a circular and continuous central opening in the anterior capsule. It allows expression or phacoemulsification of the lens nucleus. Today, the continuous curvilinear capsulorhexis (CCC) is the standard technique for the surgical approach to the anterior capsule.

This method allows an in-the-bag phacoemulsification and in-the-bag intraocular lens implantation.

Advantages of this method are a lower risk of radial tears and vitreous loss. In addition, by using this approach the capsule can be stretched by 60%.

Other anterior capsulotomy techniques with a radial discontinuity (envelope capsulotomy, can-opener technique) increase the risk of radial tears with vitreous loss.

Epidemiology

See ▶ Cataract Surgery article.

History

The idea dates back to Neuhann, Gimbel, and Shimizu. In the mid 1980s, Neuhann (capsulorhexis) and Gimbel (continuous tear capsulotomy) first described the capsulorhexis technique independently as a principle controlling continuous tearing. Shimizu defined the surgical approach as circular capsulotomy.

The outcome of these scientific achievements is today's commonly used definition of a continuous circular capsulorhexis (CCC).

Clinical Features

Conducting instruments are either a cystotome or a bended needle.

Tests

Important to ascertain an indication for cataract surgery are an efficient ophthalmological examination and a detailed anamnesis (any amblyopia, other eyes diseases, precedent eye surgeries, pharmaceutical anamnesis, and symptoms of cataract). An effective capsulorhexis is at risk by loose zonular fibers.

Differential Diagnosis

The technique of opening the anterior capsule is chosen according to operation technique.

Further capsular opening methods in the following are:

- Vitrectorhexis (vitrector-cut anterior capsulectomy)
- Can-opener technique (letter box – technique)
- Minicapsulorhexis or Two stage capsulorhexis
- Linear capsulotomy
- Capsulopuncture
- Posterior capsulorhexis, capsulotomy
- Capsulorhexis shape and size
- Fugo blade
- High Radiofrequency diathermy capsulotomy

Etiology

See "History" section above.

Treatment

The capsulorhexis should be practiced continuously, central and arched. It consists of two characteristical movements: shearing and ripping. The conducting instruments are either a cystotome or a bended needle.

Before starting to perform the capsulorhexis, a rocking test with a tip or 27- or 30-gauge cannula should be performed to evaluate lens stability.

While performing the capsulorhexis, the anterior chamber has to be deep. Either inserting of viscoelastic agent in the anterior chamber or an irrigation from an anterior chamber maintainer is possible.

After that the magnification of the microscope enhances the view of the anterior capsule with working in a dark setting and a focal light on the surgical table. The stabilization of the glob is given by grasping the paracentesis site or the limbus. The initial tear in the anterior capsule is performed centrally. Now an instrument

(cystotome or bended needle) is introduced through a paracentesis. By connecting these instruments with a syringe, the viscoelastic agent or BSS can be inserted.

Hereafter, the anterior capsule is punctured by the needle which is swept afterwards drawing a curvilinear (center – laterally – circumferentially). The created capsular flap is dragged from the forceps 45° to the limbus. The capsulorhexis is triggered by shearing. The flap is flipped and pulled in the direction of the required rhexis (parallel to the limbus).

Anterior Capsulotomy Techniques

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Anterior capsulotomy techniques are various methods for opening the anterior capsule. The major performed technique is the manual continuous curvilinear capsulorhexis for preparing the phacoemulsification surgery. Other methods include the vitrectorhexis capsulotomy, the multipuncture can opener technique, the radiofrequency diathermy, and the plasma blade capsulotomy, mainly performed in pediatric cataract surgery.

Indication

The indication is given in the severity of cataract, age of the patient, and special anatomical features.

Contraindication

There are the general contraindications for the phacoemulsification and the extracapsular cataract surgery technique.

Techniques and Principles

Depending on the method, different instruments are needed. In the following, the cystotome, the capsulorhexis forceps, the aspiration handpiece, the vitrector, and the Fugo plasma blade tip are to be mentioned.

For details of the method, it is referred to especially written articles.

Outcome

Because of today's performed advanced and sensitive methods of anterior capsulotomy techniques, the outcome is very well after a complication-free intervention.

Complications

Serious complications are rare. There are the general risks of the cataract surgery like inflammation, bleeding, retinal detachment, increase or decrease of intraocular pressure, corneal opacity, iris damage, radial tears, vitreous loss, Irvine-Gass syndrome, surgical-induced astigmatism (SIA), and over- or under-correction or temporary double vision.

History

Reference is made to the respective techniques.

Clinical Features

Depending on the method, different instruments are needed. In the following, the vitrector, the cystotome, the capsulorhexis forceps, the aspiration handpiece, and the Fugo plasma blade tip are to be mentioned.

For details, it is referred to especially written articles.

Anterior Chamber

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The anterior chamber of the eye is the space between the posterior surface of the cornea and the anterior surface of the iris and lens which is filled with aqueous humor.

Anatomy

The anterior chamber is limited anteriorly by the cornea and posteriorly by the iris and the pupil. The anterior chamber angle at the junction between cornea and iris consists of the following structures:

Schwalbe's line
Canal of Schlemm and trabecular meshwork
Scleral spur
Anterior surface of the ciliary body
Iris

The depth of the anterior chamber can vary between individuals. It is deeper in myopia, aphakia, and pseudophakia. In the adult emmetropic eye it has a central depth of about 3 mm. It is most shallow just centrally of the angle. The anterior chamber volume in the emmetropic eye is approximately 250 µl.

Aqueous Flow

The anterior chamber is filled with aqueous humor which is produced by the ciliary epithelium in the posterior chamber. The aqueous humor flows though the pupil and is drained through the trabecular meshwork and the canal of Schlemm. In a small part, it is drained via the ciliary body into the supraciliary space (uveoscleral flow). The volume of drainage of aqueous from the anterior chamber can be measured using the washout of fluorescein. The average flow rate of aqueous humor through the anterior chamber is 2.1–3.1 µl/min and varies with age and time of day. The aqueous humor in the anterior chamber is exchanged about 15 times per day.

Synonyms

Junctional scotoma

Definition

In an anterior chiasmal syndrome, also known as junctional visual field loss, the junction of the anterior portion of the optic chiasm and the optic nerve is involved by disease. This condition classically manifests as a loss of central vision in the ipsilateral eye and a loss of superior temporal vision in the contralateral eye (from inferonasal crossing fibers at the optic chiasm). In the past this was attributed to involvement of a "knee" of inferonasal fibers traveling for a short course in the contralateral optic nerve (i.e., the Willebrand knee). Later work has called in to question the anatomic existence of the Willebrand knee, but it does not matter clinically because the localizing significance of the contralateral superior visual field defect (i.e., the junctional scotoma) is not diminished by the anatomic existence or lack thereof for the knee per se. In the early manifestations of anterior chiasmal syndrome, the optic discs may appear normal, even if there are significant visual changes present. However, over time, the optic discs show atrophy. Common causes of this syndrome include pituitary adenoma, parasellar meningioma, craniopharyngioma, and vascular causes, such as aneurysm of the parasellar region of the internal carotid. Alternatively, another form of anterior chiasmal syndrome-related junctional visual field loss is a monocular hemianopic visual field loss from involvement of the crossing nasal fibers (producing a monocular temporal hemianopic visual field defect) or uncrossed temporal fibers (producing a monocular nasal hemianopic visual field defect). In order to differentiate this finding of a monocular hemianopic junctional visual field defect from the junctional scotoma (superotemporal contralateral visual field defect), this type of anterior chiasmal loss is called the junctional scotoma of Traquair.

Definition

The anterior cranial fossa contains the frontal lobes of the brain, is located superior to the nasal cavity and orbits, and is one of three divisions of the floor of the cranial cavity. It is composed of portions of the frontal, ethmoid, and sphenoid bones. The anterior and lateral portions of the floor of the anterior cranial fossa are from the frontal bone, the midline portion is from the ethmoid bone, and the posterior aspect is from the body and lesser wing of the sphenoid bone. The ethmoid sinuses lie inferior to the anterior cranial fossa and are toward the midline. The posterior portion of the frontal sinuses borders the front of the anterior cranial fossa and may be used as a surgical entry point into it.

The anterior section of the anterior cranial fossa contains an attachment point for the falx cerebri known as the frontal crest. Posterior to the frontal crest is the foramen cecum, through which emissary veins connect the nasal cavity and the superior sagittal sinus. Slightly posterior to the foramen cecum lies the crista galli, a part of the ethmoid bone that is another attachment point for the falx cerebri. On either side of the crista galli lies the cribriform plate, through which olfactory nerve fibers pass through. The cribriform plate is a very thin portion of the ethmoid bone, and this unique property may be utilized when attempting to gain transethmoidal access to the brain. Lateral to the cribriform plate on either side is the orbital part of the frontal bone. This relatively thin layer of the fossa makes up the roof of each orbit. Finally, on both sides of the posterior portion of the anterior cranial fossa, there is an optic canal, which is a passageway for the ophthalmic arteries and optic nerves to travel to the orbit.

The floor of the anterior cranial fossa can give rise to skull base meningiomas, which may involve the optic canal and impinge upon the optic nerve producing visual loss. In addition, skull base fractures may involve the anterior cranial fossa. Major areas of vulnerability include the cribriform plate and the roof of the orbit. If the roof of the orbit is fractured, known as a superior blow-out fracture or blow-in fracture, intraorbital contents may protrude into the anterior cranial fossa.

Synonyms

AICA

Definition

The anterior inferior cerebellar artery (AICA) is a branch of the basilar artery. AICA travels across the pons to the cerebellopontine angle, where it lies adjacent to cranial nerves VII and VIII, proceeds to the internal auditory meatus, and travels along the surface of the cerebellum. It supplies the anterolateral cerebellum, parts of the pons, and the labyrinth in the inner ear. AICA sometimes has connections with the posterior inferior cerebellar artery (PICA) as well as the superior cerebellar artery (SCA). AICA can be divided into three segments: the premeatal segment, meatal segment, and postmeatal segment. The premeatal segment extends from the origin of the vessel to cranial nerves VII and VIII, the meatal segment is the part proceeding to the internal auditory canal, and the post meatal segment travels along the cerebellum. The AICA has several branches that supply different sections of the brain. The internal auditory artery (labyrinthine artery) travels with cranial nerves VII and VIII to the internal auditory meatus and is the sole blood supply to the labyrinth. In 50% of people, the labyrinthine artery arises from the AICA, but it may arise from the basilar artery as well. The subarcuate artery supplies the bone in the semicircular canals. There are also cerebellar cortical branches that supply the anterolateral cerebellum, as well as perforating branches that supply the brainstem.

Ischemia in the distribution of the AICA may cause vertigo, vomiting, hearing loss, facial palsy, and ipsilateral limb ataxia. For ophthalmology, these signs and symptoms may be associated with problems with gaze-holding and pursuit or vestibular nystagmus. The ocular motor signs may be due to involvement of the labyrinth, vestibular nuclei, or cerebellar flocculus.

Anterior Lamellar Keratoplasty (ALK)

► Lamellar Keratoplasty

Anterior Lamellar Keratoplasty, Laser Assisted

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Femtosecond laser-assisted lamellar keratoplasty

Definition

Keratoplasty by programming the femtosecond laser to create bladeless, precise anterior lamellar interface, and peripheral trephination cuts with certain depths and diameters. The applanation lens which is used for LASIK flaps is also used in the laser-assisted anterior lamellar keratoplasty. Laser-assisted lamellar keratoplasty is used in eyes with pathology limited to the anterior layers such as keratoconus, corneal problems after laser in situ keratomileusis (ectasia), and corneal stromal opacities.

Epidemiology

Femtosecond laser-assisted anterior lamellar keratoplasty has already been performed in humans with good visual outcomes and is becoming an interesting and accurate alternative to non-laser keratoplasty.

History

In 2008, Yoo et al. described the use of a femtosecond laser in lamellar keratoplasty for anterior corneal pathology. Due to the fact that the femtosecond technology is becoming more and more common in several corneal procedures, this method is gaining significant weight because of its efficacy, safety, and accuracy.

Clinical Features

The femtosecond laser is a 1053 nm wavelength laser that generates pulses in the femtosecond range. This results in minimal surrounding tissue damage during the process called photodisruption. The laser vaporizes small amounts of the tissue, and a plasma and shock wave formation is followed by the release of gas and bubble formation in the corneal stroma. A dissection plane is created after many pulses have been applied in the same area within the corneal stroma.

Tests

Thorough examination of the anterior segment with the slit lamp and corneal topography, pachymetry, and measurement of uncorrected and best spectacle-corrected visual acuity are mandatory to maintain the best possible postoperative results. See also entries "► Anterior Lamellar Keratoplasty (ALK)," "► PRK," "► Laser Speckle," and "► Wavefront-Guided LASIK."

Differential Diagnosis

Other types of keratoplasty performed by femtosecond lasers:

- Femtosecond laser-assisted posterior lamellar keratoplasty
- Femtosecond laser-assisted penetrating keratoplasty

Etiology

See "History" section above.

Treatment

Primarily the femtosecond laser cut is created on both donor and recipient corneas. The donor lamellar cut has a diameter and thickness which are determined by the corneal opacity which has to be removed. After using topical anesthesia, a suction ring is positioned at the sclerolimbal margin to stabilize the eye. The trephination cut is performed by programming a circular pattern of laser sports which move in a defined direction, with starting points in the lamellar interface and ending points. Energy settings for the lamellar interface and trephination cuts are similar to those used in standard LASIK. The host corneal button is then removed and replaced with the donor lamellar button on the recipient residual corneal stromal bed. Finally, a bandage contact lens is fitted on the cornea, and the patient is placed on antibiotic and steroid eye drops.

Anterior Megalophtalmos

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

X-linked megalocornea

Definition

A congenital condition presenting with large corneal diameter (>13 mm) and a very deep anterior chamber (>4 mm), first described by Kayser (1914).

Etiology

An underlying genetic defect has been localized on the long arm of the X chromosome in a single family (Chen et al. 1989). Most likely, persistence of the early embryonic relationship between the diameter of the anterior opening of the eye cup and the equatorial diameter leads to a large cornea and deep anterior chamber (Mann 1957). The hypothesis that an increased intraocular pressure

is the principal cause was abandoned because characteristic bridges of iris tissue found in patients with anterior megalophthalmos were also found in a large portion of normal eyes.

Clinical Presentation

A large corneal diameter (13–14.5 mm, symmetrical in both eyes), a deep anterior chamber (4–6 mm), and an iris hypoplasia with transillumination defects are characteristic for eyes with anterior megalophthalmos (Meire 1994). In the majority of cases, visual acuity is not significantly affected but could be reduced by the development of cataract and central corneal mosaic dystrophy. The refraction is mostly emmetropic. Astigmatism can be present but is not obligate. Characteristically, the patients develop an arcus lipoides during their third decade of life. Gonioscopy reveals a wide angle and a heavily pigmented trabecular meshwork, often with bridges of iris tissue. Other clinical features developing later are pigment dispersion and dislocation of the crystalline lens. Axial length is increased in most eyes, mainly due to an enlargement of the anterior segment.

Diagnostics (Lab Diagnostics)

An underlying genetic defect has been localized on the long arm of the X chromosome. In families with X-linked megalocornea, DNA analysis can help to detect female carriers. DNA analysis may also help to resolve the question of whether or not a male with large corneal diameters in a family with proven X-linked megalocornea is affected.

Differential Diagnosis

Anterior megalophthalmos needs to be discriminated from other conditions with large corneal diameters and high anterior chamber depths such as simple megalocornea or megalophthalmos. Megalophthalmic eyes typically show an excessive myopia due to a high vitreous length. In infants, it is extremely important to rule out a buphthalmus due to congenital glaucoma.

Prophylaxis

There is no prophylaxis of the condition itself. However, patients should be monitored closely to prevent complications of the condition such as glaucoma, cataract, and lens subluxation.

Therapy

There is no therapy of the condition itself. However, patients should be monitored closely to prevent complications of the condition such as glaucoma, cataract, and lens subluxation.

Prognosis

The prognosis is good. Cataract, glaucoma, and in some cases the mosaic dystrophy might affect visual acuity.

Epidemiology

Anterior megalophthalmos is a rare condition with less than 100 cases reported so far. However, the real prevalence might be higher.

Anterior Optic Capture

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

ACCC–OC; Anterior CCC optic capture

Definition

The optic capture describes a capsular fixation technique performed in pediatric cataract surgery and placed in intraocular lens (IOL) complication and management. Especially the anterior optic capture is performed while a dislocated IOL sits preoperatively behind the capsule in the anterior vitreous.

Indication

The indication for an optic capture is given in pediatric patients to reduce posterior capsular opacification and rotationally stable of the IOL. Another indication is given in subluxed intraocular lenses to reposition. The position of the intraocular lens preoperatively affects the decision to proceed with anterior or posterior optic capture.

Contraindication

In the absence of a good anterior capsule shelf and no major zonular defects, a capsular fixation technique is not feasible.

Techniques and Principles

The optic sits anterior to the capsulorhexis and the haptics behind the capsule. Inversely the haptics lie in the ciliary sulcus, and the optic is posterior to the capsular remnant. The position of the intraocular lens preoperatively affects the decision to proceed with anterior or posterior optic capture.

In case a subluxed IOL must be secured by microgaspers in one hand, the IOL may further dislocate onto the posterior pole. In the mean time, an anterior chamber maintainer should be placed in a corneal incision to maintain the intraocular pressure.

Outcome

The success depends on the specific indication and location of a subluxed lens.

Complications

In case of a subluxed IOL, there is a risk of IOL's dislocation onto the posterior pole necessitating of a retinal surgeon. An elective optic capture in pediatric eyes includes the general risks of cataract surgery.

History

Reference is made to the respective techniques.

Clinical Features

Depending on the method, different instruments are needed. In the following, the vitrector, the cystotome, the capsulorhexis forceps, the aspiration handpiece, and the Fugo plasma blade tip are to be mentioned.

For details, it is referred to especially written articles.

Anterior Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Definition

A surgical procedure to access a specific area of the anterior orbit, generally considered to be within the anterior two-thirds of the orbit.

Purpose

To provide the most direct route either transcutaneously or transconjunctivally to the anterior orbit, keeping in mind normal anatomical structures (blood vessels, nerves, muscles, etc.) that may be nearby (Levine 2003; Nerad 2001).

Principle

To safely access the anterior orbit.

Indications

To access an area of the orbit for biopsy of a lesion, removal of a lesion, removal of a foreign body, fat or bony orbital decompression (Levine 2003; Nerad 2001).

Contraindication

Area necessary to access is not in the anterior orbit. Any medical contraindication to surgery.

Classification

Orbital surgery/Orbitotomy

Advantages/Disadvantages

Safe approach to anterior lesions/requires surgical intervention.

Cross-References

► Graves Ophthalmopathy
► Orbital Pain

Anterior Segment Partial Coherence Interferometry

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Anterior segment optical biometry

Definition

Anterior segment partial coherence interferometry is an optical biometry of intraocular distances in the eye from the cornea to the back of the lens.

Purpose

Anterior segment partial coherence interferometry allows precise measurement of central corneal thickness, anterior chamber depth, and lens thickness.

Principle

In dual-beam partial coherence interferometry, a Michelson interferometer splits an infrared light beam of high spatial coherence but very short coherence length into two parts, forming a coaxial dual beam. This dual light beam, containing two beam components with a mutual time delay of twice the interferometer arm length difference introduced by the interferometer, illuminates the eye. Both components are reflected at several intraocular interfaces that separate media of different refractive indices. If the delay of these two light beam components produced by the interferometer equals an intraocular distance within the coherence length of the light source, an interference signal (called partial coherence interferometry signal) is detected, similar to that of ultrasound A-scan.

Indication

Optical biometry of the anterior segment of the eye prior to cataract or refractive surgery.

Contraindication

Patients with dense cataracts or patients unable to cooperate or fixate during the measurement process.

Advantage/Disadvantage

Anterior segment partial coherence interferometry is a precise and reliable method for biometry of the anterior segment of the eye. In contrast to ultrasound contact biometry, the measurement is

independent of the examiner's ability to locate the correct position of the eye during measurement. In contrast to ultrasonic biometry, noncontact anterior segment partial coherence interferometry reduces the risk of injuring the cornea during measurement. However, in contrast to ultrasound biometry, lens thickness cannot be assessed in patients with dense cataracts or opaque media.

Synonyms

Anterior eye segment surgery

Definition

Summary of all recent events in anterior eye segment surgery. These surgical interventions include the area of lens, corneal, refractive, glaucoma, and squint surgery.

Epidemiology

Anterior segment surgery is still a growing and innovating range in ophthalmological treatment. Especially by the cataract surgery and an increasing number of refractive operative treatment, procedures of the anterior eye segment form the main part.

History

Reference is made to the respective article section.

Clinical Features

Reference is made to the respective article section.

Tests

Preoperative tests should include in addition to the efficient patient's anamnesis (drugs, past eye interventions, general diseases, familiar eye diseases) the systematic examination of anterior segment and fundus (dilated pupil) in both eyes to preclude several exclusion criteria.

The special diagnostics and including and excluding criteria depend on the type of surgery.

Differential Diagnosis

See "Treatment" section bottom.

Etiology

See "History" section above.

Treatment

The majority of anterior segment surgery is made in cataract and corneal surgery.

These days, cataract surgery technique includes phacoemulsification, ECCE, and ICCE with implantation of artificial lenses.

Corneal surgery comprehends refractive surgery and cornea transplantation. Specifically, these are mainly laser surgical procedures, phacic intraocular lenses, refractive lens exchange, UV-cross-linking, astigmatic keratotomy, and limbal relaxating incision. In the field of cornea transplantation today, there are opportunities to transplant perforating or laminating.

[2]Department of Ophthalmology, Rambam Health Care Campus, Haifa, Israel
[3]HaEmek Medical Center, Afula, Israel

Synonyms

Vitreous base avulsion, "bucket-handle sign"; Vitreous base detachment

Definition

Contusive ocular injury may avulse the vitreous base from its firm adhesion spanning the ora serrata. In fact, vitreous base avulsion is considered pathognomonic for ocular contusion injury.

Etiology

Contusive ocular injury may damage posterior segment structures by several mechanisms. The severity varies from self-limited commotio retinae to vision-threatening retinal detachment. The vitreoretinal interface plays a key role in the pathophysiology of most retinal injuries. Retinal detachment is often the final common pathway for traumatic disruption of the pars plana, vitreous base, or retina.

The vitreous most tightly adheres to the retina at the vitreous base, a band of condensed vitreous that spans the ora serrata 360°. The vitreous base extends approximately 2 mm anterior to the ora serrata and 2–4 mm posteriorly. This tight interface plays a major role in the

pathophysiology of traumatic retinal breaks and detachments.

Blunt trauma rapidly compresses the eye along its anteroposterior axis and expands it in the equatorial plane, resulting in severe traction on the vitreous base that may detach it. Although the vitreous base can be avulsed from the underlying retina and nonpigmented epithelium of the pars plana without tearing either one, usually one or both are also torn in the process.

Vitreous base avulsion has also been reported spontaneously in young patients with inferotemporal retinal dialysis, in a patient with neurofibromatosis, and as a presenting sign of child abuse.

Clinical Presentation

Contusive trauma stresses the vitreoretinal interface and vitreous base, increasing the risk of vitreoretinal interface separation. The trauma associated with vitreous base avulsion is often presumed severe considering the vitreoretinal adhesions are often strongest at the vitreous base. Consequently, avulsion without concomitant pars plana tears, retinal dialyses, or retinal tears is uncommon. Dialyses are usually located at the posterior border of the vitreous base but can also occur at the anterior border and usually occur due to blunt ocular trauma. Vitreous base avulsion is also commonly associated with iris trauma or hyphema.

Patients with an isolated vitreous base avulsion following blunt trauma may present with blurred vision and/or a "stringy" floater in the eye. In many cases it may be asymptomatic.

A special consideration should be given to trauma in young eyes. Although young patients have a higher incidence of eye injury than other age groups, only in rare instances does the retina detach immediately following blunt trauma because young vitreous has not yet undergone syneresis or liquefaction. The vitreous, therefore, provides an internal tamponade for the retinal tears or dialyses. With time, however, the vitreous may liquefy over a tear, allowing fluid to pass through the break to detach the retina. The clinical presentation of the retinal detachment is thus usually delayed, with only 12% of detachments identified immediately, 30% identified within 1 month, 50% identified within 8 months, and 80% identified within 24 months.

Diagnosis

Vitreous base avulsions appear as a stripe of translucent vitreous overlying the peripheral retina or ora serrata, creating a "bucket-handle" appearance. The presence of this finding should warrant a careful examination of the pars plana, ora serrata, and retinal periphery when the eye becomes stable enough for scleral depression.

In the acute setting, examination may be limited by the severity of injury, patient discomfort, and clarity of ocular media. Determination of pupillary light reaction and evaluation for a relative afferent pupillary defect should be performed in all cases. During the posttraumatic period, every patient should receive a complete ocular examination.

Differential Diagnosis

NA

Prophylaxis

Limited to wearing ocular protection (e.g., during sports activities)

Therapy

This condition may be asymptomatic and requires no treatment or surgical intervention if found in isolation. Close follow-up is recommended until

the ora serrata and pars plana area can be adequately visualized to rule out retinal dialysis or tears of the pars plana.

Prognosis

When isolated, vitreous base avulsion usually has no serious ocular consequences. However, prognosis varies in the presence of associated ocular pathology such as retinal tears, retinal dialysis, iris trauma, or hyphema, respectively.

Epidemiology

Much of the reported epidemiologic information regarding contusive posterior segment injury focuses on traumatic retinal detachment, a final common pathway for most posterior segment injuries. Traumatic retinal detachments account for between 10% and 19% of all aphakic retinal detachments. Trauma contributes to the peak incidence in younger years (20–29 years of age). Eighty percent of traumatic detachments occur prior to the age of 40. Men outnumber women in traumatic detachment (78% vs. 22%).

Vitreous base avulsion has been reported in 25.9% of patients with traumatic retinal detachment. Vitreous base avulsions have been reported to occur in roughly half of patients with retinal detachments secondary to squash ball injuries.

Antibiotics for Eye Infections

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Substance or compound produced by a microorganism that kills other microorganisms or inhibits their growth.

Indication

Prophylaxis or therapy of infections of the eye and orbit caused by bacteria, fungi, or protozoans.

Contraindication

Allergy or intolerance to antibiotics.

Use and Dosage

Antibiotics differ in pharmacokinetic and pharmacodynamic and may either be applied as topical (eyedrops), oral, intravenous, or intracameral or intravitreal injection.

Adverse Reactions

Depending on the antibiotics used and the microbial organisms targeted.

Interactions

Depending on the antibiotics used.

Synonyms

Anticoagulant medication; Decoagulants

Definition

Anticoagulants (Greek: anti, against; Latin: coagulation, agglomerate) are drugs used to arrest the blood coagulation. Based on the mechanism of action, we distinguish direct and indirect anticoagulants.

Medicinal products, for example, include heparin and derivative substances, coumadins (antidot, vitamin K), prostaglandin synthesis inhibitors, fibrinolytics, and tissue plasminogen activators.

Indication

A prophylactic indication is given, for example, in preventing thromboses or pulmonary embolism. A therapeutic indication is given in atrial fibrillation or atrial flutter, thromboses, or postoperative protection (heart valve replacement). Some chemical compounds are used in medical equipment.

Especially in ophthalmological treatment, anticoagulants are cardinally used in the treatment and prophylaxis of retinal artery or vein occlusion syndromes, chemical alkali burn, infective corneal ulcer, and keratitis filiformis.

Further anticoagulant ointment (containing heparin) is, for example, applied to bruising and swelling in the area of the eye. A systemic and intraocular injected use of heparin was also described in case of intraocular fibrine.

Contraindication

Contraindications vary between the different preparations of anticoagulant drugs, which generally include bleeding (especially intracranial), fresh wounds and incisions, gastrointestinal ulcer, arterial hypertension, chronic alcoholism, hemophilia, pregnancy, and severe liver and kidney diseases.

Use and Dosage

Because of the diversity of preparations of topical and systemic application in anticoagulation therapy, reference is made at this point to specific textbooks of pharmacology.

In case of sytemical appliance, it should be attended to internal medicine cooperation.

Adverse Reactions

An overdose may cause the risk of bleeding (internal organs, brain). Especially on the eye bleeding of vitreous body and hyposphagma have to be mentioned.

The effect of anticoagulants is persists about several days and should be remembered in case of surgeries (especially elective interventional treatment).

Interactions

A coadministration of salicylic acid and coumarins should be avoided. An increased effect of oral anticoagulants is seen in combination with medications that affect liver enzymes (inhibition or induction).

Interactions were also described in combination with intravenous cephalosporins and oral sulfonylureas.

In addition to that, vitamin K-rich foods should be eaten only in small quantities to prevent a reduction of the effect.

Antioxidants

Barbara Gold
Department of Ophthalmology, Tel Aviv University, Tel Aviv Medical Center, Tel Aviv, Israel

Definition

Antioxidants are protective factors against age-related macular degeneration (AMD). They may include zinc, beta-carotene, vitamin C and E, lutein/zeaxanthin, omega 3 fatty acid, and eicosapentaenoic/docosahexaenoic acid.

Indication

According to The Age-Related Eye Disease Study (AREDS) that was sponsored by the US National Eye Institute taking high levels of antioxidants and zinc can reduce the risk of developing advanced age-related macular degeneration (AMD) by about 25%. Additional research suggests that carotenoids and antioxidant vitamins may help to retard some of the destructive processes in the retina and the retinal pigment epithelium that lead to age-related degeneration of the macula. From these findings, it is recommended that antioxidants are indicated in people who are at high risk for developing advanced AMD.

Contraindication

Allergy to any of the substances.

Use and Dosage

The specific daily amounts of antioxidants and zinc used by the study researchers were vitamin C 500 milligrams (mg); vitamin E 400 International Units (IU); 15 milligrams of beta-carotene (often labeled as equivalent to 25,000 International Units of vitamin A); zinc as zinc oxide 80 mg; and 2 mg of copper as cupric oxide. The reason copper was added to the AREDS formulations containing zinc was to prevent copper deficiency anemia, a condition associated with high levels of zinc intake. There are a number of commercial formulas and patients are advised to follow the manufacture recommended manufacturer instructions.

Adverse Reaction

Beta-carotene may slightly increase the risk of cancer in patients that are heavy smokers as seen in studies by National Cancer Institute. AREDS2 showed it is possible to replace beta-carotene from the original AREDS formulation with lutein/zeaxanthin; it may decrease the risk of lung cancer in smokers. Vitamin E in excess of 400 IU is no longer protective and may exacerbate prostate cancer.

Interaction

Antioxidants interact with radiotherapy and certain forms of chemotherapy. It is recommended to have a four half-life separation used concurrently.

Definition

History

In 1948, Isaac Michaelson posited that a diffusible, hypoxia-induced "factor X" was released by nonperfused retina and caused angiogenesis. Judah Folkman later studied tumor vasculature and hypothesized that tumors secrete a diffusible, angiogenic growth factor which he termed "tumor angiogenesis factor (TAF)." He also suspected TAF was important in ocular neovascularization and theorized that angiogenesis inhibitors could be used to treat cancer and other angiogenesis-dependent diseases. In the 1980s, two groups separately described what we now know as vascular endothelial growth factor (VEGF). Dvorak and Senger described an inducer of vascular leakage and vascular permeability factor (VPF), and Napoleone Ferrara identified angiogenic VEGF. It was not until 1993, however, that Ferrara created an antibody against VEGF and proved it reduced

angiogenesis and decreased experimental tumor growth (Das and Friberg 2011). Since then, the advent of anti-VEGF therapy has greatly expanded the armamentarium for treating many cancers and vascular-mediated diseases of the eye.

VEGF, among other factors, is a key component in ocular angiogenesis, microvascular permeability, and endothelial cell survival. It is a family of isoforms that includes VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, platelet-derived growth factor (PDGF), and placental growth factor (PlGF). Alternative splicing of the human VEGF-A gene yields six principal isoforms, one of which is $VEGF_{165}$ (Nguyen et al. 2010). $VEGF_{165}$ is the most potent and prevalent among the major forms expressed during pathologic neovascularization (Das and Friberg 2011).

A variety of pathologic ocular conditions result in vision loss due to abnormal blood vessel growth. Several strategies to inhibit the action of VEGF have been explored, originating mainly in the oncology field. In ocular neovascularization, neutralizing anti-VEGF antibodies, like ranibizumab and bevacizumab, and soluble fusion proteins, like aflibercept, are the most popular treatment options. Other agents investigated include tyrosine kinase inhibitors (pazopanib, vatalanib), inhibitors of protein kinases (ruboxistaurin, sirolimus), small interfering RNA (siRNA) molecules (bevasiranib, PF-04523655) (Das and Friberg 2011), and a novel agent, squalamine, that uses the modulatory protein calmodulin to inhibit VEGF, PDGF, and bFGF.

Anti-VEGF Therapies

In 2003, clinical trials involving a humanized form of an anti-VEGF monoclonal antibody, bevacizumab (Avastin, Genentech), showed extended median survival time for patients with colorectal cancer. The FDA approved bevacizumab in 2004 for the treatment of metastatic colorectal cancer. It was soon realized that anti-VEGF therapy could also be used to target ocular angiogenesis (Das and Friberg 2011).

The initial studies with anti-VEGF therapy in the eye were directed toward the presence of choroidal neovascularization (CNV) in age-related macular degeneration (AMD). It has been shown that CNV removed with surgery is strongly reactive with anti-VEGF antibody and pharmacologic inhibition decreases experimental laser-induced CNV in animal studies (Das and Friberg 2011). Ocular VEGF levels have also shown to be elevated in other diseases of ocular neovascularization, including retinal vein occlusion, diabetic retinopathy, diabetic macular edema, neovascular glaucoma, rubeosis, and retinopathy of prematurity. Furthermore, studies have shown a correlation between intraocular VEGF levels and activity of neovascularization in diseases like proliferative diabetic retinopathy and central retinal vein occlusion (Nguyen et al. 2010).

Since then, multiple trials have investigated the safety and efficacy of various anti-VEGF therapies in ocular diseases. The original ocular anti-VEGF therapy, pegaptanib (Macugen, Eyetech), binds only the 165 kD form of VEGF, while the well-known monoclonal antibodies, ranibizumab (Lucentis, Genentech) and bevacizumab (Avastin, Genentech), bind all biologically active forms of VEGF-A. Aflibercept (Eylea, Regeneron) is a newer recombinant fusion protein with high affinity for VEGF-A, as well as VEGF-B, VEGF-C, VEGF-D, and PDGF.

Approved in 2004, pegaptanib (Macugen, Eyetech) was the first FDA-approved therapy targeting VEGF in patients with neovascular AMD. Pegaptanib is a PEGylated oligonucleotide RNA aptamer with a high binding specificity for only the $VEGF_{165}$ isoform. Compared to antibodies, aptamers are chemically synthesized nucleic acid or peptide oligomers that bind a specific target molecule, acting like a "chemical antibody," and are capable of greater specificity and affinity than antibodies. The VEGF Inhibition Study in Ocular Neovascularization (VISION) trial demonstrated that, after 2 years, those receiving intravitreal pegaptanib for CNV due to age-related macular degeneration (AMD) every 6 weeks were half as likely to lose greater than 15 ETDRS letters than those who stopped (Nguyen et al. 2010). At 2 years, 10% of treated patients gained at least three lines of vision. The

clinical trial results were promising; however, efficacy in the clinic was not dramatic or durable (Das and Friberg 2011).

Ranibizumab (Lucentis, Genentech) was the first monoclonal antibody tested in the treatment of neovascular AMD. Also known as immunoglobulins, antibodies are proteins used to help identify and neutralize objects foreign to the body's immune system. The region of the antibody responsible for binding antigens on that foreign object is the Fab (Fragment, antigen-binding) region. The base of the protein, the Fc (Fragment, crystallizable), is involved in modulating immune cell activity and ensures the appropriate response to the specific antigen. Ranibizumab is a recombinant humanized monoclonal antibody that is a Fab fragment, a refinement of the full-length monoclonal antibody bevacizumab. It differs from pegaptanib in that it binds all active forms of VEGF-A. Specifically developed for intraocular use, it binds VEGF-A with greater affinity than bevacizumab. Also, the absence of the Fc portion when compared to bevacizumab eliminates the possibility of complement-mediated or cell-dependent cytotoxicity and decreases the half-life to minimize extended systemic exposure. Ranibizumab was approved by the FDA in 2006. Compared to the previous treatments of conventional laser, photodynamic therapy (PDT), and pegaptanib, it was the first treatment for neovascular age-related macular degeneration that demonstrated overall improvement in visual acuity instead of decreased visual loss.

Bevacizumab (Avastin, Genentech) is another humanized monoclonal antibody directed against VEGF-A. It was initially approved for intravenous use in the treatment of metastatic colon cancer but has since been used off-label for many ocular diseases and has shown good tolerability and improved visual acuity. It is a full-length humanized monoclonal antibody that binds and, similar to ranibizumab, inhibits all biologically active forms of VEGF-A. There was early interest in using bevacizumab in the treatment of neovascular AMD, but animal studies conducted by Genentech comparing a full-length antibody similar to bevacizumab indicated that the radiolabeled full-length antibody did not cross the ILM, whereas the Fab fragment could diffuse through the RPE. However, in 2005, the SANA trial reported improved vision and a reduction in central macular thickness with intravenous bevacizumab in nine patients with neovascular AMD (Moshfeghi et al. 2006). Systemic side effects, including hypertension and thrombosis, however, limit its use systemically, especially in the older population. Soon thereafter, intravitreal administration of bevacizumab proved to be efficacious with fewer systemic side effects (Das and Friberg 2011).

Aflibercept (Eylea, Regeneron) is a newer anti-VEGF therapy first approved by the FDA in 2011 for the treatment of neovascular AMD. It is a 110-kDa soluble recombinant fusion protein that consists of an IgG fragment with copies of extracellular VEGFR domains from VEGFR-1 and VEGFR-2. It has a high affinity for all VEGF-A isoforms in addition to VEGF-B, VEGF-C, VEGF-D, and PDGF and binds VEGF more tightly than the native receptor or monoclonal antibodies.

Indication

The pathogenesis of many retinal disorders is based on neovascularization and increased vascular permeability. AMD was the original target and most studied for use of anti-VEGF therapy. Choroidal neovascularization (CNV) is the hallmark of neovascular AMD and responsible for 90% of cases of severe vision loss due to AMD (Ventrice et al. 2013).

The safety and efficacy of anti-VEGF agents, specifically ranibizumab, has been extensively investigated in clinical trials for neovascular AMD and more recently in trials for diabetic macular edema and retinal vein occlusion. The pivotal studies using ranibizumab in AMD were the MARINA and ANCHOR trials.

The Minimally Classic/Occult Trial of the Anti-VEGF Antibody Ranibizumab in the Treatment of Neovascular Age-Related Macular Degeneration (MARINA) trial was a 2-year, prospective, randomized, double-masked,

sham-controlled trial to investigate the safety and efficacy of ranibizumab in the treatment of patients with minimally classic or occult neovascular AMD. Patients were treated monthly with 0.5 mg ranibizumab, 0.3 mg ranibizumab, or a sham injection. At the end of 1 year, 95% of patients receiving ranibizumab injections lost fewer than 15 letters compared to 62% of patients receiving sham injections. Similarly, visual acuity improved by 15 or more letters in 24.8% of the 0.3 mg group and 33.8% of the 0.5 mg group compared to 5% of the sham-injection group. This benefit in visual acuity was maintained at 24 months.

The anti-VEGF antibody for the treatment of predominantly classic choroidal neovascularization in age-related macular degeneration (ANCHOR) study showed similar results for patients with predominantly classic CNV. It compared monthly 0.3 mg or 0.5 mg ranibizumab to photodynamic therapy (PDT was administered every 3 months as needed). In the ranibizumab-treated groups, 35–40% of patients gained three or more lines of vision compared to 5.6% of the verteporfin group, and visual acuity improved from baseline by 8.5–11.3 letters compared to a decline of 9.5 letters in the PDT group.

Similarly, early intraocular use of bevacizumab showed improvement in vision and decrease in mean central retinal thickness. However, due to its off-label use, many of the initial studies and data gathered were for ranibizumab only. The two were studied head-to-head for the first time in the Comparison of Age-Related Macular Degeneration Treatment Trials (CATT). These studies evaluated the effect of 0.5 mg ranibizumab compared to 1.25 mg bevacizumab when administered monthly or as needed. At 1 year, the mean gain in visual acuity was similar for both drugs (8.5 in the monthly ranibizumab-treated group and 8 letters in the monthly bevacizumab-treated group), and the mean gain was greater for monthly compared to as needed treatment (6.8 and 5.9 in the ranibizumab and bevacizumab groups, respectively). These results were statistically significant.

The initial trials using aflibercept, Intravitreal Aflibercept (VEGF Trap-Eye) in Wet Age-Related Macular Degeneration (VIEW), studied monthly versus every 2-month dosing (following three monthly injections in a loading phase) of intravitreal aflibercept compared to monthly ranibizumab. All aflibercept treatment groups (0.5 mg monthly, 2 mg monthly, 2 mg every 2 months after three initial monthly doses) proved noninferior and clinically equivalent to monthly ranibizumab injections for the primary endpoint, proportion of patients maintaining vision at week 52 (95.1–96.3% among all aflibercept treatment groups compared to 94.4% for the ranibizumab treatment group). Treatment with aflibercept also resulted in a similar improvement in anatomic measures. Ocular and systemic adverse events were similar across all groups (Das and Friberg 2011).

VEGF inhibitors are currently the gold standard for treatment of neovascular AMD. With more use and research in other diseases, it has also become more prevalent in the treatment of diabetic macular edema, proliferative diabetic retinopathy, retinal vein occlusion, non-AMD choroidal neovascularization (idiopathic, inflammatory, myopic, angioid streaks), retinopathy of prematurity, and neovascular glaucoma, among others.

Specifically, ranibizumab is currently FDA-approved for the treatment of patients with neovascular AMD, macular edema following retinal vein occlusion, and diabetic macular edema. Aflibercept is also approved for the same indications. Bevacizumab is still used off-label by many for a variety of ocular diseases with pathologic neovascularization.

In exudative macular diseases, visual gain and stability is expected instead of slowing of vision loss. While monotherapy with anti-VEGF agents is currently the gold standard in many of these diseases, researchers believe there is room for improvement, and investigative approaches look to increase the durability of treatments (decreasing the number of injections), increase efficacy, and minimize scarring. Specifically, current trials are investigating the use of Fovista (Ophthotech), an anti-PDGF agent used in combination with anti-VEGF therapy for the treatment of neovascular AMD. Fovista is designed to allow stripping of pericytes from around blood vessels, thereby leaving the underlying endothelial cells

more vulnerable to anti-VEGF action. Early reports are promising.

Upcoming studies will help determine the optimal dosing frequency, follow-up interval, method of administration, and role of concurrent and novel therapies.

Contraindication

Treatment with intravitreal anti-VEGF agents is contraindicated in patients with active ocular or periocular infections and known hypersensitivity to components of the medication or drug formulation.

Caution is recommended when treating pregnant or nursing patients. No studies have been conducted using ranibizumab or other intraocular anti-VEGF agents in pregnancy. Based on the mechanism of action, treatment may pose a risk to embryo-fetal development. It is not known if drug is excreted in human breast milk.

Use and Dosage

Procedure

Currently, all ocular anti-VEGF therapies are administered intravitreally. Preinjection use of topical antibiotics has been theorized to minimize bacterial flora around the surgical entry site and to have a synergistic effect with preinjection povidone-iodine placement, but this has not been clinically proven, and its use has declined in the last several years. In 2013, 78.2% of respondents of the American Society of Retina Specialists (ASRS) Preferences and Trends (PAT) survey reported not using an antibiotic with intravitreal injections.

Adequate topical anesthesia should be used prior to the injection. Options vary from topical proparacaine drops or soaked pledgets, viscous lidocaine or tetracaine jelly, or subconjunctival injection of lidocaine. The site of the injection is then isolated, and the needle, most commonly 30 or 32 gauge, is placed either 3.5 mm (pseudophakic eyes) or 4 mm (phakic eyes) posterior to the limbus. Prior to the injection, topical application of 5% povidone-iodine is strongly recommended. Proper eyelid hygiene with or without a scrub, sterile drape, and/or speculum is also encouraged.

The role of postinjection antibiotics is controversial. Fourth-generation topical fluoroquinolones were frequently used for a few days postinjection until the conjunctival and scleral openings were healed. No study, however, has demonstrated that pre- or postinjection topical antibiotics reduce the risk of endophthalmitis. In addition, recent studies report a significant increase in the resistance of ocular flora and a greater risk of endophthalmitis with use of topical antibiotics (Falavarjani and Nguyen 2013). Without evidence supporting the use of antibiotics, and new concerns over increasing resistance, many physicians have stopped prescribing them regularly (Nguyen et al. 2010).

Dosing

Unlike other systemic medications, the FDA-recommended dose (Table 1) is sufficient to neutralize elevated intraocular VEGF concentrations and is not dependent on the patient's age, gender, or renal function (Nguyen et al. 2010).

The early trials using intravitreal ranibizumab showed a treatment benefit with monthly injections compared to as-needed, or PRN, injections for neovascular AMD. However, the requirement for

Antivascular Endothelial Growth Factor, Table 1 Currently approved intravitreal anti-VEGF medications and dosing

	AMD	RVO	DME
Ranibizumab	0.5 mg monthly	0.5 mg monthly	0.3 mg monthly
Aflibercept	2 mg monthly first 3 injections then every 2 months	2 mg monthly	2 mg monthly first 5 injections then every 2 months

Bevacizumab is used at doses 1.25–2.5 mg (not FDA-approved for ocular use)

long-term monthly injections has proven to be a burden to patients, families, and physicians alike. Alternative dosing strategies have been and are still being investigated to decrease the treatment burden but maximize the benefit to the patient.

The PIER study evaluated 0.3 mg and 0.5 mg ranibizumab monthly for 3 months followed by quarterly dosing for 24 months. At 12 months, the mean change from baseline was a loss of 1.6 letters and 0.2 letters for the ranibizumab-treated arms, respectively. The sham arm lost 16.3 letters, proving that quarterly treatment decreased leakage from CNV but that the effect was not as robust as monthly treatment. The Prospective OCT Imaging of Patients with Neovascular ARMD Treated with Intraocular Lucentis (PrONTO) study looked at three monthly injections of 0.5 mg ranibizumab as a loading dose followed by PRN treatment based on OCT. At month 24, the mean visual acuity improved by 11.1 letters and improved by 15 letters or more in 43% of patients with an average of 9.9 injections. This study showed that less than monthly treatment can still yield a good visual outcome. Limitations of this study included sample size (40 patients) and the nonrandomized, noncontrolled nature of the study.

The future of anti-VEGF treatment will likely involve an individualized treatment plan for each patient, using OCT to help guide treatment and allowing for fewer injections over time. The popular treat-and-extend regimen used in clinic theoretically decreases the burden to the patient without compromising visual function; however, no large, prospective, multicenter clinical trial comparing the regimens has yet been published.

Adverse Reactions

Since VEGF has emerged as a key target for therapy, use of intravitreal anti-VEGF agents has been widely employed to reduce disease progression and improve visual outcomes. Intravitreal injections, when performed correctly, are generally safe and well tolerated. The complications related to injections have been thoroughly studied in many clinical trials and appear comparable across all treatment groups.

Each injection poses a risk of complication, including infection, inflammation, increased intraocular pressure, vitreous hemorrhage, retinal detachment, and cataract, among others (Ventrice et al. 2013). Nonserious ocular side effects include pain, floaters, chemosis, and subconjunctival hemorrhage. Serious systemic adverse events, including thromboembolic events, have also been reported.

Endophthalmitis is a serious ocular adverse event related to intravitreal injections, reported to occur in 0.019–1.6% in clinical trials, although more recent studies have quoted a lower incidence. In a review by Van der Reis, the incidence of endophthalmitis was below or equal to 0.04 and 0.05 per 100 injections for ranibizumab and bevacizumab, respectively. This included both infectious and noninfectious cases of endophthalmitis (Van der Reis et al. 2011).

The rate of endophthalmitis appears to be the same among different agents, injection settings, and geographic settings. Special attention should be paid to an aseptic preparation and injection procedure, as infection is likely due to contamination of the injection field by aerosolization or droplet spread (Falavarjani and Nguyen 2013). Sterile intraocular inflammation can also be seen after injection and is important to differentiate from infectious endophthalmitis. The time to presentation, presence of pain, and severity of clinical findings may be helpful. However, if endophthalmitis is suspected, intravitreal antibiotics should be administered.

Rhegmatogenous retinal detachment is another adverse event of intraocular injections. It has a low overall incidence rate of 0–0.67% (Falavarjani and Nguyen 2013), with other reviews reporting 0.01 and 0.07 per 100 injections for ranibizumab and bevacizumab, respectively (Van der Reis et al. 2011). It is thought to be due to induction of a posterior vitreous detachment or an incorrect injection technique.

Elevated intraocular pressure (IOP) after intravitreal injection is usually self-limited; however, patients with preexisting glaucoma have higher rates of IOP elevation than those without glaucoma, and there may be persistent elevated IOP over time. Multiple theories have been

proposed for the possible cause of persistent IOP elevation, including a pharmacologic effect of VEGF blockage, inflammation of the trabecular meshwork, impaired outflow due to protein aggregates or silicone debris, and damage to the outflow pathway (Falavarjani and Nguyen 2013). Routine IOP monitoring should be performed in all patients undergoing treatment with anti-VEGF therapy.

Ocular hemorrhage, including subconjunctival hemorrhage, vitreous hemorrhage, and retinal hemorrhage, is another complication of injection. The rates of subconjunctival hemorrhage are higher for those patients taking aspirin, and choroidal hemorrhage and subretinal hemorrhage have also been reported after intravitreal injections. However, given the risk of thromboembolic events, discontinuation of anticoagulants to avoid these adverse events is not recommended (Falavarjani and Nguyen 2013).

Other ocular events are related more to the ocular disease process than the injection itself. For patients with neovascular AMD, RPE tears may occur spontaneously or after therapeutic intervention. The reported incidence after anti-VEGF treatment is 0.06–27%, which may be higher than in the natural course of the disease process. Preexisting RPE detachment is considered a major risk factor, with large PED diameter and vertical height on OCT as predictive indicators. However, a recent study on three major AMD trials showed no statistical significance over 2 years in patients treated with ranibizumab compared to control. In patients who do suffer from an RPE tear, better visual outcomes are observed in those treated with anti-VEGF agents (Falavarjani and Nguyen 2013).

In patients with traction retinal detachment in proliferative diabetic retinopathy, 5.2% of eyes will have progression of the detachment at a mean of 13 days after treatment with intravitreal bevacizumab. There is a similar concern in treating patients with advanced retinopathy of prematurity, and physicians should be ready to operate if progression occurs. Other adverse events reported in patients with diabetes and retinal vein occlusion include decreased retrobulbar flow parameters, retinal arteriolar vasoconstriction, and worsening of macular ischemia.

Rare ocular and systemic side effects have been reported and include anterior ischemic optic neuropathy, retinal vein and artery occlusion, hemorrhagic macular infarction, development or exacerbation of ocular ischemic syndrome, visual hallucination, erectile dysfunction, and acute decrease in kidney function. The causative role of anti-VEGF agents in these cases has yet to be established (Falavarjani and Nguyen 2013).

While treatment is provided locally, systemic adverse events are still a concern. Intravenous administration of bevacizumab has been used widely in treatment protocols for solid cancers. Associated systemic adverse events include thromboembolic events, myocardial infarction, stroke, hypertension, gastrointestinal perforation, and kidney disease. However, the systemic administration of bevacizumab is several hundred-fold greater than the amount administered intravitreally (Moshfeghi et al. 2006).

For intravitreal use, there was a nonsignificant trend in ANCHOR of increased arterial thromboembolic events in the higher 0.5 mg ranibizumab dose study arm. There was also a trend for greater risk of CVA or nonvascular death for higher doses of ranibizumab in the SAILOR study, but this was not statistically significant and patients also had known cardiovascular risk factors (Das and Friberg 2011). Further studies did not demonstrate this increased risk. In CATT, the rates of death and arteriothrombotic events were similar for both bevacizumab and ranibizumab, but the proportion of patients with one or greater serious systemic adverse event was higher in the bevacizumab group. In contrast, IVAN demonstrated both medications to be equivalent in regard to visual improvement, and there was no difference between the drugs with respect to serious adverse events. Because of this trend in data, however, some physicians prefer not to treat patients with recent cerebrovascular accident.

In the review by Van der Reis, systemic adverse events occurred at a rate of 0.05 for bevacizumab and 0.09 for ranibizumab per 100 injections for cardiovascular disease. The incidence rates of CVA and TIA were below or equal to 0.07 per 100 injections. Thromboembolic

events, including nonfatal MI, CVA, and death from a vascular or unknown cause, were 0.07 and 0.18 for bevacizumab and ranibizumab, respectively. Vascular diseases such as deep vein thrombosis, iliac artery aneurysms, and femoral artery thrombosis have also been reported (Van der Reis et al. 2011).

While serious ocular and systemic adverse events do occur, their rates are low. Adverse events may occur due to the procedure itself, the drug, the drug vehicle, or underlying disease mechanism. Safety profiles appear comparable, and the rates of adverse events appear similar with all treatments.

Interactions

Drug interaction studies have not been conducted with intraocular bevacizumab, ranibizumab, and aflibercept.

Definition

Eyeglasses prescribed after cataract surgery when no intraocular lens is inserted into the eye. Today, in uneventful cataract surgery, the crystalline lens of the eye is typically replaced by an artificial lens implant. If such a lens cannot be implanted, a thick (plus-powered) convex lens is used to correct strong hyperopia. Such glasses are cumbersome, greatly distort peripheral vision (ring scotoma), and increase lateral magnification which effects a loss of stereo vision in unilateral use.

Apodized Diffractive Intraocular Lens

Oliver K. Klaproth
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Bifocal intraocular lens; Diffractive intraocular lens; Multifocal intraocular lens

Definition

Intraocular lens using a simultaneous diffractive bifocal optics principle, providing two foci at the same time to enable patients to see clearly in two different distances and apodization to limit peripheral optical phenomena.

Basic Characteristics

Refraction: Diffraction

Light is the visible spectrum of the electromagnetic radiation. Light waves are transverse waves (oscillating perpendicular to direction of propagation) and characterized by wavelength, amplitude, and frequency. Light interacts in several ways with matter. In case of transparent media, light is refracted and reflected. Refraction, however, is a theoretical model and can be explained by Huygens' principle of diffraction. A wavefront is a plane, where a light wave, exposed by the same light source, has the same phase. Huygens' principle states that every point on a wavefront is again the source of another independent wavefront. This way, when a wavefront interacts with an optical surface, a new independent wavefront results. If two or more of such independent wavefronts interact interference appears. The intensity of the resulting wavefront can be increased, decreased, or the wavefront can even be eliminated. Light rays, as used in the theoretical model of light refraction and thus construction schemes of optical system is perpendicular to the tangent of the wavefront. When passing a transparent surface the direction of this perpendicular is changed by diffraction.

Diffractive intraocular lenses use this effect by a defined modification of their surface structure. Usually, circular zones of different thickness are used to enable defined interaction between the incoming and wavefronts by changing the optical path difference. Thus, light propagation in some directions is increased and deleted in others, resulting in two or more foci.

However, about 18% of light is being directed to higher levels of diffraction and thus lost for the eye. This is one reason why multifocal diffractive lenses have a smaller light efficacy, and patients with such lenses implanted require proper illumination for tasks, that require detailed resolution, e.g., reading.

Another reason for potential postoperative optical problems is the fact that the images of both diffractive generated foci are always displayed on the retina. Therefore, another great amount of light is lost for vision in each of the defined distances. Furthermore, the overlap of the two images leads to a certain loss in contrast sensitivity.

Apodization

Apodization is a commonly used optical term, and the principle is used in many diffractive optic systems. It describes optical filtering for

Apodized Diffractive Intraocular Lens, Fig. 1 Appodized diffractive aspheric blue filtering single-piece intraocular lens. (ReSTOR, Alcon, Fort Worth, Texas, USA). One can see the central diffractive circular steps with decreasing distance from each other

enhancement of contrast sensitivity at expense of resolution. This is usually done by peripheral reduction of transmission. In case of multifocal diffractive IOL, it is performed by decreasing thickness of the circular zones from the center to the periphery to minimize optical phenomena (Fig. 1).

Definition

Apraxia of lid opening (ALO) is a potentially disabling syndrome characterized by a non-paralytic difficulty in voluntary initiation of

the act of lid elevation after lid closure. Although called an apraxia, apraxia of lid opening is not a true apraxia (typically defined as a voluntary inability to perform a motor task to command). ALO may present with difficulty to open the eyes in one instance but then be normal in other instances. The pathophysiology of ALO is poorly understood, but the predominant proposed theory is thought to be related to an abnormality in the supranuclear control of voluntary elevation of the eyelid. The normal eyelid opening requires an activation of the levator palpebrae superioris muscle (LPS) and the concomitant inhibition of orbicularis oculi muscle (OO). Electromyographic (EMG) studies have revealed involuntary LPS inhibition and persistent contraction of pretarsal OO in some patients. Anatomically the LPS receives bilateral innervation from the central caudal subdivision of the oculomotor nucleus, and the OO muscles receive unilateral innervation from the facial nucleus. The cortex, rostral midbrain, and extrapyramidal motor systems also modulate and control LPS motor neuron activity, and any disturbances of these premotor structures may result in an abnormal inhibitor of LPS. ALO is frequently associated with benign essential blepharospasm (BEB) and has been variably reported in 7–55% of patients with blepharospasm. The peak age of onset is in the sixth and seventh decades of life, and it has been reported to be more common in women with female-to-male ratio of 2:1 with no racial differences.

Etiology

Aside from its association with BEB, ALO has been described in nondominant hemisphere, medial frontal lobe, basal ganglia, and rostral brainstem lesions and in association with a variety of central nervous system (CNS) diseases such as progressive supranuclear palsy (PSP), Parkinson disease, other motor neuron diseases, idiopathic and secondary dystonias, Huntington chorea, hydrocephalus, choreoathetosis, and Shy-Drager syndrome. In addition, it has been reported in association with medication intoxication such as lithium intoxication, sulpiride, and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).

Clinical Presentation

ALO can present in isolation in healthy individuals or in patients with known neurodegenerative or neurologic disorders as above. ALO is a chronic disorder without cure; however, spontaneous improvements and remissions have been reported. Patients with ALO present with difficulty in opening the lids at will subsequent to voluntary or involuntary closure. See Fig. 1. Once the lids are opened, the LPS has normal tone and the patient usually then has no trouble keeping the lids opened. The lids usually open more easily during reflex blinking. In BEB patients, intermittent involuntary closure of the eyes may occur in the presence or absence of spasmodic contractions of the OO. In some instances attempting eye opening can result in a vigorous contraction of the frontalis muscle, backward thrusting of the head, and delay in lid closure.

Patients with ALO often adapt different "sensory tricks" and maneuvers to help with opening the eyes, such as manually lifting the lids, elevating their brows, massaging the lids, opening the mouth, and lightly touching or tapping the temporal region; however the physiology why these maneuvers help remains unknown. In general,

Apraxia of Lid Opening, Fig. 1 A patient with blepharospasm has concomitant apraxia of eyelid opening. Mechanical opening of the lids or use of an alleviating maneuver (e.g., sensory trick) can stop or reduce the spasm and allow the lids to open

the coordination of eyelid movement, pursuit eye movements, both horizontal and vertical saccades, and vestibulo-ocular reflex all are preserved. ALO is frequently confused with upper eyelid ptosis, though it usually occurs in the absence of levator weakness.

Diagnostics

The first step in the diagnosis depends on the exclusion of underlying diseases or medication intoxication that may be associated ALO. Neuroimaging studies using computed tomography (CT) scanning or magnetic resonance imaging (MRI) may help reveal whether a pathologic etiology is present. Studies showed using brain positron emission tomography (PET) has demonstrated glucose hypometabolism suggesting abnormal neuronal activity in the basal ganglia, the unilateral or bilateral medial frontal lobe, and the primary visual cortex. Other diagnostic tools have been used to demonstrate LPS and OO muscle activity during lid movements including electromyography (EMG). Neuropsychological testing may be considered to document the presence or absence of frontal lobe pathology.

Differential Diagnosis

1. Benign essential blepharospasm
2. Cerebral ptosis
3. Hemifacial spasm
4. Eyelid myokymia
5. Bell palsy
6. Facial nerve misdirection (synkinesis)
7. Spastic-paretic facial contracture
8. Drug side effect (antipsychotic, antiemetics, anorectics, nasal decongestants, levodopa)
9. Ophthalmic causes: conjunctivitis, keratitis, foreign body, allergy, keratoconjunctivitis sicca, and uveitis
10. Nonorganic lid closure

Therapy: Treat Any Underlying Etiology

Medical Management

The drugs that have been used in the management of ALO are:

1. Neuromuscular blockers such as botulinum toxin can treat blepharospasm and may improve ALO (Botox, Allergan, Inc., Irvine, CA)
2. Antiparkinsonian agents: dopamine agonists, e.g., carbidopa and levodopa (Sinemet) anticholinergic agents (e.g., trihexyphenidyl, benztropine (Cogentin))
3. Anticonvulsants (e.g., valproic acid (Depacon, Depakene, Stavzor))

Surgical Management

The procedures that have been used in the management of ALO are:

1. Frontalis suspension and myectomy
2. Levator palpebrae superioris (LPS) aponeurosis reinsertion

Aqueous

Definition

The aqueous humor is a clear, colorless fluid that fills the anterior portion of the eye which is formed from plasma by the nonpigmented cells of the ciliary body.

Basic Characteristics

Aqueous humor has several functions including providing nutrition to and removing metabolic waste from the lens, trabecular meshwork, and cornea. It maintains intraocular pressure and has a role in the optical system of the eye by having the characteristics of being clear and colorless. It also has a role in paracrine signaling and immune responses.

Aqueous is an ultrafiltrate of plasma formed by the ciliary body; however, compared to plasma, aqueous is slightly hypertonic and acidic with a pH of 7.2 and contains much less protein and relatively less bicarbonate, calcium, and glucose. However, it contains much more ascorbate and relatively more hydrogen, chloride, and lactate. It also contains small amounts of amino acids, coagulation factors, growth factors, carbonic anhydrase, lysozyme, diamine oxidase, cAMP, catecholamines, steroid hormones, and hyaluronic acid. In the setting of inflammation or trauma, there is an increase in protein concentration in aqueous.

Aqueous is formed via three mechanisms. The first process, which accounts for most aqueous production, is active transport, a process which consumes energy and moves substances against an electrochemical gradient, independent of intraocular pressure. Next, ultrafiltration allows pressure-dependent movement of substrates along that pressure gradient. Finally, simple diffusion allows passive movement of ions across a membrane related to charge.

Aqueous humor is formed at a rate of 2–3 μl/min. Since the amount of aqueous in the anterior and posterior chambers is about 250 μl, aqueous turnover is about 1% turnover of volume per minute. Its formation varies diurnally and decreases during sleep and with age, injury, inflammation, and general anesthesia.

After production in the posterior chamber, aqueous flows through the pupil into the anterior chamber and then exits the eye through the trabecular meshwork or the uveoscleral pathway. The angle of the eye is a ringlike structure that lies where the cornea and iris meet. The trabecular meshwork is one of the circular structures that are located in the angle. The trabecular meshwork functions like a filter between the anterior chamber and Schlemm's canal. Once fluid passes from the anterior chamber into Schlemm's canal, it flows into the collector channels and then aqueous

veins. The main site of resistance in this pathway is the juxtacanalicular layer of the trabecular meshwork and the adjacent endothelial lining of Schlemm's canal. Fluid exiting the eye via the uveoscleral pathway passes through the ciliary muscle and sclera.

Since the mainstay of glaucoma treatment is lowering intraocular pressure, most medications to treat glaucoma lower pressure by one of two ways: decreasing aqueous production (beta-blockers, alpha-adrenergic agonists, carbonic anhydrase inhibitors) or increasing aqueous outflow (parasympathomimetic agents, prostaglandin analogs). Surgical procedures to treat glaucoma also target aqueous production and outflow. Aqueous reduction can be achieved by applying laser to the ciliary processes of the ciliary body which reduces production of aqueous by disrupting a portion of the function of the nonpigmented epithelial cells. The most commonly used surgical techniques to increase aqueous outflow are trabeculotomy, trabeculectomy, or a variety of commercially available implants which bypass the trabecular and uveoscleral outflow pathways, as well as a few other ways.

Arachnoid membrane

Definition

The arachnoid mater makes up one of three meningeal layers surrounding the optic nerve

and brain. From outermost to innermost, the layers are dura mater, arachnoid mater, and pia mater. The three layers around the optic nerve are collectively referred to as the optic nerve sheath. The arachnoid mater is made up of several layers of meningothelial cells, connected together by desmosomes, as well as a collagen bundle network. Beneath the arachnoid mater, there is a subarachnoid space, which holds cerebrospinal fluid (CSF). Arachnoid trabeculae traverse the subarachnoid space and insert themselves into the connective tissue of the pia mater. Blood vessels reach the optic nerve through the arachnoid trabeculae and travel along the optic nerve in the connective tissue of the pia mater. Once the optic nerve reaches the orbit, the meninges blend into the outer layer of the sclera. Increased intracranial pressure in the CSF can be transmitted to the optic nerve head along the optic nerve sheath meninges (i.e., papilledema). Tumors of the meninges can arise from or involve in the optic nerve sheath (i.e., optic nerve sheath meningioma). Infiltrative and inflammatory disease can also occur in the sheath primarily or extend from the intracranial meninges.

Synonyms

Flash burn; Phototoxic maculopathy; Welder's flash or arc eye; Welders maculopathy

Definition

Welding arcs emit radiation over a broad range of wavelengths – from 200 to 1,400 nm. This includes ultraviolet (UV) radiation (200–400 nm), visible light (400–700 nm), and infrared (IR) radiation (700–1,400 nm). The light emitted can cause injuries to various structures of the eye, mainly to the cornea.

The acute cornel damage from arc welding is photokeratitis. It is caused by UV rays, which irritate the superficial corneal epithelium, causing inhibition of mitosis, production of nuclear fragmentation, and loosening of the epithelial layer. An inflammatory response occurs, which includes edema and congestion of the conjunctiva and a stippling of the corneal epithelium. The first signs are foreign body sensation, photophobia, tearing, blepharospasm, and pain, occurring 6–12 h after the injury. The major finding on examination is superficial punctate keratitis (SPK), characterized by small pinpoint defects in the superficial corneal epithelium, which stain with fluorescein. If SPK is severe, it may be followed by total epithelial desquamation, with conjunctival chemosis, lacrimation, and blepharospasm. The goal of photokeratitis therapy is to treat the pain associated with damage to the corneal epithelium and to

prevent infection while the cornea heals. Usually the treatment includes topical antibiotics, topical cycloplegics, and oral analgesics. Reepithelialization usually occurs within 36–72 h, and long-term sequelae are rare. Chronic UV radiation exposure from arc welding is associated with a high prevalence and incidence of long-term changes in the outer segments of the eye, including pterygium, pingueculum, keratoconjunctivitis, and allergic conjunctivitis.

UV light (100–400 nm) is absorbed by the cornea and the lens, while visible light and IR light radiation (400–1,400 nm) penetrates the eye and absorbed by the retina and may cause thermal or photochemical damage. The type of retinal damage depends on wavelength, energy level, duration of exposure, and degree of pigmentation. Retinal damage induced by arc welding is referred to as phototoxic maculopathy. It is caused by a photochemical cascade of reactions which may release free radicals, hyperoxide anions, and hydrogen peroxide, which may react with the tissue and membranes to form aldehydes when these substances are not degraded promptly. Several retinal mechanisms are existing to prevent a phototoxic injury, including molecular detoxification, antioxidants, and lipofuscin deposits. Phototoxic retinal changes include damage to the outer retinal layers and to the retinal pigment epithelium (RPE). These changes are typically subtle and it is difficult to identify and document them clinically. Optical coherence tomography (OCT), multifocal electroretinography (ERG), and perimetry have been reported as effective methods for documenting the retinal layer changes with this type of injury. OCT revealed an interruption or defect of the inner/outer segment (IS/OS) and/or the RPE layer in various degrees. Most of these affected welders have a good corrected visual acuity. This finding suggests that subtle macular damages and visual acuity can be relative independent factors. In most cases, retinal injuries heal spontaneously without loss of vision. However, if there is a severe damage to the RPE or outer layers of the retina, it may lead to permanent, complete, or partial loss of central vision.

Argon laser photocoagulation

Definition

Argon laser obtains its energy delivery in the ions of argon gas. It has an ability to produce tens of watts of continuous wave power in the region of blue (488 nm) and green (514.5 nm) wavelengths.

Selected tissues, such as retinal pigment epithelium (RPE), can be heated by thermal reaction, classified as photocoagulation, and induced by the argon laser. Because melanin in RPE cells absorbs wavelengths in the range of argon better than those in the range of other ions of noble gas, it is the preference for photocoagulation of the RPE. In addition, since the blue wavelength of argon can cause damage to inner retina, the green wavelength is more commonly used for photocoagulation of the neurosensory retina and RPE (L'Esperance 1989; Karlin 1995).

Argon laser photocoagulation was used in many major randomized controlled clinical trials that were landmarks and set the standards for treatment of common retinal vascular diseases.

Indication

The eyes with proliferative diabetic retinopathy (PDR) that have reached the high-risk stage should receive prompt treatment with argon panretinal photocoagulation (PRP). The high-risk PDR was defined in the Diabetic Retinopathy Study (DRS) and used commonly in clinical practice as neovascularization of the optic disk (NVD) larger than one-third disk area alone or any NVD or any neovascularization elsewhere (NVE) with vitreous hemorrhage (VH) (Royle et al. 2015).

However, the eyes with PDR that have not yet reached this stage may also have benefits from early PRP if the patients have type I diabetes, poor systemic controls, or difficulty in following up.

The eyes with clinically significant macular edema (CSME), defined as clinical observation of retinal thickening within the center of macula in the Early Treatment Diabetic Retinopathy Study (ETDRS), should receive argon focal laser photocoagulation of the macula. In the current era of optical coherent tomography (OCT), which allows better detection of diabetic macular edema than clinical examination, recent randomized controlled trials have demonstrated visual benefits of anti-vascular endothelial growth factor (anti-VEGF) agents over focal laser photocoagulation for treatment of center-involved diabetic macular edema (DME).

However, selected eyes with persistent DME that are not improved with anti-VEGF agents may be treated with focal laser photocoagulation. Selected eyes with DME, such as those with focal areas of thickening, may also receive the initial treatment with argon laser photocoagulation to those areas.

The eyes with central retinal vein occlusion (CVO) and the eyes with branch retinal vein occlusion (BVO) should receive PRP and quadratic scatter photocoagulation, respectively, only when rubeosis ($\geq$2 clock-hour of iris or any angle neovascularization), NVD, NVE, or neovascular glaucoma develops (Weingeist and Sneed 1992).

The eyes with extrafoveal choroidal neovascularization in neovascular age-related macular degeneration or other diseases may also be treated with argon focal laser photocoagulation.

The eyes with retinal breaks and rhegmatogenous retinal detachment are indicated for argon focal laser photocoagulation to create strong adhesion between the neurosensory retina and RPE.

Argon focal laser photocoagulation is also used for treating leakage points of long-standing or recurrent central serous chorioretinopathy. It may be used for treatment of various retinal vascular diseases, such as macular telangiectasia, retinal arterial macroaneurysms, and Coats' disease with variable results. Certain retinal or choroidal tumors may be treated with argon laser photocoagulation if the tumors contain pigment that absorbs the laser, such as choroidal melanoma (Weingeist and Sneed 1992).

Contraindication

Argon blue laser may not be used for photocoagulation in macular area. The macula may be damaged due to high absorption of this wavelength by xanthophyll pigment in this area (L'Esperance 1989; Karlin 1995).

Techniques and Principles

Energy of argon laser can be delivered to an eye via slit lamp, binocular indirect ophthalmoscope (BIO), or endolaser probe during vitrectomy.

The conventional slit-lamp delivery system requires contact lens for focusing laser beam on target tissues. There are two types of the contact lens: plano-concave and high plus. The former creates a virtual, upright, image with limited field of view; the latter creates a real, inverted, image with wider field and is more appropriate for PRP (Weingeist and Sneed 1992).

The binocular indirect ophthalmoscope (BIO) system has advantages in treating patients who are not able to sit at the slit lamp and treating retinal periphery with or without scleral indentation. This system is commonly used for photocoagulation of retinopathy of prematurity. Special care should be taken while performing BIO laser since its power may be variable with change in head position of the surgeon or the patient.

For conventional PRP, applying moderate intensity of 800–1,600 burns (500-μm spot size) in separated sessions is recommended. The laser burns with pulse durations from 0.1 to 0.2 s are placed one by one in a grid pattern outside the vascular arcades. Direct treatment on flat NVE on retinal surface is possible; however, elevated NVE should be treated with caution. PRP may regress NV in PDR and other retinal vascular diseases by improving oxygen flow to the retina from choroids through the photocoagulation scar and destruction of ischemic retina that produces VEGF.

Modified-ETDRS focal photocoagulation technique is currently recommended for treatment of DME. This technique requires 50 μm of burn size and 0.05–0.1 s of burn duration for both direct treatment on leaking microaneurysms and grid treatment on all areas of edema not associated with the microaneurysms. The burn intensity should be barely visible and change in color of microaneurysms is not required.

In current clinical practice, the treatment of retinal and choroidal diseases by argon laser has mostly been taken by frequency-doubled Nd:YAG laser which provides an output wavelength of 532 nm. The typical wavelength of 1,064 nm of the solid-state Nd:YAG laser is transformed by an arrangement of nonlinear potassium titanyl phosphate (KTP) crystal within the system. The system of this practically "green" Nd:YAG laser has overcome some limitations of argon laser system, such as requirement of special electrical hookup and plumbing attachment, while maintaining all the clinical properties of argon green laser photocoagulation (Karlin 1995).

Outcome

Argon laser PRP in high-risk PDR, according to the DRS, can decrease the incidence of severe visual loss by 50% or more. Argon focal laser photocoagulation for CSME, according to the ETDRS, can reduce moderate visual loss by 50% or more (Royle et al. 2015). The modified-ETDRS technique of focal treatment of center-involved DME shows similar results as the ETDRS.

Argon PRP can regress significant NV in CVO, according to Central Vein Occlusion Study (CVOS). However, prompt regression of the NV in response to PRP is more likely to occur in eyes that have not been treated previously. Prophylaxis PRP does not completely prevent the NV to occur in CVO. Argon quadratic scatter photocoagulation can decrease the risk of VH in BVO compared to eyes without the treatment, according to Branch Vein Occlusion Study (BVOS). However, similar to CVOS, photocoagulation before neovascularization develops is not beneficial.

Complications

Although less likely than other lasers with longer wavelengths, argon laser photocoagulation can also break Bruch's membrane and cause choroidal neovascularization. This may occur when very high power or very short burn duration is used. For example, argon endolaser photocoagulation in vitreoretinal surgery, which delivers high energy very close to the retina, may rupture Bruch's membrane and causes choroidal hemorrhage more frequently than the slit lamp system (Weingeist and Sneed 1992).

Inadvertent foveal photocoagulation is the worst and most feared complication of both focal laser treatment of the macula and PRP.

For PRP, potentially severe but avoidable complications are accidental photocoagulation of the posterior pole and contraction of the existing

fibrous tissue at the vascular arcade of PDR. To avoid this complication, laser burns should not be placed close to the fibrosis.

Very extensive PRP, such as applying more than 1,000 spots of too strong burns in a single session of treatment, can cause transient changes of choroids, such as choroidal detachment, myopic shift from anterior displacement of lens-iris diaphragm, and exudative retinal detachment. Secondary intraocular pressure rising can also occur. These transient changes may improve spontaneously within a few weeks after PRP.

PRP may cause macula edema or worsening of existing macular edema. It is recommended to treat macular edema before initiating PRP.

Mild and unavoidable side effects of PRP include peripheral and paracentral visual field loss. Scotopic visual impairment can occur due to damage to rod cells. Damage to short ciliary nerves is uncommon, but it may cause partial internal ophthalmoplegia.

Accidental coagulating anterior segment structures, such as iris, cornea, and lens, is possible when the laser beam is not focused properly on the retina or when there is an air bubble between the contact lens and cornea during the procedure. Poorly reactive pupil or decrease in accommodation is a side effect when the pupil is injured.

Definition

The Argyll Robertson (AR) pupil refers to small, irregularly shaped pupils bilaterally that can accommodate to a near stimulus but do not react well to direct light stimulus. Historically, this finding indicates neurosyphilis but other conditions can produce AR pupils.

Differential Diagnosis

AR pupil primarily affects patients suffering from neurosyphilis but can also be associated with diabetes, multiple sclerosis, Wernicke encephalopathy, Charcot-Marie-Tooth disease, herpes zoster, Lyme disease, sarcoidosis,

midbrain lesions, Dejerine-Sottas hypertrophic neuritis, and von Economo encephalitis.

Pathogenesis

The AR pupil is due to a lesion in the midbrain involving the connections to the Edinger-Westphal nucleus for the pupil which are rostral within the periaqueductal gray matter. The rostral location of the midbrain pathology allowing for disrupts the pupillary light reflex but spares the accommodation fibers. More extensive caudal lesions would likely affect both the pupillary and accommodation pathways.

Clinical

The AR pupil is characterized by small (miotic) pupils which are irregular, do not respond to light, and then become even more miotic (pinpoint) to near stimulus. Serologic testing for syphilis is recommended including non-Treponemal (e.g., rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL)) testing as well as Treponemal testing (e.g., FTA-Abs or MHA-TP). Neuroimaging and lumbar puncture with cerebrospinal fluid analysis for neurosyphilis testing is generally also recommended.

Treatment

Treatment is generally directed against the cause for the AR pupils (e.g., intravenous penicillin therapy for neurosyphilis).

Prognosis

The prognosis depends upon the etiology, duration of findings, and efficacy of treatment of the underlying etiology.

Arterial tear

Definition

An arterial dissection is defined as a tear in an arterial wall. The tear involves the intima of the

artery, creating a false lumen and allowing blood to enter the intima and media space of the artery. Most dissections with ophthalmic symptoms occur in the cervicocranial arteries, which is the internal carotid artery and/or the vertebral artery. The dissection is often extracranial but can extend or involved the intracranial arteries. Cervicocranial arterial dissections usually occur at the sites where the artery is mobile, and not fixed to the dura mater or to other arteries, thus making extracranial arteries the most common locations for dissections. They can be caused by trauma or can be spontaneous. Most cases are traumatic, but the trauma necessary for a cervical dissection can be as minimal as a quick turn or minor manipulation of the neck. Blood may pool inside the false lumen and cause ischemia due to compression. The blood may also clot in the false lumen and be released into the true lumen, causing a thromboembolic stroke.

Epidemiology

Cervical artery dissection has an annual incidence of 2.6–3.0 per 100,000. These arterial dissections account for a small percentage of all ischemic strokes, roughly about 2%, but account for 10–25% of strokes in young and middle-aged patients.

History

The earliest documentation of an arterial dissection is from the year 1760, when King George II of England died from a fatal cardiac tamponade due to an aortic dissection that had ruptured into the pericardial sac. The term "aortic dissection" was established in 1802, but the term "dissecting aneurysm" was favored at the time. In Houston, in the 1950s, Dr. DeBakey and his team performed the first successful surgical repair of a dissecting aortic aneurysm.

Clinical Features

Most patients with cervicocranial dissections will experience a headache and may have sharp pain in the jaw, neck, or face. The ophthalmic symptoms that usually occur are a painful ipsilateral Horner syndrome, transient or permanent vision loss from thromboembolic retinal arterial disease, and scintillations or flashing lights. One study found that 52% of patients with cervicocranial dissections presented with ophthalmic symptoms (Biousse et al. 1998). The sympathetic fibers travelling along the internal carotid artery are disturbed and lead to a partial or complete ipsilesional Horner syndrome (ptosis and miosis). Anhidrosis is not typically seen because the innervation to the sweat glands travels along the external carotid artery. Many patients with cervical dissections will present with symptoms very similar to a migraine, mainly headache and scintillations. The presentation of an acute Horner syndrome with ipsilateral head or neck pain is characteristic of cervical dissection and should be considered as suggestive of an internal carotid artery dissection until proven otherwise.

Tests

The diagnosis of a cervical dissection can be made noninvasively through imaging (e.g., ultrasound, magnetic resonance imaging (MRI), magnetic resonance angiogram (MRA), or computed tomography (CT)). MRI with MRA is typically performed for the diagnosis of a cervicocranial arterial dissection. T1-weighted MRI of the head and neck is highly sensitive and specific for diagnosing cervicocranial dissections in combination with MRAs. CT and CT angiography (CTA) of the head and neck however have also been proven effective for diagnosing a dissection and are a faster study than MRI/MRA. There is some radiation exposure with CT/CTA, but CT may be necessary for patients with MRI contraindications or in those who require an emergent study. Any patient who presents with an unexplained Horner syndrome in conjunction with neck or head pain should be evaluated for a possible cervicocranial dissection.

Differential Diagnosis

The differential diagnosis of arterial dissection includes migraine, atherosclerosis, subarachnoid

hemorrhage, ischemic or hemorrhagic stroke, cervical strain, cervical fracture, and giant cell arteritis

Etiology

The etiology of cervical artery dissections is not well understood. It is believed that most patients who experience a cervical artery dissection have an underlying vessel wall weakness and then undergo an environmental trigger (i.e., trauma) to cause their dissection. People with acquired irregularities of the vessel walls, such as connective tissue disorders (e.g., Marfan syndrome, Ehlers-Danlos syndrome), fibromuscular dysplasia, and cystic medial necrosis are more likely to experience arterial dissections. The main environmental risk factor that has been studied and found to be consistently involved in cervical artery dissections is trauma. The trauma can be minor, such as a violent cough or quick turn of the neck, or major, such as a motor vehicle accident.

Treatment

In the acute phase of cervicocranial artery dissection treatment, anticoagulant or antiplatelet therapy is recommended to prevent any further ischemic events from occurring. There has not been a sufficiently powered randomized controlled clinical trial for evaluating the efficacy of treatment, and thus therapeutic decisions are made on a case-by-case and institutional basis. Anticoagulation may be more favorable when there is severe stenosis or occlusion with a large risk of embolization. Antiplatelet therapy is favored if there is a contraindication to anticoagulation or if the dissection is associated with a large infarct, for theoretic risks of hemorrhagic conversion. For long-term therapy, anticoagulants are usually given for a period of 6 months. The duration of antiplatelet therapy has not been established but can be reassessed with follow-up imaging. If the cervical dissection presents with an ischemic stroke, thrombolytic therapy should not be withheld and should be administered as protocol for ischemic strokes.

Alagille-Watson syndrome (AWS); Arteriohepatic dysplasia (AHD); Cholestasis with peripheral pulmonary stenosis; Syndromatic hepatic ductular hypoplasia

Definition

Alagille syndrome (ALGS; OMIM #118450) is an autosomal dominant inherited multisystem disease. The syndrome affects primarily the liver, heart, eyes, face, and skeleton. The penetrance is highly variable within and between different affected families. The syndrome was first described by Alagille et al. in 1969, and additional cases were reported by Watson and Miller in 1973, and again by Alagille et al. in 1975, leading to the establishment of diagnostic criteria. Prevalence of ALGS is estimated to be in the range of 1:30,000–1:70,000 live births taking into account the variability and the low penetrance of the disease. The most common characteristic manifestations of the disease are juvenile cholestasis combined with bile duct paucity on liver biopsy; congenital cardiac defects, primarily involving the pulmonary arteries; posterior embryotoxon in the eyes; typical facial features; and butterfly vertebrae.

Etiology

ALGS is classified into two subtypes based on the mutated gene. The majority of cases (about 97%) are classified as ALGS type 1 which is associated with haploinsufficiency of the Jagged-1 gene (*JAG1*) on chromosome 20p12 (encoding JAGGED1 protein). Approximately 60% of the mutations are *de novo*. Less than 1% of the cases are caused by mutations in the *NOTCH2* gene on chromosome 1p12, encoding the NOTCH2 transmembrane protein, causing ALGS type 2 (OMIM #610205). Both genes are components of the notch signaling pathway which is known to take part in normal angiogenesis. No consistent phenotype-genotype correlation was reported.

Clinical Presentation

ALGS involves multiple organs including the liver, heart, eye, skeleton, face, kidneys, vessels, pancreas, growth, and learning abilities (Table 1).

Ocular defects affect mainly the anterior segment of the eye, but defects in the retina and optic disc are also common.

Arteriohepatic Dysplasia (Alagille Syndrome), Retinal Degeneration, Table 1 Classic criteria, based on five body systems, for a diagnosis of Alagille syndrome (Adapted from Turnpenny and Ellard (2012))

System/problem	Description
Liver/cholestasis	Usually presenting as jaundice with conjugated hyperbilirubinemia in the neonatal period, often with pale stools
Dysmorphic facies	Broad forehead, deep-set eyes, sometimes with upslanting palpebral fissures, prominent ears, straight nose with bulbous tip, and pointed chin giving the face a somewhat triangular appearance
Congenital heart disease	Most frequently peripheral pulmonary artery stenosis, but also pulmonary atresia, atrial septal defect (ASD), ventricular septal defect (VSD), and tetralogy of Fallot (TOF)
Axial skeleton/ vertebral anomalies	"Butterfly" vertebrae may be seen on an anteroposterior radiograph and occasionally hemivertebrae, fusion of adjacent vertebrae, and spina bifida occulta
Eye/posterior embryotoxon	Anterior chamber defects, most commonly posterior embryotoxon, which is prominence of Schwalbe's ring at the junction of the iris and cornea

The largest series of patients with Alagille syndrome was published by Hingorani et al. (1999) and reported 22 patients with ALGS and their parents; the characteristic ocular pathologies were summarized. The most prevalent ophthalmic defects were posterior embryotoxon (95%), iris abnormalities (45%), diffuse fundus hypopigmentation (57%), speckling of the retinal pigment epithelium (33%), and optic disc anomalies (76%). No serious functional effect and no relation to nutrient vitamins A and E were demonstrated.

- **Posterior embryotoxon** (**PE**): The hallmark ophthalmic feature associated with ALGS is posterior embryotoxon. It is defined as central dislocation and thickening of the border of the Schwalbe's line of the cornea, at the junction between the corneal endothelium and the trabecular meshwork. This finding was associated

with other pathologies including Axenfeld-Rieger syndrome, Peter's anomaly, and DiGeorge syndrome, and it manifests in 8–15% of the normal population. PE can be detected by routine slit-lamp examination and usually it does not affect the visual function.

- **Iris anomalies**: Hingorani and colleagues described some iris abnormality in 10 out of 22 patients (45%) with ALGS including hypoplastic anterior iris stroma, corectopia, and radial strands/cords. Axenfeld anomaly and Rieger anomaly, as separate entities or combined as Axenfeld-Rieger syndrome, are common findings in ALGS. Axenfeld anomaly was described in 1920 as a prominent circular gray-white line in the posterior surface of the cornea (Schwalbe's line) with iris strands. When it is accompanied by glaucoma, it is called Axenfeld syndrome. Rieger described in 1935 patients with similar findings with anomalies of the iris such as iris atrophy or corectopia. When these findings are associated with facial or dental anomalies, it is called Rieger syndrome. As these phenotypes overlap, the term Axenfeld-Rieger syndrome is often used. Axenfeld-Rieger syndrome can present as isolate ocular finding or associated with other ocular defects (sclerocornea, developmental glaucoma, persistent pupillary membrane, microphthalmos, and iris coloboma).
- **Diffuse fundus hypopigmentations and maculopathy**: Fundus defects were found in 90% of the patients examined by Hingorani and colleagues (1999); such defects included diffuse RPE hypopigmentation in 57% and speckling of the RPE in 33%. Both features were commonly detected in the mid-peripheral and peripheral zones. More recently, chorioretinal atrophy with punched out lesions encroaching on the posterior pole and subsequently causing visual acuity decrease in patients with ALGS was described (Makino et al. 2012).
- **Optic nerve head (ONH) drusen**: El-Koofy and colleagues (2011) examined 13 patients with ALGS and 19 patients with neonatal hepatitis and reported optic nerve head drusen in 91% of the ALGS patients compared to only 5.3% of patients with neonatal hepatitis making ONH drusen the most prevalent finding in ALGS patients.

  ONH drusen were demonstrated in at least one eye in 95% and bilaterally in 80% of patients with ALGS. Clinically, it was demonstrated in at least one eye in 90% of cases and bilaterally in 50% of ALGS patients. In contrast, these findings were not found in any of the eight non-ALGS-related cholestasis control patients. The incidence of ONH drusen in the general population is 0.3–2% (Nischal et al. 1996).
- **Optic disc edema**: Few cases with ALGS were reported to have idiopathic elevated intracranial hypertension with optic disc edema as a consequence. These patients had also the typical finding associated with ALGS, posterior embryotoxon (Mouzaki et al. 2010).
- **Myelinated nerve fiber layer**: Bilateral myelinated nerve fiber layer was also described in one case with ALGS (Voykov et al. 2009).
- **Miscellaneous ocular abnormalities**: Additional rare abnormalities were found in patients with ALGS including optic disc pit, serous macular detachment, and xerophthalmia. In that context, it should be noted that many of the associations of such findings with ALGS are based on case reports or small case series. Such associations might be incidental and further research is needed to establish their connection to ALGS.

Diagnosis

The diagnosis of ALGS is primarily based on clinical features. The following tests should be performed to support the clinical impression:

- Blood tests: for liver and kidney functions
- Urinalysis: to evaluate the kidney function and the elevated bilirubin levels
- X-ray: to look for butterfly vertebra and skeletal defects
- Abdominal ultrasound: to demonstrate enlarged liver and to rule out other causes for jaundice
- Cardiology exam: including physical exam by a cardiologist and echocardiography test for congenital cardiac abnormalities

- Slit-lamp exam: for ocular abnormalities including fundoscopy with pupil dilation
- Genetic tests: genotyping to identify mutations in the causative genes

Due to the variable expressivity and penetrance of the disease, it was suggested that three out of the five criteria in Table 1 should be diagnosed in an affected subject.

Alternatively, a diagnosis can be made in a subject who does not meet the classical criteria but harbors a mutation in either *JAG1* or *NOTCH2* genes.

Prognosis

Ocular abnormalities in ALGS are usually not associated with reduced visual functions unless complicated with secondary pathologies such as glaucoma or corneal insufficiency. The major morbidity and mortality of the syndrome are related to non-ocular multi-organ defects such as cardiovascular and hepatic diseases. Mortality of approximately 10% was reported among ALGS patients due to liver, cardiac, and vascular diseases.

AVM

Definition

An arteriovenous malformation (AVM) is a vascular lesion that directly connects the arterial and venous circulations without an intervening capillary bed, and AVMs can occur most anywhere in the body including cerebral AVMs. AVMs are being increasingly documented and can cause several neurological symptoms and even death.

Epidemiology

The overall incidence and prevalence of cranial AVMs is not well known, but has been estimated by autopsy and limited population-based studies.

Autopsy data shows that there is a frequency of detection of AVMs in about 4.3% of the population. Population-based studies report a detection rate of 1/100,000 adults per year and a prevalence of 18/100,000 adults/year (Scottish population-based registry). A population-based study in Minnesota found a detection rate of 1.1/100,000 adults and 2.1/100,000 adults when autopsy cases were included. Cerebral AVMs underlie 1–2% of all strokes and ~9% of all subarachnoid hemorrhages.

History

AVMs have been recognized since the ancient Egyptians in 1500 BC, and they were known to both the Roman and the Arab worlds. It was first described in Western medicine in 1757, but the first clinical diagnosis of an AVM has been attributed to Steinheil who diagnosed it in 1895. Operative interventions have been tried and modified since 1908. Cerebral angiography was developed in 1927 and has revolutionized the diagnosis and treatment of cerebral AVMs. The methods of treatment continue to evolve, including multimodal therapy (e.g., radiation therapy, interventional radiology, and surgery), and treatment should be individualized and with multidisciplinary input.

Clinical Features

Most cerebral AVMs are asymptomatic and are usually diagnosed before the age of 40 years. About 50% of patients with cerebral AVMs present with intracranial hemorrhage. The hemorrhage can be intracerebral (most common), subarachnoid, or intraventricular. Another 20–25% of patients with cerebral AVMs present with seizures; the seizures may be generalized or focal but are more often focal. Other presentations include headache, seen in 15% of patients, neurological deficits seen in 5% of patients, and pulsatile tinnitus. The headaches of cerebral AVMs have not been found to have any particular pattern, but may sometimes be accompanied by visual symptoms, such as blackouts. This is thought to be due to ischemia or change in flow of the occipital cortex. AVMs carry a 2–3% risk of hemorrhage per year, with mortality from the first hemorrhage lying between 10 and 30%. After the first hemorrhage, the risk of recurrence for the first year is about 6% and then drops back to baseline rate.

Tests

AVMs can be diagnosed through several different imaging studies, including computed tomography (CT), angiography (CTA), magnetic resonance imaging (MRI), and angiography (MRA). Standard digital subtraction catheter angiography is the gold standard for defining AVM anatomy and in treatment planning. CT scans may be done with or without contrast; although a CT scan without contrast has a very low sensitivity for AVM, a noncontrast CT may be useful to define intracranial hemorrhage. A contrast CTA or MRA might be diagnostic for an underlying AVM. MRI scans may also be done and are very sensitive; they also provide valuable information regarding localization of the lesion. In the presence of an AVM, a standard catheter digital subtraction angiogram is still generally needed to get a proper visualization of the AVM lesion and its anatomy.

Differential Diagnosis

Aneurysm, capillary telangiectasia, cavernous angioma, venous malformations

Etiology

AVMs are considered sporadic congenital vascular lesions, and their natural history and pathogenesis are poorly understood and variable. There are some associations between AVMs and hereditary diseases, such as hereditary hemorrhagic telangiectasia, an autosomal dominant disease associated with both pulmonary and cerebral AVMs. Although there are a few candidates, a gene has not been located as causing or predisposing to AVMs.

Treatment

There are four established treatments for cerebral AVMs; they include expectant monitoring,

microsurgery, endovascular embolization, and radiosurgery. Microsurgery has been the gold standard for treatment due to its immediate and complete obliteration of the AVMs. The Spetzler-Martin grading scale helps categorize the severity of the lesion as well as predict morbidity and mortality depending on nidus size and location and deep venous drainage. Endovascular embolization involves using microcatheters to navigate inside intracranial vessels and embolize the AVMs. Embolization can be performed with solid or liquid agents. Solid agents include fibers, microcoils, and microballoons, while liquid agents include cyanoacrylate monomers and polymer solutions. Embolization is usually done presurgically in very large malformations or before radiosurgery to reduce nidus size. Embolization can also be done as a palliative measurement to reduce flow size without removing the malformation in order to diminish symptoms. Lastly, radiosurgery irradiates the vessels of the malformation, causing the obliteration of the lumen and preventing rupture and hemorrhage. All three of these treatments have proven successful in treating cerebral AVMs.

Synonyms

Arteritic AION

Definition

Arteritic anterior ischemic optic neuropathy (A-AION) is an ischemic disorder of the optic nerve that affects the anterior portion or head of the optic nerve due to vasculitis from giant-cell arteritis (GCA).

Etiology

A-AION specifically affects the anterior optic nerve head due to ischemia from the posterior ciliary arteries. Although A-AION is typically due to GCA, other vasculitic causes of AION

might include infection (e.g., herpes zoster vasculitis) or immune-mediated and inflammatory disorders (e.g., Crohn disease, rheumatoid arthritis, Behcet disease, anti-neutrophilic cytoplasmic antibody (ANCA) vasculitis, and systemic lupus erythematosus).

Clinical Presentation

Most patients with A-AION present with a sudden onset of visual loss, although in up to 30% of patients, transient monocular symptoms may precede vision loss. The visual loss in A-AION is variable but can range from 20/20 to no light perception vision, and severe visual loss is seen in over half of patients. Patients with GCA may have other systemic symptoms including jaw claudication; palpable, tender, or pulseless temporal artery; joint or muscle pains or myalgias (polymyalgia rheumatica); ear pain; headache; fatigue; fever; and chills.

Diagnostics

In addition to the visual acuity and/or visual field loss, patients with A-AION may have a relative afferent pupillary defect (RAPD) in unilateral or bilateral but asymmetric cases. The optic disk may show edema or in severe cases of A-AION, the disk may appear "chalky white" (i.e., pallid edema). In contrast to the non-arteritic form of AION (NAION), the after resolution of the disk edema, the optic disk may appear pale with an excavated glaucomatous-appearing optic cup. A-AION may be associated with concomitant cilioretinal artery, choroidal, retinal (cotton wool patches), or retinal artery ischemia. Fundus fluorescein angiography (FFA) might show impaired choroidal circulation in A-AION. Laboratory tests for GCA might reveal an elevated erythrocyte sedimentation rate (ESR), elevated platelet counts, or high levels of C-reactive protein (CRP). Temporal artery biopsy (TAB) is the gold standard however for definitively diagnosing GCA in patients with A-AION.

Differential Diagnosis

Non-arteritic anterior ischemic optic neuropathy (NAION), infectious optic neuropathy, inflammatory optic neuropathy, or infiltrative optic neuropathy.

Prophylaxis

GCA is considered the most common cause of A-AION. Patients diagnosed with GCA should be treated expediently with corticosteroids to prevent the development of A-AION in the fellow eye.

Therapy

A-AION is considered an ophthalmological emergency due to the rapid onset of vision loss. Currently, steroid administration is the mainstay treatment option. High doses of corticosteroids (oral or intravenous) can be used to reduce the risk of fellow eye visual loss in patients that have developed GCA and may prevent worsening unilateral or bilateral visual loss. Although steroid treatment may slow the progression of vision loss and protect the contralateral eye, only a small percentage of patients that have developed A-AION experience improvement in visual acuity.

Prognosis

A-AION often begins unilaterally but may occur simultaneously or progress to bilateral loss within days or weeks in untreated patients. Treatment with corticosteroids can prevent this progression to the fellow eye in unilateral cases but in most cases, loss of vision is irreversible once it commences.

Epidemiology

GCA and A-AION are seen in older patients (i.e., over the age of 50) with an incidence of 20 per 100,000 persons above the age of 50. The average age for diagnosis is 73 years old. Females are twice as likely as males to develop GCA and are thus also twice as likely to develop A-AION.

Giant cell arteritis; Horton's arteritis; Temporal arteritis

Definition

Arteritic anterior ischemic optic neuropathy (A-AION) is the most important ophthalmologic manifestation of a systemic vasculitis commonly known as giant cell arteritis (GCA). GCA is a large- and medium-sized granulomatous arteritis that characteristically involves the extracranial branches of the carotid arteries, especially the temporal artery, but has a predilection for causing visual loss from involvement of the blood supply to the eye. GCA is the most common primary vasculitis among the older population. Early diagnosis and treatment of A-AION is critical since if untreated it may lead to bilateral blindness.

Etiology

GCA is an idiopathic chronic inflammatory disorder affecting medium- and large-sized arteries. Familial predominance, conjugal cases, and an association with the HLA-DR4 haplotype have been reported. Some authors have hypothesized that GCA might be infectious in origin (e.g., *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Burkholderia*, and parvovirus B19). Some immunological research has demonstrated an antigen-driven disease with local T-cell and macrophage activation in the vessel wall. The initial process may be a foreign body giant cell attack on calcified internal elastic membrane and on calcified atrophic parts of the aortic media.

Histopathology shows the presence of granulomatous vasculitis and thrombosis of the short posterior ciliary vessels in addition to variable involvement of the superficial temporal, ophthalmic, central retinal, and choroidal arteries. Ischemic necrosis is observed in the laminar and retrolaminar portions of the optic nerve producing A-AION and sometimes posterior ION (PION).

Clinical Presentation

The systemic symptoms and signs of GCA may appear subacutely or chronically (e.g., headache, fever, polymyalgia rheumatica, weight loss), but

the visual loss typically presents acutely in one or both eyes. Anterior ischemic optic neuropathy (AION) is the most common ophthalmological presentation of GCA. However, other presentations can include posterior ischemic optic neuropathy, central retinal artery occlusion, cilioretinal artery occlusion, amaurosis fugax, eye pain, diplopia, and ocular muscle paresis. Visual ischemic complications are found in up to 25% of patients with GCA, and unfortunately irreversible visual loss is found in 1–15% of patients. A history of amaurosis fugax, jaw claudication, cerebrovascular accident, absence of anemia, and a higher platelet count have been associated with an increased risk for permanent visual loss in one study.

The vision loss in A-AION is typically severe and may be as poor as 20/200 or worse in up to 60% of patients. Less severe visual loss may also occur in GCA however and patients may have no visual complaints at onset. Optic disc edema is often more pale and swollen at onset (i.e., pallid edema) in comparison to the non-arteritic form of anterior ischemic optic neuropathy (NA-AION) where the disc is typically hyperemic and shows non-pallid sector or diffuse disc edema. No optic disc edema is seen in the posterior form of ION (PION) and is a red flag for GCA in the elderly patient (visual loss, RAPD, and normal fundus). Cotton wool spots may also be a presenting finding in GCA. Choroidal ischemia may produce visual loss and may manifest as peripapillary pallor with or without optic disc edema. This choroidal-level ischemia might only be visualized on fluorescein angiography.

Constitutional symptoms in GCA are common (e.g., anorexia, fatigue, weight loss, fever), and many patients have polymyalgia rheumatica (proximal hip and shoulder girdle joint pain and morning stiffness). A new onset of or a new type of headache in elderly patients is a worrisome and common presenting symptom of GCA. Some patients experience carotidynia, and the pain of GCA may involve the head, scalp, face, neck, ear, tongue, or eye. The superficial temporal arteries may be thickened, nodular, tender, and erythematous, and temporal artery pulses may be decreased or absent. Jaw claudication is a less frequent and thus less sensitive but highly specific symptom of GCA (although it can also present in various other conditions including atherosclerosis, amyloidosis, and other vasculitis). Claudication of the tongue or necrosis of the tongue and scalp is less common but also highly suggestive signs of GCA.

GCA has been reported to cause other systemic and neurologic manifestations. Both the central and peripheral nervous system can be involved, resulting in transient ischemic attacks, strokes, dementia, spinal cord infarction, mononeuropathies, polyneuropathies, and subarachnoid hemorrhage. Thoracic and abdominal aortic aneurysms and dissection can also be seen in GCA. Intestinal infarction, coronary ischemia, pulmonary artery thrombosis, intra-alveolar hemorrhage, cough, sore throat, hoarseness, peripheral arthritis, hematuria, renal failure, and secondary amyloidosis are less common findings in GCA.

Diagnostics

The clinical presentation of A-AION is similar to that of NAION. Several red flags should raise suspicion for GCA (i.e., A-AION) however including (1) presence of systemic symptoms of GCA in a patient with AION (e.g., headache, jaw claudication, scalp tenderness, etc.); (2) episodes of transient visual loss (30%) or transient diplopia (5–10%) before A-AION presentation which would not be expected to occur in NAION; (3) peripapillary, retinal, or choroidal ischemia; (4) severe visual loss (e.g., light perception or no light perception vision); (5) bilateral simultaneous or rapidly sequential disease (if untreated, A-AION becomes bilateral in up to 95% of cases within days to weeks); (6) the affected swollen disc which is acutely pale and swollen (i.e., pallid edema) or appears normal despite RAPD and visual loss (i.e., posterior ION); and (7) the lack of the structural small, crowded, “disc at risk” for

NAION which may be absent in the contralateral eye of A-AION.

The work-up for A-AION is usually aided by laboratory evaluation. An elevated erythrocyte sedimentation rate (ESR) may be present. An ESR greater than 40 mm/h is seen in at least 77% of active untreated disease. However, the ESR is a nonspecific marker, and it can be present in a variety of inflammatory, infectious, and neoplastic disorders. Unfortunately, the ESR may be normal in 7–10% of GCA patients. A C-reactive protein in conjunction with the ESR may have a higher sensitivity (97%) and specificity (78%) for GCA. Normochromic, normocytic anemia and a reactive thrombocytosis may also be found in GCA.

The gold standard for the diagnosis of GCA is a temporal artery biopsy (TAB). The TAB typically demonstrates a vasculitis characterized by a predominance of mononuclear infiltrates or granulomas, usually with multinucleated giant cells. A normal TAB however does not exclude GCA since skip lesions can occur especially in small TAB specimens. Long specimens (>20 mm) may be more likely to yield a positive result. Unilateral temporal artery biopsy may be sufficient to exclude the diagnosis of GCA in patients with low clinical suspicion and has a sensitivity of about 96%. However, a contralateral biopsy should be considered in patients with high clinical suspicion to eliminate the remaining 4% false-negative rate. Some rare patients despite negative bilateral TAB might still need to be empirically treated if the clinical suspicion remains high for GCA.

Differential Diagnosis

Differential diagnosis of GCA includes:

1. Other medium/large vessel vasculitides: Takayasu, granulomatosis with polyangiitis (formerly Wegener granulomatosis), polyarteritis nodosa
2. Primary central nervous system (primary angiitis of CNS)
3. Trigeminal neuralgia
4. Sinus, dental disease, otological disease

Differential diagnosis of A-AION includes:

1. Non-arteritis anterior ischemic optic neuropathy
2. Optic neuritis
3. Other optic neuropathies: infection, inflammatory, genetic, neoplasm, compressive, toxic/metabolic, trauma

Prophylaxis

Non-applicable. Adequate and early high-dose steroid treatment might prevent first or fellow eye-related visual loss however in GCA.

Therapy

The initial treatment of choice for GCA is corticosteroids. The usual initial oral dose is 1–1.5 mg/kg of prednisone per day or its equivalent, and the response of systemic symptoms and elevated acute phase reactants (e.g., ESR and CRP) is generally rapid. Gradual and slow tapering after the initial high prednisone dose for 1–2 months based upon symptoms and lab testing is recommended. Typically, lower-maintenance doses or even a complete taper can be achieved after 12–18 months of treatment, but some patients require longer (e.g., 2–3 years) or even lifelong treatment. Flare-ups and relapses based upon symptoms and blood work usually respond to an increase in steroid dose to the last tolerated and effective dose, but there is significant variability in the response of the disease to steroids. Relapses may be more common during the first 18 months of treatment and the first week after suspension of steroid treatment. Although intravenous (IV) steroids may be considered (especially in patients with visual loss from A-AION or central retinal artery occlusion (CRAO)), there has been no head-to-

head direct comparison of oral versus IV to prove greater efficacy. Nevertheless, we consider IV steroids in GCA for patients who are monocular, who have transient visual loss episodes and severe or bilateral visual loss, or who are still symptomatic despite oral steroids at conventional doses.

A strong initial systemic inflammatory response may be associated with a more prolonged steroid course. Visual loss due to GCA treated with steroids improves only in a few patients. There is a better chance of improvement with early diagnosis and treatment. In suspected cases of GCA, it is reasonable to begin steroid treatment before biopsy results are available.

Prognosis

Corticosteroids can usually be reduced and discontinued in the majority of patients, but the course and duration of steroid treatment is quite variable from patient to patient. Some patients have a more chronic disease and may require chronic low doses of steroids for a number of years or even lifelong therapy. Permanent partial or complete visual loss has been found in 15–20% of patients, and steroids rarely restore any degree of visual loss in affected eyes. The new onset of visual loss in contralateral eyes is unusual once appropriate high-dose steroid treatment has been initiated. The mortality of treated patients with GCA does not seem to be increased compared with controls, but death may be due to cardiovascular disease, steroid therapy, or other complications of systemic vasculitis (e.g., aortitis).

Epidemiology

The most important risk factor for A-AION is older age. GCA occurs predominantly in white women older than 65 years of age; A-AION has a mean age of 70 years. It has an annual incidence of two per 10,000 persons. Diagnosis is more common in the northern latitudes; the highest incidences have been described in Scandinavian countries and North American population.

Synonyms

Iris-fixated phakic intraocular lens; Verisyse iris-supported phakic intraocular lens

Definition

A phakic IOL that is enclavated on the iris with specially designed "iris-claw" haptics.

Epidemiology

Before introduction of the lastest phakic IOL model (AcrySof), the iris-supported phakic IOL models (Artisan/Verisyse and Artiflex/Veriflex) were the most frequently implanted anterior chamber phakic IOLs (Kohnen and Koch 2006).

History

The iris-claw phakic IOL was initially used in aphakic eyes after intracapsular cataract extraction. Starting in 1953, the first-generation models such as the Binkhorst lens and the Medallion lens were associated with cystoid macular edema, corneal decompensation, lens dislocation, uveitis, and glaucoma. In 1978, J. Worst designed the iris-claw or "lobster-claw" IOL, a coplanar one-piece PMMA IOL, which was enclavated in a fold of mid-peripheral iris stroma, a relatively immobile portion of the iris. Many surgeons have used the iris-claw lens after intracapsular cataract extraction or as secondary implantation in aphakia. In 1986, Fechner implanted the first sighted myopic phakic eye (Fechner and Alpor 1986). Follow-up of Fechner-Worst lens implantation showed good predictability but a progressive corneal endothelial cell loss. The currently available iris-claw model is basically the original IOL with few changes.

Clinical Features

The Artisan phakic IOL is made of a single-piece, non-foldable, ultraviolet light-absorbing PMMA material. It is available for the correction of myopia, hyperopia, and astigmatism, as well as for aphakia. The optic vaults approximately 0.87 mm anterior to the iris, allowing for an important clearance from both the anterior lens capsule and the corneal endothelium. The distance from the optic edge to the endothelium ranges from 1.5 to 2 mm depending on dioptric power, anterior chamber anatomy, and diameter of the optic. There are two models available to correct myopia: model 206 has a 5.0-mm optic with power ranging from −3 to −23.5 diopters (D) in 0.5 D increments and model 204 has a larger 6.0-mm optic and is consequently limited to a smaller range of powers because of its greater proximity to the endothelium in the periphery of the IOL, −3 to −15.5 D in 0.5 D increments. For the correction of hyperopia, model 203 incorporates a 5-mm optic, and it is available in dioptric powers ranging from +1 to +12 D in 0.5 D increments. Myopic lenses require more clearance than hyperopic due to thicker peripheral edges. The thickest part of the hyperopic IOL on the other hand is central, where the anterior chamber depth is greater. Rhetoric model has a 5-mm optical zone and is available in powers ranging from +12 D to −23.5 D in 0.5-D increments, with additional cylinder from +1.0 D to +7.0 D, also in 0.5-D increments, and oriented either at 0° or at 90°. It has a fixed overall length of 8.5 mm (7.5 mm for pediatric implantations or small eyes), which is a great

advantage to the surgeon who does not wish to deal with sizing measurements.

Tests

Anterior chamber depth for Artisan/Verisyse phakic IOL implantation must be at least 2.7 mm. Other inclusion criteria for phakic IOL implantation must be considered (see also "▶ Phakic Intraocular Lens").

Differential Diagnosis

Other currently available types of phakic IOLs are anterior chamber angle (AcrySof) or posterior chamber (Phakic Refractive Lens and Implantable Collamer Lens) phakic IOLs (Hardten et al. 2003).

Etiology

On the European market, this phakic IOL is distributed as Artisan® (Ophtec B.V., Groningen, The Netherlands) and in the USA as Verisyse® (Abbott Laboratories, Abbott Park, Illinois, USA). The foldable model of the iris-claw lens is the Artiflex/Veriflex phakic IOL, which has a hydrophobic polysiloxane foldable design with a 6.0-mm optic (Güell et al. 2010).

Treatment

For Artisan/Verisyse implantation, retrobulbar or peribulbar anesthesia is recommended. A two-plane, 5.2 or 6.2-mm posterior corneal incision is centered at 12 o'clock, and two vertical paracenteses directed to the enclavation area are performed at 2 and 10 o'clock. Alternatively, scleral incision may be used. Pupil should be constricted to protect the crystalline lens from contact with the phakic lens or instruments. After the anterior chamber is filled with viscoelastic material, the lens is introduced and rotated 90° into horizontal position. The lens is fixed with an enclavation needle that has a bent shaft and a bent tip that pushes the iris into both claws. Peripheral iridectomy should be performed to prevent pupillary block situation. Alternatively, Nd:YAG laser can be used preoperatively to create one or two small iridotomies 90° apart. The corneal wound is then sutured with five interrupted 10–0 nylon stitches, the scleral incision with one running suture.

Aspergillosis and Mucormycosis, Orbital Infections

Michael T. Yen[1] and Gregory Nettune[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Cornea Associates of Texas, Dallas, TX, USA

Definition

Aspergillosis is a group of diseases caused by a fungal infection of the genus *Aspergillus* primarily or secondarily involving the orbit.

Mucormycosis (also known as phycomycosis) is a fulminant, invasive fungal infection that can involve the orbit and that most commonly is caused by the genera *Mucor* and *Rhizopus* (Anaissie et al. 2009).

Etiology

Aspergillus is an opportunistic pathogen and invasion of the orbit most often occurs via the paranasal sinuses. Route of infection is thought to be via inhalation of *Aspergillus* conidia. Rarely, orbital infection may occur via hematogenous spread or from surgical and traumatic inoculation. Orbital infection can occur in both immunocompetent and immunocompromised hosts (Levin et al. 1996; Sivak-Callcott et al. 2004; Arndt et al. 2009). In the immunocompetent host, *Aspergillus* often causes a chronic indolent sinusitis or an allergic sinusitis characterized by chronic mucosal inflammation without frank orbital invasion (Klapper et al. 1997). In the immunocompromised host, aspergillosis may also cause a chronic indolent sinusitis, but it often leads to a rapidly progressive sinus infection with direct orbital invasion. Orbital invasion in the immunocompromised host typically occurs secondary to direct extension via paranasal sinuses although other foci of infection such as dacryocystitis have been described. Vascular invasion is rarely seen but can lead to thrombosis and tissue necrosis.

Orbital mucormycosis usually develops from direct extension of infection into the orbit from the nasal and paranasal sinus mucosa (Yohai et al. 1994; Arndt et al. 2009). These fungi have a predilection for vascular invasion, resulting in thromboses and extensive tissue necrosis. *Mucor* and *Rhizopus* are typically low virulence organisms found in soil and decaying organic material which are inhaled as conidia and colonize the nasal and paranasal sinus mucosa. Like invasive aspergillosis, mucormycosis has a strong predilection for the immunocompromised host occurring in patients with HIV, cancer, renal failure, diabetes mellitus, and in those on immunosuppressive agents (Pagano et al. 1997; Maiorano et al. 2005).

Epidemiology

Orbital aspergillosis and rhino-orbital-cerebral mucormycosis are rare, and definitive epidemiological data do not exist.

Aspergillus is an aerobic fungus that is often found as molds growing in many oxygen rich environments. In immunocompetent hosts, aspergillosis is the most common fungal sinus infection. Immunocompetent hosts rarely develop an invasive infection; however, cases have been reported. Invasive aspergillosis occurs more often in the immunocompromised host. HIV, malignancy, chemotherapy, immunosuppressive agents, diabetes mellitus, and neutropenia have been shown to be risk factors for the fulminant form of aspergillosis (Sivak-Callcott et al. 2004). Of the hundreds of species of *Aspergillus*, *Aspergillus fumigatus* is the most common species that infects the paranasal sinuses.

Similar to invasive aspergillosis, mucormycosis occurs in the immunocompromised host. An Italian multicenter review of 37 cases of patients treated for acute leukemia found that 1% had mucormycosis, although the orbit was an infrequent site of disease. Of all patients who are diagnosed with mucormycosis,

over half have poorly controlled diabetes mellitus and ketoacidosis which leads to poor neutrophil phagocytosis and increased host susceptibility to fungal invasion (Pagano et al. 1997).

Clinical Presentation

In the immunocompetent host, the presentation of *Aspergillus* infection can be varied but is rarely aggressive. Most cases present as a chronic sinusitis secondary to allergic fungal sinusitis or to chronic granulomatous inflammation resulting from a fungal ball (aspergilloma). Often patients will describe nasal discharge or facial discomfort. However, a small subset of patients with allergic fungal sinusitis may describe symptoms of orbital involvement characterized by decreased vision, diplopia, proptosis, epiphora, or cranial nerve palsies (Bray et al. 1987). Immunocompromised hosts with fulminant *Aspergillus* sinusitis may present with invasion of the face, the intracranial cavity as well as the orbit. Signs and symptoms of orbital invasion may include severe pain, decreased vision, proptosis, chemosis, and diplopia. Direct extension of infection can lead to extraocular muscle dysfunction as well as cranial nerve involvement. Orbital apex syndrome can occur and cavernous sinus thrombosis has been described.

Like invasive aspergillosis, rhino-orbital-cerebral mucormycosis may present with a variety of symptoms. Early symptoms may be nonspecific and include fever, headache, and sinus congestion or discharge and may progress to orbital and facial pain, decreased vision, diplopia, and altered mental status. Classically with mucormycosis, necrotic tissue on the nasal mucosa may appear as a black crust. In both invasive aspergillosis and mucormycosis, examination may show signs of orbital cellulitis, proptosis, chemosis, decreased ocular motility, and an afferent papillary defect (Yohai et al. 1994; Arndt et al. 2009).

Diagnostics

Diagnosis is suggested by clinical history and radiological imaging of the orbit and paranasal sinuses. Imaging also is important in monitoring for progression and in constructing a treatment plan. Samples should be obtained and sent for stains, cultures, and in vitro susceptibility testing to evaluate for amphotericin resistance. Microscopic diagnosis is the gold standard. *Aspergillus* has characteristic features including 45° branching, septate hyphae seen with Gomori methamine silvers and periodic acid Schiff stains. The fungi causing mucormycosis have irregularly branching, broad, nonseptate or sparsely septate hyphae seen with Gomori methamine silvers and periodic acid Schiff stains. Some suggest that multiple samples should be obtained both via direct tissue biopsy and via nasal debridement and sinus or abscess aspiration. Obtaining biopsy with vascular specimen may be particularly useful in histological diagnosis of mucormycosis as hyphae may be seen invading vessel walls (Anaissie et al. 2009).

Differential Diagnosis

Cavernous sinus thrombosis
Orbital pseudotumor
Sarcoidosis
Leukemic infiltration
Lymphoma
Metastatic carcinoma
Rhabdomyosarcoma
Thyroid ophthalmopathy
Wegener granulomatosis
Other vasculitides and collagen tissue disorders

Prophylaxis

Prophylactic antifungal therapy with polyenes, azoles, or triazoles has been described. Some experts suggest the use of prophylactic antifungals in patients who are expected to be severely granulocytopenic for over 7 days at institutions with high incidence of invasive fungal infections. It may also be considered for patients who will be on significant immunosuppression therapy following bone marrow or stem cell transplants.

Treatment

Prompt diagnosis and early treatment with aggressive debridement and antifungal medication is the main treatment modality. Surgical removal of necrotic tissue may require multiple surgeries and repeat imaging studies to evaluate for progression. Exenteration was the mainstay of treatment until relatively recently but is no longer considered crucial in most cases. Systemic antifungal medication should be initiated promptly and typically consists of amphotericin B at 1–1.5 mg/kg/day. After a few days of treatment it can be decreased to a maintenance dose of 0.8–1 mg/kg/day. Some experts advocate spacing treatment out to every other day once the disease is in remission. In addition to amphotericin B, the azole class of antifungals has been shown to be effective as well although efficacy data is lacking in direct comparisons to amphotericin B. Treatment may be enhanced by local injection or packing of surgical area with antifungal agents. Hyperbaric oxygen may complement surgical and antifungal therapies. Systemic antifungal treatment should continue for long after the infection is shown to be controlled. Some experts advocate indefinite treatment in immunocompromised patients. Treatment of underlying immunocompromising condition is also important when possible such as in cases of ketoacidosis.

Prognosis

Until relatively recently the prognosis was bleak with survival rates as low as 10%; however, earlier diagnosis and more aggressive management has improved survival to 65–85%. Orbital aspergillosis has a better survival rate than mucormycosis (Yohai et al. 1994). Poor prognostic indicators include delayed treatment, leukemia, hemiparesis, hemiplegia, iron chelation therapy, renal disease, and bilateral sinus involvement. Early treatment initiation is key as a review article in 1994 found that patient survival with rhino-orbital-cerebral mucormycosis was 81% when surgery was undergone within 6 days of symptoms but declined to 52% when undergone at day 7–12 and fell further to 42% when undergone between day 13 and 30. Morbidity is also high, and extensive surgical debridement often results in severe facial disfigurement.

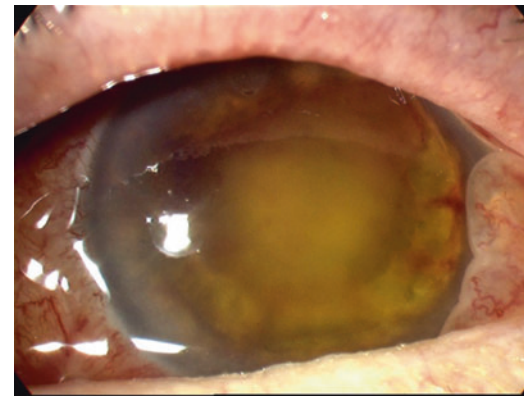
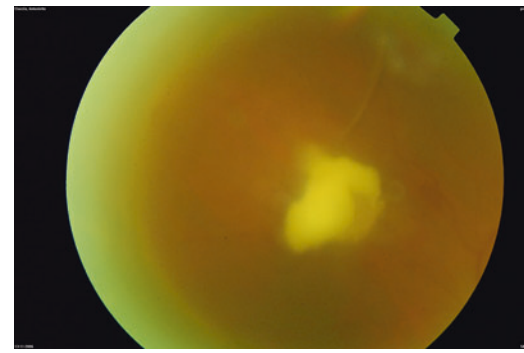
Definition

The *Aspergillus* species is a member of the deuteromycetes fungi. They are highly aerobic and are found in the air we breathe. It is commonly involved in pulmonary and paranasal sinus infections, and while it occasionally occurs in immunocompetent patients and can lead to orbital involvement and keratitis, it is most commonly related to immunocompromised patients and is the second most common cause of endogenous endophthalmitis following the *Candida* species. Risk factors for developing *Aspergillus* infection include neutropenic patients, following solid organ transplantation in those taking systemic corticosteroids or immunosuppression drugs, diabetes mellitus patients, cystic fibrosis patients, intravenous drug users, or those with an impaired immune system, such as those with human immunodeficiency virus infections. *Aspergillus flavus*, *A. fumigatus*, *A. niger*, *A. terreus*, *A. glaucus*, and *A. nidulans* have all been reported to cause endophthalmitis, with A. *fumigatus* and *A. Flavus* the most commonly identified. *Aspergillus* endogenous endophthalmitis results from hematogenous spread of the fungus from a distant, infected site, such as an infected heart valve, urinary tract, or following prolonged intravenous drug use. Alternatively, sinus involvement can result in direct spread into the orbit and later reaching the globe.

Clinically, *Aspergillus* endogenous endophthalmitis has a rapid time to presentation and is usually evident within 5 days of infection, which is much faster than other fungi such as *Candida*. Patients may complain of visual loss, red eye, photophobia, severe ocular pain, and floaters. There is a panuveitis with or without a hypopyon (Fig. 1), and there may be yellow subretinal and retinal infiltrates that preferentially affect the macula, with subhyaloid and subretinal exudation (Fig. 2). As the disease progresses, a dense vitritis may develop, obscuring the fundus. Invasion of the choroidal vessels may result in exudative or purulent retinal



***Aspergillus* (Aspergillosis), Endogenous Endophthalmitis, Fig. 1** Anterior chamber involvement



***Aspergillus* (Aspergillosis), Endogenous Endophthalmitis, Fig. 2** Macular chorioretinal lesion with overlying vitritis

detachments, with retinal involvement leading to extensive retinal necrosis that includes the optic nerve and macula in many cases. Corneal involvement and orbital involvement occur in many cases and are significant risk factors for permanent severe vision loss.

Diagnosis requires a high level of suspicion and is based on obtaining a careful history aimed at identifying patients at high risk of endogenous endophthalmitis. The definitive diagnosis and identification of the responsible pathogen are based on obtaining a vitreous sample, followed by immediate processing in order to maintain the viability of the sample. Samples should be viewed using direct microscopy following KOH preparation in order to dissolve the human cells and allow direct visualization of the fungi. The use of Gram or Giemsa staining can yield up to 90% positive identification. Cultures are needed for identification of specific fungal species and in vitro susceptibility to various antifungal agents, and samples are typically incubated for 2–4 weeks before a negative culture result is confirmed.

Vitrectomy with intravitreal injection of antifungal drugs is the mainstay for treatment of advanced *Aspergillus* endogenous endophthalmitis. It clears the vitreous of inflammatory debris and allows the obtaining of a vitreous sample for diagnosis and the administration of intravitreal drugs. While treatment approaches also involve the use of systemic antifungal agents, with amphotericin B the most widely used, these drugs have poor intraocular penetration and therefore require the addition of intravitreal injections to achieve a therapeutic dose. Other intravitreal agents, including voriconazole or miconazole, are also effective in treating *Aspergillus* endogenous endophthalmitis. Systemic voriconazole has good intraocular penetration and can be used as an alternative to amphotericin B in treating *Aspergillus*.

The outcome of these patients can be variable with immunocompromised patients faring the worst. However, the utilization of prompt diagnosis with aggressive intravitreal antifungal treatment has improved the outcome of these patients, preventing vision loss and increasing their survival.

Aspheric Ablation Profile

- ▶ Aspheric Profile Photorefractive Keratectomy
- ▶ Q-Factor Customized Ablation Profile

Aspheric Profile Photorefractive Keratectomy

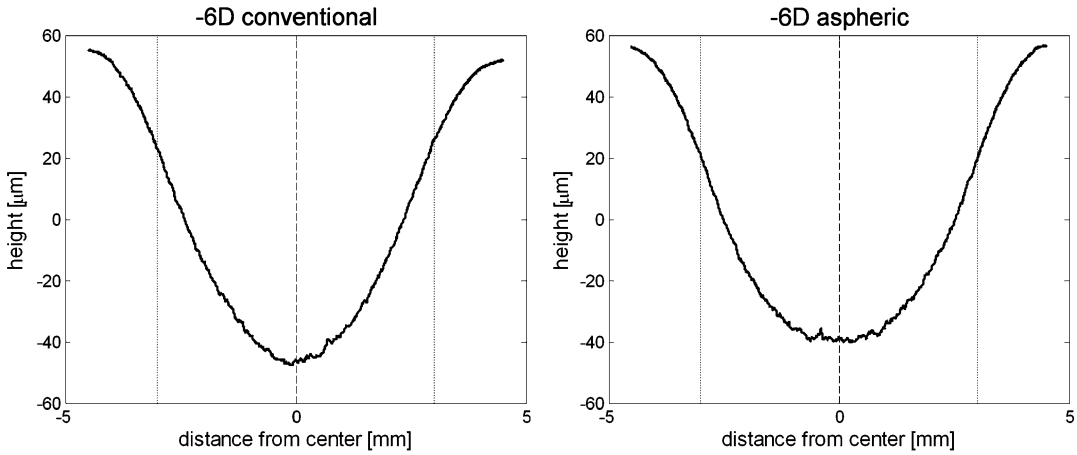
Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Aspheric ablation profile; Q factor-optimized ablation profile; Wavefront-optimized ablation profile

Definition

An ablation profile that aims at minimizing postoperative spherical aberration, either by compensating for the amount of spherical aberration expected to be induced by the ablation or by maintaining preoperative corneal asphericity (q factor) (Fig. 1).



Aspheric Profile Photorefractive Keratectomy, Fig. 1 Conventional and aspheric ablation profile for a myopic corneal ablation of -6 D

History

Corneal topographic and aberrometric measurements revealed an induction of positive spherical aberration (Applegate and Howland 1997) which was found to be proportional to the attempted spherical equivalent (Moreno-Barriuso et al. 2001; Oshika et al. 2002). This deviation of induced optical effects from Munnerlyn's formula effect was first attributed to biomechanical effects (Roberts 2000). Later, studies with PMMA lenses suggested physical rather than biomechanical effects, namely, the decrease of laser fluence in the corneal periphery (Bühren et al. 2010; Dorronsoro et al. 2006). These findings and the fact that spherical aberration significantly deteriorates retinal image quality prompted the development of aspheric ablation profiles with less induction of spherical aberration than conventional profiles (Mrochen et al. 2004). Aspheric profiles can be used both for LASIK and for surface ablation techniques. Also customized (wavefront-guided) profiles can be aspheric. Aspheric profiles for hyperopia are still under development.

Tests

Most algorithms require a preoperative corneal topography to determine the preoperative corneal asphericity (q factor). Together with other data like refraction and aberrometry, programmed optical zone, and corneal pachymetry, these data are integrated in the treatment algorithm. The treatment itself is identical to a treatment with a conventional profile. The predictability of an aspherical ablation can be checked with postoperative corneal topography or aberrometry.

Aspherical Intraocular Lens

Oliver K. Klaproth
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Aberration free intraocular lenses

Definition

Aspheric intraocular lenses are defined as lenses that try to modify the spherical aberration of the optical system of the eye to achieve improved quality of vision. This is done by the modification of the curvature of at least one surface in an aspherical manner.

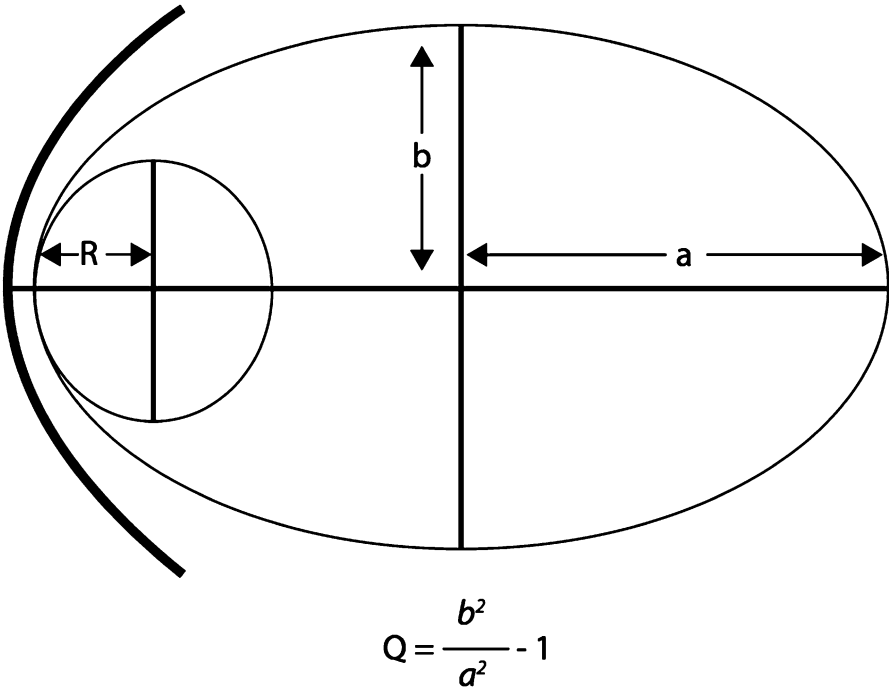
Basic Characteristics

Asphericity in IOL Optics

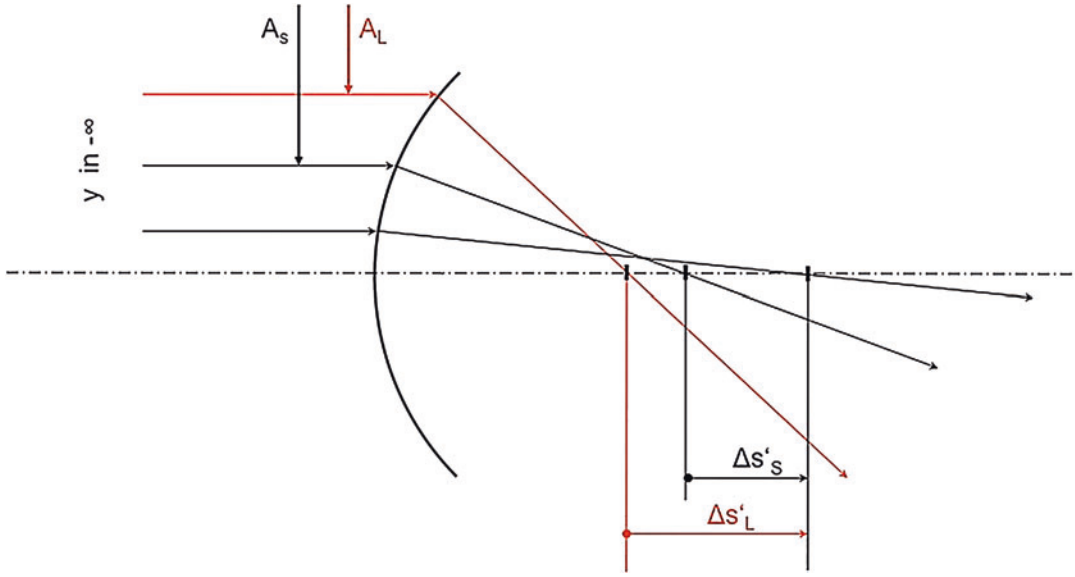
In IOLs, asphericity usually describes a lens with at least one nonspherical surface of usually rotational symmetric shape and continuously changing radii from center to periphery. An exception is any kind of toric aspheric IOL, which is not rotationally symmetric but still keeps up the same asphericity in each meridian, even with changing radii in the meridians. Asphericity is described by the Q factor, which characterizes different types of spherical, elliptic, or nonelliptic shapes. $Q = 0$ characterizes a spherical shape, $Q > 0$ an oblate ellipse, $Q < 0$ but > -1 a prolate ellipse, $Q = -1$ parabolic, and $Q < -1$ a hyperbolic shape (Fig. 1).

Spherical Aberration

Spherical aberration describes the effect of changing angles of incidence with increasing distance



Aspherical Intraocular Lens, Fig. 1 Defining the Q factor and thus asphericity of a surface by the metrics of an ellipse



Aspherical Intraocular Lens, Fig. 2 Schematic principle of spherical aberration. With increasing distance from the optical axis in lenses (not only in spherical ones) the angle of incidence changes (in this case increases) and thus refractive power increases. The result is the difference in spherical aberration (Δs') for small (*S*) and large (*L*) apertures (*A*)

from the optical axis of light rays at a lens. With increasing angle of incidence also the refractive power increases and thus the vertex power increases for peripheral rays compared to central ones (Fig. 2). This again results in an increased depth of focus but also aberrates the image. It is important to keep in mind that the effect is stronger with larger apertures (in the eye this is the pupil). For very small pupils the effect thus is, as for all aberrations, almost not existent.

Of course aspheric lenses also have a certain amount of spherical aberration. Only in the very special case of neutrality of spherical aberration, they do not suffer from it.

Mode of Action

From the cornea it is known that its asphericity and positive spherical aberration remains stable in aging. The lens however changes from negative to positive spherical aberration with age. Thus, the compensation of the cornea's positive spherical aberration decreases with age. Spherical intraocular lenses now try to modify the spherical aberration of the optical system of the eye, to increase quality of vision.

Aspheric Intraocular Lens Models

Today intraocular lenses can be divided into three major groups, when defined by their asphericity only:

1. Lenses with positive spherical aberration (all spherical lenses, but also aspheric ones)
2. Lenses with negative spherical aberration (all aspheric)
3. Lenses that do not induce spherical aberration (all aspheric)

The latter are often misleadingly marked as "aberration free lenses." However, no lens is free of aberrations, aberrations make a lens a lens. This term only refers to the spherical aberration.

Reasonable Range of Application

The effect of intraocular lens asphericity is highly dependent on pupil diameter, as spherical aberration itself is the optical aberration representing the errors induced by large apertures. Trials show that pupil sizes larger than at least 4 mm are needed to measure a decrease in spherical aberration that can provide a benefit in quality of vision. However, in what magnitude this measurable difference is of subjective

relevance for the patients is not fully evaluated yet. As cataract patients most often have very small pupils, they do hardly ever profit from aspheric lenses. As implants used in refractive lens exchange to correct ametropia of young patients with large mesopic pupils, they seem to be of more benefit.

Aspiration Curette

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

An instrument used in cataract surgery. It was designed to polish the anterior capsule leaf efficiently and safely to reduce fibrotic after-cataract and to avoid capsular contraction syndrome.

Clinical Features

The tip of the aspiration curettes is equipped with an upward-facing, slit-like aspiration port (0.23 mm in width, 1.5 mm in length). The parallel edges of the slip are sharp; the edge at the proximal and distal turning points is rounded. The curette fits into the aspiration handpiece of a standard bimanual irrigation/aspiration set. One can differentiate between two different instrument types: one non-venting system with a sharp edge and a sharp edge venting curette.

Tests

The anterior capsule polishing with aspiration curette may be used in the eyes with pseudoexfoliation syndrome and resulting zonular weakening to reduce the capsular contraction syndrome.

Another application can be considered in the eyes with peripheral retinal disease to retain the transparency of the peripheral optic of the IOL.

Differential Diagnosis

Other methods to reduce the postoperative incidence of after-cataract:

- Sharp posterior optic edge as barrier effect, combined with a circular rhexis optic overlap
- Haptics of intraocular lense with capsular bag design and a slim junction to the optic
- Fibrosis-inducing optic materials

Treatment

See "Clinical Features" section above.

Synonyms

Acetylsalicylic acid; ASA; Bayer; Ecotrin

Definition

Acetylsalicylic acid (ASA)

Indication

Aspirin is used as an analgesic, antipyretic, anti-inflammatory, as well as an antiplatelet medication. It is used as treatment in several diagnoses that require the aforementioned medicinal properties.

Contraindication

Aspirin is generally contraindicated in patients with hypersensitivity to aspirin or any of its components, hemophilia or other active bleeding disorders, bleeding ulcers, or in a hemorrhagic state. It is relatively contraindicated in peptic ulcer disease, pregnancy, children, gout, and liver and kidney disease.

Use and Dosage

The dosage of aspirin given to treat patients depends on the indication for treatment. In treatment for coronary artery disease, it is recommended to start with low-dose aspirin. A dose of 75–100 mg per day is recommended for an indefinite period of time in these cases. This dose may be used in patients with established coronary heart disease as well as for prevention of coronary heart disease in asymptomatic patients above the age of 50. In the case of a myocardial infarction, a dose of 160–325 mg could be given immediately after the event, and a reduced dosage of 75–100 mg could be continued thereafter. In ophthalmology, although there is no proven randomized controlled clinical trial data on efficacy for neuro-ophthalmologic disease, many authors recommend aspirin in patients with vasculopathic neuro-ophthalmic disease (e.g., nonarteritic and arteritic anterior ischemic optic neuropathy, giant-cell arteritis, ischemic ocular motor cranial neuropathies, carotid and vertebral dissections, ischemic nonhemorrhagic

cerebrovascular accidents, and transient ischemic attacks including ischemic amaurosis fugax).

Adverse Reactions

Aspirin may cause several adverse effects, which include gastrointestinal bleeding, nausea, heartburn, constipation, upset stomach, dizziness, headache, and tinnitus. Studies performed evaluating the adverse effects of aspirin have found that the occurrence of adverse effects is related to dosage. With the small doses used in coronary artery disease treatment and prevention, few side effects are experienced. As the dosage of aspirin increases in patient treatment, the side effects become a more prominent barrier and obstacle for treatment.

Interactions

Aspirin has several interactions with other medications due to the fact that it acetylates albumin and therefore may alter the binding of other drugs to albumin. Aspirin may decrease the effects of ACE inhibitors, diuretics, uricosuric agents, anticonvulsants, and beta-blockers. It may increase the effects of sulfonylureas, causing hypoglycemia, as well as increase the concentration of carbonic anhydrase inhibitors and methotrexate. Aspirin may also increase the risk of bleeding when taken with other anticoagulants or nonsteroidal anti-inflammatory medications.

Aspirin: Usage, Effects, and Dosage in Ophthalmology

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Acetylsalicylic acid.

Indication

Aspirin is used as an anticoagulant in patients with thromboembolic risk factors. Moreover, aspirin is used as an analgesic, antipyretic, and anti-inflammatory drug.

Contraindication

Allergy or intolerance to nonsteroidal anti-inflammatory drugs, gastric ulcers, liver and kidney disease, gout, hyperuricemia, glucose-6-phosphate dehydrogenase deficiency, pregnancy, and asthma.

Use and Dosage

Analgesia and antipyretic effect, 300–1,000 mg one to three times daily; anticoagulant, 75–300 mg 1/daily.

Adverse Reactions

Patients under aspirin therapy in theory have an increased risk for hemorrhagic complications when ophthalmic surgeries are performed. However, several studies have shown that vitreoretinal surgeries, cataract surgeries, glaucoma surgeries,

and intravitreal injections on systemically anticoagulated patients were not associated with significant intraoperative or postoperative bleeding complications. In patients with diabetic retinopathy, the use of aspirin does not increase the occurrence of vitreous/preretinal hemorrhages.

Interactions

Combination therapy with other anticoagulants may increase bleeding complications. Aspirin must not be applied in patients under methotrexate therapy in a dose of >15 mg/week.

Asteroid Bodies or Scintillation Nivea

▶ Asteroid Hyalosis

Asteroid Hyalitis

▶ Asteroid Hyalosis

Asteroid Hyalosis

Anat Loewenstein[1,3] and Gilad Rabina[1,2]
[1]Department of Ophthalmology, Tel Aviv Medical Center, Tel Aviv, Israel
[2]Department of Ophthalmology, Oculoplastic and Orbital Institute, Tel Aviv University, Tel Aviv, Israel
[3]Department of Ophthalmology, Sackler Faculty of Medicine, Tel Aviv Medical Center and Incumbent, Sydney A. Fox Chair in Ophthalmology, Tel Aviv University, Tel Aviv, Israel

Synonyms

Asteroid bodies or scintillation nivea; Asteroid hyalitis

Definition

Asteroid hyalosis was first described by Benson in 1894. While minute white opacities are found in the otherwise normal vitreous, this condition presents as cream-white spherical bodies distributed throughout the vitreous either randomly or in chains or sheets. The biomolecular composition of asteroid bodies has only recently been explored, and many questions remain unanswered. The asteroid bodies feature a multilamellar structure formed of a mineral compound containing calcium, phosphorus, and oxygen, presumably a calcium apatite like material, with chondroitin-6-sulfate at the periphery and hyaluronic acid in the inner matrix.

The prevalence of asteroid hyalosis has been reported to range from 0.36% to 1.96%. In 75% of cases, the condition is unilateral, and it only rarely causes a significant decrease in visual acuity.

Clinical studies have showed associations of asteroid hyalosis with diabetes, hypercholesterolemia, hypertension, gout, increased serum calcium levels, hyperopia, male gender, and age over 50 years. Because asteroid hyalosis is basically the deposition of complexes of calcium and lipids, an association of asteroid hyalosis with serum cholesterol and serum calcium levels is credible. Yet the exact etiology of asteroid hyalosis is not known.

Although asteroid hyalosis is generally considered to have only a minor impact on visual acuity, some patients are sufficiently disturbed by their visual symptoms to undergo surgical treatment to remove opacities.

Astigmatic Keratotomy

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Arcuate keratotomy; Hexagonal keratotomy; Transverse keratotomy; Trapezoidal keratotomy

Definition

Corneal incision technique for reducing the grade of astigmatism by changing the cornea from a football shape to a more rounded one.

Epidemiology

Due to high levels of success with LASIK procedures, the number of astigmatic keratotomies has reduced significantly.

History

In the early nineteenth century, Shiotz, Lans, and Bates first described the astigmatic keratotomy as an incisional surgery. Troutman was one of the first surgeons who discussed the benefits of corneal incisions to decrease astigmatism. Further developments of his ideas included adding nomograms, transverse or arcuate incisions. As toric intraocular lenses and LASIK were introduced, the frequency of astigmatic keratotomy has been reduced.

Clinical Features

See "Treatment" section.

Tests

Thorough examination of the anterior segment with the slit lamp and corneal topography, pachymetry, and measurement of uncorrected and best spectacle-corrected visual acuity are mandatory to maintain best possible postoperative results. See also entries Astigmatism, PRK, LASEK, and LASIK.

Differential Diagnosis

Other types of incisional keratotomy:

- Arcuate and transverse keratotomy
- Trapezoidal keratotomy
- Hexagonal keratotomy
- Radial keratotomy
- Limbal relaxing incisions

Etiology

See "▶ History" section.

Treatment

The refractive surgeon places either a transverse or arcuate incision perpendicular to the steep axis of the cornea. The result is a flatter cornea by an increased radius of curvature in the meridian and a

steeper meridian 90° away. Incisions are between 5 and 7 mm away from the pupil center.

Astigmatism

Oliver K. Klaproth
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

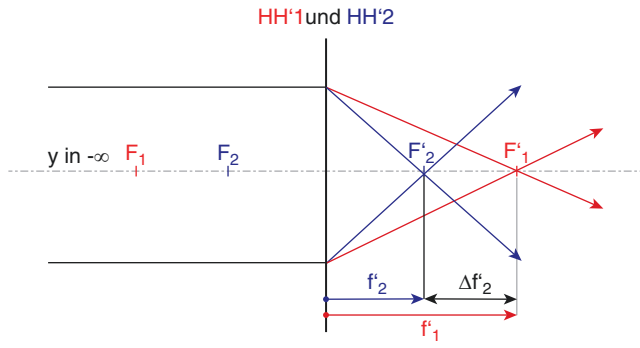
Ophthalmic astigmatism

Definition

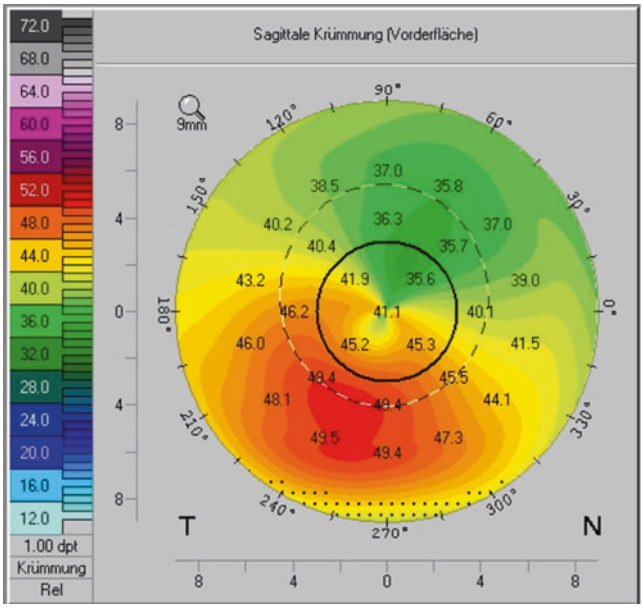
An optical system with astigmatism is one where rays that propagate in two perpendicular planes have different foci. The term comes from the Greek α- (a-) meaning "without" and στίγμα (stigma), "a mark, spot, puncture."

Basic

In ophthalmology the phrase astigmatism is used to describe the effect of toricity of the optical effective media of the eye, the cornea, and the lens. If two meridians of the respective optical system (e.g., the cornea, the anterior corneal surface, the lens, or the whole eye) with the least and highest refractive power are positioned perpendicular to each other, the resulting aberration is defined as regular astigmatism. Instead of one focal point, regular astigmatism results in two perpendicular focal lines and a circle of least confusion (Fig. 1). However, significant mild correlations were found between total and corneal astigmatism, which is why the phrase astigmatism is often used to name the entity of different curvatures in corneal meridians (McKendrick and Brennan 1996). Between the astigmatism axes of two eyes, a mirror symmetry of astigmatism (McKendrick and Brennan 1997) can often, but not always, be found.



Astigmatism, Fig. 1 Sturm's conoid, showing the principle of toric optics and resulting regular astigmatism in a positive refractive power lens, represented by the principal planes $HH'_{1,red}$ and $HH'_{2,blue}$ of its meridians 1 and 2, which are located 90° to each other. y – image. F – focal points. f – focal lengths. Δf – difference in focal lengths of the two meridians: astigmatism



Astigmatism,
Fig. 2 Topographic analysis of the corneal first surface of a keratoconic cornea, showing the typical irregular astigmatism with an inferior steepening

Characteristics

Regular Astigmatism

Regular astigmatism is defined as "with-the-rule" (WTR) when the steepest meridian of the optical system is positioned between approx. 75° and 105° and as "against-the-rule" (ATR) when the steepest meridian is positioned between approx. 165° and 195°. Astigmatism in other directions (approx. 15–75° and 105–165°) is defined as oblique.

Irregular Astigmatism

In opposite to regular appearances of astigmatism, irregular astigmatism is characterized by, e.g., three or more main meridians of the optical system (generating higher-order aberrations like trefoil, quatrefoil, etc.). This is why in clinical ophthalmology higher-order aberrations are often named irregular astigmatism. Corneal dystrophies like keratoconus also result in irregular astigmatism. This astigmatism does not follow a typical kind of regular pattern. Figure 2 shows irregular keratoconus astigmatism of the corneal first surface. A progression of corneal first surface astigmatism might be an indicator of developing keratoconus.

Correction of Astigmatism

The effect of astigmatism on visual acuity is approximately 50% of the influence of defocus and always has a negative impact on optical quality (Naeser and Hjortdal 2011). As technical optical systems can be designed easily with regular toricity, they are able to correct astigmatic aberrations of another toric optical system, just like spherical optics that correct defocus aberrations of defocused optical systems. This is the basic principle of astigmatism correction of, e.g., soft contact lenses, glasses, and toric intraocular lenses (TIOL) (Kohnen et al 2008). Other surgical options to correct astigmatism include the modification of the corneal curvature (Ortho-K contact lenses, laser in situ keratomileusis, photorefractive keratectomy, relaxing incisions, and others).

Astrocytoma

Definition

An astrocytic hamartoma is a benign retinal tumor occurring in the retinal nerve fiber layer that is made up of glial cells and arises from retinal astrocytes. Astrocytic hamartomas are most commonly seen in the presence of tuberous sclerosis (Bourneville disease) but may also be seen in the setting of neurofibromatosis or as solitary or sporadic lesions.

Etiology

Astrocytic hamartomas have been linked to two genetic loci TSC1 (9q34) and TSC2 (16p13) which cause the autosomal dominant disease tuberous sclerosis. TSC1 encodes for the protein hamartin while TSC2 encodes the protein tuberin. These two proteins work together to help control cell growth and size, making them tumor-suppressing genes. The mutations associated with tuberous sclerosis deactivate the tumor suppressor gene. It is thought that tuberous sclerosis, like other tumor suppressor gene syndromes, arises from the two-hit mechanism. This means that patients with tuberous sclerosis are born with a mutation in one allele of TSC1 or TSC2 and environmentally acquire a second mutation, which inactivates the second allele of that same gene.

Clinical Presentation

The majority of patients who have astrocytic hamartomas have tuberous sclerosis, characterized by a triad of seizures, mental retardation, and skin lesions. Although astrocytic hamartomas are not included in the triad, more than half of patients with tuberous sclerosis will have astrocytic hamartomas. It is estimated that around 80% of patients with astrocytic hamartomas will have them between ages 2–6 years, making it one of the first clinical signs of tuberous sclerosis. Astrocytic hamartomas most commonly occur near the optic disk; patients may present with strabismus, leukocoria, or reduced vision. A large portion of

patients with astrocytic hamartomas are asymptomatic. Astrocytic hamartomas can have different presentations depending on the location in the retina. Those seen in the periphery of the retina are usually flat, poorly defined, and semi-translucent lesions in the retinal nerve fiber layer. The lesions seen in the posterior pole are raised, opaque, white, and more nodular in appearance. These nodular lesions can become increasingly calcified and take on what is commonly referred to as a "mulberry appearance."

Diagnosis

Retinal astrocytic hamartomas can be diagnosed based on clinical appearance alone, although there are several other tests that can help support and further evaluate the diagnosis. The three main studies used for evaluating astrocytic hamartomas are optical coherence tomography (OCT), ocular ultrasonography, and fluorescein angiography (FA). Ocular ultrasonography is a noninvasive procedure that can be done to evaluate the extent of the lesion as well as any other accompanying retinal problems, such as a serous detachment. Some of the vessels in the astrocytic hamartoma are fragile and have abnormalities, making them gradually and increasingly hyperfluorescent during the FA. Lastly, the OCT will show a gradual conversion from normal retina to a hyperreflective mass with retinal disorganization and "moth-eaten" spaces. The OCT can also show the presence of additional problems, such as retinal detachments.

Differential Diagnosis

Retinoblastoma is the most important differential diagnosis to consider and rule out. Retinoblastomas will have slight differences on OCT (abrupt transition from lesion to normal retina as opposed to gradual transition seen in hamartoma) and may be differentiated on ophthalmic exam as well. Other differential diagnoses include amelanotic choroidal melanoma, retinocytoma, choroidal osteoma, juxtapapillary choroiditis, drusen, glioma, and other intraocular malignancies.

Prophylaxis

Not available.

Therapy

Anytime an astrocytic hamartoma is encountered, the patient should be sent for further evaluation of a systemic disease. Treatment for astrocytic hamartomas depends on the symptoms experienced by the patient, as most patients are asymptomatic. Therapy for astrocytic hamartomas of the retina usually involves close observation and photodocumentation, monitoring for growth and spread of the tumor. In the case that the lesion does spread or cause a retinal detachment, argon laser photocoagulation may be used to reduce the lesion as well as resolve the detachment.

Prognosis

A retinal astrocytic hamartoma is usually a benign finding but should be monitored for growth and invasion periodically. Because retinal astrocytic hamartomas are so closely tied to tuberous sclerosis, the patient should promptly be evaluated for systemic diseases. The majority of astrocytic hamartomas are asymptomatic and do not require treatment aside from close monitoring. Therefore, prognosis is usually excellent.

Epidemiology

The incidence of tuberous sclerosis is about 1/6,000–1/10,000 births. Astrocytic hamartomas are seen in approximately half of the patients with tuberous sclerosis. They also occur in neurofibromatosis or as solitary lesions, but the incidence of those cases is rare and unknown.

Visuomotor ataxia

Definition

Optic ataxia is a neurologic sign characterized by an impaired ability of the patient to reach and grasp visually target objects. Patients may complain of misjudging distance or difficulty localizing objects in space.

Epidemiology

The cause of optic ataxia is often unknown and prevalence difficult to estimate. It can be caused by several different diseases and is often misdiagnosed or overlooked because it frequently presents in conjunction with several other symptoms.

History

Optic ataxia was first described in 1909 by Rudolf Balint, and the Balint syndrome is characterized by three symptoms: optic ataxia, simultanagnosia, and oculomotor apraxia. For several decades it was thought that optic ataxia only occurred in the setting of Balint syndrome. It was not until 1967 that Garcin et al. first described a case of optic ataxia without simultanagnosia or oculomotor apraxia. All of Balint's patients had bilateral posterior parietal lesions, but it was later discovered that unilateral lesions could also result in optic ataxia.

Clinical Features

The main characteristic of optic ataxia is that patients have trouble reaching for and grasping visual targets in the absence of other sensory cues. The difficulties with reaching and grasping are present in the contralateral visual field. Patients who experience a left hemispheric lesion also experience difficulties reaching with the contralateral hand, regardless of the visual field. The difficulties in grasping objects are similar to those seen in cerebellar ataxia, which include overshooting and undershooting the target. Unlike patients with cerebellar ataxia, patients with optic ataxia will be able to reach the target successfully when given auditory or

proprioceptive cues to help them reach the object. The difficulty in grasping objects seems to be worse when the object is in the patient's peripheral vision as opposed to his or her point of fixation. Patients with isolated optic ataxia do not experience any visual field loss, difficulty with stereopsis, motor difficulty, or sensory difficulty.

Tests

At the moment there is no standardized exam to diagnose optic ataxia. Testing each patient's reach and grasp toward an object, such as a pencil or pen, is the exam that has been performed in most patients with optic ataxia since it was described in 1988. Another common exam performed in conjunction with reaching and grasping is drawing of objects, such as a clock, on a piece of paper. Patients with optic ataxia cannot adequately orient and localize objects, which will be reflected in their drawing. There are efforts to create a standardized bedside exam to diagnose optic ataxia. There have also been studies where patients have undergone fMRI while asked to reach, point, or grasp an object. Patients with optic ataxia will usually show lesions in the posterior parietal cortex.

Differential Diagnosis

Cerebellar ataxia, nystagmus, and visual agnosia.

Etiology

Optic ataxia is thought to be caused by a lesion in the posterior parietal cortex, more specifically in the superior parietal lobule as well as in areas around the intraparietal sulcus. Lesions in either of these two areas only cause integrative sensorimotor deficits without primary motor or sensory deficits. Optic ataxia frequently occurs within the context of Balint syndrome. Balint syndrome has several causes, including vascular infarcts, infection, and neurodegenerative and inflammatory disease. Vascular infarcts causing optic ataxia most commonly occur in the watershed regions involving the terminal branches of the middle cerebral artery and the posterior cerebral artery. The neurodegenerative diseases that can cause optic ataxia include Alzheimer disease, posterior cortical atrophy, Parkinson disease, and Creutzfeldt-Jakob disease. There have also been cases of optic ataxia caused by brain tumors that extend into the parietal region. Isolated optic ataxia is rare and is usually caused by isolated infarcts, hematomas, or localized brain injury.

Diagnosis

Patients with optic ataxia demonstrate misreaching under visual guidance to objects in their environment but can perfectly point accurately to their own body parts (e.g., touch their own nose or ear with each hand upon request).

Treatment

Treatment for optic ataxia involves treating the underlying disease. The Prognosis for recovery from optic ataxia varies depending on the etiology of the ataxia.

Louis-Bar syndrome

Definition

A-T is a progressive neurocutaneous disorder that is characterized by cerebellar ataxia, dysarthria, ocular and dermatologic abnormalities, recurrent infections, and a predisposition to malignancy. A-T was first widely recognized in 1957 when two physicians wrote an eight-patient case series, and by 1963, they were able to compile a list of 101 patients.

Etiology

A-T is an autosomal recessive disease caused by a mutation in the ATM gene located in chromosome 11q22-23. Most commonly it involves a nonsense mutation, which leads to an early termination of translation and a highly unstable and rapidly degradable protein. Most mutations that cause A-T are unique, so patients who have the disease have inherited one mutation from each parent, making them a compound heterozygote. The ATM protein is a serine/threonine kinase and phosphorylates approximately two-dozen substrates, including p53. Most of the substrates' functions are DNA repair, transcription regulation, and response to oxidative stress. Due to the deficiency of the ATM protein, these substrates do not get phosphorylated and cannot function at an optimal level.

Clinical Presentation

The first sign of A-T is usually seen when the patient presents with ataxia when learning to walk. Patients will usually begin to walk at a normal age, but then experience instability with walking that becomes slowly progressive. This symptom usually leads to a misdiagnosis of cerebral palsy, episodic ataxia, or other encephalopathies. It will be observed that children prefer to run and will do so on a more narrow base, because it provides them the most stability while walking. By 8–12 years of age, most children are confined to a wheelchair. The other signs and symptoms of the disease can develop at different moments in the patient's life, but most are apparent by the age of ten. Patients will also begin to experience choreiform movements, dysarthria, difficulty swallowing, recurrent infections, lymphoid malignancies, and ocular abnormalities. Patients are found to have a deficiency in IgG2, IgE, and IgA and experience recurrent sinopulmonary infections. They have a substantial increased risk of lymphoreticular malignancy as well as sensitivity to radiation therapy. The ocular

abnormalities seen in A-T include ocular telangiectasia, strabismus, abnormalities in saccade and pursuit, nystagmus, poor convergence ability, and optokinetic nystagmus abnormalities. Ocular telangiectasias first appear in the exposed areas of the medial and lateral bulbar conjunctiva. Mental status is normal in most cases.

Diagnosis

Most patients are diagnosed around the age of ten when all of the symptoms are apparent. The symptom that most commonly leads to ocular diagnosis is the presence of ocular telangiectasia. Ocular telangiectasia presents about 4–5 years, on average, after the presentation of the first symptom, most commonly ataxia. Three routine tests are easily available to help support a diagnosis of A-T: serum alpha fetoprotein (AFP), karyotyping, and immune status of B and T cell compartments. The majority of patients (>95%) will have an elevated AFP. T cells are unusually low, although some patients may show only minor deficiencies. Gamma and delta T cells are unusually elevated in these patients, and B cells are normal to slightly elevated. Patients will also show deficiencies in IgE, IgA, and IgG2. Cerebellar atrophy will also be present on MRI, due to the depletion of Purkinje cells. A molecular diagnosis has been conceived, but due to the large size of the gene and the occurrence of unique mutations, it is very labor intensive and not routinely performed.

Differential Diagnosis

Cerebral palsy, acute infectious or episodic ataxia, malignancy, and mitochondrial disorder.

Therapy

Unfortunately there is no cure for A-T and therapy remains supportive. The goal of treatment in this disease is to manage signs and symptoms such as infections and the physical limitations experienced by the patient. Neurorehabilitation may be useful for patients and can involve speech, physical, and occupational therapy. Certain medications, such as fluoxetine and amantadine, can be used to help patients with their incoordination and imbalance. Patients will also receive medications such as propranolol to help with their tremor. When using medications in these patients, side effects must be monitored closely, and medications must be constantly reevaluated due to the appearance of new diseases and therapies, such as malignancy.

Prognosis

Life expectancy in patients with A-T is highly variable; some patients may live into the sixth decade. The three main causes of death in patients with A-T are malignancy, infection, and pulmonary failure.

Epidemiology

A-T has an incidence in the United States as high as 1/30,000–1/40,000 live births. The incidence usually ranges from 1/30–40,000 live births to 1/300,000 live births.

Atopic Dermatitis

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Definition

A chronic, relapsing inflammatory skin disorder caused by hypersensitivity to common allergens; usually seen in individuals with a personal or family history of other atopic disorders such as asthma and allergic rhinitis.

Etiology

The precise etiology is unknown, but is likely related to IgE sensitization and disruption of epithelial barrier function. It is commonly seen in conjunction with other allergic conditions, including food allergy, asthma, and allergic rhinitis. Flares are often associated with stress, seasonal changes, and staphylococcal colonization. Patients with eyelid dermatitis frequently have associated disorders, including allergic contact dermatitis.

Clinical Presentation

Patients traditionally present with eczematous eyelid lesions associated with intense pruritus, xerosis, and lichenification. Lesions tend to be bilateral and symmetric. Other commonly affected areas include the cheeks, perioral region, antecubital fossae, and popliteal flexures. Patients with atopic dermatitis are also susceptible to ocular surface disorders, including atopic keratoconjunctivitis, neovascularization, cicatrization, and herpetic keratitis. Aqueous tear deficiency and meibomian gland dysfunction are frequently observed.

Diagnosis

Atopic dermatitis is usually diagnosed based on clinical criteria. These include typical relapsing and remitting course, early age of onset, typical age-related shifts in lesion distribution, pruritus, xerosis, and personal or family history of atopic disease. An adult onset variant does exist but is extremely rare. Atopic dermatitis is a diagnosis of exclusion, and entities listed in the differential section should be ruled out. Total IgE is often elevated but is neither sensitive nor specific. Patch testing may be pursued to evaluate for allergic contact dermatitis. KOH scrapings are occasionally performed to rule out *tinea*. Biopsy findings are nonspecific.

Differential Diagnosis

Allergic contact dermatitis
Irritant contact dermatitis
Seborrheic dermatitis
Blepharochalasis
Dermatomyositis (Heliotrope rash)
Periocular rosacea
Psoriasis
Tinea
Lichen simplex
Mycosis fungoides
Scabies
Phototoxicity/photoallergy

Prophylaxis

Early use of probiotics may protect against sensitization, but evidence is not conclusive.

Therapy

Therapy includes medications, trigger avoidance, and other behavioral modifications. Skin moisturizers and topical steroids are first-line treatments. Immunomodulators such as tacrolimus are considered second line. Short courses of antibiotics may be useful when over-colonization by *Staphylococcus aureus* is suspected. Non-sedating antihistamines may provide pruritus relief. Use of humidifiers and mild laundry detergents may also help. Many ophthalmic drops, particularly those with benzalkonium chloride preservatives,

are potential triggers. It is important to remember that allergy to both topical corticosteroids and tacrolimus is possible.

Prognosis

Symptom relief can be achieved, but exacerbations are common. Corneal neovascularization and epithelial defects associated with atopic keratoconjunctivitis must be managed aggressively to prevent serious ocular sequelae.

Epidemiology

Atopic dermatitis is common, affecting 10–15% of children and 2–10% of adults. Eyelid finding is seen in a modest portion of these patients, and the risk of lid involvement increases with age. Eighty-five percent of cases manifest within the first year of life and 95% manifest before the age of 5.

- ▶ Retinal Hole

Atrophic Retinal Tears

- ▶ Retinal Hole

Atrophy, Geographic

Moritz Lindner, Monika Fleckenstein, Steffen Schmitz-Valckenberg and Frank G. Holz
Department of Ophthalmology, University of Bonn, Bonn, Germany

Synonyms

GA; Geographic atrophy

Definition

Well-defined area of retinal pigment epithelium (RPE), outer retinal layer, and choriocapillaris atrophy developing secondary to non-exudative age-related macular degeneration (AMD).

Etiology

Retinal pighment epithelium (RPE) atrophy represents a downstream pathogenetic pathway in various retinal diseases (see "Differential Diagnosis"). In the elderly, it is most frequently associated with non-exudative AMD and it then terment geographic atrophy (GA). While various pathways may be involved, the precise pathogenesis in the context of AMD is yet unclear.

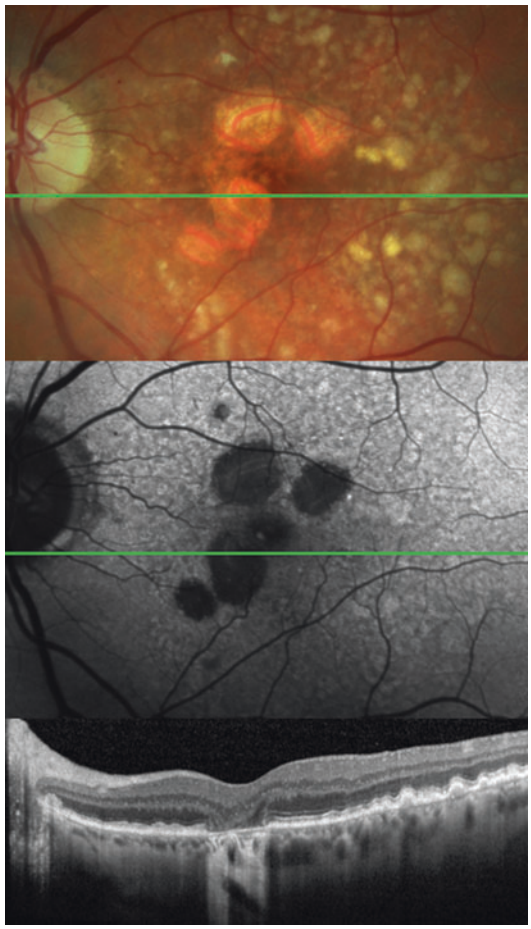
Clinical Presentation

Fundoscopically, GA appears as a sharply demarcated area with depigmentation and enhanced visualization of larger deep choroidal vessels. GA may occur unifocal or multifocal. The horizontal configuration may vary including roundish or oval to lobular patterns. Over time, GA enlarges in size, frequently sparing the fovea

unitl late in the disease process for yet unknown reasons ("foveal sparing phenomenon"). Areas of GA are associated with a corresponding absolute scotoma. Therefore, development and progression of GA is associated with vision loss (Holz et al. 2013, Fig. 1).

Diagnosis

Due to RPE atrophy and, thus, loss of intrinsic fluorophores at the level of the retinal pigment epithelium, GA is associated with a marked decrease in fundus autofluorescence (FAF) signal. This allows for more precise delineation of the atrophic areas as compared to fundus photography (Schmitz-Valckenberg et al. 2009). On SD-OCT imaging, GA is characterized by loss of the outer retinal layers, including the outer nuclear layer, the external limiting membrane, ellipsoid zone, myoid zone, and interdigitation zone, respectively, and by loss of the inner part of the RPE/Bruch's membrane complex (assumed RPE-layer; Holz et al. 2013, Fig. 1).



Atrophy, Geographic, Fig. 1 Fundus photography, fundus autofluorescence, and spectral domain optical coherence tomography (*top* to *bottom*) of a patient with geographic atrophy due to AMD showing the characteristic findings. Besides the atrophic area, also drusen and pigmentary changes are visualized. *Green line* indicates the position of the OCT-Scan

Differential Diagnosis

While only RPE atrophy secondary to non--exudative AMD is termed GA, it may be associated with a multitude of other retinal diseases, including Stargardt macular dystrophy, central areolar chorioretinal dystrophy, maternally inherited diabetes and deafness syndrome, pseudoxanthoma elasticum, late-onset retinal dystrophy, and several others. Careful recording of the history including onset of symptoms, non-ocular complaints, and family history can help to identify the underlying disease (Saksens et al. 2013). Furthermore in FAF, the area surrounding the GA may show different patterns of abnormal autofluorescence which allows for subclassification as well as differential diagnosis of GA (Schmitz-Valckenberg et al. 2009). In contrast to "pure" or "primary" GA, RPE atrophy may develop secondary to, e.g., neovascular AMD, central serous retinopathy following laser treatment, photodynamic therapy, or intense anti-VEGF therapy.

Prophylaxis

See underlying disease causing RPE atrophy.

While the AREDS trial showed a reduction in progression from intermediate AMD to neovascular late-stage manifestations by supplementation with β-carotene, vitamins C and E, and zinc, no beneficial effect on development or progression of GA was observed (Aronow and Chew 2014).

Therapy

There is no established therapy yet. Current approaches include visual cycle inhibitors, neuroprotective agents, complement inhibitors, and anti-inflammatory drugs (for review, see Holz et al. 2014).

Prognosis

GA secondary to AMD shows a progression of 1.3–2.6 mm^2 per year on average (Holz et al. 2013). The atrophic process is typically continuous and is not limited to the macular area. Central vision may be preserved for some time due to foveal sparing. However, despite good central vision, marked visual impairment may be present due to parafoveal scotoma, which, for example, strongly impairs reading and recognition of faces.

Epidemiology

The advanced form of dry AMD, or GA, is responsible for approximately 20% of all legal cases of blindness in North America with increasing incidence and prevalence due to a higher life expectancy.

Atrophy, Gyrate

Roy Schwartz
Tel Aviv Medical Center, Tel Aviv, Israel

Synonyms

Gyrate atrophy of the choroid and retina

Definition

A rare genetic choroidal disease characterized by thinning and atrophic appearance of the choroid, retinal pigment epithelium (RPE), and outer retina in the mid-periphery and periphery of the fundus that may lead eventually to total atrophy of the choroid.

Etiology

Gyrate atrophy is an inherited disorder transferred as an autosomal recessive trait, although dominant cases have also been reported (Ryan et al. 2013). Patients have a deficiency of the enzyme ornithine-delta-aminotransferase (OAT), a mitochondrial-encoded enzyme with B_6 as a cofactor that catalyzes the interconversion of ornithine, glutamate, and proline. This results in an increase in the concentration of plasma ornithine to 10–15 times the normal levels and reduction in plasma lysine, glutamine, glutamate, and creatine. A number of different mutations have been identified within the OAT gene on chromosome 10.

Clinical Presentation

Symptoms usually begin in the second and third decades. They include poor night vision and

constricted peripheral vision. Most patients have posterior subcapsular cataracts by the end of the second decade. Myopia is also frequently observed and vitreous opacities may be present. Visual acuity loss is a later complaint in the disease, as structural changes spread from peripheral to central locations (OMIM 2010; Retina and Vitreous 2015–2016).

Fundus changes in gyrate atrophy begin in the mid-peripheral and peripheral retina with thinning and atrophy of the RPE, with the underlying choroidal vessels appearing normal or sclerotic. These areas are characteristically scalloped in shape and separate but tend to become confluent with progression of the disease. The fundus appears hyperpigmented. Additional changes with progression of the disease include pigment clumping, RPE and choriocapillary atrophy, and eventually total atrophy of the choroid, exposing the white sclera. In late stages, an annular ring of choroidal atrophy may be seen from the periphery to the posterior pole of the retina, usually sparing its center – the macula. In later stages, retinal vessels may appear attenuated and the optic disc may appear pale. There are reports of cystoid macular edema (CME) in patients with the disease. Visual function varies and depends on the extent of fundus involvement.

It was shown that type II muscle fibers were atrophic in patients with gyrate atrophy and had tubular aggregates. However, no muscle symptoms are reported, although some patients showed impaired performance when speed or acute strength was required. With disease progression, there is almost complete loss of type II fibers, which is slower than the progression of the ocular pathology.

Other reported features included mental retardation, as well as MRI changes characteristic of degenerative lesions in the white matter and premature atrophic changes.

Diagnosis

The clinical diagnosis can be confirmed by measuring serum or plasma ornithine levels. Molecular confirmation can be obtained by mutational analysis of the OAT gene.

Visual field testing most commonly shows a concentric peripheral constriction of the visual field. With time, an annular ring and paracentral scotomas may develop. With foveal involvement, a central scotoma may be seen.

Full-field electroretinogram (ERG) testing shows a mild abnormality in the amplitude of rods and cones (photoreceptor cells of the retina). With disease progression, the ERG responses deteriorate and may eventually become undetectable. Dark adaptation testing is also abnormal, with mild threshold elevations in the beginning and eventually significant elevation in most patients. The electrooculogram (EOG) is normal or only mildly reduced at the early stages of the disease, but in later stages, it is markedly reduced. Muscle biopsy shows atrophic type 2 muscle fibers with tubular aggregates visible on electron microscopy. Histopathology shows early changes in RPE cells, with subsequent loss of photoreceptors and choriocapillaries.

Differential Diagnosis

It is important to distinguish gyrate atrophy from retinitis pigmentosa (RP). RP is a group of inherited disorders in which abnormalities of the photoreceptors lead to progressive visual loss. Symptoms resemble those of gyrate atrophy and include night blindness and loss of peripheral vision and eventually of central vision. The main distinguishing features between the diseases are the hyperornithemia of gyrate atrophy, as well as the fundus appearance. In RP, there is RPE hyperpigmentation in the form of "bone spicules," attenuation of arterioles, and waxy pallor of the optic disk.

Another important entity to be distinguished from gyrate atrophy is choroideremia, a hereditary chorioretinal dystrophy. Patients present with night blindness and constricted visual fields. There is diffuse and progressive degeneration of the RPE and choriocapillaries. It first manifests as mottled areas of pigmentation in the anterior equatorial region of the retina and the macula. The anterior areas gradually degenerate to confluent

scalloped areas of RPE and choriocapillary loss, with preservation of larger choroidal vessels. The finding of generalized hyperpigmentation of the remaining RPE in gyrate atrophy, as well as the hyperornithemia, helps to distinguish it clinically from choroideremia.

Prophylaxis

Since the disease is genetically inherited, no prophylaxis can prevent its occurrence. However, an arginine-restricted diet may slow its progression (see section "Therapy").

Therapy

Since ornithine is produced from other amino acids, primarily arginine, an arginine-restricted diet appears to have therapeutic value. Studies have shown that such diet started at an early age might appreciably slow the progression of the chorioretinal lesions and, to a lesser extent, the progressive loss of retinal function.

Orally administered vitamin B_6 can result in a reduction in plasma ornithine levels in some patients, while others are nonresponsive to such treatment. Those that respond to B_6 treatment show better maintained ERG responses.

For patients with CME, a short-term therapeutic effect was shown with the use of intravitreal triamcinolone acetonide injection. After drug clearance, the edema recurred, with return of decline in visual acuity to pretreatment level.

Prognosis

The prognosis in gyrate atrophy is poor, as with time the disease advances, with progressive loss of visual field and visual acuity. The arginine-restricted diet may slow disease progression, although it is very difficult to maintain.

Epidemiology

The prevalence of gyrate atrophy was reported to be 1:50,000 in Finland, where the incidence of the disease is highest. The estimated frequency of heterozygotes is 1:110 individuals. More than 200 confirmed cases have been published in the literature so far.

Atropine Drug, Usage in Ophthalmology

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Anticholinergic/antimuscarinic drug.

Indication

Dilation of the pupil and cycloplegia for diagnostic (eye examination, cycloplegic refraction) or

therapeutic (uveitis, inflammation after surgery) reasons. Atropine penalization may also be applied in the treatment of amblyopia.

Contraindication

Known sensitivity or allergy to any ingredient of atropine eye drops.

Use and Dosage

Atropine 1% eye drops are usually applied one to four times a day.

Adverse Reactions

Blurred vision, sensitivity to light, lacrimation, hyperemia, edema or inflammation of the conjunctiva, stinging and burning, dizziness, fainting, change in heart rate, flushing of the skin, dryness of the mouth, giddiness, mental confusion, lightheadedness, vomiting and nightmares, and difficulty urinating. In patients with narrow iridocorneal angles, atropine eye drops may cause acute angle closure.

Interactions

The effect of antimuscarinic medicines may be enhanced by the concurrent administration of other medicines with antimuscarinic properties (e.g., amantadine, antihistamines, butyrophenones, phenothiazines, tricyclic antidepressants).

Axenfeld-Rieger Syndrome; Mesodermal Dysgenesis; Leukomas

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Synonyms

Anterior chamber cleavage syndrome; Mesodermal dysgenesis of the cornea and iris

Definition

Axenfeld-Rieger syndrome (AR) is a spectrum of anomalies involving the peripheral anterior segment, iris, and systemic features, previously designated as three separate entities: Axenfeld's anomaly, Rieger's anomaly, and Rieger syndrome.

Etiology

AR is typically associated with autosomal dominant inheritance, and frequently a family history of AR is reported; however, sporadic cases are common.

Clinical Presentation

AR is usually bilateral, without sex or race predilection and diagnosed from birth to adulthood. A typical but not pathognomonic finding is posterior embryotoxon. Other exam findings include high peripheral iris strands (which are adherent to the posterior embryotoxon), ectropion uveae, iris stromal thinning, abnormally shaped pupils or decentered pupils (corectopia), and/or the appearance of multiple pupils (polycoria).

Systemic defects include dental anomalies (microdontia, hypodontia, and anodontia), craniofacial anomalies (maxillary hypoplasia with midface flattening), skeletal anomalies (short stature), umbilical anomalies cardiac anomalies, deafness, and mental retardation.

Diagnostics (Lab Diagnostics)

Diagnosis of AR is based primarily on clinical exam. Genetic studies could be considered as some genes have been identified (PITX2, FOXC1, REIG2).

Differential Diagnosis: Iridocorneal endothelial syndrome, Peter's anomaly, Aniridia, Posterior polymorphous dystrophy, Iridogoniodysgenesis, Oculodentodigital dysplasia, Ectopia lentis et pupillae, Ectropion uveae, Uveitic glaucoma, Iris coloboma, Iridodialysis, Iridoschisis

Therapy: Detection and management of glaucoma is imperative. Typically medical therapy is maximized first and surgical intervention considered later (trabeculectomy and glaucoma drainage device implantation).

Prognosis

Occasionally the central iris changes will progress in AR; however, the peripheral iris and angle changes typically do not. About 50% develop glaucoma which typically begins in childhood or young adulthood and can be challenging to control. The development of glaucoma is secondary to trabeculodysgenesis (not peripheral anterior synechiae or angle changes).

Epidemiology

AR is inherited in an autosomal dominant fashion.

Axial Chromatic Aberration

► Chromatic Aberration: Definition

Axial Length

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Distance from the anterior curvature of the cornea to the retinal pigment epithelium in alignment along the optical axis of the eye.

Basic Characteristics

Final axial length is normally reached during the emmetropization process of the eye. Shorter axial length is associated with a hyperopic refractive error of the eye; longer axial length is associated with a myopic refractive error of the eye. Measurement of axial length is one of the most crucial steps in intraocular lens power calculation since an accuracy of <0.1 mm would result in a significant refractive error. Axial length can either be assed by ultrasonic contact biometry or by optical biometry applying partial optical coherence interferometry. Axial length assessed in ultrasonic biometry is usually shorter than axial length measured with optical biometry, since ultrasound measures the distance from the corneal surface to the internal limiting membrane of the retina, while optical biometry measures the distance from the anterior surface of the cornea to the retinal pigment epithelium.

B

Bacteria, Endophthalmitis Caused by, Endogenous

Amir Rosenblatt and Shulamit Schwartz
Department of Ophthalmology, Tel Aviv Medical Center (Ichilov) and Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Synonyms

Endogenous infectious endophthalmitis; Metastatic endophthalmitis

Definition

An infection of the intraocular cavities, i.e., the vitreous and/or aqueous humor, resulting from a hematogenous spread of bacteria, fungi, or protozoa.

Etiology

Endogenous endophthalmitis is the result of a hematogenous spread of an infection from a distant location in the body (most commonly endocarditis or urinary tract infection) or the insertion of a pathogen via medical devices such as needles and urethral or intravenous catheters.

Endogenous endophthalmitis is more common in the presence of chronic immune-compromising illnesses or following immunosuppressive treatment.

Pathogens

Bacterial Endogenous Endophthalmitis

Usually causes a more acute and rapidly progressive fulminant infection.

Unlike exogenous endophthalmitis, the most common pathogens in endogenous endophthalmitis are gram-positive bacteria such as:

- *Streptococcus pneumoniae* – commonly secondary to meningitis.
- *S. viridans* – commonly secondary to endocarditis.
- Other *Streptococcus* spp. such as:
  - Group G *Streptococcus*, appearing in older patients with skin wounds or malignancies
  - Group B *Streptococcus*, noted to be found in neonates with meningitis
- *S. aureus* – commonly secondary to cutaneous infections.
- *B. cereus* such as *Salmonella* and *Campylobacter* – most commonly found in IV drug abusers. These cases may present with a typical ring-shaped corneal ulcer and a brownish anterior chamber exudate.

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

Less commonly found are the enteric gram-negative pathogens:

- *Klebsiella pneumoniae* – most common of the gram-negative pathogen
- *Escherichia coli*
- *H. influenza*
- *P. aeruginosa*
- *Serratia* spp.

Slowly progressive or late-onset disease may be caused by:

- *Listeria monocytogenes* – infection is characterized by a brownish hypopyon and should be considered in the absence of corneal involvement (as opposed to *B. cereus*).
- *P. acnes*, though commonly related to postsurgical endophthalmitis, was described in several case reports depicting endogenous spread.

Fungal Endogenous Endophthalmitis

Fungal infections account for 50–60% of cases of endogenous endophthalmitis and are more common in immunosuppressed patients. Such infections may be more indolent than bacterial endophthalmitis, with signs and symptoms that progress over weeks:

- *Candida albicans* by far is the most common pathogen of this group, accounting for 70–80% of fungal endophthalmitis.
- *Aspergillus* is the second most common pathogen and may be present in immunocompromised patients after an organ transplant, leukemia patients, and IV drug users.
- Infection by other *Candida* species has been reported.

Viral endophthalmitis is virtually nonexistent as it usually causes uveitis.

Clinical Presentation

Endogenous endophthalmitis can occur as early as a week or as late as a month after the onset of a systemic infection.

It can present as an anterior (focal or diffuse) or posterior (focal or diffuse) panophthalmitis. It begins most commonly as a focal or multifocal chorioretinal lesion that spreads into the vitreous.

The severity and onset of symptoms may vary depending on the size of the inoculum and the type and virulence of the infective pathogen. Presentation may vary from a minimal inflammation with conjunctival injection and mild anterior uveitis to mild vitritis presenting with "snowball" opacities (especially with fungi) and even severe panophthalmitis with hypopyon, fulminant vitritis, and retinal or choroidal lesions. Rapidly progressive endophthalmitis can lead to blindness and phthisis bulbi. Furthermore, fulminant uncontrolled endophthalmitis can eventually cause cavernous sinus thrombosis, which may result in patient mortality.

Symptoms

Systemic symptoms: consistent with sepsis such as weakness chills and general malaise.

Ocular Symptoms

- Visual loss or impairment
- Pain and/or irritation
- Photophobia
- Ptosis

Suspicion of endogenous endophthalmitis should be raised in any immunosuppressed or postsurgical patient with these symptoms.

Signs

Systemic signs: consistent with sepsis, ranging from mild fever to septic shock.

Ocular Signs

- Eyelid edema and erythema
- Purulent discharge
- Conjunctival and scleral injection
- Chemosis
- Corneal edema
- Microabscesses
- Keratic precipitate (KP)
- Anterior uveitis – presenting as cells and/or flair
- Hypopyon
- Iris nodules

- Reduced or absent red reflex
- Vitritis – presenting as cells, haze, snowballs, and/or snowbanks (in cases of fungal hyphae)
- Papillitis
- Chorioretinal lesion – initially flat or only slightly elevated
- Cotton-wool spots
- Roth spots
- Retinal vasculitis
- Proptosis (in late and chronic endophthalmitis)

Epidemiology

The incidence of all types of endophthalmitis is 5/10,000 hospitalizations, with endogenous endophthalmitis accounting for 2–15% of cases. Endogenous endophthalmitis is becoming more common, as treatment with immunosuppressive and chemotherapeutic agents is constantly rising, and the numbers of AIDS patients are on the rise.

Twenty-five percent of endogenous endophthalmitis cases are bilateral. In unilateral cases, the left eye is twice as commonly affected than the right one. This is probably due to the relative proximity of the left common carotid artery to the left ventricle.

Risk Factors

Underlying Medical Condition
- Diabetes mellitus
- Malignancy and lymphoproliferative disorders
- Chronic obstructive pulmonary disease
- End-stage renal disease
- Human immunodeficiency virus (HIV) infection
- Endocarditis
- Hepatobiliary tract infections
- Skin infections
- Joint infections
- Gastrointestinal tract infections

Iatrogenic Factors
- Immunosuppressive drugs
- Intravenous and intraurethral catheters
- Recent extended surgical procedures
- Parenteral alimentation

Patient Characteristics
- Intravenous drug abuse
- Alcoholism
- Gender – in some studies a slightly higher incidence that was found in male subjects

Diagnosis

Diagnostic tests comprise ocular and systemic examination. While the former are centered on validating the diagnosis and following the progression of the disease, the systemic tests are aimed at locating the origin of the infection.

Systemic Diagnosis

General physical examination – for signs of systemic illnesses and injuries

Lab Work
- Complete blood count – for signs of infection, immunosuppressive or septic state
- Creatinine and BUN
- Erythrocyte sedation rate and CRP – to assess signs of chronic inflammation and malignancy
- Blood cultures
- Urine cultures
- Intravenous or intraurethral catheter cultures
- Other suspected infection site cultures (pharyngeal, cerebrospinal fluid, sputum, etc.)

Imaging

In the absence of a known infection site, the following imaging tests are recommended:

- Chest X-ray
- Transesophageal echocardiogram – to rule out heart valve vegetations and malformations
- Abdominal and/or chest computed tomography (CT) – to rule out perinephric or prostatic abscess

Ocular Diagnosis

- Full ocular exam and fundoscopy
- Ocular ultrasound – in cases of significant media opacities, in order to assess vitreal and choroidal involvement
- Orbital CT/MRI

- Vitreous and/or aqueous tap – for smears and culture
- Polymerase chain reaction (PCR) – for rapid diagnosis of specific pathogens

Differential Diagnosis

- Chorioretinal infection (such as CMV retinitis, toxoplasmosis, and *Pneumocystis jirovecii* (*P. carinii*), etc.)
- Noninfectious posterior or intermediate uveitis
- Neoplastic conditions
- Vitreous hemorrhage

Therapy

Although the prognosis of endogenous endophthalmitis patients is often less than encouraging, quick diagnosis and aggressive treatment may be the key to prevent severe visual loss.

Ocular Treatment

As swift and aggressive treatment is needed, when a substantial suspicion of endogenous endophthalmitis arises, often the first procedure performed is **tap** and **inject**, a bedside procedure where the "tap" refers to obtaining 0.1 cc of vitreous for culture and smears and the "inject" refers to the injection of an initial empiric antimicrobial therapy (usually vancomycin and ceftazidime). In cases in which it is unclear whether the pathogen is bacterial or fungal, empiric treatment of both etiologies is required. Additional treatment is later adjusted and added according to the culture, smear, or PCR results.

Commonly, the empiric antibiotic regimen of choice is a combination of vancomycin [1 mg/0.1 ml] and ceftazidime [2 mg/0.1 ml] with or without antifungal agents (amphotericin B, 5–10 μg/0.1 mL, or voriconazole 100 μg/0.1 m).

Vitrectomy has a key role in the treatment of endophthalmitis, as it decreases the pathogen, debris, and inflammatory mediator levels while allowing for a larger sample of the vitreous to be obtained and for the injection of intravitreal antibiotics and/or antifungal agents.

The role of vitrectomy and its timing in endogenous endophthalmitis are less established, as the indications and guidelines formulated from the Endophthalmitis Vitrectomy Study (EVS) relate to exogenous post-cataract endophthalmitis. Vitrectomy is considered mandatory when there is worsening of the signs and/or symptoms after initial treatment, in rapidly progressive cases, retinal necrosis, and extensive subretinal abscess or in the presence of retinal detachment.

Systemic Treatment

Contrary to exogenous endophthalmitis and the guidelines formulated from the EVS, in endogenous endophthalmitis, systemic antimicrobial or antifungal medication has a key role in the treatment of the condition.

Bacterial: A long-term intravenous antibiotic treatment is imperative. Initial dosing and drug selection should be adequate for the treatment of the underlying systemic infections. It is therefore recommended that such treatment should be administered after consultation with infectious disease specialist.

In the absence of systemic diagnosis, broad-spectrum coverage is indicated, usually comprised of vancomycin for gram-positive bacteria and ceftazidime for gram-negative infection.

Fungal: If the patients' history, physical examination, or culture suggests a fungal infection, intravenous treatment with amphotericin B, fluconazole, or the newer caspofungin or micafungin is warranted. Treatment duration and dosing may vary with response to underlying medical conditions. Toxic side effects such as renal and hepatic toxicity mandate consideration while monitoring the ocular and systemic clinical response.

Prognosis

Overall, despite prompt and aggressive treatment, visual prognosis in cases of endogenous endophthalmitis is usually unsatisfactory with

40–50% having a final vision of light perception (LP)/no light perception (NLP).

The prognosis is directly related to the pathogen virulence, the patient's systemic condition, and the extent and location of the ocular infection. A poorer visual prognosis is observed in cases of optic nerve or macular involvement and delayed diagnosis and a better prognosis in cases with more anterior and localized involvement.

Bacterial Adhesion in Ophthalmology, Characteristics of

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Ability of bacteria to adhere to biomaterials.

Basic Characteristics

Bacterial adhesion, primarily during the implantation process of ocular implants such as intraocular lenses, is followed by bacterial accumulation. Bacteria replicate, congregate, and form multiple layers of microcolonies embedded in an exopolysaccharide matrix, leading to the formation of a confluent structured biofilm. Implant-related infections such as endophthalmitis after cataract surgery are caused by biofilm. *Staphylococcus epidermidis* is the most common organism responsible for infections of implanted medical devices. Bacterial adhesion depends on the net sum of attractive and repulsive forces generated between the bacterial and substratum surfaces. Among the nonspecific interactions that play a role in primary bacterial adhesion, hydrophilic/hydrophobic interactions are believed to have an important influence. Bacteria, such as *staphylococcus epidermidis*, are mainly negatively charged and show greater adhesion to hydrophobic polymers. Hydrophobic intraocular lens materials such as silicone, polymethyl methacrylate, or hydrophobic acrylic intraocular lenses are more prone to bacterial adhesion than hydrophilic intraocular lenses. Recent epidemiological studies of endophthalmitis rates after cataract surgery with implantation of different intraocular lens materials have shown that implantation of silicone intraocular lenses is associated with increased rates of endophthalmitis as compared to hydrophilic intraocular lenses.

Bacterial Keratitis

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Infectious keratitis caused by bacteria.

Epidemiology

The reported incidence of post-refractive surgery bacterial keratitis ranges from 0.035% to 1.5%.

Clinical Features

Patients report about decreased vision, foreign body sensation, pain, photophobia, tearing or are asymptomatic. In slit-lamp examination, corneal infiltrates can be identified in the interface (LASIK) or superficial with epithelial involvement (Lasik, surface ablation). Infectious keratitis after refractive surgery has been classified as early onset (occurring within the 1–2 weeks after surgery) or late onset (occurring after 1 or 2 weeks to 3 months after the surgery). While in cases of early-onset bacterial keratitis is often associated with gram-positive bacteria, atypical mycobacteria have been identified in late-onset keratitis.

Tests

Corneal scraping should be done for microbiological analysis (culture, polymerase chain reaction) prior to antibiotic therapy.

Differential Diagnosis

Diffuse lamellar keratitis, viral keratitis, fungal keratitis, parasitic keratitis.

Etiology

In most cases, it is difficult to determine the origin of infection. Bacterial keratitis after refractive surgery is often associated with a compromised epithelial barrier, excessive surgical manipulation, intraoperative contamination, delayed postoperative reepithelialization of the cornea, bandage contact lens, healthcare environment, blepharitis, dry eye, and use of topical corticosteroids. Several sources of infection have been reported and include surgical instruments, surgeons' hands, environmental factors, and periocular flora originating from the eyelids and conjunctiva.

Treatment

Empirical broad-spectrum antibiotic treatment should be started immediately (e.g., combination of vancomycin with either an aminoglycoside or fluoroquinolone) and modified according to microbiological findings. In case of corneal infiltrates in the interface, immediate flap lifting and irrigation with antibiotics should be performed. In severe cases, amputation of a LASIK flap may be necessary.

Balint Syndrome

Jason E. Hale[4], Sumayya J. Almarzouqi[1], Michael L. Morgan[1,6] and Andrew G. Lee[1,2,3,4,5]
[1]Department of Ophthalmology, Blanton Eye Institute, Houston Methodist Hospital, Houston, TX, USA
[2]Departments of Ophthalmology, Neurology, and Neurosurgery, Weill Cornell Medical College, Houston, TX, USA
[3]Department of Ophthalmology, The University of Texas Medical Branch, Galveston, TX, USA
[4]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Balint syndrome (BS) is an uncommon but often debilitating neurological disorder characterized by the triad of simultagnosia, optic ataxia, and ocular apraxia. Simultagnosia is the inability to interpret complex visual displays due to difficulty with processing multiple items (i.e., "missing the forest for the trees"). Patients with simultagnosia have difficulty recognizing more than one object at a time in the presence of multiple distracting objects in the same field. Optic ataxia is an impairment in visuospatial perception where visually guided reaching for objects in space is impaired. Optic apraxia is the poor initiation of conjugate eye movements.

Etiology

BS is usually due to damage to the superior temporal-occipital lobes (Brodmann areas 19 and 7). The "two-stream" hypothesis for higher-order visual processing helps to understand the pathogenesis of BS. In this model, the ventral stream moves from the occipital lobe (i.e., primary visual cortex) through the temporal lobe, and the dorsal ventral stream moves from the occipital lobe through the parietal lobe. Disruption of the dorsal stream typically bilaterally produces the BS. BS can be the result of bilateral ischemic or hemorrhagic strokes, intracranial tumors, traumatic brain injury, and neurodegenerative diseases (e.g., posterior cortical atrophy with Alzheimer's disease).

Diagnosis

BS is a clinical diagnosis supported by characteristic neuroimaging of bilateral occipital-temporal-parietal lobe damage.

Differential Diagnosis

The differential diagnosis of BS includes primary or secondary dementia, psychosis, or cortical blindness.

Clinical

BS can be severely debilitating. Simultagnosia may present with reading difficult despite normal visual acuity and relatively normal comprehensive eye exams. Visuospatial difficulties can manifest as problems walking, eating, and drinking. Patients with optic ataxia may have problems reaching for and grasping objects accurately in their visual field.

Treatment

The treatment of BS should be directed at the underlying etiology. Visual and neurocognitive rehabilitative approaches include adaptive (functional) approaches, focused targeting and other compensatory strategies, and retraining in perceptual skills (e.g., tabletop activities and sensorimotor exercises).

Prognosis

The general prognosis for BS is variable but often poor because most of the etiologies for BS are severe and irreversible (e.g., trauma, stroke, neurodegenerative disease).

Epidemiology

There is no racial predilection for BS but the epidemiology of BS depends in part upon etiology. For example, older age is a risk factor for ischemic stroke or primary neurodegenerative disease (e.g., posterior cortical atrophy) versus younger age in trauma.

Bardet–Biedl Syndrome, Renal

Barbara Gold
Department of Ophthalmology, Tel Aviv University, Tel Aviv Medical Center, Tel Aviv, Israel

Synonyms

BBS; Laurence–Moon–Bardet–Biedl syndrome; Laurence–Moon–Biedl syndrome; Laurence–Moon syndrome; LMBBS; LMS

Definition

Bardet–Biedl syndrome (BBS) is a ciliopathic human genetic disorder that is characterized principally by truncal obesity, rod–cone dystrophy, retinitis pigmentosa, postaxial polydactyly, male hypogonadism, complex female genitourinary malformations, and renal abnormalities and/or failure in some cases.

Etiology

Bardet–Biedl syndrome can result from mutations in at least 14 BBS genes regulating the protein expression for cilia that are involved in cell movement, perception of sensory input, and many different chemical signaling pathways.

Clinical Presentation

The retinal dystrophy appears as an atypical pigmentary retinal dystrophy of the photoreceptors with early macular involvement. One of the major features of Bardet–Biedl syndrome is vision loss from gradual retina deterioration. Problems with night vision become apparent by mid-childhood, followed by blind spots that develop in the peripheral vision enlarging over time and produce tunnel vision. Most people with Bardet–Biedl syndrome also develop poor visual acuity and become legally blind by adolescence or early adulthood.

Cone–rod dystrophy is a form of retinal dysfunction. The photoreceptor cells in the retina gradually deteriorate (cone–rod dystrophy), causing vision loss. Symptoms associated with cone–rod dystrophy may not become apparent until 7 or 8 years of age when an impaired ability to see in dim light or the dark (night blindness) may develop.

The progression and degree of visual impairment varies among affected individuals. In most cases, vision becomes progressively worse through the first and second decade. Affected individuals often experience loss of peripheral vision, a condition sometimes termed tunnel vision. At some point during childhood or adolescence, many affected individuals eventually lose central vision as well, resulting in severe visual impairment or blindness. In some cases, the degeneration of the retina may follow the characteristic course of retinitis pigmentosa, with night blindness, loss of the ability to discriminate color, and progressive tunnel vision.

Additional ocular findings may occur including strabismus, abnormal, nystagmus, cataracts, and glaucoma.

Differential Diagnosis

Kaufman–McKusick syndrome
Typical retinitis pigmentosa

Therapy

Standard of care includes supportive diet intervention as obesity progresses, appropriate HgA1c levels maintained as type 2 diabetes develops, antihypertensive agents protective of renal function, and anticholesterol agents.

Prognosis

Very poor prognosis as end-stage renal failure, and blindness often occurs in Bardet–Biedl syndrome.

Epidemiology

Autosomal recessive disorder displaying pleiotropism and genetic heterogeneity.

In most of North America and Europe, Bardet–Biedl syndrome has a prevalence of 1 in 140,000–1 in 160,000 newborns. The condition is more common on the island of Newfoundland where it affects an estimated 1 in 17,000 newborns. It also occurs more frequently in the Bedouin population of Kuwait, affecting about 1 in 13,500 newborns.

Synonyms

Bartonella neuroretinitis; Cat scratch disease

Definition

Bartonella henselae is an aerobic intracellular gram-negative bacillus that infects both humans and cats. It is responsible for a broad range of clinical syndromes including optic neuropathy. Bartonella optic neuropathy commonly occurs in the setting of infectious neuroretinitis characterized by optic disk swelling, retinal infiltrates, localized vasculitis, subretinal fluid, and eventually a characteristic macular stellate exudate.

Etiology

Bartonella henselae may be transmitted from its major reservoir of cats to humans via cat scratches, cat bites, or flea bites, leading to infection. In immunocompetent patients, response to the infection tends to be suppurative and granulomatous and is associated with microabscess formation, while in immunocompromised patients the response tends to be vasoproliferative.

Clinical Presentation

There are a variety of clinical presentations associated with *Bartonella henselae* infections. The eye is the most commonly affected nonlymphatic organ in those with *Bartonella henselae* infection, and one of the ocular manifestations is neuroretinitis. Neuroretinitis often presents with a febrile prodromal illness followed by acute painless unilateral visual loss with optic nerve swelling and a macular star figure. Visual acuity at presentation varies and may worsen over the first several days. Optic nerve disc swelling may be seen but the degree of swelling is variable. The disc edema phase followed by subretinal fluid in the macula usually presents before the formation of macular star. Many patients develop macular exudates days after the visual loss leading to a macular star figure that is more prominent in the first 2–3 weeks. Other symptoms and signs that may be present in cat scratch disease include dyschromatopsia, segmental optic neuritis, relative afferent pupillary defect, retinal white dot syndrome, focal choroiditis, and variable visual field defects (cecocentral, central, or arcuate).

Diagnostics

The clinical diagnosis is confirmed by acute and convalescent serology for *Bartonella henselae* IgM and IgG antibodies.

Differential Diagnosis

The most common cause of infectious neuroretinitis is cat scratch disease. Tuberculosis, Lyme disease, syphilis, leptospirosis, toxoplasmosis, viral disease, and toxocariasis are less common infectious etiologies. The clinical presentation however can be mimicked by ischemic optic neuropathy, diabetic papillitis with diabetic exudative retinopathy, hypertensive optic neuropathy with retinovascular disease, papilledema (e.g., pseudotumor cerebri), and sarcoidosis. Although an etiologic diagnosis after can usually be made, many cases of neuroretinitis are idiopathic.

Prophylaxis

Prevention of *Bartonella henselae* infection consists of minimizing the outdoor and free-ranging behavior and flea infestation of domestic cats. Treating infected cats has been controversial in preventing human infection, as recurrent bacteremia is common and force-feeding antibiotics may lead to more scratches and trauma. We do not generally recommend treatment or elimination of the cat. However, disinfecting and washing of any cat scratches or bite wounds may reduce the risk for infection. Immunocompromised patients should definitely avoid scratches and control flea infestation in their cats.

Therapy

Treatment of *Bartonella henselae* infection varies based on clinical manifestation as well as the

immune status of the patient. There is a lack of randomized controlled data in the literature regarding the most effective proven therapy for Bartonella infection. The current treatment for neuroretinitis is based on observational case studies, and doxycycline is one drug used for its ability to produce intraocular and central nervous system penetration. Azithromycin, ciprofloxacin, and other antibiotics have also been used. Erythromycin may be substituted for doxycycline for children younger than 8 years of age in which tooth discoloration is a concern. Some studies have shown that the addition of rifampin may promote disease resolution, improve visual acuity, and decrease optic disc edema and duration of disease. Treatment duration in immunocompetent patients is usually 2–4 weeks, and duration in immunocompromised patients is about 4 months.

Prognosis

The swelling of the optic nerve usually spontaneously resolves in 2–8 weeks, either leaving a mild pallor or recovering to a normal disc appearance. Macular exudates tend to reach prominence over the first 2 or 3 weeks and stabilize for several weeks before they are gradually resorbed. However, even after the resolution of macular exudates, patients may experience mildly decreased visual acuity, abnormal color vision and evoked potentials, residual disc pallor, subnormal contrast sensitivity, retinal pigment changes, and relative afferent pupillary defects.

Epidemiology

Bartonella henselae's major reservoir is in domestic cats and infection spread is via flea transmission. In the USA most cases occur between the months of July and January. Bartonella infection was thought to be mostly a disease of children, but recent studies have suggested that its incidence in adults is higher than previously recognized. However, children and young adults have been reported to have a higher risk for systemic infection. Immunocompromised patients are also at greater risk of infection and systemic dissemination.

Synonyms

Basal cell cancer (BCC); Basal cell epithelioma

Definition

A skin malignancy that originates from ▶ basal keratinocytes in the top layer of the skin, the ▶ epidermis. BCC is a locally invasive tumor; metastases are rare.

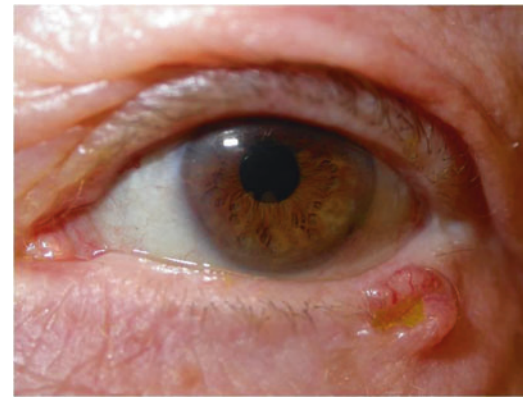
Etiology

Neoplastic transformation of basal cells of the epidermis or infundibular cells of the external root sheath of the hair follicle. Unlike other skin cancers, there are no known precursor lesions to BCC. The risk factors are:

- Ultraviolet light (both UVA and UVB) – chronic sun exposure
- White race (fair skin color, blue-eyed, red or blond hair)
- Geographic location with abundant sun exposure
- Increased age
- Exposure to ionizing radiation
- A history of premalignant ▶ skin lesions or skin cancer
- Genetic disorders such as nevoid basal cell carcinoma syndrome (Gorlin syndrome), ▶ xeroderma pigmentosum, and albinism
- Immunosuppressed states (AIDS or an organ transplant)

Clinical Presentation

Slow growing, locally destructive, and rarely metastasize. May arise anywhere on the eyelid skin, but may be more common on the medial canthus or lower eyelids, where more exposure may occur. Typically, the lesion presents as a firm nodule, raised, rolled, pearly, waxy, or translucent borders with fine telangiectasias and ulcerated or umbilicated center. Other suspicious findings are loss of lashes (madarosis) or eyelid margin notching. Many types of BCC can affect the periocular region, including nodular, nodulouloulcerative, pigmented, cystic, morpheaform, and superficial varieties. The most common form affecting the eyelid is nodular (Fig. 1).



Basal Cell Carcinoma of Eyelid, Fig. 1 Nodulouloulcerative BCC in lower eyelid. Note the loss of cilia on the lower eyelid and telangiectasias of the tumor

Basal Cell Carcinoma of Eyelid, Fig. 2 Morpheaform BCC involving lower eyelid near medial canthus

Morpheaform or infiltrating forms are less common, but more aggressive (Fig. 2). These lesions may be pale, indurated, or patchy. If along the eyelid margin, BCC can mimic blepharoconjunctivitis. The nodular form may be pigmented and confused with ▶ melanoma (Curtis et al. 1993; Albert and Jakobiec 2008; Shields and Shields 2008).

Diagnostics

Clinically by typical appearance and confirmed with ▶ biopsyand histopathologic interpretation.

Differential Diagnosis

Differential Diagnosis includes ▶ keratoacanthoma, ▶ melanocytic nevus, ▶ melanoma, ▶ seborrheic keratosis, ▶ sebaceous carcinoma, ▶ trichoepithelioma, ▶ squamous cell carcinoma, ▶ Bowen disease, and ▶ actinic keratosis.

Prophylaxis

Avoidance of sun and UV exposure (use of sunscreens, sunglasses, umbrellas, and hats).

Therapy

Complete surgical resection with histologic control of margins either by frozen sections or Mohs' micrographic surgery. When surgery is not appropriate or possible, radiotherapy, cryotherapy, or pharmacotherapy can be considered but may be associated with higher recurrence rates than surgical resection.

Prognosis

Depends on the size of the tumor, anatomic location (medial canthus has a worse prognosis), and pattern of infiltrative growth. High cure rates (98%) if early detected and properly treated. However, a tumor recurrence suggests an aggressive propensity.

Epidemiology

In the United States, 380,000–400,000 people each year develop a new BCC. It is the most common malignant tumor of the skin and responsible for 80–90% of malignant eyelid tumors (Curtis et al. 1993; Albert and Jakobiec 2008; Shields and Shields 2008).

Basal Cell Nevus Syndrome (Gorlin Syndrome)

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Basal cell nevus syndrome; Gorlin syndrome; Nevoid basal cell carcinoma syndrome

Definition

A rare autosomal dominant disorder characterized by multiple nevoid basal cell carcinomas early in life. It is a multisystemic disease involving multiple organ systems.

Etiology

Tumors are indistinguishable from noninherited forms of basal cell carcinoma, arising from the basal cell layer of the epithelium. The gene thought to be responsible for Gorlin syndrome is the patched gene (PTCH), found on 9q22.3-q31. It is thought to be a tumor suppressor with one germ line defect in affected families. Complete penetrance with variable expressivity is observed (Gorlin 1995; Bale 1997; Shields and Shields 1999; Albert and Jakobiec 2008).

Clinical Presentation

Gorlin syndrome may present with multiple basal cell carcinomas at a young age. Eyelid basal cell carcinomas occur in 25% of cases and are indistinguishable from noninherited forms of basal cell carcinoma.

Other ophthalmic findings in Gorlin syndrome include congenital cataracts, orbital cysts, hypertelorism, colobomas, and medullated nerve fiber layer of the retina. Other features include mandibular cysts, macrocephaly, frontal bossing, polydactyly, palmar or plantar pits, and medulloblastoma (Gorlin 1995; Shields and Shields 1999; Albert and Jakobiec 2008).

Diagnostics

Excisional biopsies of suspect lesions are histologically indistinguishable from basal cell carcinoma. Imaging is necessary when clinically correlated, including MRI of the brain, dental radiography, and a skeletal survey.

Differential Diagnosis

Xeroderma pigmentosa

Prophylaxis

Patients with Gorlin syndrome may be extremely susceptible to ionizing radiation and sun exposure. Patient should be counseled to avoid sun exposure.

Therapy

Surgical excision is recommended for a patient with a limited number of lesions. Topical 5-fluorouracil with or without topical tretinoin may be useful for patients with extensive lesions. Oral isotretinoin may be an option for patients who are at high risk for developing many additional lesions.

Prognosis

Patients may have multiorgan involvement and will need care by appropriate specialists, including dermatologists, dentists, oncologists, cardiologists, and orthopedic surgeons.

Epidemiology

Incidence is rare and occurring in about 1 per 50,000–150,000 people and in 0.7 % of patients with basal cell carcinoma. Fair-skinned patients with substantial sun exposure may be more susceptible (Gorlin 1995; Shields and Shields 1999; Albert and Jakobiec 2008).

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Battle sign, also called mastoid ecchymosis, consists of subcutaneous blood/bruising over the mastoid process of the skull. It can be an indication of fracture in the posterior cranial fossa of the skull, and the finding is a result of extravasation of blood along the path of the posterior auricular artery, which runs vertically and posterior to the external ear. Most posterior cranial fossa fractures occur following lateral and/or posterior blow to the occiput. Posterior fossa fractures can cause injury to the facial nerve, resulting in ipsilateral facial paralysis.

Clinical

Patients with the Battle sign can also present with other signs or symptoms of skull base fracture such as periorbital ecchymosis (i.e., raccoon eyes), cerebrospinal fluid (CSF) rhinorrhea (usually more indicative of an anterior skull fracture), cranial nerve palsy, bleeding from the nose or ears, hemotympanum, hearing loss, nystagmus, vomiting, and optic nerve compression.

The pattern of cranial nerve involvement will depend on the specific location of the fracture. Facial nerve injuries due to longitudinal fractures most commonly occur at the level of the geniculate ganglion, which is located within the facial canal near the middle and inner ear. Fractures through the jugular foramen can also disrupt function of the glossopharyngeal, vagal, and spinal accessory nerves.

Diagnosis

Clinically, patients with lower cranial neuropathies after trauma with or without the Battle sign should be evaluated for a skull base fracture. These skull base fractures are radiographically detected with skull x-rays or more commonly computed tomography (CT) imaging, although if small may be difficult to detect.

Differential Diagnosis

Battle sign can be confused with an expanding hematoma caused by fracture of the mandibular condyle.

Treatment

Skull base fractures may require surgical repair especially if there is associated intracranial injury requiring decompression, persistent cerebrospinal fluid (CSF) leak, or significant cranial nerve or vascular injury.

Prognosis

Prognosis depends on the severity of the trauma and the extent of damage to the cranial nerves. Full recovery is possible depending on severity and rapidity of appropriate evaluation and treatment.

DUSN

Definition

Diffuse unilateral subacute neuroretinitis (DUSN), previously known as "unilateral wipeout syndrome," was first termed by J. Donald M. Gass in 1978 (Gass and Scelfo 1978). The syndrome refers to a unilateral, potentially blinding, inflammatory disease characterized by mild to severe vitritis, deep white retinal lesions, marked diffuse retinal pigment epithelium changes, and eventual optic atrophy in the late stages, caused by a parasitic infection (Arevalo et al. 2013).

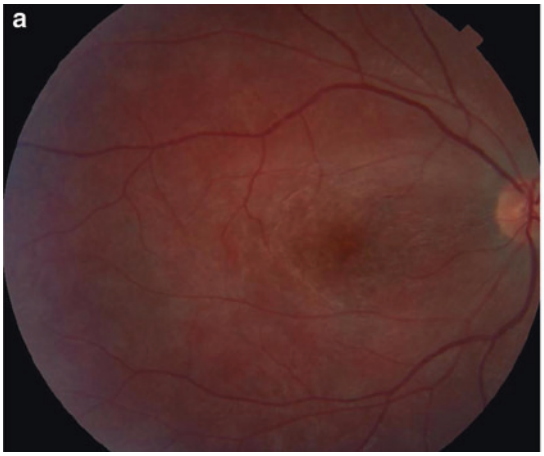
Etiology

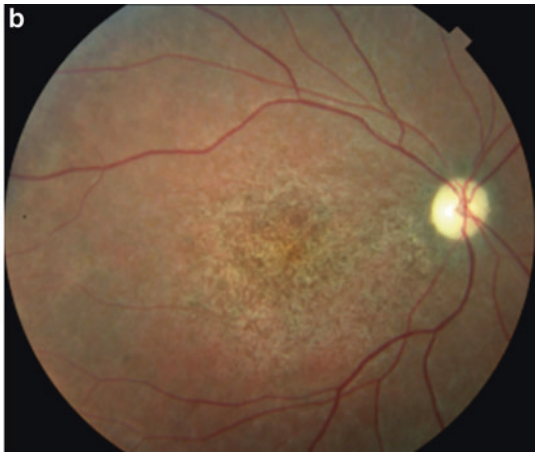
Nematodes of varying sizes have been reported in association with diffuse unilateral subacute neuroretinitis. Although no nematodes have ever been identified, *Baylisascaris procyonis*, also known as the "Raccoon roundworm," is thought to be the larger-sized nematode (1,500–2,000 μm) often isolated in north Midwestern United States, and *Ancylostoma caninum* is thought to be the smaller-sized (400–700 μm) nematode often isolated in Southeastern United States.

Clinical Features

The diagnosis can be obvious with clinical visualization of a subretinal, motile nematode; however, more often the diagnosis is challenging and presumptive when no nematode can be found. DUSN is most frequently seen in healthy children or young adults with no significant ocular or systemic illness. Common ocular symptoms include unilateral paracentral scotoma and blurring of vision.

Early recognition of DUSN is important since prompt removal and destruction of the causative nematode may prevent progressive visual loss. Unfortunately, clinical manifestations of DUSN in the early stages of the disease such as vitritis, deep white retinal lesions, and optic disc swelling may be easily mistaken as multifocal choroiditis, multiple evanescent white dot syndrome, or



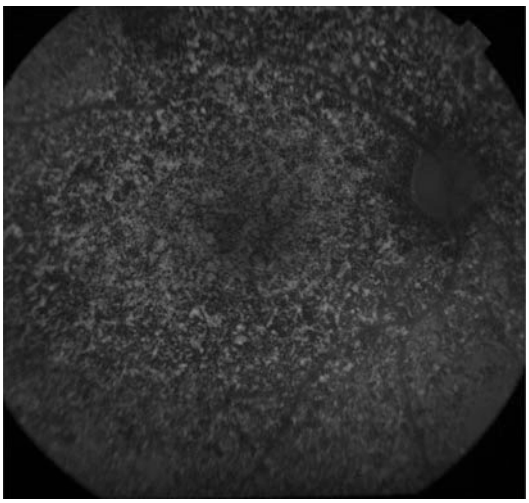


***Baylisascaris procyonis* (Raccoon Ascarid), Diffuse Unilateral Subacute Neuroretinitis, Fig. 1** Color fundus photograph of diffuse unilateral subacute neuroretinitis at presentation and 1 month after. **a** Color fundus photograph at presentation showing nonspecific retinal pigment epithelial changes at the central macula. Note the relatively normal appearing optic disk at this stage. **b** Color fundus photography of the same eye taken 1 month later showing diffuse retinal pigment epithelial changes and severe optic atrophy (Images courtesy of Dr K. Bailey Freund, Vitreous-Retina-Macula Consultants of New York, New York, USA)

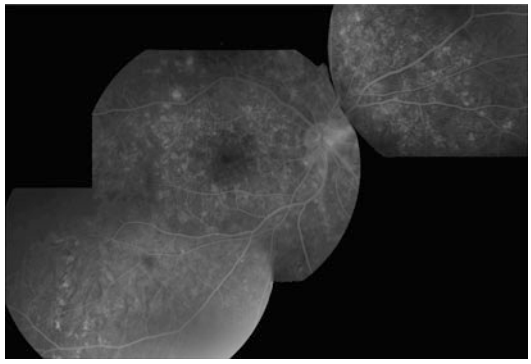
nonspecific optic neuritis and papillitis (Sabrosa and de Souza 2001).

In the early stages, focal retinal pigment epithelial (RPE) changes may be explained by the travel pattern of the worm, while diffuse RPE changes may be explained by a toxic reaction. The focal chorioretinal white spots may be an immune response to the secretion or excretion of the nematode. These lesions may disappear in 1–2 weeks as the nematode moves elsewhere in the eye. In the late stages, retinal arteriolar attenuation, diffuse atrophic changes in the retinal pigment epithelium, and optic atrophy may develop, resulting in irreversible profound vision loss. Choroidal neovascularization may occur as a complication due to breaks in Bruch's membrane presumably created by the movement of the nematode (Gass and Olsen 2001).

The progression of this disease from its early to late stage can be impressively rapid. In the early stage, there may be nonspecific RPE changes and gray-white retinal lesions, with a relatively normal appearing optic disk. Within a short duration, as short as 1 month, there may be progression to widespread RPE atrophy and optic atrophy (Fig. 1). The extensive involvement of the retina may be rather impressive as evident with fundus autofluorescence (Fig. 2)



***Baylisascaris procyonis* (Raccoon Ascarid), Diffuse Unilateral Subacute Neuroretinitis, Fig. 2** Fundus autofluorescence of diffuse unilateral subacute neuroretinitis showing widespread retinal pigment epithelial changes (Image courtesy of Dr K. Bailey Freund, Vitreous-Retina-Macula Consultants of New York, New York, USA)



***Baylisascaris procyonis* (Raccoon Ascarid), Diffuse Unilateral Subacute Neuroretinitis, Fig. 3** Fluorescein angiographic montage of diffuse unilateral subacute neuroretinitis showing widespread retinal pigment epithelial changes (Image courtesy of Dr K. Bailey Freund, Vitreous-Retina-Macula Consultants of New York, New York, USA)

***Baylisascaris procyonis* (Raccoon Ascarid), Diffuse Unilateral Subacute Neuroretinitis, Fig. 4** Color fundus montage of diffuse unilateral subacute neuroretinitis with a visible nematode in the peripheral retina superiorly (*arrow*) (Image courtesy of Dr K. Bailey Freund, Vitreous-Retina-Macula Consultants of New York, New York, USA)

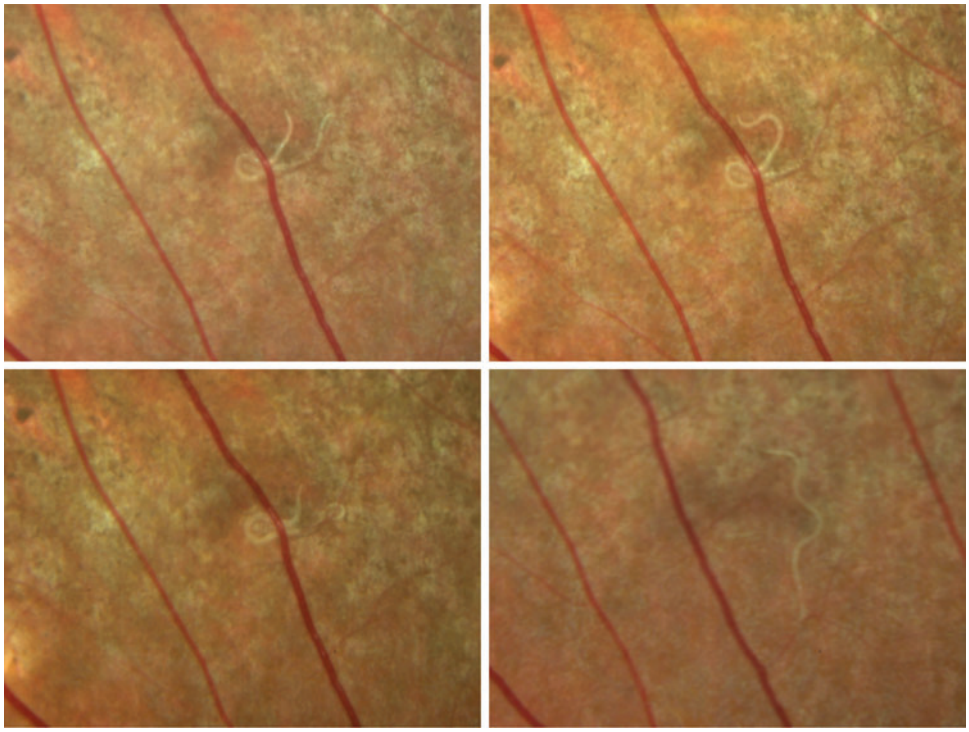
and fluorescein angiogram (Fig. 3). The diagnosis is usually made with documentation of the intraocular nematode with the aid of ultrawide field or montage color photography (Fig. 4) and serial photographs, which demonstrate the motility of the intraocular nematode (Fig. 5).

Diagnostics

Identification of the intraocular nematode requires meticulous examination of the entire retina. In many cases, the intraocular nematode is so minute that it can be easily overlooked. As mentioned, serial fundus photography documenting nematode motility is often the most useful diagnostic test (Fig. 5). Fundus autofluorescence shows widespread hypofluorescent granularity due to RPE abnormalities (Fig. 2). Fluorescein angiography in the early phase may show hypofluorescence of the retinal lesions followed by late staining and leakage of dye from the optic nerve capillaries or peripheral venules. In the later phase, there may be widespread hyperfluorescent window defects from retinal pigment epithelial damage (Fig. 3). Indocyanine green angiography shows hypofluorescent dark spots in the early phase that either disappear or persist in the late phase, indicative of choroidal infiltration. Optical coherence tomography may show a decrease in retinal nerve fiber layer thickness. Visual field studies are nonspecific but may be useful for evaluating visual field before and after treatment. Electroretinography may be highly variable including mild to moderate decrease in rod and cone function and in more severe cases with ischemic retina, a negative electroretinogram. Multifocal electroretinography may show decreased foveal responses, which may improve following treatment. Systemic investigations including serology are often unrevealing unless eosinophilia is present.

Differential Diagnosis

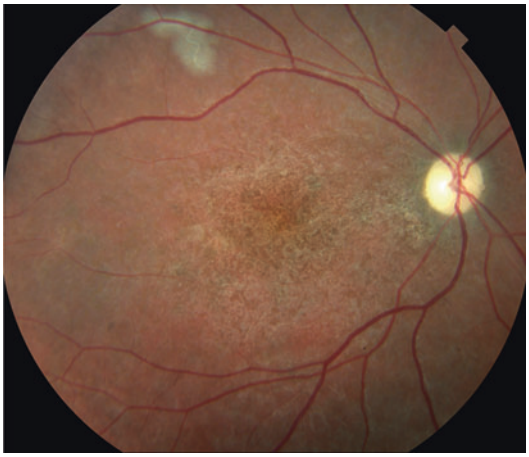
Differential diagnosis of DUSN includes vitritis, multifocal choroiditis, multiple evanescent white dot syndrome, or nonspecific optic neuritis and papillitis.



***Baylisascaris procyonis* (Raccoon Ascarid), Diffuse Unilateral Subacute Neuroretinitis, Fig. 5** Serial color fundus photographs of diffuse unilateral subacute neuroretinitis showing the motility of the nematode (Image courtesy of Dr K. Bailey Freund, Vitreous-Retina-Macula Consultants of New York, New York, USA)

Treatment

The best treatment option of a visible worm is laser photocoagulation as it presumably kills the intraocular nematode as evident by its lack of motility, without causing significant intraocular inflammation. Pretreatment immunosuppression with corticosteroids may reduce retinal inflammation if any. After laser photocoagulation, there may be improvement in vision and resolution of the active vitritis and chorioretinitis. Laser photocoagulation should be aimed at achieving white burns surrounding the nematode (Fig. 6) (Garcia et al. 2004). Other treatment options including oral antihelminthic therapy such as albendazole and pars plana vitrectomy have been tried with variable success. It may be reasonable to treat the patient with 400 mg of albendazole for 30 days if there is any suspicion of systemic involvement.



***Baylisascaris procyonis* (Raccoon Ascarid), Diffuse Unilateral Subacute Neuroretinitis, Fig. 6** Color fundus photograph of diffuse unilateral subacute neuroretinitis after treatment with laser photocoagulation to the nematode (Image courtesy of Dr K. Bailey Freund, Vitreous-Retina Macula Consultants of New York, New York, USA)

Surgical extraction of the nematode using vitrectomy may be difficult in view of the small size and motility of the intraocular nematode, however may be considered if there are any relative contraindications to laser photocoagulation such as if the patient is uncooperative to laser treatment or if the nematode is situated near the posterior pole or macula.

Synonyms

CN VII palsy; Idiopathic facial palsy; Idiopathic facial paralysis

Definition

A Bell palsy is characterized by sudden onset of unilateral, lower motor neuron weakness of CN VII (the facial nerve).

Etiology

The etiology of Bell palsy remains largely unknown, but it is believed to originate from a viral infection, likely herpes simplex, in at least

some of the cases. A certain subset of patients may be at an increased risk for developing Bell palsy; this includes those with diabetes or multiple sclerosis and those that are currently pregnant. While the exact cause remains unknown, the signs and symptoms of Bell palsy are caused by a peripheral lesion to CN VII (the facial nerve) which involves all of its distal branches.

Clinical Presentation

The main characteristic of Bell palsy is unilateral facial weakness which involves the forehead. Although facial weakness on both sides is a rare presentation, this does not completely rule out Bell palsy as a diagnosis. Full facial nerve weakness is usually reached within a few days from the onset of symptoms. Other symptoms may be seen on the same side as the facial weakness and include sensitivity to loud sound (hyperacusis), impaired tear production, subjective mild numb sensation or pain of the ear, tongue, or face, changes in taste and reduced secretion of saliva. Just over half of those with Bell palsy will present with a viral prodrome as well which may include fever, malaise, tingling, or itching of skin over the area to be affected.

Diagnostics

A clinician diagnoses Bell palsy from the patient's history, including time of onset, associated symptoms and precipitating factors, and physical exam findings such as weakness of the muscles of facial expression and the extent of involvement. The diagnosis is made largely by exclusion of other causes. When evaluating a patient for facial paralysis it is important to determine whether the lesion is central or peripheral before doing anything else. This is easily done by asking the patient to raise their eyebrows, if the forehead fails to contract then a peripheral palsy (like Bell palsy) is likely, but if the forehead is able to contract then a central VII nerve palsy is more likely and the patient should be evaluated for a possible cerebral vascular accident. There are no laboratory or imaging tests used to definitively diagnose Bell palsy.

Differential Diagnosis

Cerebral vascular accident, Möbius syndrome, facial colliculus syndrome, acoustic neuroma, Lyme disease, sarcoidosis, metastatic lesions, temporal bone fracture, Ramsay Hunt syndrome, otitis media, congenital facial palsy, Guillain-Barré syndrome, and hemangioma.

Prophylaxis

There is no known prophylactic treatment for this condition.

Therapy

Due to the idiopathic nature of the disease, treatment for Bell palsy is controversial and limited. Most patients will recover spontaneously within a few weeks even without treatment. Corticosteroids such as prednisone have been reported to speed the recovery of Bell palsy. High quality evidence, however, has shown no significant benefit from anti-herpes simplex antivirals compared with placebo in producing complete recovery from Bell palsy, and lesser quality evidence has suggested that antivirals were significantly less likely than corticosteroids to produce complete recovery.

For patients that are not able to close their eyelid due to the paralysis, artificial tears or ointment should be used to prevent drying of the eye and related ophthalmic complications.

Prognosis

In general, the prognosis for those with Bell palsy is excellent. Most patients begin to recover within

3 weeks from the onset of their symptoms, and the remainder will show improvement within 3–6 months. Most individuals can expect to recover full function of the facial nerve, but some will have residual weakness. Although all patients will show some improvement in their symptoms, a very small subset will have poor return of function. Those that begin to recover sooner generally have the best chances of regaining full function. Patients that experience hyperacusis or decreased tear production, are after over 60 years of age, or suffer from diabetes, hypertension, or a psychiatric disease have a poorer prognosis. Once a patient has made a full recovery, they do not typically experience any adverse sequelae. Recurrence is seen in less than 20% of cases.

Epidemiology

The annual incidence of Bell palsy is approximately 20–25 per 100,000 individuals. It occurs equally in both genders and among races. There is an increasing incidence with increasing age. A small percentage of those affected have a history of prior facial palsy or have a family history of Bell palsy. Geographic location does not have any influence on the prevalence of this condition. Paralysis of the facial nerve occurs equally on the left as the right. Those that are pregnant or have a history of diabetes or multiple sclerosis may be at an increased risk to develop Bell palsy.

Benign episodic unilateral mydriasis; Episodic anisocoria; Migraine with benign episodic unilateral mydriasis; Springing pupil; Transient benign unilateral pupillary dilation

Definition

Benign episodic unilateral mydriasis (BEUM) or benign episodic pupillary dilation (BEPD) is an isolated benign cause of intermittent transient pupil asymmetry. It comprises a heterogeneous set of conditions. BEPD usually affects young,

healthy women but can occur in any age and in any gender. It has a benign prognosis and does not necessitate further workup.

Etiology

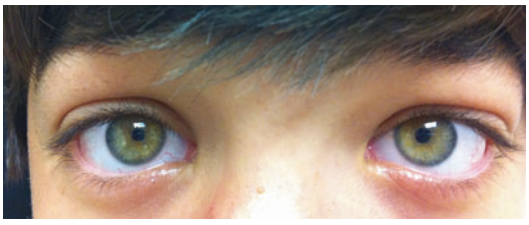
The exact pathophysiology for BEPD is unclear. It had been hypothesized that alterations in the interplay between the sympathetic and parasympathetic activity of the iris (e.g., parasympathetic insufficiency of the iris sphincter in some cases, or sympathetic hyperactivity of the iris dilator in others).

Clinical Presentation

Typically patients present with transient BEPD, and each episode may last from minutes to hours is self-limited, and spontaneously resolves. BEPD can be seen in patients with the history of headache; however, it has also been described without accompanying headache. The association with BEPD and migraine had been reported in the literature, and some authors consider it to be a limited form of ophthalmoplegic migraine. BEPD may be associated with blurring of vision, periocular pain, and photosensitivity; however, it has not been reported to be associated with any systemic or neurologic disease. The only ocular finding during the event is pupil asymmetry (anisocoria) (see Fig. 1).

Diagnostics

A detailed medical history including medications and physical examination, including ophthalmic and neurological evaluation, is crucial in the diagnosis of BEPD. BEPD appears to have a benign neurological prognosis and does not require further neurodiagnostic studies.



Benign Episodic Pupillary Mydriasis, Fig. 1 Minimal Mydriasis seen in left eye.

Differential Diagnosis

- Physiologic anisocoria
- Mydriasis secondary medication side effect
- Adie's tonic pupil
- Intermittent angle-closure glaucoma
- Partial third nerve palsy
- Posterior cerebral artery aneurysm
- Tentorial herniation
- Horner syndrome
- Traumatic mydriasis

Therapy

Patient education and reassurance are typically all that is necessary for BEPD.

Benign Essential Blepharospasm: Orbital and Oculoplastic Considerations

Michael T. Yen[1] and Joshua Udoetuk[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Kelsey Seybold Clinic, Houston, TX, USA

Definition

Benign essential blepharospasm is a form of focal dystonia which involves involuntary contraction of the orbicularis oculi, resulting in uncontrollable eyelid twitching (Anderson et al. 1998). Meige's syndrome is a combination of blepharospasm and oromandibular dystonia, the latter of which is described by a constellation of symptoms including marked difficulty opening or closing the jaw, lateral jaw deviation, teeth grinding, and jaw pain (Jankovic 1988).

Etiology

The etiology of benign essential blepharospasm and Meige's syndrome is not entirely understood. Formerly thought of as a predominately psychological condition, evidence from advances in neuroimaging and research techniques support potential neurolopathologic etiologies (Hallet 2002). Eyelid blinking is normally an involuntary response involving sophisticated neuronal circuitry, including cranial nerves 2 (afferent), 5 (afferent), and 7 (efferent) (Ben Simon and McCann 2005). A central area that coordinates eyelid blinking is thought to inhabit deep cerebral structures, such as the basal ganglia and/or brain stem. A single causative factor has not yet been identified in the pathophysiology of blepharospasm. Given the complex neuroanatomy underlying this disorder, the etiology is likely to be as complex (Jankovic 1988; Hallet 2002; Ben Simon and McCann 2005).

Epidemiology

Blepharospasm is an uncommon disorder that is frequently misdiagnosed. The prevalence of blepharospasm is estimated to be approximately 1 in 20,000 with a female predominance of nearly 2:1. Average age of onset is in the mid-50s, with most patients older than 60 (Anderson et al. 1998).

Clinical Presentation

Benign essential blepharospasm may go mis- or undiagnosed for a prolonged period of time. Eyelid twitching may be ignored by the patient until it worsens to a point where they seek medical attention. Physicians unfamiliar with this condition may underestimate a patient's complaints or prescribe ineffective treatments such as artificial tears or sunglasses (Anderson et al. 1998; Ben Simon and McCann 2005).

Patients complain of involuntary, painless, episodic eyelid twitching or closing that is usually bilateral. In severe episodes, patients cannot open their eyes at all. Spasms can be provoked or unprovoked and often worsen as the patient ages. Patients may also complain of dry eyes, allergic symptoms, photophobia, and eye strain with reading or watching television (Jankovic 1988; Anderson et al. 1998). These symptoms can cause marked emotional distress and can lead to social embarrassment and even withdrawal. Patients with Meige's syndrome present with multiple jaw-related complaints in addition to blepharospasm (Jankovic 1988).

Diagnosis

Oftentimes, benign essential blepharospasm or Meige's syndrome can be diagnosed in the office based on direct observation of the spasms. As

these conditions generally worsen with time, blepharospasm is often quite apparent by the time patients seek medical attention. Other times when blepharospasm is not apparent in the office, the physician must rely solely upon history or ask patients to videotape episodes (Jankovic 1988; Defazion and Livrea 2004).

When considering the diagnosis of benign essential blepharospasm or Meige's syndrome, it is important to rule out secondary causes of blepharospasm. The most common cause of reflexive blepharospasm is dry eye and other ocular surface abnormalities (Ben Simon and McCann 2005). Other causes of secondary blepharospasm include ocular inflammatory disorders, seizure activity, meningeal irritation, and brain stem abnormalities (vascular insufficiency, space occupying lesion, etc.).

In benign essential blepharospasm or Meige's syndrome, treatments for coincidental dry eye or ocular inflammation are not impressive. Serologic investigations and standard neuroimaging studies do not reveal a causative factor (Anderson et al. 1998).

Differential Diagnosis

Bell's palsy
Cerebral vascular accident
Cerebral space occupying lesion
Drugs (antipsychotics, cholinergics, cocaine)
Dry eye
Eyelid myokymia
Hemifacial spasm
Meningeal irritation
Intra- and extraocular inflammation
Seizure

Treatment

There is no cure for benign essential blepharospasm and Meige's syndrome. Treatment anchors on temporally alleviating spasmodic episodes and begins with identifying and treating any afferent-arc-related issues that may be exacerbating the condition. This includes artificial tears for dry eye, lid hygiene for blepharitis and meibomian gland dysfunction, and sunglasses for photophobia. Benzodiazepines have been reported to provide temporary relief, but effectiveness cannot be predicted (Anderson et al. 1998).

Serial injections of Botulinum A toxin is considered by most physicians to be the most effective treatment for blepharospasm (Anderson et al. 1998; Defazion and Livrea 2004). Botulinum A toxin prevents the exocytosis of presynaptic vesicles containing acetylcholine, which decreases the concentration of acetylcholine in the motor end plate, resulting in paralysis of skeletal muscles. Patients begin to experience relief within 1 week and the effect lasts a mean of 3–5 months. Treatment can be repeated and adjusted to optimize results based on previous treatments.

There are more invasive surgical options for blepharospasm when medical options fail. One very effective option is the protractor myectomy procedure (Gillum and Anderson 1981). In this procedure, much of the orbicularis oculi muscle and the corrugator supercilii muscle are extirpated from the eyelid. Other alternative treatments include proximal and distal facial neurectomy and the superior cervical ganglion block (Ben Simon and McCann 2005).

Prognosis

For most patients, the prognosis is good. Once the condition is diagnosed, customized treatment alleviates blepharospasm in over 95% of patients (Anderson et al. 1998).

Definition

BEB is an uncommon neurological disorder that causes an involuntary, intermittent muscle spasms and contractions of the facial muscles around the eyes bilaterally. Symptoms can range from mild intermittent eyelid twitching to excessive blinking and sometimes constant or debilitating persistent spasm and closure of the eyes. There is no clear cause but is believed to be a form of localized dystonia.

Etiology

Although BEB was thought to be a psychological disorder in the past, most authors now believe that BEB is multifactorial in origin. Some have postulated a defect in the control circuits in the basal ganglia, midbrain, and brain stem that regulate and coordinate the normal eyelid and blinking activities. Several studies have shown decreased corneal sensitivity, and a relationship to impaired cortical processing of sensory input and secondary loss of the inhibition of the blink reflex as a mechanism has been proposed. The efferent (motor) pathway for eyelid closure primarily includes the facial nerve and its innervation to the orbicularis oculi, corrugator, and procerus muscles.

Clinical Presentation

Patients with BEB may complain of tearing, eye irritation, photophobia, and vague ocular pain before or during the spasm episodes. In the early stages, BEB is typically characterized by intermittent forced blinking (77%) and subjective eye irritation (55%) that can be triggered by different stimuli (e.g., bright lights, emotional stress or tension, fatigue, wind, or air pollution). BEB in contrast to hemifacial spasm is bilateral. The muscle spasms (66%) and contractions symptoms often increase gradually and in severe cases BEB may progress to a continuous or disabling cycle leading to functional blindness. Usually BEB symptoms occur during the day while awake and disappear while sleeping. BEB symptoms may be temporarily relieved by sleep (75%), relaxation (55%), inferior gaze (27%), artificial tears (24%), talking (22%), eyelid traction (22%), singing (20%), and humming (19%). Although BEB is typically an isolated disorder, it may be associated with dystonia of the face, mouth, or jaw. BEB may also be associated with or triggered by dry eyes (49%). The vast majority of BEB is neurologically isolated, but rare cases are due to underlying neurological disease (8%). Patients with BEB may also have apraxia of eyelid opening (AELO) characterized by a temporary inability to open the lids voluntarily. Some patients develop a "sensory trick" to help them to open the lids. Typically, once the lids open either spontaneously or with manual elevation, they remain open in AELO.

Diagnostics

The diagnosis of BEB is a clinical diagnosis, and there is no diagnostic laboratory or radiographic finding.

Differential Diagnosis

1. Meige syndrome
2. Apraxia of lid opening
3. Myokymia
4. Fasciculation
5. Hemifacial spasm
6. Dystonia
7. Bell's palsy

Prophylaxis

Non-applicable.

Therapy

Although no cure currently exists, patients have different options for treatment. The first line of treatment measures includes reducing the environmental and other triggers, using tinted sunglasses or specific filters to reduce painful light sensitivity (photo-oculodynia), lid hygiene to decrease irritation and any concomitant blepharitis, and treatment of dry eyes (e.g., artificial tears, topical drops, punctal occlusion).

Pharmacotherapy includes an extensive list of drugs that have been used to treat BEB; however, they have partial and transient relief (e.g., lorazepam, clonazepam, and Artane). Local injection of botulinum A toxin is considered the most effective (95%) treatment of choice for BEB. Botulinum toxin interferes with acetylcholine release from the nerve terminals, leading to a temporary paralysis of muscles. The paralytic effect is dose related, and the peak effect is at 5–7 days after injection with a mean duration of action of 3 months. Complications of botulinum toxin injections include ptosis, diplopia, corneal exposure, dry eye, entropion, ectropion, epiphora, photophobia, and ecchymosis.

Surgical treatment of BEB is reserved for patients who fail maximal medical therapy and includes myectomy and frontalis suspension. One other treatment modality that has shown some anecdotal benefit in the treatment of BEB is superior cervical ganglion block.

Prognosis

The prognosis of BEB is variable and the severity ranges from mild to debilitating.

Epidemiology

There are up to 2,000 new BEB cases diagnosed annually with a prevalence of approximately 5 in 100,000 of the general population. There are up to 50,000 cases of BEB in the United States. It's preponderance in female with female to male ratio of 1.8:1. The mean age of onset is 56 years, with around two thirds of patients 60 years or older.

Best Disease

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Best vitelliform macular dystrophy; Vitelliform macular dystrophy; Vitelliform macular dystrophy type 2

Definition

Best disease is an autosomal dominantly inherited bilateral disorder of variable penetrance and expressivity characterized by variable deposition of yellow yolk-like macular cysts, good visual acuity, subnormal electrooculogram (EOG), and progression throughout life.

Etiology

Best disease is caused by mutations in the VMD2 gene on chromosome 11q13 that codes for bestrophin-1, a calcium-sensitive chloride (Cl^-) channel protein that is found on retinal pigment epithelial (RPE) cells. Disease-causing mutations in bestrophin-1 protein result in defective Cl^- channel conductance. Abnormalities in EOG are thought to be a result of this defective Cl^- conductance. The yolk-like yellow macular lesions characteristic of the vitelliform stage of Best disease are thought to be due to abnormal accumulations of lipofuscin and possibly unphagocytized outer photoreceptor segments in the RPE and subretinal space.

Clinical Presentation

Most vitelliform lesions are found on routine exam. Visual acuity is often only minimally affected, although poor vision is possible, especially in older patients. Findings are usually bilateral; however, unilateral changes have been reported. For most patients, there is a very gradual progressive vision loss. Carriers of Best disease usually have no fundus findings.

Several clinical stages exist with Best disease. These are summarized in Table 1. Although vitelliform lesions have been reported as early as the first week of life, patients usually have a normal appearing fundus during the first few months to years of life. Typically, the vitelliform stage occurs between 3 and 15 years of age. A central, round or oral, sharply circumscribed subretinal yellow cyst that resembles a yolk of a sunny-side up egg is the classic vitelliform lesion. This lesion usually measures 1/2 to 2 disk diameters in size and is uniform in color. Sometimes multiple vitelliform cysts may occur.

Best Disease, Table 1 Clinical stages of best disease

Clinical stage	Description
Normal fundus	Normal fovea but abnormal EOG
Previtelliform	RPE defects, small round yellowish dot in foveola or tiny honeycomb-like structure centrally
Vitelliform	Round or oval, sharply circumscribed, smooth macular subretinal lesion uniformly filled with yellow material of ½ to 2 disk diameters in size with appearance similar to yolk of an egg
Scrambled egg	Yellowish material begins to disintegrate with borders of lesion becoming more irregular and less discrete. Visual acuity ranges from 20/30 to 20/40
Pseudohypopyon or cystic phase	Yellowish material disintegrates and layers in the lower half of cyst, resembling a hypopyon
Round chorioretinal atrophy stage	Macula becomes atrophic. Subretinal fibrous scar formation can occur. Patients may develop choroidal neovascularization. Visual acuity usually 20/100 or less

With time, the yellowish material within the lesion may begin to disintegrate, making the "yolk" appear more like "scrambled eggs." This change is usually accompanied by a decrease in visual acuity to about the 20/40 level. Occurring often in puberty, the yellowish material may also layer in the inferior half of the lesion. The lesion appears to have a fluid layer similar in appearance to a hypopyon, so this stage is sometimes referred to as the pseudohypopyon stage.

With time, the yellowish material may disappear and the retina becomes atrophic, resulting in decreased vision to the 20/100 or worse range. Pigment hyperplasia can also occur. Occasionally a fibrous subretinal scar may develop. Choroidal neovascularization can occur with these lesions.

Diagnosis

Diagnosis of Best disease is based on clinical fundus exam findings, family history, electrophysiologic testing, and genetic analysis. Electrooculogram (EOG) is a key factor in diagnosis and will be abnormal even when clinical exam findings are minimal. The EOG light-peak to dark-trough amplitude ratio is rarely higher than 1.4 (normal $\geq$ 1.8). The degree of EOG impairment does not correlate with visual acuity loss. Full-field electroretinogram (ERG) in is normal. Carriers of the VMD2 mutation who may not show any fundus changes will still have a definite subnormal EOG.

Genetic testing for mutations of the gene, VMD2, for Best disease is available.

Differential Diagnosis

Adult-onset vitelliform foveomacular dystrophy (pattern dystrophy)

Vitelliform lesions associated with basal laminar drusen or dominant drusen

Fundus flavimaculatus (Stargardt's disease) with large central flecks

Central serous chorioretinopathy

Serous detachments of the RPE

Toxoplasmic retinochoroiditis

Old foveal hemorrhages

Scars associated with macular degeneration or other causes of choroidal neovascularization

Prophylaxis

Potential carriers of Best disease can be screened by EOG or genetic testing. Prenatal diagnosis is possible once the familial mutation is identified.

Therapy

No therapy exists to treat or prevent Best disease.

Prognosis

Visual prognosis is generally good. Most patients retain reading vision in at least one eye. Severe visual loss is possible, however, if extensive macular atrophy or scarring occurs.

Epidemiology

Best disease is an autosomal dominantly transmitted disease of variable penetrance and expression.

Males and females are equally affected. Affected individuals or carriers will demonstrate an abnormal EOG.

Best-Fit Sphere

Oliver K. Klaproth
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The characterization of the corneal anterior or posterior surface elevation maps can be used. Elevation maps show the deviation of the elevation from a reference plane. This reference plane usually is a sphere, as a flat reference plane would not allow for local analysis of elevation irregularities. The BFS is calculated by the method of the least root mean square of deviation offer the area analyzed. Today different reference planes are being used for elevation maps, i.e., best-fit ellipsoids or best-fit spheres ignoring the central part of the cornea to detect early keratoconus.

Beta Carotene, Use and Dosage of

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Carotenoid; Vitamin A

Definition

Beta carotene is a type of carotenoid, a highly pigmented, fat-soluble compound found in a variety of green and yellow fruits and vegetables.

Absorbed in the small intestine, beta carotene is a provitamin that is converted to vitamin A. Vitamin A is an essential vitamin found in many tissues of the body, including the eye where it plays an important role in the visual transduction cycle. Vitamin A is transported to the eye as a vitamin A alcohol, or retinol. Retinol is stored in the retinal pigment epithelium (RPE). The aldehyde derivative of vitamin A, retinal, combines with the protein opsin in the photoreceptor outer segments of the retina to form the light-sensitive rhodopsin, an important visual pigment of the rod photoreceptors. Deficiency of vitamin A can result in visual symptoms and ultimately blindness. Toxicity is also possible with megadoses of vitamin A.

Indication

Vitamin A is essential for vision. Deficiencies can result from malnutrition, extreme diets, and poor intestinal absorption due to bowel abnormalities such as Crohn's disease and short bowel syndrome and from liver dysfunction seen with liver failure or alcoholism. Vitamin A deficiency results in nyctalopia and xerophthalmia with findings in the conjunctiva, cornea, and retina. Unfortunately, xerophthalmia is a major cause of blindness in children worldwide.

High doses of beta carotene and vitamin A may be helpful for some ocular diseases and disorders. The Age-Related Eye Disease Study (AREDS), a large, multicentered trial looking at high doses of antioxidants including beta carotene in patients with age-related macular degeneration (AMD), found that subsets of patients with AMD had reduced risk of progressing to severe forms of AMD with high-dose antioxidant supplementation. Patients with other retinal diseases such as advanced retinitis pigmentosa, Sorsby's fundus dystrophy, and Stargardt's disease may also benefit from beta carotene or vitamin A supplementation.

Contraindication

Use of beta carotene or vitamin A supplementation is not recommended for people who smoke or have a long-term history of smoking or who have known exposure to asbestos because of a potential increased risk of developing lung cancer.

People who are pregnant or may become pregnant should not take vitamin A supplementation because of the risk of major birth defects.

Use and Dosage

Dosage of beta carotene and vitamin A varies depending on use.

For patients with vitamin A deficiency and xerophthalmia over 1 year of age and not pregnant, a dose of 200,000 IU of vitamin A should be given immediately, the next day, and 2 weeks later.

For patients with less severe vitamin A deficiency, who have liver or kidney problems, and who are pregnant or are on dialysis, a doctor should be consulted for correct dosage.

For patients with macular degeneration, AREDS-based vitamins contain 15 mg of beta carotene (equivalent to 25,000 IU of vitamin A) in a daily dose.

Adverse Reactions

Excessive dosages of vitamin A, especially in children, can produce toxicity. Toxic changes can include exfoliation of the skin, alopecia, rash, hepatomegaly, splenomegaly, arthritic pains, hypothrombinemia, and increased intracranial pressure with papilledema. Use of isotretinoin (Accutane, Hoffmann-La Roche, Inc., Nutley, NJ), an oral form of vitamin A used to treat acne, has led to ocular adverse effects of anterior segment inflammation, keratitis sicca, contact lens intolerance, refractive changes, photophobia, and nyctalopia.

Interactions

Interactions with various medications and vitamin A have been reported. If other prescription drugs are being taken, a doctor should be consulted before high-dose vitamin A supplementation.

Bichrome (Red-Green/Duochrome) Test

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

Synonyms

Red-green/duochrome

Definition

Method of subjective refraction, based on chromatic aberration of the eye. A transparent eye chart is half coated with red and green filter. The density of the filters is chosen that the brightness for the eye based on wavelength 550 nm is equal. It is also equal for the dioptric difference caused by the chromatic aberration. Both halves of the chart have similar number and kind of optotypes, which can be graduated in visual acuity steps. Indication of the kind of ametropia is given through the comparison of clarity of the presented optotypes. Is the brightness dominant on the red half the eye is myopic an should be corrected with minus-lenses. Is it dominant on the green half the eye is hyperopic an should be corrected with plus-lenses. It can be used for validation of the correcting lens in far and near visibility.

[2]Department of Ophthalmology, Tel Aviv Medical Center and Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Synonyms

Bietti crystalline corneoretinal dystrophy; Bietti crystalline dystrophy; BCD

Definition

Bietti crystalline dystrophy is an autosomal recessive disease characterized by glistening crystalline-like changes in the posterior pole of the retina and atrophy of the retinal pigment epithelium (RPE) and choroid. Furthermore one-third of patients may present with crystal deposits in the superficial stromal layer of the paralimbal region of the cornea. This disease is named after Dr. G. B. Bietti, an Italian ophthalmologist, who described three patients with similar symptoms in 1937 (Okialda et al. 1993–2014; Ryan et al. 2012).

Epidemiology

Bietti crystalline dystrophy is rare and has been estimated to occur in 1 in 67,000 people (Okialda et al. 1993–2014). It is more common in people of East Asian descent, especially those of Chinese and Japanese background. Researchers suggest that Bietti crystalline dystrophy may be under diagnosed because its symptoms are similar to those of other eye disorders that progressively damage the retina.

BCD has also been reported in persons of Lebanese and Mexican origin and in persons of European origin presenting with retinitis pigmentosa (Okialda et al. 1993–2014; Ryan et al. 2012; Schubert 2014–2015).

Etiology

Bietti crystalline dystrophy is an autosomal disease caused by mutations in the *CYP4V2* gene, which was identified in 2004 by Gekka and colleagues. This gene is responsible of enzyme formation from the cytochrome P450 family of enzymes. The CYP4V2 enzyme is involved in a multistep process called fatty acid oxidation in which lipids are broken down and converted into energy. *CYP4V2* gene mutations that cause Bietti crystalline dystrophy impair or eliminate the function of this enzyme and are believed to affect lipid breakdown. However, it is unknown how they lead to the specific signs and symptoms of Bietti crystalline dystrophy (Okialda et al. 1993–2014).

Clinical Presentation

BCD is characterized by progressive atrophy and degeneration of the retinal pigment epithelium (RPE) and choriocapillaris, presenting with symptoms which overlap with other forms of retinal degeneration namely:

1. Reduced visual acuity – visual acuity can range from normal to hand motion (HM). Although the reduction in visual acuity has been reported to typically result in legal blindness by the fifth or sixth decade, central vision can sometimes be spared even in persons with severe disease.
2. Nyctalopia – progressive night blindness which is typical to many forms of retinal dystrophies.
3. Visual field loss – visual field defects correspond to areas of RPE and choriocapillaris

atrophy, manifesting as paracentral scotomas or peripheral field loss depending on the severity of the disease (Okialda et al. 1993–2014; Ryan et al. 2012; Schubert 2014–2015).

Onset of disease is typically during the second to third decade of life but ranges from the early teenage years to beyond the third decade. Marked asymmetry between eyes with respect to fundus appearance, reduction in visual acuity, and visual field loss is not uncommon.

Clinical Findings

Crystalline deposits in the corneal limbus can be found among approximately one-third of patients. It has been shown by several researches that these corneal deposits may be more common in patients of northern European descent than in Asians.

Funduscopic findings include small, glistening yellow-white crystal deposits scattered throughout the posterior pole, which sometimes might extend to the mid-periphery. Both diffuse and localized forms of retinal degenerative changes may be found. It has been described that the crystalline deposits tend to diminish or even disappear in areas of severe chorioretinal atrophy as the disease progresses in severity (Okialda et al. 1993–2014; Ryan et al. 2012). Areas in which crystals are still present may represent the retina that is still only mildly degenerated or in the progress of degenerating. The retinal vessels and optic nerve are usually normal but there may be some vascular attenuation and/or disc pallor in advanced cases.

Complications may include development of macular hole and choroidal neovascularization (CNV) in rare cases.

Furthermore the cholesterol or cholesterol esters can be found in fibroblasts as well as circulating lymphocytes, suggesting that the disorder may be a systemic abnormality of lipid metabolism.

Further Tests

Fluorescein angiography (FA) shows patchy hypofluorescent areas of RPE and choriocapillaris atrophy and a generalized disturbance of the RPE.

Electroretinogram (ERG) can show varying degrees of rod and cone dysfunction, ranging from normal to reduced amplitudes of scotopic and photopic responses to undetectable responses. ERG amplitude reduction often parallels the degree of fundus pigmentary changes.

Spectral domain optical coherence tomography (SD-OCT) is an important tool for diagnosis and management of BCD. The degeneration in BCD detected by OCT is most prominent in the outer retina layers. It is characterized by findings of hyper-reflective dots which represent the crystalline deposits that reside in the RPE-choriocapillaris complex. In addition to these crystalline deposits, other abnormalities due to loss of retinal tissue such as retinal tubulation can be found (Okialda et al. 1993–2014; Ryan et al. 2012).

Diagnosis

The majority of cases are diagnosed by the clinical appearance and can be confirmed by molecular testing of *CYP4V2*. Furthermore, testing for at-risk relatives who may be carriers and prenatal testing in high-risk pregnancies are possible (Okialda et al. 1993–2014).

Differential Diagnosis

Crystalline deposits in the retina may be associated with:

- Primary hyperoxaluria type 1 and primary hyperoxaluria type 2
- Cystinosis
- Sjögren-Larsson syndrome

- Drug toxicity (e.g., the tamoxifen, the anesthetic methoxyflurane, the oral tanning agent canthaxanthin)
- Drug abuse (talc retinopathy)
- Idiopathic juxtafoveal retinal telangiectasia

Obtaining detailed medical history, thorough systemic and ocular examination, and fluorescein angiography are usually sufficient to exclude these conditions (Okialda et al. 1993–2014; Schubert 2014–2015).

Therapy

No treatment for BCD currently exists. Patients may benefit from low vision aids. In the future, findings from gene research might be helpful in finding treatments for patients with BCD (Okialda et al. 1993–2014).

Though CNV is uncommon in BCD, anti-vascular endothelial growth factor (anti-VEGF) therapy can be used to treat this complication.

Prognosis

The presenting symptom, rate of disease progression, and disease severity are also highly variable in BCD, even among those of the same age, within the same family, and with the same *CYP4V2* mutation. However, with time, loss of peripheral visual field, central acuity, or both result in legal blindness in most affected individuals (Okialda et al. 1993–2014).

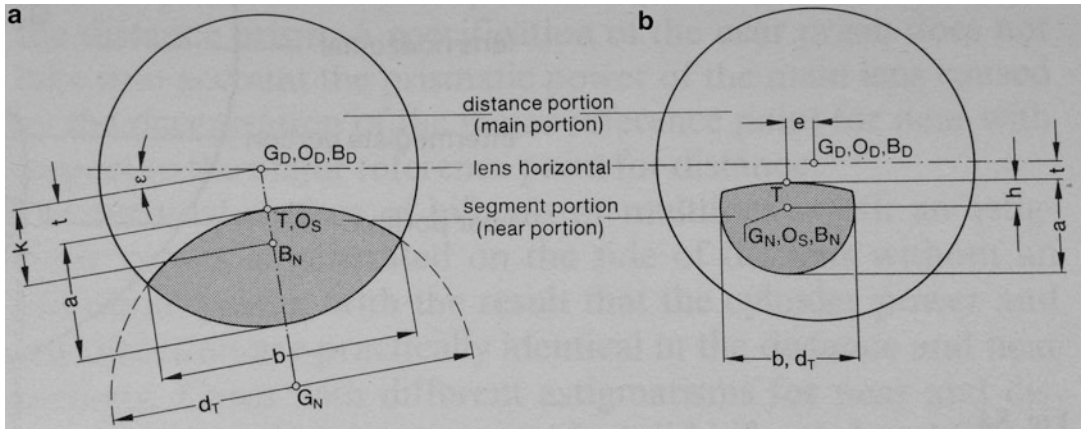
Synonyms

Multifocal lenses

Definition

Bifocal and multifocal lenses have different, visibly separate areas characterized by their different spherical powers. A bifocal lens is composed of a



Bifocal Lenses, Fig. 1 (**a**) Rotatable (**b**) nonrotatable

main lens and additional or segment lens. A trifocal has two segment lenses which are either separated or adjacent. The area in which the power of the main lens alone is effective is called the main portion. Here the lens has the same dioptric power as an equivalent single-vision lens. The area in which the powers of the main lens and the additional lens are combined is called the additional or segment portion. The dioptric power of the segment portion must not be confused with the power of the segment lens in its own right.

In the majority of bifocal and multifocal lenses, the optical center of the segment lens is decentered with respect to the optical center of the main lens.

The main portion or a segment portion can be used for distance vision (distance portion), intermediate vision (intermediate portion), or near vision (near portion). In most cases, the main portion is the distance portion. A dividing line separates the different portions (Fig. 1).

The segment lenses are either cemented, fused – in which case they have a different refractive index – or ground onto the surface of the main lens. While the main portion is generally point focal, this is not always the case in the segment portion. If the segment portion is fused onto the main portion, it is more favorable for point-focal imagery to perform the fusion on the back surface of the lens.

Different shapes are possible for the segment portion, a distinction being made between rotatable and nonrotatable types. Circular or types located at the periphery of the main lens are rotatable.

Prismatic Jump

If different prismatic powers exist on either side of the dividing line between two portions of a bifocal lens, the object perceived appears to jump when the fixation line of the eye crosses the dividing line. The difference between these two prismatic powers is called the prismatic or image jump, as it is not the object but the image produced by the spectacle lens which is in fact jumping.

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Diplopia is the term used to describe double vision or the perception of two images of a single object. Diplopia can be classified as either monocular or binocular. Binocular diplopia refers to double vision that is present with both eyes open, but which resolves when either eye is closed. In contrast, monocular diplopia persists in the affected eye(s) even when the other eye is closed and can be unilateral or bilateral (Guluma 2014). Binocular diplopia is the physiologically appropriate response when an object falls onto two different areas of the intact retina, the fovea of one eye and the non-foveal region of the other eye. This then causes the perception that a single object has two different locations in space. The most common cause of binocular diplopia is misalignment of the visual axes (Buffenn 2008). On physical exam, the patient will often have ocular deviation of one of their eyes (Perlmutter and Moster 2014). Presentation of binocular diplopia will vary with age since young children are better able to ignore the problem than older children and adults (Buffenn 2008). Also, many patients will describe the change in vision as being "blurry" rather than have frank double vision. When assessing a patient, it is important to note that ocular movement in which direction(s) causes the double vision occur and whether it is worse when focusing at objects at a distance or upclose, as this helps guide the diagnosis (Guluma 2014).

Treatment for binocular diplopia requires identification and appropriate therapy for the underlying etiology.

Prognosis is dependent upon the underlying etiology.

Binocular Indirect Ophthalmoscope (BIO), in Retinal Examination

Barbara Gold
Department of Ophthalmology, Tel Aviv University, Tel Aviv Medical Center, Tel Aviv, Israel

Synonyms

BIO

Definition

Precise binocular viewing of the fundus with adjustments from 48 to 75 mm in order to examine patients with pupils less than 2 mm in size.

Basic Characteristics

There are numerous advantages to using the indirect ophthalmoscope. The image is not affected by the patients' refractive power. For children, this technique is easier to use. It is also used in operating room for cryo-/scleral buckling. With superior illumination, full visualization of periphery is achieved. Disadvantages to this technique include difficulty to master, reversed and inverted image, and relative lack of magnifications (Figs. 1 and 2).

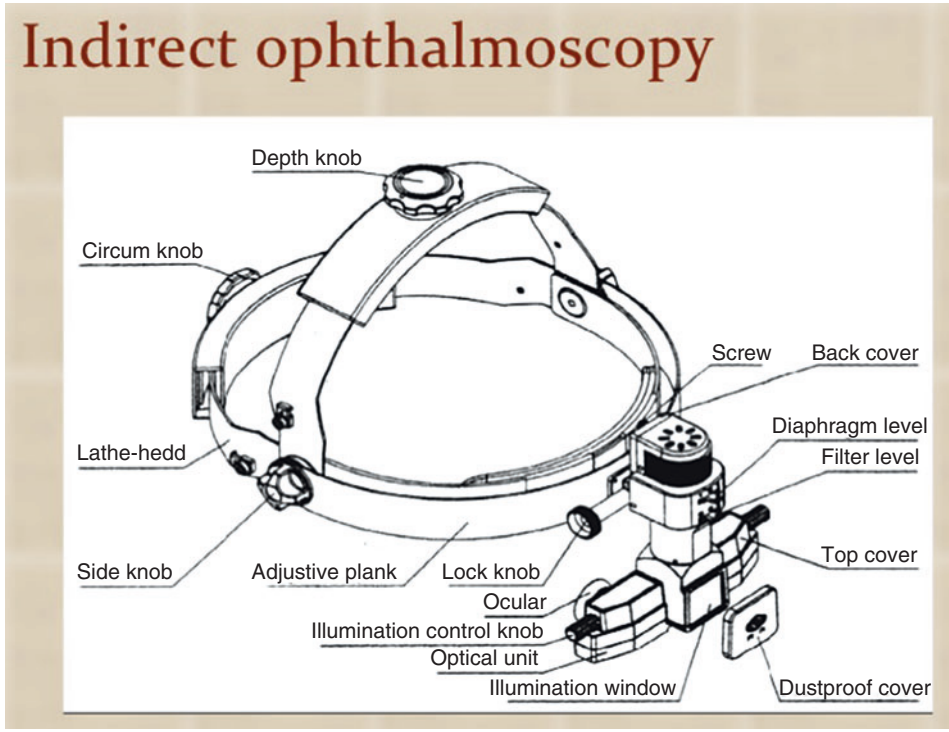
Comparison with Direct

Feature	Direct	Indirect (+20lens)
Magnification	14×	3×
Field diameter	2DD	9DD
Ratio of area	1	20
Illumination	Limited	High
Depth of focus	Small	Large
Stereopsis	Absent	Present
Orientation of image	Direct	Inverted, reversed
View of periphery	Limited	Full
Scleral indentation	Difficult	Easy

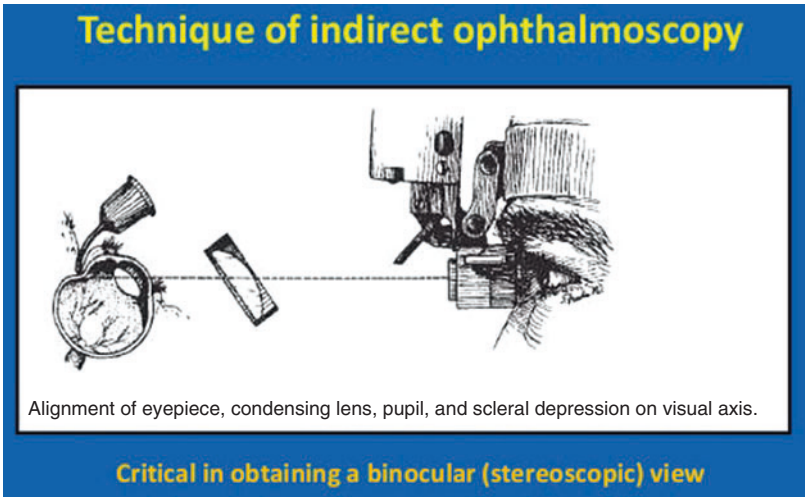
Examination Technique

The headband piece is adjusted to be sitting in a stable position. Halogen illumination is turned on. If examining the periphery, the diffuser filter is turned on. There is a convergence control for very small pupils.

The patient is either sitting in a reclined chair or lying on a couch. The pupil may be dilated and the



Binocular Indirect Ophthalmoscope (BIO), in Retinal Examination, Fig. 1 Indirect ophthalmoscopy



Binocular Indirect Ophthalmoscope (BIO), in Retinal Examination, Fig. 2 Technique of indirect ophthalmoscopy

room dimmed. Alignment of the patients' eye and the examiner's eye is in a straight line. Check for the red reflex, then bring the condensing lens in front of the patient's eye. Some units come with an advanced video alignment system to have precise orientation for accurate viewing. The image is inverted and reversed. The ora serrata can be viewed by scleral indentation with the free hand of the examiner using local anesthetic like proparacaine, tetracaine, or proxymetacaine.

Biometry, Use and Principle of

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Axial measurement of the eye by ultrasound.

Purpose

Biometry of the eye prior to cataract or refractive surgery.

Principle

Ultrasonic biometry is based upon the differential return of ultrasonic waves by varying tissue types in the eye. Sound waves are emitted by a piezoelectric crystal and delivered with a probe. For axial measurements, the probe is placed perpendicular to the corneoscleral surface. Ultrasonic biometry can either be performed with the contact method when direct contact between the corneal surface and probe is made or with immersion biometry applying an eyecup between the eyelids filled with immersion fluid (e.g., balanced salt solution, methylcellulose). Optical biometry is based on partial coherence interferometry, Scheimpflug imaging, or optical coherence tomography.

Indication

Biometry is applied for measurement of central corneal thickness, anterior chamber depth, lens thickness, and axial length of the eye.

Advantage/Disadvantage

Ultrasonic biometry is a reliable method for biometry of the eye prior to cataract or refractive surgery. A correct position of the probe is mandatory during measurement and the results depend on the experience of the examiner. In contrast to optical biometry, ultrasound biometry can be performed even with opaque optical media such as dense cataract or vitreous hemorrhage. Compared with optical biometry ultrasound biometry is more time consuming and requires topical anaesthesia of the eye.

[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

UBM

Definition

Ocular imaging applying ultrasound with frequencies of 35 MHz and above.

Purpose

Ultrasound biomicroscopy allows noninvasive real-time imaging of anatomy and pathology of the anterior segment of the eye.

Principle

Ultrasound consists of waves of compression and rarefaction propagating through a medium. Acoustic reflection occurs at interfaces between regions of different acoustic impedance. Scattering occurs where these discontinuities are smaller than a wavelength. Attenuation of ultrasound occurs as it propagates through tissues as a consequence of reflection, scattering, and absorption.

Indication

Ultrasound biomicroscopy is applied for imaging of the cornea, iridocorneal angle, anterior chamber, iris, ciliary body, and the lens. Ultrasound biomicroscopy can be used for diagnostics in anterior segment neoplasms, trauma, and glaucoma.

Contraindication

In open-globe injury, ultrasound biomicroscopy should only be done when the potential benefit justifies the potential risk.

Advantage/Disadvantage

In contrast to optical anterior segment imaging technologies (optical coherence tomography, Scheimpflug imaging, scanning slit-lamp systems), ultrasound biomicroscopy can be applied to visualize structures of the anterior segment obscured by the iris and the sclera and with opaque media. Ultrasound biomicroscopy is

more difficult to use than optical imaging technologies and needs fluid coupling to the eye.

Biomicroscopy, Ultrasound, of Anterior Segment

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Synonyms

High-resolution ultrasound biomicroscopy, UBM

Definition

UBM is a type of ultrasonography which uses a high-frequency transducer (35–50 M Hz, compared to standard ultrasonography which uses a 10 M Hz transducer), which allows higher resolution of structures, but shallower penetration of tissue, and produces excellent imaging of the anterior segment. This technique produces resolution of about 20–50 μm; however, tissue penetration is limited to approximately 5 mm.

Purpose

To visualize anatomy of the anterior segment including the anterior chamber angle

B

Principle

The higher the frequency emitted by the transducer, the higher the resolution of the tissue structures that can be obtained. However, the higher the frequency emitted by the transducer, the shallower the tissue penetration, and therefore deeper structures are not visualized. With lower-frequency transducers, as in conventional ultrasound, deeper structures can be visualized but with much less resolution.

Indication

UBM is used to visualize details of the cornea, drainage angle, ciliary body, supraciliary space, zonules, and iris and to characterize the relationship of these structures to each other. It is helpful in patients with plateau iris and has been used to show reversal of iris concavity after laser peripheral iridotomy in patients with pigmentary glaucoma. It can help identify angle recession and malignant glaucoma.

Contraindication

Corneal abrasion, keratitis, infection, hyphema, acute trauma, penetrating injury, or perforated globe.

Advantage

Noninvasive, relatively inexpensive.

Disadvantage

Limitation to the depth of structures which can be visualized, requires supine positioning and much cooperation from the patient.

Bipolar Cells

Joseph J. Carroll
Department of Ophthalmology, Eye Institute-Medical College of WI, Milwaukee, WI, USA

Definition

Excitatory inner retinal neurons that convey gradients between photoreceptors and retinal ganglion cells. Release of a single neurotransmitter (glutamate) by the cone photoreceptors causes OFF bipolar cells to depolarize and ON bipolar cells to hyperpolarize. ON bipolar cells utilize a metabotropic glutamate receptor and have a sign-inverting synapse with the cone, while OFF bipolar cells utilize an ionotropic glutamate receptors and have a sign-conserving synapse with the cone. Rod photoreceptors connect to a single, structurally distinct, bipolar cell – the rod bipolar cell.

Birdshot Retinochoroidopathy (Vitiliginous Chorioretinitis)

Michal Kramer
Head, Uveitis Service, Department of Ophthalmology, Rabin Medical Center, Petah-Tikva, Israel
Sackler School of Medicine, Tel Aviv University, Tel-Aviv, Israel

Synonyms

Vitiliginous chorioretinitis (no longer used)

Definition

Birdshot retinochoroidopathy (BSRC) is a rare distinct intraocular inflammatory condition. It is characterized by the presence of multiple cream-colored round or oval choroidal lesions in the post-equatorial region, mainly the peripapillary area at the level of the outer retina/choroid. The lesions appear in a pattern resembling the scatter of birdshot pellets from a shotgun (Nussenblatt et al. 1982; Priem et al. 1988).

Pathogenesis

BSRC is considered a T-cell-mediated disease. Findings of higher than normal levels of IL-17 in the serum and aqueous humor of affected patients suggest that the Th17 subset is involved in the pathogenesis of BSRC (Miossec et al. 2009; Brezin et al. 2011). About 95% of patients with BSRC are positive for HLA A-29 – the highest class 1 haplotype association of any disease – but its pathogenic role remains unclear. Molecular mimicry triggered by antecedent infection is a popular hypothesis.

Epidemiology

BSRC typically occurs in the sixth decade of life. It has a slight gender predilection for women and a

higher incidence in white individuals of Northern European descent (Nussenblatt et al. 1982; Priem et al. 1988). There is no published data on the incidence and prevalence of this disorder. Small retrospective case series reported a 0.6–1.5% rate of diagnosing birdshot chorioretinopathy among patients who were referred to tertiary care centers for uveitis, accounting for 6–7.9% of all posterior uveitides.

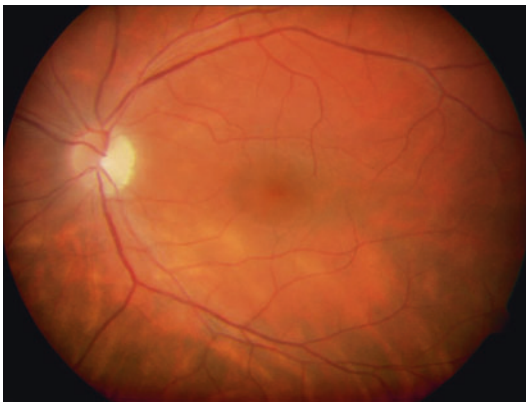
Clinical Presentation

Patients usually complain of a gradual decrease in visual acuity, floaters, photopsia, and nyctalopia, and impaired color vision, with symptoms surpassing clinical findings. The disturbances may be initially asymmetric, evolving to bilateral disease. A high index of suspicion is required in the early stages.

Diagnosis

The diagnosis of BSRC is based on clinical findings of at least three typical "birdshot" lesions. The appearance of the lesions may be preceded or accompanied by mild inflammation, without anterior segment complications.

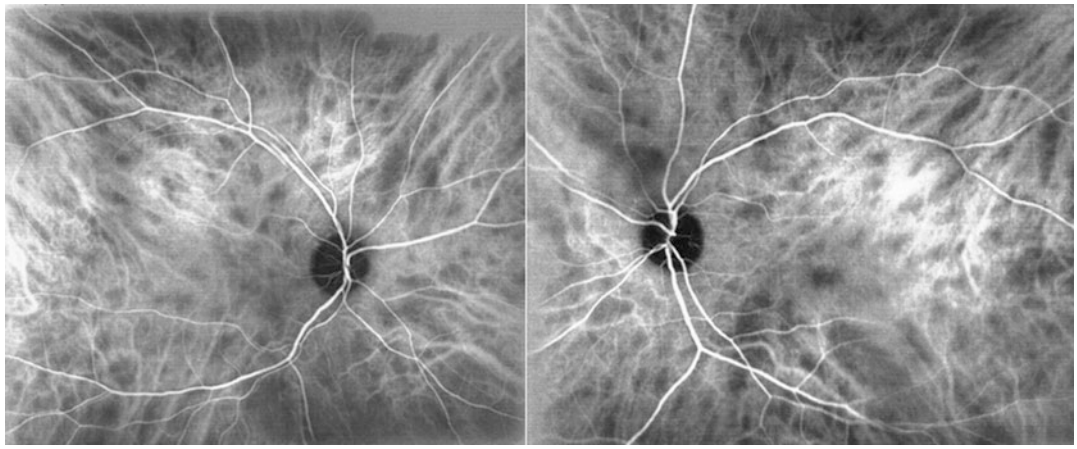
Multimodal imaging of the retina and choroid provides structural and functional information and is important to establish the diagnosis. Figure 1 is a color fundus photograph of representative chorioretinal lesions. Fluorescein angiography (Fig. 2) demonstrates retinal vascular leakage, with no apparent involvement of the overlying retina or underlying retinal pigment epithelium (RPE). Indocyanine green angiography (ICGA) (Fig. 3), seldom used nowadays for other indications, shows the typical pattern of oval hypofluorescent lesions, located mostly along the medium-sized choroidal vessels. In the early stages of disease, some lesions may represent hypoperfusion of small choroidal vessels, whereas others represent inflammation, producing a masking effect. In long-standing disease, the choroidal vessels appear well-preserved, and retinal involvement becomes



Birdshot Retinochoroidopathy (Vitiliginous Chorioretinitis), Fig. 1 Color photograph of the left eye of a 43 year-old male demonstrating typically scattered oval creamy subretinal lesions

Birdshot Retinochoroidopathy (Vitiliginous Chorioretinitis), Fig. 2 Flurescein angiography of the same eye in Fig. 1, demonstrating mild retinal vascular leakage, optic nerve head leakage and faint appearance of the subretinal lesions

clinically evident. The hypofluorescent spots are thought to represent foci of choroidal atrophy or persistent choroidal granulomas. Fundus autofluorescence has gained popularity in the recent years owing to the high-quality images provided by confocal imaging techniques, mainly of the RPE-outer retina complex. The hypoautofluorescent areas correlate with RPE atrophy but not necessarily with visible fundus lesions, suggesting both choroidal and RPE damage in BSRC. Macular hypoautofluorescence indicates



Birdshot Retinochoroidopathy (Vitiliginous Chorioretinitis), Fig. 3 Indocyanine green angiography of both eyes of the same patient, demonstrating the typical oval hypofluorescent spots, located mostly along medium-sized choroidal vessels

macular RPE damage and correlates with poor visual outcome (Koizumi et al. 2008).

Abnormalities on electroretinography (ERG) are often found in patients with BSRC, reflecting retinal dysfunction. An impaired pattern ERG in the early stages indicates macular edema. Photopic and scotopic ERG findings support the concept that the neuro-retinal dysfunction is primarily located in the inner retina, and this is manifested by a low b:a wave ratio.

Though not essential for diagnosis, positive findings of HLA-29 may serve as supportive evidence (Levinson et al. 2006). HLA A-29 is an inefficient screening factor for BSRC because it is present in about 8% of the general population.

Differential Diagnosis

Posterior uveitis entities with similar deep retinal and subretinal lesion should be excluded. These include infectious diseases, such as syphilis and tuberculosis, and noninfectious diseases, i.e., sarcoidosis and masquerade syndrome. Patients who present initially with retinal vascular leakage, while retino-choroidal lesions are faint, will undergo workup for retinal vasculitis. In typical cases, no such workup is required.

Clinical Course

BSRC has a chronic clinical course, with slow deterioration of visual functions including visual acuity and visual fields, and a steady increase in structural damage to the retina. Cystoid macular edema (CME), which occurs in up to 50% of patients, is the most common cause of central visual impairment. Later in the disease course, macular thinning and atrophy may evolve. Photoreceptor dysfunction also occurs later. The progressive retinal involvement with diffuse atrophy affecting mainly the outer layers resembles the behavior of a neurodegenerative disorder (Fardeau et al. 1999; Herbort et al. 2004).

Treatment

The mainstay of treatment of BSRC is corticosteroids followed by chronic immunosuppression. The immunosuppressive drugs are

administered mainly because of the unacceptable side effect profile of long-term corticosteroids in the required dose. They usually include antimetabolites, such as methotrexate, azathioprine, and mycophenolate mofetil. Cyclosporine may also be a favorable option owing to the presumed T-cell involvement in the pathogenesis of the disease, but it is less likely to be used in elderly patients because the risks of renal toxicity and hypertension. Biologic antitumor necrosis alpha (TNF-α) agents have also shown a beneficial effect, specifically in refractory cases (Artornsombudh et al. 2013).

Since BSRC is limited to the ocular area, local treatment is appealing, but the modalities need to be long-acting. Intravitreal Retisert (fluocinolone acetonide) implants have been suggested, but they require surgery for both implantation and explantation and are associated with a need for cataract surgery within 3 years in all patients and trabeculectomy surgery in 40% of patients. Ozurdex, an injectable implant, may also be beneficial, but its therapeutic effect usually lasts only 4–6 months, and repeated injections are necessary (Lowder et al. 2011). A study of posterior uveitis, the Multicenter Uveitis Steroid Treatment Trial, reported similar efficacy for systemic and local therapy, with acceptable side effects of systemic intramuscular therapy (The Multicenter Uveitis Steroid Treatment (MUST) Trial Research Group et al. 2011).

However, the effect of treatment on the clinical course of BRSC is still equivocal. One study suggested that treatment did not affect visual outcome, with visual deterioration occurring at a similar rate with and without treatment (Rothova et al. 2004). By contrast, one case report demonstrated restoration of the retinal structure accompanied by visual field improvement following immunosuppressive therapy (Forooghian et al. 2010). A recent longitudinal study showed that chronic progression occurred despite treatment, although in patients receiving long-term immunosuppression (with mycophenolate mofetil in this study), the visual fields were preserved, implying a beneficial effect on peripheral retinal function (Tomkins-Netzer et al. 2014).

The choice of the best targeted therapy still needs to be investigated in controlled clinical trials.

Follow-Up

Long-term monitoring is required. Visual acuity and visual fields should be assessed regularly. It is noteworthy that visual acuity may be preserved and clinical signs and symptoms may improve despite retinal function deterioration. Therefore, clinical symptoms cannot serve as reliable indicators of disease progression, complicating clinical decision making. The pattern of photoreceptor dysfunction – initially rods followed by cones – reflects the late preserved visual acuity. Optical coherence tomography (OCT) is used regularly to document and follow CME. ERG has also become an important objective tool for monitoring disease activity and response to treatment. Impaired pattern ERG usually reflects macular edema at early stages of the disease, and improvement correlates with resolution of the edema. Delayed 30 Hz cone flicker implicit time, often present before treatment, appears to be a sensitive indicator of retinal function (Holder et al. 2005).

Summary

BSCR is a rare chronic disease causing diffuse atrophic damage; therefore, visual function should be assessed based on VA, VF, and electrophysiology of the retina.

Early treatment with immunosuppression is correlated with better visual outcome. Biologic agents may offer benefit in refractory cases. Local intravitreal modalities may be used in selected cases.

Long-term monitoring is required. The choice of the best targeted therapy should be studies in controlled clinical trials.

Definition

Bitemporal hemianopsia (BTH) is a form of visual field loss of the temporal half of the visual field in both eyes that generally respects the vertical midline. This type of vision loss results from disruption of the nasal crossing fibers of both eyes due to lesions at the optic chiasm. Bilateral retinal lesions in the nasal portion of the retina or tilted optic nerves may mimic a bitemporal hemianopsia from chiasmal lesions.

Etiology

A BTH is caused by a lesion at the optic chiasm. The most common chiasmal lesions in adults

include pituitary adenoma, craniopharyngioma, meningioma, or suprasellar internal carotid artery aneurysm. In children, optic pathway glioma and dysgerminoma are more common than meningioma or aneurysm, but pituitary adenoma and craniopharyngioma remain in the differential diagnosis. Pituitary lesions arise from the pituitary gland in the sella turcica and then extend to the suprasellar space and thus compress the nasal crossing fibers in the chiasm from below producing a BTH that is denser superiorly. In contrast, suprasellar lesions arising from above the optic chiasm may produce a BTH that is denser inferiorly. In addition to neoplastic etiologies, trauma (i.e., traumatic chiasmopathy), demyelination (e.g., multiple sclerosis, neuromyelitis optica), and infiltrative and inflammatory (e.g., sarcoidosis) or toxic/nutritional (uncommon) chiasmal lesions may also produce a BTH.

Diagnosis

A cranial magnetic resonance imaging (MRI) with and without contrast is usually indicated for patients with an unexplained BTH. MR or computed tomography (CT) angiography can be used to identify suprasellar aneurysms if suspected clinically.

Differential Diagnosis

The differential diagnosis includes the neoplastic (most common) and less commonly vascular, demyelinating, and inflammatory diseases (e.g., sarcoidosis, lupus, and lymphocytic hypophysitis).

Clinical

Patients with BTH, depending on etiology, may also present with other symptoms and signs (e.g., headaches) or endocrine abnormalities in pituitary lesions (e.g., acromegaly, Cushing syndrome, pituitary apoplexy, hypopituitarism, central diabetes insipidus, and hyperprolactinemia). Patients may also experience non-paretic diplopia (double vision) in the absence of extra-ocular muscle palsies (i.e., non-paretic diplopia). This is believed to be due to patients' inability to fuse the two nonoverlapping intact remaining nasal visual fields leading to slip of the images (i.e., the retinal hemifield slide phenomenon).

Treatment

Treatment of BTH depends on the etiology. Surgical treatment is generally recommended for symptomatic compressive BTH. Infectious etiologies are treated with antibiotics; and inflammatory or demyelinating etiologies are treated with immunosuppressive or immunomodulatory agents. Some pituitary adenomas which are prolactin secreting (i.e., prolactinomas) can be treated with bromocriptine or cabergoline (dopamine agonists that can suppress prolactin production) and can cause the tumor to shrink.

Prognosis

Recovery of vision depends on the extent of damage to the optic chiasm and the underlying etiology.

Epidemiology

There is no racial predilection for BTH, but the epidemiology of BTH depends upon etiology. For example, pituitary adenomas are quite common with a prevalence of about 16% in the general population.

Blepharitis

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Definition

Blepharitis is an inflammation of the eyelid that causes symptoms of itching, tearing, redness, and swelling. It can occur on the anterior or posterior eyelid and may be caused by bacterial infection, seborrheic dermatitis, oil gland dysfunction, or other skin conditions like rosacea.

Cross-References

▶ Blepharoconjunctivitis
▶ Seborrheic Blepharitis

Blepharochalasis

Pete Setabutr
Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA

Definition

An eyelid disorder with episodes of painless edema that leads to atrophic changes in the eyelid skin.

Etiology

Numerous triggers have been reported including menstruation, fatigue, upper respiratory tract infections, bee stings, fever, wind, emotional stress, minor lid trauma, and lymphocytic leukemia, among others. Most often however, there is no known cause for blepharochalasis.

Clinical Presentation

Recurrent episodes of painless, non-erythematous edema of the upper eyelids. The edema typically does not resolve with steroids or antihistamines. In severe cases, the lower eyelids may be involved. Episodes typically last a few hours to days. Frequency of attacks varies from weekly to three to four times per year. The episodes typically decrease in severity over time and most cases become relatively quiescent. After numerous episodes the eyelid skin becomes wrinkled, lax, discolored, thinned, and invested with tortuous vessels. The skin has been described as “tissue paper”-like. Ptosis with good levator function is commonly coexistent. Lateral and medial canthal attachments to the eyelid skin tend to become lax with time as well. In certain variants orbital septal weakness develops and leads to marked prolapse of orbital fat. More atrophic variants tend to have eyelids with a hollow appearance.

Diagnostics

Clinical examination, biopsy.

Differential Diagnosis

Dermatochalasis, recurrent angioedema, hereditary angioedema, Melkersson-Rosenthal syndrome, cutis laxa.

Therapy: Treatment should be undertaken only in the quiescent phase of the disease. The primary treatment for blepharochalasis is surgical including blepharoplasty, recreation of the eyelid crease, resuspension of the lacrimal gland, removal of orbital fat, and levator aponeurosis repair. Special attention should be paid to patients undergoing ptosis repair with blepharochalasis syndrome as patients are frequently overcorrected. Lateral canthal tendon repair is often indicated and should precede ptosis repair to avoid temporal peaking of the eyelid. Medial canthal tendon placation may be indicated as well. Lower eyelid disease may be treated with blepharoplasty and/or canthoplasty. It is useful to take pathologic specimens for analysis during surgical repair.

Prognosis

Episodes tend to become less frequent with age. Recurrences may occur after surgery. The length of postoperative attacks does not seem to be influenced by corticosteroid use or cold compresses.

Epidemiology

As of 2007 only 67 cases had been reported in the literature – 22 men and 45 women. The average age of onset was 11 years old. Twenty-seven of 67 cases were unilateral.

Bloch-Siemens syndrome; Bloch-Sulzberger disease; Incontinentia pigmenti (IP); Melanoblastosis cutis; Nevus pigmentosus systematicus

Definition

Bloch-Sulzberger syndrome is a rare disorder characterized by X-linked dominant inheritance and integumentary, central nervous system (CNS), and ocular manifestations. It was defined in the literature by Bruno Bloch in 1926 and Marion Sulzberger in 1928, both dermatologists. Abnormal skin pigmentation is observed in almost all patients affected, and lesions progress through four classic stages: blistering, verrucous, swirling macular hyperpigmentation, and linear hypopigmentation. Alopecia and dental irregularities are also seen. CNS pathology occurs less frequently and can take the form of cognitive delay, seizures, or spastic paralysis. The syndrome is typically observed in females, as the mutation is often lethal to males in utero.

Etiology

Roughly 80% of patients studied share a deletion in the *IKBKG* or *NEMO* gene on the long arm of the X chromosome (Xq28). Two intact copies of *NEMO* are required for effective counterbalance of proapoptotic signals. *NEMO* is key to the activation of nuclear factor kβ (NF-kβ), which in turn protects cells against the proapoptotic signal tumor necrosis factor α (TNF-α).

Clinical Presentation

Typically, the ocular manifestations of this syndrome are retinal. The damage manifests along a spectrum, ranging from normal vision to blindness in approximately 40% of patients. The mechanisms resemble those of retinopathy of prematurity. Retinal vaso-occlusion is an early finding, leading to patchy retinal infarction and subsequent neovascularization and chorioretinal scarring. Arteriovenous anastomoses form, marked by anomalous vessel morphology, and are coupled with avascular regions, usually at the periphery. This can progress to retinal detachment and resultant loss of vision, with poor response to surgical correction. Retinal detachments occur most commonly in the first year of life, and almost all occur within the first 2–3 years of life.

In addition, the vascularization of the normal foveal avascular zone in several patients has been found to contribute to decreased visual acuity. Hypoperfusion can affect the optic nerve as well,

producing optic nerve pallor. In a subset of patients, optic nerve atrophy also contributes to visual loss. Central nervous system involvement due to vascular occlusive disease can result in occipital lobe infarction, homonymous hemianopic visual field loss, and cortical blindness.

It has been postulated that the vaso-occlusion results from an eosinophilic vasculitis. Eosinophilic infiltrates have been described in the dermal vasculature, as well as in the brain and retina. The NF-kβ signaling pathway is thought to play a role in this, as it is involved in eosinophil chemotaxis via the intermediate signal eotaxin.

Other ocular changes occur less commonly and include scleral and conjunctival pigmentation, neovascularization-related vitreous hemorrhage, corneal and lens abnormalities, myopia, amblyopia, and strabismus.

Diagnosis

It is recommended that all patients with incontinentia pigmenti undergo full eye examinations and consideration for fluorescein angiography. Many authors recommend that patients should be screened at least once followed by monthly or annual screening varying by case and severity. Fluorescein angiogram is superior to indirect ophthalmoscopy in the identification of neovascularization and occlusion and allows pathology to be recognized and thus treated earlier in the course of the disease. In adults diagnosed with this syndrome, it is important to be cognizant of new-onset retinal detachment, particularly at the borders separating avascular and adequately perfused retina. Symptomatic patients should be examined carefully.

Differential Diagnosis

Naegeli syndrome, retinopathy of prematurity, and familial exudative vitreoretinopathy.

Therapy

The progression of vascular insults can be treated by application of laser photocoagulation or cryoablation to the ischemic segments of the retina. However in some cases the retina goes on to detach regardless.

Prognosis

Prognosis varies in accordance with severity of the disease in each patient. In the case of vision, prevention of further retinal detachment is occasionally possible with laser or cryoablation.

Epidemiology

Less than 1,200 cases of IP have been reported in the literature to date. The syndrome is most prevalent among Caucasians. It is possible that it is underdiagnosed, as the obvious skin findings can be mild in some patients.

Blood-Aqueous Barrier

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Definition

The blood-aqueous barrier is located in the nonpigmented cells of the ciliary epithelium.

Structure

The ciliary epithelium consists of the pigmented layer which is located on the stromal side and the nonpigmented layer that faces the posterior chamber. The blood-aqueous barrier is located on the nonpigmented layer. These cells are connected by tight junctions of the leaky type. However, they do not form a solid barrier allowing some protein to pass from the ciliary processes into the posterior chamber.

The blood-retinal barrier and the blood-aqueous barrier appear to overlap in the pars plana.

Function

The blood-aqueous barrier prevents the movement of intermediate- and high molecular weight substances into the posterior chamber, while other substances are actively transported into the posterior chamber and establish osmotic gradient. Breakdown of the blood aqueous barrier reduces the efficiency of the osmotic gradient, which leads to a reduction in aqueous flow.

Clinical Relevance

Breakdown of the barrier is seen in patient's eyes with inflammation from uveitis or injury.

Blood-Retina Barrier

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Definition

The blood retinal barrier results from the relationship between the retinal capillaries and the retinal pigment epithelium. It is responsible for homeostasis of the retina.

Structure

The blood-retinal barrier is located on the endothelial cells of the retinal capillaries. The endothelial cells are connected to each other by tight junctions. An extensive network of zonulae occludentes is present around the endothelial cells and the apicolateral aspect the RPE cells.

Function

The barrier prevents water-soluble molecules from entering the retina. It blocks macromolecules from the lumen toward the interstitial space and prevents diffusion of molecules in the opposite direction. The non-leaky tight junctions are associated with active transport of organic anions and glucose in the retinal vessels.

Clinical Relevance

Evidence of blood-retina barrier breakdown is seen as leaking on fluorescein angiogram. Disruption of this barrier is seen in the presence of diabetic retinopathy in the form of retinal edema and exudates. Other causes of barrier breakdown are hypertensive retinopathy, retinal vein obstruction, retinal ischemia, posterior uveitis, pars planitis, retinal vasculitis, coats disease, and retinoblastoma.

Blowout Fractures

Gary Joseph Lelli[1] and Christopher Zoumalan[2]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA

Synonyms

Floor fracture; Maxillary roof fracture; Orbital floor fracture

Definition

A blowout fracture, or orbital floor fracture, is an isolated fracture of the maxillary and/or palatine bones of the orbital floor with an intact orbital rim, usually caused by blunt trauma to the inferior orbital rim (Holck and Ng 2006).

Etiology

Motor vehicle accidents, interpersonal altercations, assaults, falls, sports-related injuries.

Clinical Presentation

Orbital floor fractures may be associated with life-threatening injuries and damage to the eyeball. Once these injuries are ruled out, attention can be directed to the clinical examination of the floor fracture (Lelli et al. 2007). Patients may present with periocular ecchymoses and edema, pain with eye movements, facial numbness, double vision, and blurred vision. Ophthalmic examination initially focuses on ruling out globe damage. Once achieved, a focused oculoplastic examination often shows extraocular motility disturbance, with vertical misalignment most common. Hypoesthesia in the region of the infraorbital nerve distribution is common. Enophthalmos may be seen, but often in the acute setting, patients are not enophthalmic secondary to periocular and periorbital edema and ecchymoses. Occasionally, an associated rim fracture may be palpable as a step-off deformity; periocular emphysema is a less common examination finding.

Diagnostics

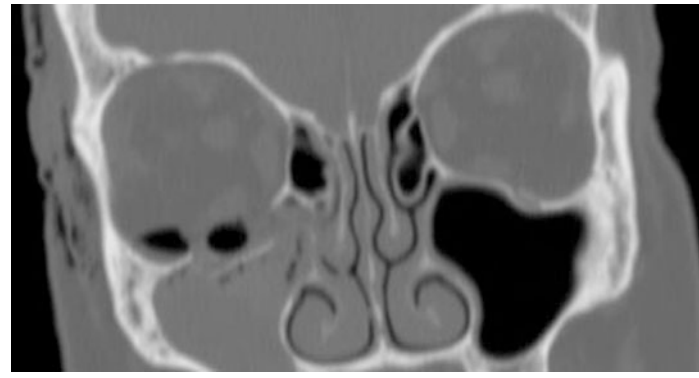
Facial fractures often occur as the result of significant trauma, and evaluation should begin with airway control and hemodynamic stabilization (Scherer et al. 1989; Mohammadi and Mohabbi 2007). Spinal cord injury should be ruled out. A thorough history and physical, including a complete head, neck, and ophthalmic, exam may then be performed. Orbital CT scanning with direct coronal imaging is considered the modality of choice for diagnosis of blowout fractures (see Fig. 1).

Differential Diagnosis

Zygomaticomaxillary (ZMC) complex fracture, medial orbital wall fracture, orbital hematoma, naso-orbital-ethmoid fracture, LeFort fracture, and maxillary (Guerin) fracture.

Prophylaxis

The use of restraints, seat belts, and protective headgear can help prevent orbital fractures.



Blowout Fractures, Fig. 1 Coronal imaging of a right orbital floor fracture with a large displaced portion of maxillary bone in the maxillary sinus. Orbital emphysema is seen, as is hemorrhage within the maxillary sinus

Therapy

Many patients with small orbital floor fractures, or those with intact periosteum, may be followed conservatively. Urgent repair of orbital floor fractures is exceedingly rare, and is warranted in two conditions: (1) The "white-eyed" orbital floor fracture with entrapment of the inferior rectus in a trap-door fracture; or (2) an unresolved oculocardiac reflex with vital sign instability. If these two conditions are not met, orbital floor fracture repair can proceed, when indicated, after initial periocular swelling has subsided. Indications for non-emergent blowout fracture repair are (1) extraocular muscle abnormality with clinical (forced duction testing) or radiographic evidence of entrapment of the extraocular muscle or perimuscular tissue or (2) significant enophthalmos ($\geq$2 mm) or the risk of significant enophthalmos from a fracture involving greater than 50% of the orbital floor and orbital periosteum. Perioperative antibiotics should be considered in patients with orbital fractures. Fractures should be repaired after adequate decrease in initial posttraumatic swelling, preferably within 2 weeks of the injury. For those patients treated conservatively, close ophthalmic follow-up is recommended.

Prognosis

Long-term prognosis after repair of blowout fractures is excellent. Postoperative infection rates are low and generally resolve with oral antibiotics. A small percentage of patients may develop postoperative asymmetry, globe or eyelid malposition, or extra-ocular muscle abnormality requiring revision surgery.

Epidemiology

Orbital floor fractures are most common in males (80%) and are usually the result of assault with a blunt object or fist, followed by motor vehicle accidents and falls. The orbital floor is the most commonly fractured orbital wall.

Blue Cone Monochromatism

Hadas Newman
Department of Ophthalmology, Tel-Aviv Sourasky Medical Center, Tel Aviv, Israel

Synonyms

S-cone monochromacy; X-linked incomplete achromatopsia

Definition

Blue cone monochromatism (BCM) is characterized by the absence of long-wavelength-sensitive (L) and medium-wavelength-sensitive (M) cone function in the retina. Thus, color discrimination is severely impaired from birth, and vision is derived from the remaining preserved short-wavelength-sensitive (S) cones and rod photoreceptors.

BCM belongs to the heterogeneous group of cone dystrophies. It is congenital, shows an X-linked recessive inheritance, and is generally considered as a stationary cone dysfunction syndrome.

Etiology

The normal human visual system achieves color vision by comparing the rate of quantum catches in three classes of cones – the short (S)-wavelength-sensitive, medium (M)-wavelength-sensitive, and long (L)-wavelength-sensitive cones – which are maximally sensitive to light at 430 nm, 535 nm, and 565 nm, respectively. The L (red) and M (green) pigment genes are located on the X chromosome, while the S-cone (blue) pigment is encoded by a gene located on chromosome 7.

The L and M genes in the genomic array on Xq28 are situated in a head-to-tail tandem arrangement with a single L opsin gene in a 5′ position, followed by one or more M opsin genes. Approximately 25% of male Caucasians have a single M gene, while 50% have two M genes, and the remainder have three or more genes. Expression of the L and M genes is regulated by the locus control region (LCR), a conserved sequence situated roughly 3.5 kb upstream of the L gene. The LCR ensures that only one opsin gene in the array is expressed in a single cone photoreceptor. It has also been demonstrated that only the first two genes of the array are expressed in the retina. The L and M cone opsins are encoded by six-exon genes, which are highly homologous sharing 96% amino acid identity, while their homology to S-cone opsin and rod opsin is approximately 40%. The highly homologous L and M opsin genes are as a consequence predisposed to unequal intergenic and intragenic recombination.

Mutations in the L and M pigment gene array that result in the lack of functional L and M pigments, and thus inactivate the corresponding cones, have been identified in the majority of BCM. These mutations fall into three classes. In the first class (about 40% of cases), a normal L and M pigment gene array is inactivated by a deletion in the LCR. In the second class of mutations (about 60% of cases), the LCR is preserved, but changes within the L and M pigment gene array lead to loss of functional pigment production. This is due to a two-step mutation mechanism. The first step involves nonhomologous recombination between the L and M opsin genes, which reduces the number of genes in the opsin array to one. This step is followed by a single nucleotide sequence alteration (point mutation), which inactivates the residual gene. The most common BCM genotype in this class consists of a single inactivated L–M hybrid gene with a C203R mutation: thymine to cytosine transition at nucleotide 648, which results in a cysteine to arginine substitution at codon 203 (Cys203Arg), disrupts the folding of cone opsin molecules. A third class of mutation includes partial or complete deletion of an entire exon.

Clinical Presentation

BCM typically presents in infancy with reduced visual acuity (6/24 to 6/60), pendular nystagmus, photophobia, and normal fundi. Cone dysfunction is mostly stationary. The nystagmus often wanes with time. Eccentric fixation may be present, and myopia is common. Color discrimination depends upon the luminance of the task: at mesopic (dark-adapted) levels, they have rudimentary dichromatic color discrimination based upon a comparison of the quantum catches obtained by the rods and the S cones. Color discrimination deteriorates with increasing luminance.

Findings

BCM is typically a stationary cone dysfunction and presents with normal funduscopy. A few families with pigmentary macular disturbances have been reported, with subsequent deterioration of visual acuity and color vision.

A recent study used adaptive optics scanning laser ophthalmoscopy and spectral-domain optical coherence tomography (SD-OCT) in 11 subjects, with mutations in the L and M cone opsin genes. Significant disruption of retinal lamination and cone mosaic topography and significant macular thinning were demonstrated in all subjects. The four subjects with C203R mutations and one subject with exon 2 deletion presented a classical BCM phenotype. The subjects with C203R mutations showed more normal total and central subfield thickness; retinal thinning was restricted to the outer nuclear layer and Henle fiber layer, and focal disruption of the ellipsoid zone of the inner segment was evident in SD-OCT. The subject with exon 2 deletion showed parafoveal thinning of the inner retina as well.

Diagnosis

- X-linked recessive inheritance trait
- Full field electroretinography (ERG) demonstrates absent or profoundly reduced photopic ERG: the 30 Hz cone ERG cannot be detected, while single flash photopic ERG is often recordable, although small and delayed. S-cone ERG is well preserved. The rod-specific and maximal responses usually show no definite abnormality.
- Psychophysical testing of color vision suggests retained tritan discrimination. These tests include the Farnsworth–Munsell 100 Hue test, Berson color plates; Hardy, Rand, and Rittler (HRR) plates; and the standard and enlarged Mollon–Reffin (MR) Minimal test.

Differential Diagnosis

- Rod monochromatism (RM) – an absence of all functioning cone photoreceptors with visual perception depending almost exclusively on rods. The rod monochromat has markedly reduced visual acuity and total color blindness. BCM is distinguished from RM via psychophysical and electrophysiological testing. The photopic ERG is profoundly reduced in both, although the S-cone ERG is well preserved in BCM. Classification can also be aided by family history, because BCM is inherited as an X-linked recessive trait, whereas rod monochromacy shows autosomal recessive inheritance. Blue cone monochromats are reported to display fewer errors along the vertical axis in the Farnsworth 100 Hue test (fewer tritan errors), and they may also display protan-like ordering patterns on the Farnsworth D-15 compared to RM.
- Progressive cone dystrophies – onset is usually in childhood or early adult life. Patients show worsening of cone function with deteriorating visual acuity, photophobia, and color vision and often develop rod photoreceptor dysfunction in later life.

Prophylaxis

Prenatal diagnosis can be performed in families in which the responsible gene has been identified.

Therapy

There is currently no specific treatment for BCM.

Prognosis

BCM is generally accepted to be a stationary disorder. A small number of families, with slow progression of cone dysfunction, have been reported.

Epidemiology

Affects approximately 1 in 100,000

[2]Department of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Synonyms

Congenital ocular melanocytosis; Melanosis oculi; Ocular melanosis

Definition

A congenital pigmentary lesion of the episclera caused by increased number of subepithelial melanocytes.

B

Etiology

Primarily congenital.

Clinical Presentation

Ocular melanocytosis is characterized by irregular diffuse or sectorial blue or slate-gray discoloration of the sclera and episclera. The lesions are deep, immobile, and almost invariably unilateral. Heterochromia iridis is often a predominant feature, with part or the entire affected iris being darker than the iris of the fellow eye. Also, the background fundus pigmentation is greater in the affected eye (Albert et al. 2008).

Half of patients with ocular melanocytosis have periocular pigmentation of the skin in the first and second dermatomes of the trigeminal nerve. The combination of ocular and periocular pigmentation is called oculodermal melanocytosis or nevus of Ota.

Patients with ocular melanocytosis are at increased risk of developing glaucoma secondary to hyperpigmentation and increase the outflow resistance through the trabecular meshwork; this occurs in 10% of patients with ocular melanocytosis. Affected patients with fair skin have an increased risk of developing malignant melanoma in the skin, conjunctiva, uvea, or orbit. The lifetime risk of uveal melanoma in a patient with ocular melanocytosis is 1 in 400, compared to 1 in 13,000 of general population. Also, a higher incidence of optic nerve melanocytoma in affected eyes has been recognized (Gonder et al. 1982).

Diagnosis

Based on clinical presentation and examination with slit-lamp bimicroscopy, fundus examination

should be done to exclude uveal melanoma. Investigations are not usually required unless the lesion is atypical or undergone changes where biopsy is indicated.

Differential Diagnosis

- Conjunctival nevus
- Primary acquired melanocytosis (PAM)
- Malignant melanoma
- Choroidal melanoma with scleral extension
- Scleral thinning

Therapy

Ocular melanocytosis is a benign condition that does not require treatment. However, because of increased incidence of glaucoma and uveal melanoma, patients should be carefully examined periodically for their entire life to look for uveal, orbital and brain melanoma, and development of glaucoma (Krachmer et al. 2011).

Prognosis

Morbidity and mortality are mainly due to the development of complications including glaucoma and the increased risk of developing uveal melanoma in the affected eye.

Epidemiology

Ocular melanocytosis is an uncommon condition that is usually present at birth. It is more common in the black, Hispanic, and Asian populations. There is no difference in prevalence between males and females (Shields and Shields 2007).

Blue Sclera

Aazim A. Siddiqui[1] and Allen O. Eghrari[2,3]
[1]Imperial College London School of Medicine, South Kensington Campus, London, UK
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[3]Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Definition

Blue sclera refers to thinning and subsequent transparency of scleral type I collagen, which allows increased visibility of underlying choroidal pigment, giving sclera a seemingly blue appearance. Osteogenesis imperfecta (OI) is a hereditary disorder of type I collagen production, and patients with this condition demonstrate a diffuse blue appearance to the sclera (Agarwal and Jacob 2010; Basak 2011).

Etiology

Blue sclera is the most consistent manifestation of OI, which results from a mutation in *COLIA1* and *COL1A2*, coding for type I procollagen. However, classifications of this condition (types IV–VI) have been identified with normal sclerae. This rare disorder is also associated with abnormal fragility of bones and deafness.

Brittle cornea, blue sclera, and red hair are associated with the brittle cornea syndrome, a condition that also presents with skeletal, dental, and skin abnormalities. A missense mutation in *ZNF469* has been found to be causative for disease.

Other underlying conditions associated with the formation of blue sclera include Ehlers-Danlos syndrome (type VI), pseudoxanthoma elasticum, cornea plana, peripheral sclerocornea, buphthalmos, keratoconus, keratoglobus, high myopia, ciliary/equatorial staphyloma, oculodermal melanocytosis, and microcornea. Rarely, blue sclera occurs with Hallermann-Streiff syndrome, Marfan syndrome, Turner syndrome, Cheney syndrome, Menkes syndrome, pyknodysostosis, brittle corneas, or ectodermal dysplasia.

Blue sclera may also occur in normal infants during the first several months of life; however, persistence of blue discoloration over time may suggest the presence of elevated intraocular pressure. Premature infants frequently demonstrate blue sclerae, particularly those of Caucasian origin.

Blue sclera may also occur in isolation as an inherited autosomal dominant or autosomal recessive anomaly (Hunt 2002; Hoyt and Taylor 2012).

Clinical Presentation

Blue sclera presents with a bluish appearance to the sclera and may be associated with pathologic or non-pathologic etiology. Other ocular characteristics of connective tissue disorders associated with blue sclera include thin cornea, epicanthal fold, myopia, keratoconus, and angioid streaks. Systemic characteristics of connective tissue disorders associated with blue sclera include skin abnormalities, cardiac abnormalities, kyphoscoliosis, joint hypermobility, fragile bones, hearing abnormalities, vascular abnormalities, and gastrointestinal abnormalities (Agarwal and Jacob 2010; Kanski and Bowling 2011).

Diagnosis

Diagnostic evaluation of blue sclera involves external examination, slit lamp biomicroscopy, and systemic evaluation for associated disorders. Although no definitive test exists for OI, genetic testing can confirm or exclude known mutations (Agarwal and Jacob 2010).

Differential Diagnosis

Pediatric and orthopedic evaluations should be considered to exclude inherited causes of blue sclera and to identify systemic manifestations of disease. For instance, brittle cornea syndrome is characterized by blue sclera, brittle cornea, and red hair.

Oculodermal melanocytosis is a congenital condition which results in a bluish hue to the episclera. Unlike typical congenital blue sclera, this is secondary to dysfunctional melanocyte migration and tends to be unilateral. Patients are not at risk for thinning such as in OI but are at increased risk of uveal melanoma and glaucoma.

Scleromalacia perforans, most frequently associated with rheumatoid arthritis, induces focal thinning of the sclera and a similar blue appearance due to visualization of the underlying sclera. This generally occurs at an older age and is focal, in contrast to the genetic etiology and diffuse effect of the aforementioned conditions (Basak 2011; Kanski and Bowling 2011).

Prophylaxis

No gene therapy is currently available. However, genetic counselling for associated inherited disorders may be beneficial for patients with blue sclera and other manifestations of systemic disease.

Therapy

Surgical intervention may be indicated in cases of extreme thinning and perforation. Structural support can be provided by a preserved scleral graft or autologous fascia lata, particularly in cases requiring suturing of a device such as a tube implant. Systemic investigations and treatment should be considered to address underlying pathology. Appropriate referrals to pediatric and orthopedic evaluations may be indicated for non-ocular manifestations (Kanski and Bowling 2011).

Prognosis

Prognosis varies with the presence of ocular and systemic manifestations of the underlying disorder. Patients with blue sclera are at increased risk for globe rupture or intraoperative scleral perforation during routine eye surgery. Systemic disorders are also prevalent in patients such as carotid-cavernous fistula, arterial rupture, hearing loss, and bone fractures (Agarwal and Jacob 2010; Basak 2011).

Epidemiology

Blue sclera is associated with systemic connective tissue disorders, most commonly osteogenesis imperfecta, which presents at approximately 1 in every 20,000 live births. Prevalence is relatively similar worldwide, with higher frequency reported in Zimbabwe. Brittle cornea syndrome, although rare, presents largely from the Middle East and North Africa and was identified primarily in consanguineous families of Tunisian-Jewish descent; it has since also been described in Europeans (Kanski and Bowling 2011).

Blunt Trauma

Adiel Barak, Oded Ohana and Eyal Cohen
Tel Aviv Sourasky Medical Center,
Tel Aviv-Yafo, Israel

A blunt ocular trauma is defined as eye trauma by an object that does not penetrate the eye; the trauma may damage the structures at the anterior segment of the eye (the eyelid, conjunctiva, sclera, cornea, iris, and lens) and those at the posterior segment of the eye (retina and optic nerve) as well as surrounding structures of the orbital bones and the sinuses. The most devastating injury from ocular blunt trauma is open-globe rupture caused by suddenly elevating intraocular pressure; the ruptures are typically at the site of greatest structural weakness near the equator, at the limbus, and directly behind the insertion of the rectus muscles.

A blunt ocular injury can be due to any high-velocity objects. The most common blunt objects reported by May et al. from the US Eye injury Registry were rocks, fists, baseballs, lumber, and fishing weights. A blunt ocular injury can be due to any high-velocity objects including rocks, fists, baseballs, and lumber.

Risk Factors

Male gender is a predominant risk factor for ocular trauma as well as sport occupation and the use of power tools in the home environment.

Evaluation and Diagnosis

Assessment of a patient after ocular trauma should include complete history such as when and where the injury occur, what was the mechanism of the injury, what was the offending object, do the patient wore eye protection or glass, when was the patients last oral intake, and what was the eye status before the injury including previous ocular surgeries.

Ophthalmic examination can be difficult after an eye trauma; the injured eyes may be very swollen and difficult to open; in patients with a high likelihood of scleral rupture, the clinician should avoid

any examination procedure that might apply pressure to the eyeball, such as eyelid retraction or intraocular pressure measurement by tonometry.

The ophthalmic examination should include visual acuity, relative afferent pupillary defect, extraocular movements, palpation of orbital rim for step-off fractures and subcutaneous emphysema, sensation of the V1 and V2 on the forehead and cheek, measuring the degree of proptosis or enophthalmos, careful slit lamp examination of anterior segment, and a dilated fundus examination.

Imaging should include head and orbit axial and coronal computed tomography (CT) without contrast, utilizing 1–2 mm cuts. Ultrasound examination may be useful in the eyes with opaque media; although it may be necessary to defer ultrasonography until a scleral rupture is excluded, magnetic resonance imaging (MRI) can be a useful imaging modality for detecting intraocular foreign bodies made of wood, plastic, or stone but must be avoided when high suspicion of metal foreign bodies exists.

Clinical Findings

Subconjunctival Hemorrhage

The conjunctiva contains many small and fragile blood vessels; any eye trauma can cause bleeding underneath the conjunctiva from these small blood vessels, causing a solid red patch of blood on the white of the eye. The presence of subconjunctival hemorrhage, particularly with 360° of bullous SCH, can mask a scleral laceration and therefore must raise high suspicion of globe rupture.

Hyphema

Blood accumulating in the anterior chamber of the eye (the space between the cornea and the iris) called hyphema usually results from marked elevation in intraocular pressure with sudden distortion of intraocular structures and bleeding from blood vessels supplying blood to the iris, ciliary body, and angle structures.

The three most common complications from hyphema are elevated intraocular pressure, rebleeding at 4–6 days after the event, and corneal blood staining.

Angle Recession

The angle is located between the peripheral cornea and the peripheral iris. The angle contains the trabecular meshwork, which acts as a filtration system for the aqueous fluid draining from the eye. Angle recession is a common sequela of blunt ocular trauma and characterized by a variable degree of cleavage between the circular and the longitudinal fibers of the ciliary muscle. The angle of the eye can be visualized through a procedure known as gonioscopy.

Vitreous Hemorrhage

Traumatic vitreous hemorrhage can occur in the setting of blunt ocular trauma; the causes for bleeding into the vitreous cavity are rupture of blood vessels of the iris, ciliary body, retina choroid, and sclera; in this setting ultrasound examination is indicated for the detection of the cause for the bleeding and to rule out retinal tear, retinal detachment, and scleral rupture.

Macular Hole

Posttraumatic macular hole can be seen after a blunt trauma; the mechanisms for this complication are vitreous traction, severe berlins edema, subretinal hemorrhage caused by choroidal rupture, and contusion necrosis in the fovea. The macular hole can be seen immediately after the trauma or within days and even weeks.

Commotio Retinae

A disruption in the photoreceptor outer segment, characterized by gray-white discoloration of the outer retina. It can occur centrally or peripherally, and when it involves the macula, it is called Berlin's edema; usually there is no leakage of fluid and therefore it is not considered a true edema. When it involves the macula, a severe decrease in visual acuity can occur; fortunately, the prognosis for visual recovery is good and these changes gradually resolve spontaneously.

Choroidal Rupture

Blunt trauma causing mechanical compression of the eyeball in the anterior–posterior axis with concomitant rapid hyperextension in the horizontal axis. The sclera's tensile strength and retinal

elasticity resist this compression. However, Bruch membrane breaks because it does not have sufficient tensile strength or elasticity and with it a disruption in the choriocapillaris and the RPE occurs. Over time, choroidal neovascularization can develop.

Initial Treatment

Treatment in the emergency room for a known globe rupture or in highly suspicious cases includes avoidance of further examination or manipulation and the placement of a protective eye shield to prevent accidental pressure on the globe. The patient should be kept with nothing by mouth and a tetanus injection given as needed. Antiemetics should be given if the patient is nauseated. Broad-spectrum IV antibiotics should be instituted.

Borrelia burgdorferi

Jason E. Hale[4], Sumayya J. Almarzouqi[1], Michael L. Morgan[1,6] and Andrew G. Lee[1,2,3,4,5]
[1]Department of Ophthalmology, Blanton Eye Institute, Houston Methodist Hospital, Houston, TX, USA

[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Borrelia burgdorferi is a spiral-shaped (spirochete) bacterium that is endemic in North America and Europe. It is neither gram negative nor gram positive, and it is most commonly known as the causative agent of Lyme disease.

Microbiology

Borrelia burgdorferi is a spiral-shaped, microaerophilic two-membrane bacterium that is primarily extracellular. *B. burgdorferi* is one of the few pathogenic bacteria that can survive without iron, instead requiring manganese for proper function of some of its enzymes. The bacterium is covered with flagella and peptidoglycan and can be mistaken for a gram-negative organism because of its double membrane.

The *B. burgdorferi* genome contains 21 plasmids, more than any other known bacterium. The outer membrane is composed of various unique outer-surface proteins (Osp) that are presumed to play a role in virulence.

Transmission and Life Cycle

The bacterium is predominantly transmitted to humans by the *Ixodes* tick, and these ticks, typically in the larval stage, become infected with the spirochete after feeding on infected rodents (mice are the preferred host). Once mature, deer are the preferred host, but the *Ixodes* ticks cannot become infected from deer. Humans can become infected after being bitten by an infected tick.

Clinical

B. burgdorferi is primarily known for causing Lyme disease. Early symptoms can include fever, headache, fatigue, and the characteristic "bull's eye" rash (erythema migrans) on the skin. Later symptoms can include myocarditis, cardiomyopathy, arrhythmia, radiculopathy, arthritis, arthralgia, meningitis, neuropathies, hearing loss, and facial nerve palsies. If left untreated, patients may develop permanent neurological deficits.

Optic nerve involvement is considered rare in the context of Lyme disease but can occur if the

patient develops neuroborreliosis, a condition in which the infection affects the central nervous system. Interestingly, *B. burgdorferi* has also been linked to non-Hodgkin lymphomas.

Diagnosis

The diagnosis of Lyme disease is based upon clinical history and epidemiological risk of exposure to *Ixodes* ticks. For a patient with disseminated disease, serological testing is used to confirm the diagnosis. Serological testing involves an ELISA screening followed by a confirmatory Western blot. Centers for Disease Control and Prevention (CDC) criteria require five or more specific bands for IgG and two or more different bands for IgM.

Treatment

Because *B. burgdorferi* is microaerophilic, it grows slowly and requires the use of longer treatment courses, predominantly with doxycycline.

Botox: Spastic Entropion

Bryan Seiff
Delaware Eye Institute, Rehoboth Beach, DE, USA

Synonyms

Overriding orbicularis

Definition

Spastic entropion results from ocular irritation or inflammation which then triggers sustained orbicularis muscle contraction and inward rotation of the eyelid margin.

Indication

Spastic entropion that is causing corneal irritation, which then exacerbates the orbicularis spasm and perpetuates the irritation/entropion cycle.

Contraindication

Eyelids with underlying involutional changes that require definitive surgical repair.

Techniques and Principles

Botulinum toxin type A is injected subcutaneously into the overriding preseptal orbicularis muscle to relieve the spasm. A total of 5–10 U of botulinum toxin type A may be divided between two injection sites, one medial and one lateral. The underlying cause of the ocular irritation or inflammation must also be treated to eliminate the trigger for the orbicularis spasm.

Outcome

Botulinum toxin type A takes 48–72 h to have an effect and can last an average of 3–4 months.

When used in the treatment of spastic entropion, a single treatment is usually sufficient to break the irritation/entropion cycle and return the lid to its normal anatomic position, as long as the underlying cause of the ocular irritation is treated as well.

Complications

Excessive relaxation or paralysis of the orbicularis muscle may cause a loss of orbicularis tone and result in an ectropion. Deeper injection into the postseptal space may allow diffusion of the toxin to the lower lid retractors, resulting in reverse ptosis, or to the extraocular muscles, resulting in diplopia. These complications will resolve as the effect of the toxin dissipates.

Bowen's Disease

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Intraepidermal carcinoma; Squamous carcinoma in situ

Definition

Bowen's disease is a squamous carcinoma in situ of the skin. This premalignant squamous lesion may progress to invasive squamous cell carcinoma in less than 5% of patients.

Etiology

Bowen's disease occurs in the keratin-producing cells of the epidermis and respects the basement membrane. It is encountered in elderly, fair-skinned individuals with a history of chronic sun exposure. Other risk factors include arsenic exposure and the human papillomavirus.

In the past, Bowen's disease was thought to have an association with primary internal malignancies; however, current evidence does not support this hypothesis (Reizner et al. 1994; Shields and Shields 1999; Cox et al. 2007; Albert and Jakobiec 2008).

Clinical Presentation

Presents as velvety, scaly, erythematous plaques with well-defined borders on sun-exposed areas. The lesions are asymptomatic and slow growing. Bowen's disease presents as a single lesion in two thirds of cases.

Diagnostics

Definitive diagnosis is determined with excisional biopsy. Histolopathologically, Bowen's disease demonstrates hyperkeratosis, parakeratosis, acanthosis, and dysplasia within the full thickness of the epidermis (Shields and Shields 1999; Albert and Jakobiec 2008).

Differential Diagnosis

Actinic keratosis
Squamous cell carcinoma
Keratoacanthoma
Paget disease
Lichen simplex

Benign lichenoid keratosis
Tinea corporis
Eczema
Psoriasis, plaque

Prophylaxis

Patient should have a complete skin examination of sun-exposed areas and counseled to avoid sun exposure. Routine screening of these patients is necessary to avoid delay in treatment of additional lesions.

Therapy

Complete surgical excision is recommended to rule out squamous cell carcinoma. For smaller lesions, 4 mm margins are recommended. Frozen sections or Mohs micrographic surgery are alternative techniques for larger, recurrent lesions in critical areas. Other treatments include radiation, cryotherapy, photodynamic therapy, and topical chemotherapy. Observation can be offered in patients with short life expectancy or small lesions not suspected to progress to invasive squamous cell carcinoma rapidly (Shields and Shields 1999; Cox et al. 2007; Albert and Jakobiec 2008).

Prognosis

Prognosis is good, with less than 5% of cases advancing to invasive squamous cell carcinoma.

Epidemiology

More commonly observed in Caucasians in sun-exposed regions. Incidence has been reported to be 14 cases per 100,000 whites in Minnesota in 1991 and 142 cases per 100,000 whites in Hawaii in 1994 (Reizner et al. 1994; Shields and Shields 1999; Albert and Jakobiec 2008).

Bright-Flash Electroretinogram

Ido Perlman[2] and Shiri Soudry[1,2]
[1]Department of Ophthalmology, Rambam Health Campus, Haifa, Israel
[2]Ruth and Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel

Synonyms

The electrical response of the retina to a light flash of very high intensity (energy)

Definition

The electroretinogram (ERG) is the electrical mass response of the retina to a light stimulus and is commonly used to objectively measure global retinal function. In clinical practice, ERG serves to identify disorders of retinal function in patients complaining of visual disturbances, to monitor progression of retinal degenerative diseases, and to assess the response to treatment in maintaining retinal function. Bright-flash electroretinogram (bright-flash ERG) refers to the recording of the electroretinogram in the dark-adapted state using a very bright flash of light to elicit a response of maximal amplitude.

Of note, a distinction should be made between the retinal response to bright light measured as a routine part of the standard ERG testing protocol and the bright-flash ERG discussed here, which refers to the electrical response of the retina to a super bright-light stimulus.

Purpose

Bright-flash ERG testing is beneficial in cases of dense media opacity where light transmission to the retina through the ocular media is diminished or when retinal function is minimal such that intense light exposure is required to elicit a measureable response (Fuller et al. 1975; Wendel et al. 1984).

Otherwise, under most physiological and disease conditions tested in routine clinical practice, sufficient information regarding retinal function is achieved with the standard ERG protocol without the need to use very bright flashes of white light for ERG recording. Furthermore, the light intensity employed for this test, even though brief, is often uncomfortable for the patient. Lastly, not all commercial or assembled electrophysiological systems, currently available for ERG recording, are furnished to deliver sufficiently bright white-light stimulus.

Principle

Bright-flash ERG is recorded with differential amplifiers using three electrodes: a corneal active electrode, a reference electrode, and a ground electrode. Additional essential component for bright-flash ERG recording is a Ganzfeld light source that can deliver a sufficiently bright-light stimulus (minimum energy 300 cd-s/m^2). For recording electrode, a bipolar corneal electrode is needed that will not generate a photoelectric artifact in response to the bright-light stimulus.

Indication

Bright-flash ERG can be beneficial in the following cases:

1. Opaque optical media: In cases of severe ocular media opacity (e.g., opaque cornea, hypermature cataract, dense vitreous hemorrhage, etc.), light transmission to the retina is minimal such that the standard ERG response may be non-recordable. In these cases, when an assessment of retinal function is needed, using a very bright white-light stimulus often allows sufficient light to reach the retina and to elicit a recordable ERG response. Even though often of subnormal amplitude, such a response can provide helpful information about the functional status of the retina (Fuller et al. 1975; Wendel et al. 1984).
2. Candidates for implantation of retinal neuroprosthesis: Electrical neuroprosthetic devices have been developed and approved for clinical use in blind patients suffering from advanced retinitis pigmentosa. A bright-flash ERG can be used in these candidates in order to verify the extent to which retinal function has been lost.
3. Assessing photoreceptor pathology: Inherited retinal degenerations are a group of disorders caused by a mutation of a gene, encoding a protein which is specific to photoreceptors, RPE, or extracellular matrix. To date, more than 200 genes are known to cause photoreceptors degeneration. Although many inherited retinal degenerations share a similar phenotype, they differ in the underlying pathological mechanism leading to photoreceptors apoptosis and loss of vision. The bright-flash ERG elicits a

maximal, saturated a-wave that can be used to assess the underlying pathological mechanism/s of photoreceptors loss of function. Although currently this information is used mainly for experimental purposes, it is expected to become a valuable measure of retinal function in future clinical trials assessing the response to treatments targeting specific gene mutations (Cideciyan 2000; Hood and Birch 2006).

4. Monitoring of response treatment: When treatments for specific photoreceptors degenerative diseases will be developed, their efficacy will need to be assessed. Measurements of visual acuity and visual fields are subjective, while ERG recording is objective. Bright-flash ERG is an option to record the remaining retinal function of patients in advanced degenerative stage before treatment and during treatment to document treatment efficacy.

Contraindication

The intensely bright flash can elicit a substantial photoelectric artifact when using monopolar recording with corneal electrodes such as DTL electrode or with skin electrodes. This artifact can mask the actual ERG. Therefore, bright-flash ERG cannot be recorded in patients that cannot tolerate a bipolar corneal electrode or when there are contraindications for the use of such electrode, e.g., corneal abrasion, severe external eye infection, etc.

Advantage/Disadvantage

Advantage: assessment of minimal remaining retinal function, can be used with opaque optical media, indicate mechanism of photoreceptors loss of function.

Disadvantage: very bright and uncomfortable for the patient.

Brightness (Radiance)

Timo Eppig
Institute of Experimental Ophthalmology, Saarland University, Homburg, Germany

Synonyms

Radiance

Definition

Brightness L_e [$Wsr^{-1}\ m^{-2}$] is a radiometric measure of the amount of radiant power Φ_e [W] that is emitted from a surface with specified area A [m^2] within a given solid angle Ω [sr] into the specified direction angle ε. It is used to measure radiation emitted by a surface that can be received by the eye looking from angle ε. A lambertian radiator emits with homogeneous brightness which is independent of the angle of observation ε.

The definition of radiance $L_e \equiv \frac{\delta^2 \Phi_e}{\delta \Omega dA \cos \varepsilon}$.

Buccal Mucous Membrane Graft

Ronald Mancini
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Mucosal graft

Definition

Free mucosal tissue graft transplanted from the oral cavity to the eyelid as a conjunctival substitute.

Indication

Used during eyelid reconstruction surgery when there is posterior lamellar, in particular, conjunctival inadequacy. Tissue loss may be secondary to cancer resection surgery (including Mohs surgery), trauma, cicatricial changes, or congenital inadequacy.

Contraindication

Patients with significant oral disease or extensive prior oral surgery on mucosal surfaces may not be adequate donors. Graft size is limited anatomically and assurance must be given to spare the region of Stensen's duct.

Techniques and Principles

Assessment of the degree of conjunctival loss or foreshortening is performed and the proper graft

size determined. Potential donor sites for buccal mucosal tissue include the mucosal surfaces of the lower and upper lip (avoiding the midline frenula) and the lateral walls of the oral cavity (avoiding the area surrounding Stensen's duct). The graft is harvested by first creating an incision with a #15 Bard-Parker blade and the mucosa removed with Stevens scissors. The graft should be harvested as thin as possible, without creating buttonholes, to avoid deeper unnecessary submucosal dissection. The oral cavity wound is left to heal by secondary intention. The graft is further thinned if necessary and sutured into the conjunctival defect with absorbing gut suture.

Outcome

Once the graft has taken, in approximately 7 days time, it provides an excellent substitute for conjunctiva in both function and appearance. Some degree of graft contracture can be anticipated over the following several weeks.

Complications

Graft failure and slough with failure to reconstruct the conjunctival surface are possible. Donor site complications include potential infection, injury to Stensen's duct, and contracture and phimosis of the oral mucosal lining.

Bullous keratopathy; Epithelial edema; Microcystic edema

Definition

Bullae, or bullous keratopathy, refer to the condition in which excess fluid accumulates within or between corneal epithelial cells, causing disruption of the normal corneal epithelial architecture and the formation of epithelial blisters or cystic spaces. The loss of a smooth epithelial surface results in scattering of light and loss of vision. The fluid-filled bullae can shift or rupture to cause pain and foreign body sensation and may become secondarily infected, resulting in microbial keratitis. Patients with bullous keratopathy will complain of various levels of eye discomfort, decreased visual acuity, loss of contrast, glare, and photophobia Krachmer et al. (2011).

Etiology

The two common causes of corneal epithelial edema are endothelial dysfunction and epithelial hypoxia or trauma. Corneal transparency is reliant on a high density of functional endothelial cells to maintain the cornea in a dehydrated state. Endothelial dysfunction leads to stromal edema. Stromal edema occurs when the corneal water content exceeds 78% and is manifested as a thickened cornea with gray, ground-glass haze. Stromal swelling can displace the epithelial basement membrane and Descemet's membrane, causing

folds called *shift lines* and *corneal striae*, respectively. If stromal edema is chronic and advanced, subsequent epithelial edema with bulla formation ensues.

Endothelial dysfunction can be the result of Fuchs' endothelial corneal dystrophy, a disorder that causes bilateral, progressive corneal endothelial cell loss and dysfunction. Gradual edema and subsequent opacification of the cornea in Fuchs' endothelial corneal dystrophy typically results in symptomatic loss of visual acuity between the ages of 40 and 50. Other types of primary corneal endothelial failure include congenital hereditary endothelial dystrophy, posterior polymorphous dystrophy, and iridocorneal endothelial syndrome. Endothelial dysfunction can also result from an infectious or inflammatory condition, such as in herpetic or cytomegaloviral corneal endotheliitis. Intraocular surgery, particularly cataract surgery, is an important cause of direct endothelial injury, which can result in generalized endothelial dysfunction, particularly in patients predisposed to endothelial dysfunction or with preoperative endothelial cell counts Suh et al. (2008). Laser iridotomy used for the treatment or prevention of angle closure glaucoma can be complicated by corneal endothelial trauma and subsequent bullous keratopathy. Sudden rises in intraocular pressure can result in stromal edema and secondary epithelial microcystic edema due to overwhelming the ability of the corneal endothelium to maintain stromal dehydration. In patients who have undergone corneal transplantation, endothelial cell loss in the graft tissue results in stromal edema and subsequent epithelial edema.

Contact lens overuse or poor contact lens fit can lead to epithelial hypoxia, hypercapnia, or trauma, all of which can subsequently result in intracellular epithelial edema.

Occurrence

Bullous keratopathy secondary to cataract surgery is among the most common indications for corneal transplantation worldwide. In a review of indications for penetrating keratoplasty in a large US academic institution, pseudophakic bullous keratopathy was the leading indication for penetrating keratoplasty and accounted for 22.9–28.4% of penetrating keratoplasties performed in each 5–7 year interval between 1983 and 2005.

The prevalence of Fuchs' endothelial dystrophy is difficult to assess given its later onset and lack of symptoms in the early stage; however, it accounts for a significant proportion of corneal transplantations performed in the United States, up to 29% in some studies and 10.8–16.3% in the aforementioned study of penetrating keratoplasties between 1980 and 2005 Ghosheh et al. (2008).

Bullous keratopathy after laser peripheral iridotomy is a rarely reported complication. However, in a nationwide study of Japanese patients, laser peripheral iridotomy was the second leading cause of bullous keratopathy in patients undergoing keratoplasty, accounting for 23.4% of cases. Cataract surgery was the leading cause, associated with 44.4% of cases Shimazaki (2007).

Classification

Bullous keratopathy as a complication of cataract removal can be classified as *pseudophakic bullous keratopathy* if an intraocular lens implant is in place or *aphakic bullous keratopathy* if the patient is aphakic.

Epithelial bullae are associated with stage III and stage IV Fuchs endothelial dystrophy.

Epithelial edema with microcysts rather than larger bullae, often associated with acutely elevated intraocular pressure, is usually referred to as microcystic edema.

Burns

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Definition

Thermal, electrical, or chemical injury to the eyelids, adnexal structures, and/or ocular surface, resulting in soft tissue damage (management of chemical injuries is discussed elsewhere).

Etiology

Scald burns from hot water are the most common cause of thermal injury to the periocular region. Children, the elderly, and seizure sufferers are particularly vulnerable. Flame injuries are more likely to be seen in an occupational context and typically cause deeper burns. Electricity may cause arc, flash, and/or flame burns. Other sources include sunburns, motor vehicle accidents, house fires, and propane tank explosions.

Clinical Presentation

Clinical manifestations depend on the structures involved and severity of the burn. Eyelid skin is among the thinnest in the body, and deeper burns occur easily. First-degree burns involve only the dermis. They present with erythema and superficial blistering that typically heals within 1 week. Second-degree burns involve a variable depth of dermis. More superficial insults create painful, fluid-filled blisters with a moist red base. Healing occurs within 2 weeks with minimal scarring. Deeper insults result in blisters with a pale or mottled base; healing often requires 3 weeks or more and is accompanied by significant scarring and contraction. Third-degree burns involve the full epidermal-dermal thickness. Sensation is lost due to destruction of nerve fibers, and healing occurs only peripherally due to coagulation of the dermal blood vessels. Fourth-degree burns also involve the underlying muscle, bone, and/or vital structures.

Fortunately, thermal injuries rarely damage the ocular surface primarily. A variety of mechanisms, including a 150 ms reflex blink, Bell's phenomenon, and reflex protective movements of the head and arms, decrease this risk. Most damage arises secondarily, due to lagophthalmos and exposure from cicatricial ectropion or other eyelid deformities. Fluid resuscitation, sedation, and mechanical ventilation often exacerbate lagophthalmos via chemosis and loss of orbicularis tone.

Facial burns also raise the specter of laryngeal edema from smoke inhalation. There should be a low threshold to secure the airway and initiate mechanical ventilation.

Diagnosis

Diagnosis is based on history and exam. Careful inspection of the eyelids, brow and eyelash hairs, ocular surface, and fornices is paramount. Fluorescein and cobalt blue light are critical for assessing integrity of the ocular surface.

Differential Diagnosis

Bullous pemphigoid
Pemphigus vulgaris
Toxic epidermal necrolysis
Blistering drug eruptions
Photosensitivity reactions

Prophylaxis

Occupational, motor vehicle, and home safety measures.

Therapy

Therapy is directed toward protecting and/or reestablishing the integrity of the ocular surface. Restoring function to the eyelids is an important but secondary goal. Aggressive lubrication should be initiated early, and antibiotics covering *Pseudomonas* should be added if punctate staining or epithelial defects are present. Elevating the head of the bed may reduce chemosis and periocular edema. Orbital compartment syndrome is occasionally seen in patients receiving massive volume resuscitation for burns involving a large percentage of the body surface area. Standard canthotomy/cantholysis should be performed in these cases. Eschar should be debrided, and raw tissues protected with emollients and occlusive dressings. Moisture chambers are rarely effective in the face of significant lagophthalmos, and temporary suture tarsorrhaphy should be performed immediately in response to ocular surface decompensation. The timing of skin grafting to correct cicatricial ectropion is controversial, but recent evidence suggests benefit from intervention within the first week.

Prognosis

Prognosis is highly variable depending of the severity of injury.

Epidemiology

Up to one quarter of patients admitted to burn units have eyelid involvement.

Calcific Band Keratopathy

Farhan I. Merali
Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Band keratopathy; Calcific keratopathy; Calcium hydroxyapatite deposition

Definition

First described by Dixon in 1948, calcific band keratopathy refers to calcific degeneration, often in a "band"-like distribution, of the superficial cornea that mainly involves the Bowman layer and the anterior stroma. Involvement often begins in the interpalpebral region and is initially characterized by fine, dust-like deposits that are basophilic on H&E pathology staining, usually with a clear zone between the limbus and the border of the deposition. Over time, the deposits can coalesce to form dense calcific plaques that can obscure the visual axis. Scattered "holes" throughout the band are thought to occur at sites where corneal nerves penetrate Bowman's layer. Elevation of the epithelium secondary to extensive and irregular calcium deposition can result in pain, photophobia, foreign body sensation, recurrent corneal erosions, and decreased vision or glare.

Etiology

While calcific band keratopathy can be idiopathic, the major known causes fall into the categories below:

1. **Chronic ocular diseases**, especially intraocular inflammation, can lead to band keratopathy. Examples include chronic uveitis associated with juvenile idiopathic arthritis, interstitial keratitis, severe dry eye and corneal exposure syndromes, phthisis bulbi, long-standing glaucoma, spheroidal keratopathy, and the presence of a keratoprosthesis.
2. **Hypercalcemia** associated with the following conditions: hyperparathyroidism, vitamin D toxicity (e.g., sarcoidosis, oral intake, and osteoporosis), milk–alkali syndrome, renal failure (e.g., Fanconi syndrome), hypophosphatasia, multiple myeloma, carcinoma metastatic to the bone, and Paget's disease.
3. **Hyperphosphatemia** with normal levels of serum calcium, as can occur in some patients suffering from renal failure.
4. **Systemic diseases** such as gout, discoid lupus, tuberous sclerosis, and Norrie disease.
5. **Chemical exposure**, such as with the chronic use of older glaucoma medications or dry-eye drops with mercury-derived preservatives (phenylmercuric nitrate or acetate), can also lead to calcific band keratopathy. Others include silicone oil in an aphakic eye, exposure to mercury fumes, and phosphate-containing drops.

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

6. **Hereditary** transmission of calcific band keratopathy has also been reported, occurring in an autosomal recessive fashion. Thus far, only the human NBC1 (sodium-bicarbonate co-transporter one) gene has been implicated in band keratopathy, mutations of which result in severe ocular and renal dysfunction (band keratopathy, cataracts, and proximal renal tubular acidosis).

Classification

While calcific band keratopathy can vary in the distribution and severity of deposition, there have not been literature reports of consistent differences in the characteristics of calcific keratopathy based on etiology or other factors.

Management

The most appropriate first step in the management of calcific band keratopathy is to conduct workup, such as serum electrolytes and urinalysis, to assess for the presence of systemic metabolic or renal disease, especially if there is no clear ocular cause for the keratopathy. Consequently, underlying ocular and systemic conditions should be treated or controlled to the extent possible to prevent the progression or recurrence of the keratopathy.

Indications for treating band keratopathy mainly include vision impairment and physical discomfort. With extensive calcium deposition, mechanical removal may be helpful and is widely used in parts of the developing world as the primary treatment method given the ease of surgery and minimal cost involved. Chelation with disodium ethylenediaminetetraacetic acid (EDTA) remains the mainstay of therapy, especially in the developed world; please refer to the separate section on "Chelation Therapy, for Calcific Band Keratopathy" for further discussion of this method. The ability to control the depth and area of ablation with excimer laser phototherapeutic keratectomy (PTK) can make it a useful modality of treatment in calcific band keratopathy, especially if residual opacification remains after initial EDTA chelation. However, since calcium ablates at a different rate from corneal stroma, PTK can result in an irregular surface. A masking agent to protect normal tissue may help achieve a smoother corneal surface post-ablation. Amniotic membrane transplantation (AMT) may also be used in the treatment of band keratopathy, usually as an adjunctive modality given it facilitates healing and provides long-term stability to the corneal epithelium. It can serve to replace damaged basement membrane after chelation or ablation, and protease inhibitors in the amniotic membrane may inhibit surface neovascularization.

Canaliculitis

Jessica Selter
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Chronic conjunctivitis

Definition

Canaliculitis is a disease characterized by inflammation of the proximal lacrimal draining system (Fulmer et al. 1999). It is often chronic and caused by infection of the lacrimal canaliculi. It is often misdiagnosed as conjunctivitis (Fulmer et al. 1999).

Etiology

The most common cause of canaliculitis is infection, but it can also be caused by a complication of punctal or intracanalicular plug insertion or intubation (Fulmer et al. 1999). The most common pathogens that cause infection include *Staphylococcus* spp., *Streptococcus* spp., *Actinomyces* spp., and *Propionibacterium* spp. (Freedman et al. 2011). The infection will often cause small concretions that consist of sulfur granules, and these can form pockets where the antimicrobial property of tears cannot reach (Freedman et al. 2011).

Clinical Presentation

Patients with canaliculitis will typically present with epiphora, lower eyelid erythema, medial canthal swelling, and recurrent conjunctivitis (Freedman et al. 2011). There is often the presence of what is known as pouting punctum, where the punctum is erythematous and raised. The pouting punctum can also be associated with mucopurulent discharge (Kanski and Bowling 2011). The involved area is often tender to touch (Kanski and Bowling 2011). Patients often have a history of unilateral conjunctival inflammation and discharge that persisted despite the use of antibiotic drops (Freedman et al. 2011).

Diagnosis

The diagnosis of canaliculitis can be made clinically. Pressure over the punctum that leads to purulent discharge can be useful in confirming the diagnosis. However, canaliculitis is often misdiagnosed due to its coincidental symptomatology with other eye disorders (Freedman et al. 2011). Objective tests for canaliculitis with an infectious etiology include those that attempt to determine the causative organism. Swabbing and needles are used to obtain samples for staining and culture. Histopathological examination including gram, periodic acid-Schiff, and Grocott's methenamine silver staining is helpful in determining the causative organism (Freedman et al. 2011). More recently, ultrasound is being used to confirm diagnosis (Freedman et al. 2011).

Differential Diagnosis

The differential diagnosis includes:

- Chronic conjunctivitis
- Dacryocystitis
- Obstruction of nasolacrimal duct
- Carcinoma of the lacrimal canaliculus

Prophylaxis

None is indicated for canaliculitis.

Therapy

Medical Management

Medical management of canaliculitis is rarely curative (Freedman et al. 2011). However, topical and systemic antibiotics have been shown to improve symptoms. Systemic use of penicillin and topical neomycin, polymyxin, or bacitracin has all been shown to help symptoms. The failure for antibiotics to be curative is thought to be due to the inability of antibiotics to penetrate canalicular concretions. Warm compresses and digital massage are other techniques that are utilized.

Surgical Management

Surgical management is the definitive treatment for canaliculitis (Freedman et al. 2011). Canaliculotomy is the procedure most commonly utilized to cure canaliculitis. In a canaliculotomy, a probe is passed through the canaliculus in order to open it. Then the concretions are extracted using a curette. An antibiotic solution is then added to the canaliculus. Risks to the procedure include canalicular scarring, lacrimal pump dysfunction, and failure to treat concretions that are deeper in the canaliculus.

Prognosis

The prognosis of the patient's illness is likely to depend on the duration of the disease prior to diagnosis, the treatment employed to manage the disease, comorbidities, and other less understood variables (Freedman et al. 2011). After treatment with canaliculotomy, continued symptoms have been shown to occur in 27% of patients (Zaldivar and Bradley 2009).

Epidemiology

Canaliculitis is a relatively rare disorder, but it is also generally underreported and frequently misdiagnosed (Freedman et al. 2011). It is most common in patients over the age of 50. There is a high female/male ratio, and there does not seem to be any racial or ethnic association (Freedman et al. 2011).

Synonyms

Cancer-associated retinopathy; CAR

Definition

Paraneoplastic syndrome is a complex of signs and symptoms mediated by hormones or immune

response among cancer patients. It is estimated to occur in as many as 10% of cancer patients (Retina and Vitreous 2014–2015).

Paraneoplastic syndromes involving the visual system are rare and estimated to affect as little as 0.01% of patients. One of the main two visual paraneoplastic syndromes is cancer-associated retinopathy (CAR), which can cause retinal degeneration by immunologic mechanism.

The most common malignancies which are associated with CAR include: small-cell lung carcinoma, ovarian cancer, endometrial and cervical cancer, and breast cancer. In rare cases CAR may be associated with non-small-cell lung cancer, lymphoma, other hematological malignancies, and bladder carcinoma (Rahimy and Sarraf 2013).

The mean age of CAR symptoms onset is 65 years. It is more common in women and recently reported to be 2:1 female-to-male ratio. Visual loss is painless, develops over weeks to months, and precedes the diagnosis of underlying malignancy in nearly half of patients.

Molecular mimicry has been proposed as the pathogenic mechanism behind the disease. It is hypothesized that the cancerous tumors express protein antigens that are similar or can cross-react with retinal proteins. The two most common and specific retinal proteins shown to be the target of the antigenic cross-reactivity in CAR patients are the 23-kDa retinal antigen (recoverin) and the 46-kDa antigen (a-enolase). Other retinal proteins which have been found to be antigenic include: arrestin, transducin, and neurofilament protein.

Both rods and cones are affected. Symptoms include photosensitivity, photopsias, glare, severely reduced central vision, and impaired color perception. Rod dysfunction may present as nyctalopia, impaired dark adaptation, ring scotoma, or other peripheral visual field loss (Rahimy and Sarraf 2013).

Patients with CAR involving anti-recoverin antibodies typically experience a more rapidly progressive loss of vision, often prior to the cancer diagnosis. In contrast, patients with anti-enolase are characterized predominantly by cone dysfunction, with slow progression of central vision loss, often among patients with prior diagnosed malignancy (Rahimy and Sarraf 2013).

Fundus examination in CAR varies from unremarkable to findings of optic nerve pallor, arterial narrowing, and retinal pigment epithelial (RPE) thinning and mottling. A subtle vitritis may be present, as there may also be retinal vasculitis with or without cystoid macular edema (CME).

Goldmann visual field examinations document dramatic loss of visual field over a few months, and the ERG signal is severely reduced for a and b waves. Fluorescein angiography (FA) is unremarkable in the vast majority of CAR patients, and optical coherence tomography (OCT) typically reveals severe macular atrophy, often associated with thinning of the photoreceptor layer, disruption or loss of the inner segment/outer segment (IS/OS) junction, and loss of the inner highly reflective layer.

Although no effective treatment for CAR exists, immunosuppressive therapy given in close cooperation with the patient's oncologist may halt and sometimes reverse the vision loss in patients with CAR. A combination of systemic corticosteroids, plasmapheresis, and intravenous immunoglobulin (IVIg) that presumably decrease circulating autoantibody titers and their resultant destruction of photoreceptors might be beneficial in some cases (Rahimy and Sarraf 2013; Retina and Vitreous 2014–2015).

Synonyms

Autoimmune retinopathies; Cancer-associated retinopathy (CAR); Paraneoplastic retinopathy; Recoverin-associated retinopathy (RAR)

Definition

Cancer-associated retinopathy (CAR) belongs to a spectrum of uncommon autoimmune disorder in which autoantibodies are directed against various retinal components and can lead to progressive vision loss.

Etiology

There are many antibodies that have been discovered directed against specific retinal proteins (e.g., recoverin (23-kD retinal protein), anti-enolase, anti-arrestin, transducin B, TULP1, heat shock protein (HSC 70), carbonic anhydrase, and other antibodies to the photoreceptor cell-specific nuclear receptor (PNR) gene products). These antibodies can trigger a cascade of events, leading to increased phosphorylation of rhodopsin, which causes increased intracellular levels of calcium and activates apoptotic pathways, resulting in photoreceptor cell death. CAR usually affects both rods and cones but there are forms that preferentially or predominantly affect rod or cone function.

CAR is considered the most common form of paraneoplastic retinopathy and the most common associated malignancy is small-cell lung cancer. Multiple different malignancies however including gynecologic, breast, non-small cell lung cancer, Hodgkin lymphoma, pancreatic, prostate, bladder, laryngeal, and colon cancers have also been reported to cause CAR.

Clinical Presentation

Patients with CAR typically present with rapid, painless vision loss associated with photopsias and photosensitivity. Symptoms are usually bilateral, but occasionally occur sequentially, and then are relentlessly progressive over weeks to months. In most cases of CAR, vision loss occurs before malignancy is diagnosed. In contrast to CAR, vision loss due to melanoma-associated retinopathy (MAR) usually occurs in patients with known melanoma (often at the stage of metastasis). Symptoms and signs depend on which retinal elements are affected. Cone dysfunction causes photosensitivity, hemeralopia (day blindness or prolonged glare after light exposure), loss of central vision, and loss of color vision. On the other hand, rod dysfunction causes nyctalopia (night blindness, difficulty seeing in dim illumination), prolonged dark adaptation, and peripheral field loss. In either case, positive visual phenomena (i.e., photopsias) are often prominent, including flashing of lights, flickering, smoky, or swirling vision. At presentation the fundus findings are often normal**.** Characteristic changes occur over time however including vascular attenuation and sheathing of the retinal arterioles; thinning and mottling of the retinal pigment epithelium (RPE), vitreous cells, and periphlebitis; and eventual optic atrophy OU.

Diagnostics

There is no universal diagnostic criterion for CAR, and the diagnosis is usually made by a combination of patient's clinical symptoms, exam findings, electrophysiologic (e.g., ERG), and laboratory testing (e.g., serum paraneoplastic CAR antibodies).

The diagnostic procedures that may help in the diagnosis of CAR include visual field testing which may show central, cecocentral, or equatorial scotomas. Fluorescein angiography may be normal or might show mild peripheral vascular leakage consistent with vasculitis.

Retinal optical coherence tomography (OCT) may show thinning of the inner retinal layers.

Full-field electroretinogram (ERG) is almost always abnormal in CAR with attenuated or the absence of photopic and scotopic responses. Multifocal electroretinogram (MERG) is useful in selected cases in which visual field loss is localized centrally (e.g., paraneoplastic cone dysfunction). Laboratory testing for positive antibodies against retinal proteins is often diagnostic but may vary between laboratories. Physicians should keep a high index of suspicion based on the clinical findings, and a full work-up for an occult malignancy (e.g., PET scan) should be performed in CAR.

Differential Diagnosis

- Optic neuropathy includes compressive optic neuropathy, demyelinating optic neuropathy, ischemia optic neuropathy, toxic-nutritional optic neuropathy, and hereditary optic neuropathy.
- Retinitis pigmentosa, other hereditary or acquired retinopathies.
- Cone dystrophy.
- Acute zonal outer occult retinopathy (AZOOR).

Prophylaxis

Non-applicable

Therapy

Systemic immunosuppression medication is the mainstay of CAR therapy (e.g., steroid, cyclosporine, or azathioprine). Other immunemodulator therapies, such as intravenous immunoglobulin (IVIG), plasmapheresis, rituximab, and alemtuzumab, had been used with variable success and sometimes combinations of these treatments may be necessary.

Treatment of the underlying primary tumor is important (e.g., surgery, chemotherapy, and radiation therapy) but may not alter the visual prognosis.

Prognosis

Overall there is little to no significant visual improvement in patients with CAR despite treatment and the prognosis is generally poor.

Epidemiology

CAR is rare but the exact prevalence is unknown. It usually affects older adults, but it had been reported in younger patients too. There is no known ethnic or sex predilection.

Candida (Candidiasis), Ocular Infection/Inflammation Caused by, Endogenous Endophthalmitis

Oren Tomkins-Netzer[1] and Sue Lightman[2,3]
[1]Department of Ophthalomology, Moorfields Eye Hospital, Institute of Ophthalmology, University College London, London, UK
[2]Department of Ophthalmology, Institute of Ophthalmology, University College London; Moorfields Eye Hospital, London, UK
[3]Department of Clinical Ophthalmology, UCL Institute of Ophthalmology (IO), London, UK

Synonyms

Candidiasis; Candida endophthalmitis; Endogenous endophthalmitis

Definition

Candida is the most common cause of endogenous endophthalmitis. It typically affects patients who are sick, have undergone surgical procedures such as bowel surgery, and have required intravenous lines over a period of time that can result in permanent vision loss. Diagnosis is based on clinical signs and may be supported by positive fungal cultures and PCR for fungal DNA when available. Treatment includes combining systemic and intravitreal antifungal drugs, though a poor visual outcome is still a common occurrence.

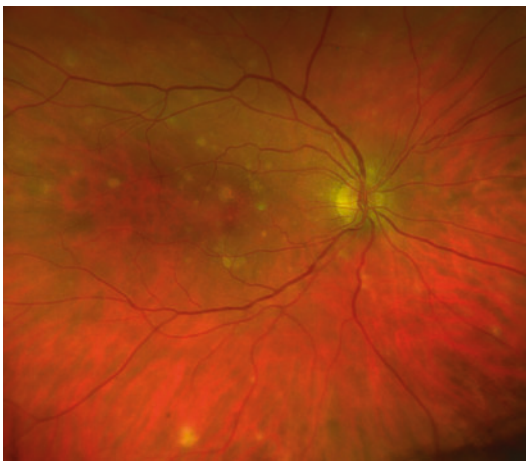
Etiology

Candida is a genus of yeasts and is the most common cause of fungal infections worldwide. Grown in the laboratory, *Candida* appears as large, round, white, or creamy colonies with a yeasty odor on agar plates at room temperature. Many species are harmless commensals or endosymbionts of hosts including humans and form part of the normal mucosal flora of the respiratory, gastrointestinal, and female genital tracts. However, when mucosal barriers are disrupted or the immune system is compromised, they can invade and cause disease. Certain factors, such as prolonged antibiotic use, increase the risk of *Candida* infection and can lead to gastrointestinal *Candida* overgrowth and penetration of the intestinal mucosa. People with uncontrolled diabetes mellitus, patients requiring intensive care, surgical patients (particularly those who have had bowel surgery), patients with a central venous catheter, very low-birth-weight infants, or those with an impaired immune system, such as those with human immunodeficiency virus infections, are more susceptible to yeast infections (Sallam et al. 2006; Das et al. 2011). While there are over 20 species of *Candida* yeasts that can cause infection in humans, *Candida albicans* is the most commonly isolated species, found in over half of cases, and can cause infections (candidiasis) in humans and other animals. Other strains that are related to human disease include *Candida tropicalis*, *Candida parapsilosis*, and *Candida*

glabrata, all of which can be involved in endogenous endophthalmitis and might have different drug sensitivities than *Candida albicans. Candida* can infect many organs and symptoms vary depending on the area of the body that is involved. Invasive candidiasis occurs when *Candida* species enter the bloodstream (candidemia) and spread throughout the body, involving vital organs such as the brain, heart, kidneys, and eyes. Endogenous *Candida* endophthalmitis is an uncommon intraocular infection that occurs as a complication of candidemia (Sallam et al. 2006).

Clinical Presentation

Following hematogenous spread the choroid is the primary site involved in ocular infection, with secondary involvement of the retina (chorioretinitis) and the vitreous, formation of multiple small vitreous abscesses and a dense suppurative vitritis. Patients typically present with subacute onset of new floaters, blurred vision, and occasionally photophobia or ocular pain. In cases where the retinal lesions are few or peripheral (Fig. 1), patients may be asymptomatic and be referred for ophthalmic examination as they are known to have systemic fungal infection.



***Candida* (Candidiasis), Ocular Infection/Inflammation Caused by, Endogenous Endophthalmitis, Fig. 1** Retinal view of a patient with scattered chorioretinal lesion of *Candida albicans*

Anterior segment involvement, with or without a hypopyon or keratic precipitates, may occur. The most distinct feature of chorioretinal involvement with *Candida* is fluffy, creamy-white, chorioretinal lesions, which may be single or multiple, associated with vitreous haze (Fig. 2). Lesions may be bilateral, even when symptoms are uniocular. With extension of the lesions from the retina into the vitreous, puff ball-like vitreous abscesses may be formed. Other nonspecific lesions such as retinal hemorrhages, nerve fiber layer infarcts, and white-centered hemorrhages (Roth spots) may be seen in up to 20% of cases. Retina vessel involvement can lead to vascular occlusion, which is a poor visual prognostic factor.

Diagnosis

The diagnosis of *Candida* endophthalmitis is usually based on the appearance of typical clinical findings in patients with known systemic infection or risk factors. In cases when *Candida* endophthalmitis is suspected, the isolation of the fungus from the blood, urine, or other suspected sites can support the diagnosis. However, blood cultures may be negative in up to 50% of *Candida* endophthalmitis cases, possibly due to intermittent blood fungemia. Similarly, positive cultures from vitreous samples can have a very poor yield,

***Candida* (Candidiasis), Ocular Infection/Inflammation Caused by, Endogenous Endophthalmitis, Fig. 2** Macular involvement of *Candida albicans*

and though samples obtained by vitrectomy are more likely to be positive, over 50% of them may still be negative (Das et al. 2011). The use of polymerase chain reaction systems for detection of fungal DNA may increase the chance of identifying the causative organism and may even be able to detect *Candida* DNA through aqueous humor samples obtained from an anterior chamber paracentesis (Ogawa et al. 2012).

Differential Diagnosis

While *Candida* is the leading cause of fungal endophthalmitis and should be considered in any patient with a positive blood or urinary culture or in immunocompromised patients, bacteria remain the most common cause of endophthalmitis and vitreous samples must be examined for bacteria as well as other fungi known to be related to endogenous endophthalmitis, including *Aspergillus* and *Dimorphic* species. Acute retinal necrosis from herpetic viral infection causes extensive necrotizing retinal damage with vitritis and anterior chamber inflammation and together with toxoplasma retinochoroiditis should be considered in any case of an anterior chamber inflammation with a dense vitritis and retinitis.

Prophylaxis

Patients at high risk of developing systemic and ocular *Candida* infection should be examined repeatedly while they are at risk, as ocular infection may develop up to 2 weeks after the initial positive blood culture. In cases of patients with known candidemia, prompt use of systemic antifungal treatment can reduce the risk of developing ocular involvement. Once the patient has been identified, early ophthalmic examination should be performed or immediately in case of any ocular complaints.

Therapy

Treatment for *Candida* endophthalmitis should be instituted as soon as the diagnosis is made, and both ocular and systemic treatments should be initiated. Though there are no clear guidelines for the duration of treatment, it should be continued for at least 6–12 weeks, until all visible lesions resolve, to ensure eradication of both ocular and systemic infections. Systemic antifungal agents are effective in controlling the systemic infection as well as any choroidal involvement as the choroid is outside the blood-retinal barrier (BRB). Amphotericin B is the most commonly used agent for systemic candidiasis which is usually given as an intravenous infusion over several hours and may be given in liposomal form to reduce renal toxicity. However, when given systemically either in the soluble or liposomal form, amphotericin B does not penetrate the BRB well and does not achieve a therapeutic level within the eye. Fluconazole both orally and intravenously does cross the BRB well and achieves therapeutic levels within the eye.

While systemically administered antifungal drugs should be used in any case of *Candida* endophthalmitis to address the systemic infection, additional intravitreal therapy should also be given to achieve a high therapeutically effective intraocular level of the drug amphotericin B, which is the most widely used agent for intravitreal injections at a recommended dose of 5–10 μg in 50–100 μl. In cases of *Candida* species known to be resistant to fluconazole and amphotericin, voriconazole can be used both systemically and intravitreally.

Vitrectomy should be considered in all patients with severe vitreous involvement. This can reduce the fungal load and improve the drug effect, as well as provide further specimens for diagnosis. Most importantly, vitrectomy can also reduce the risk of retinal detachment following vitreous infection as this can occur from vitreous contraction pulling on the retina.

Prognosis

The prognosis of *Candida* endophthalmitis depends on the location of the abscesses and the extent of ocular damage before the start of effective treatment. Visual loss is commonly related to the

development of retinal detachments, fibrotic membranes, or infective lesions which involve the optic disk or macula. However, patients with candidemia and tissue invasive candidiasis can have a high mortality rate that can reach up to 50%.

Epidemiology

Candida is an uncommon cause of endogenous endophthalmitis and accounts for approximately 6% of culture-proven endophthalmitis (Schimel et al. 2013). The most common fungus is *Candida albicans* followed by the *Aspergillus* species, and endophthalmitis has been diagnosed in 2.5% of patients with known candidemia (Sallam et al. 2006).

Synonyms

Fungal corneal infection; Keratomycosis

Definition

Candida keratitis is a potentially sight-threatening corneal infection that most commonly develops in patients after trauma or in those with a compromised corneal surface.

Etiology

Fungi are a group of microorganism that has rigid walls and a distinct nucleus with multiple chromosomes containing both DNA and RNA. The two main types of fungi causing keratitis are:

1. Yeast (e.g., genus *Candida*), ovoid unicellular organism that reproduces by budding, is responsible for most cases of fungal keratitis in temperate climates. Yeast is a common offender in the northern and coastal regions of the United States, constituting 32–43% of the keratomycoses, and commonly occurs in the eyes with predisposing alterations in host defenses.
2. Filamentous fungi (e.g., genera *Fusarium* and *Aspergillus*), multicellular organisms that produce tubular projection known as hyphae, are the most common pathogens in tropical climates.

Fungi gain access to the corneal stroma through a defect in the epithelial barrier. Once in the stroma, they multiply and cause tissue

necrosis, leading to a host inflammatory reaction. Organisms can penetrate deep into the stroma and through an intact Descemet's membrane. It is thought that once organisms gain access to the anterior chamber, eradication of the organisms becomes extremely difficult. Likewise, fungi that extend from the cornea into the sclera become difficult to treat.

Risk Factors

1. Trauma to the cornea with plant or vegetable material is the leading risk factor for fungal keratitis.
2. Wearing contact lens is another risk factor for the development fungal keratitis.
3. Topical corticosteroids are a major risk factor as well, as they appear to activate and increase the virulence of fungal organisms by reducing the cornea's resistance to infection.
4. Candida species cause ocular infections in immunocompromised host and in corneas with chronic erosions/ulceration from other causes.
5. Other common risk factors include corneal surgery (e.g., penetrating keratoplasty) and chronic keratitis (e.g., herpes simplex virus, herpes zoster).

Clinical Presentation

Presentation is with a gradual onset of pain, grittiness, photophobia, blurred vision, and watery or mucopurulent discharge.

Signs

– Candida keratitis: yellow-white densely suppurative infiltrate and collar-stud morphology may be seen. Candida ulcers occasionally have distinct oval outlines with a plaque-like surface.
– Filamentous keratitis: gray or yellow-white stromal infiltrate with indistinct fluffy margins. Progressive infiltration often is associated with satellite lesions.
  - Feathery branch-like extension or a ring-shaped infiltrate may develop.
  - Rapid progression with necrosis and thinning can occur.
  - Penetration of an intact Descemet's membrane may occur and lead to endophthalmitis without evident perforation.
  - An epithelial defect is not invariable and is sometimes small when present.
  - Other features include anterior uveitis, hypopyon, endothelial plaque, increased intraocular pressure, scleritis, and sterile or infective endophthalmitis.

Diagnostics (Lab Diagnostics)

- History of trauma involving vegetative matter is highly suggestive.
- Lack of response to conventional antibacterial therapy.
- Corneal scraping for staining with gram, Giemsa, Gomori methenamine silver, and calcofluor-white stains.
- Cultures, media include sheep blood agar, chocolate agar, and thioglycolate broth. Initial growth occurs within 72 h in 83% of cultures and within 1 week in 97% of cultures.
- Corneal biopsy may be required if smear and cultures are negative and is indicated in the absence of clinical improvement after 3–4 days.
- Other less widely used methods for identification of fungi include electron microscopy and polymerase chain reaction.

Differential Diagnosis

Differential diagnosis includes bacterial, herpetic, and *Acanthamoeba* keratitis. It is important to be aware of coinfection, including with an additional fungal species.

Prophylaxis

The patient's chief concern should be noted, and a complete systemic and ocular history, eliciting specific risk factors for infection of the external eye, should be obtained. A detailed history and

physical examination are essential to proper diagnosis of external eye infections.

Therapy

Initially the fungal infection should be treated medically and potentially surgically, as fungal infection can be rapidly destructive to the integrity of the eye. Hospital admission may be necessary. Topical and systemic treatment usually lasts for several weeks to months. Lack of disease progression is the first therapeutic response.

Medical Therapy

- Removal of the epithelium over the lesion may enhance penetration of the antifungal agents.
- Topical treatment of the antifungal agents should initially be given hourly for 48 h and then reduced as signs permit. Because most antifungals are fungistatic, treatment should be continued for at least months.
- Candida is treated with amphotericin B 0.15% or econazole 1%; alternatives include natamycin 5%, fluconazole 2%, and clotrimazole 1%.
- Filamentous infection is treated with natamycin 5% or econazole 1%; alternatives are amphotericin B 0.15% and miconazole 1%.
- A broad-spectrum antibiotic prevents bacterial coinfection.
- Cycloplegia for comfort.
- Subconjunctival fluconazole may be used in severe cases.
- Systemic antifungals may be given in severe cases, when lesions are near the limbus, or for suspected endophthalmitis, options include oral voriconazole, itraconazole, or fluconazole 200 mg.
- Tetracycline (e.g., doxycycline) may be given for its anti-collagenase effect when there is significant thinning.
- IOP should be monitored.

Surgical Therapy

Debridement and superficial keratectomy, although mostly of diagnostic benefit, may enhance the effectiveness of medical treatment.

Conjunctival flaps have been advocated for nonhealing ulcers and are often effective. Therapeutic keratoplasty (penetrating or deep anterior lamellar) is considered when medical therapy is ineffective or following perforation or impending scleral extension.

Prognosis

The prognosis varies depending on the depth and size of the lesion and the causative organism. In general, small superficial infections respond well to topical therapy. Deep stromal infections and infections with concomitant scleral or intraocular involvement are much more difficult to eradicate.

Three factors significantly associated with treatment failure of fungal keratitis: large ulcer size (greater than 14 mm), the presence of hypopyon, and Aspergillus as causative organism.

Epidemiology

Fungi may be part of the normal external ocular flora; they have been isolated from the conjunctival sac in 3–28% of healthy eyes in various series and can be recovered from diseased eyes with greater frequency (17–37%).

Aspergillus species are the most common organism responsible for fungal keratitis worldwide. However in the United States, Candida species is the most common etiology.

Overall, the incidence of fungal keratitis is low (6–20%). More reports of fungal keratitis originate from the southern United States, and it continues to be a disease most commonly encountered in patients who come from a rural setting.

Candle Power (Luminous Intensity)

Timo Eppig
Institute of Experimental Ophthalmology, Saarland University, Homburg, Germany

Definition

Candle power is a photometric measure of the quantity of light I [lm] emitted by a light source into a solid angle Ω [sr]. The unit for candle power is candela [cd] which is equal to [$lm \cdot sr^{-1}$]. Its physical definition as one of the base units in the International System of Units (SI) is the amount of light at a frequency of $540 \cdot 10^{12}$ Hz with an intensity of 1/683 $W \cdot sr^{-1}$.

Can-Opener Capsulotomy

► Can-Opener Technique

Can-Opener Technique

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Can-opener capsulotomy; Letter-box technique; Multipuncture capsulotomy

Definition

Technique of opening the anterior capsule by perforation, traditionally used in pediatric cataract surgery.

The terms describing the mentioned method derive either from the postage-stamp application technique or can-opener method.

Epidemiology

This technique has been largely superseded by the introduction of the capsulorhexis. Therefore, recent epidemiology is unknown.

History

Years after the introduction of anterior capsulotomy technique associated with intraocular lens implantation (IOL), Little and Pearce developed the multipuncture capsulotomy before Ganald and Baikhof established the envelope capsulotomy (horizontal) in 1979. Back then the can-opener technique came to common use.

Clinical Features

A bent-needle cystotome is stitched several times through the anterior capsule. Jointly punches form a circular opening.

Tests

See "► Cataract Surgery" entry.

Differential Diagnosis

Other capsular opening methods in the following are:

- Can-opener technique (letter-box technique): traditionally used in pediatric cataract surgery, for the planned extracapsular extraction, using a disposable or commercially available cystotome, several punctuations (60–80)
- Linear capsulotomy

  Capsulopuncture

Etiology

See "History" section above.

Treatment

The technique uses single stitches around the anterior capsule (60–80). After that, the edges of the anterior capsule show a jagged design which disappears shortly during retraction.

Canthal Reconstruction

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Medial and/or Lateral canthal reconstruction

Definition

Reconstruction of the medial and/or lateral canthal structures.

Indication

Canthal reconstruction is utilized for defects arising from cancer resection surgery (including Mohs surgery), trauma, involutional changes, or congenital deformities in the medial and/or lateral canthus. The goals of canthal reconstruction include recreation of a stable canthus with adequate eyelid support while maximizing cosmesis and symmetry.

Contraindication

Patients with significant trauma to the canthal regions should be evaluated for other injuries whose repair would take precedence, such as a ruptured globe. Incisions utilized in canthal

reconstruction can result in scarring of the canthal region and possible rounding or phimosis of the canthal angle.

Techniques and Principles

Techniques for canthal reconstruction are dictated by the extent of the defect and the structures involved.

Medial canthal injuries and defects are unique in that they may involve the lacrimal outflow system. A thorough evaluation of the lacrimal outflow system is of the utmost importance in evaluating medial canthal injuries, and any coexisting injury to these structures should be repaired at the time of canthal reconstruction. Injury to the medial canthal tendon often portends canalicular system injury, which should be evaluated and repaired. Repair of an avulsed medial canthal tendon can be achieved by multiple techniques depending on the status of the surrounding boney structures. The ultimate goal is that of recreation of a normal medial canthal region with a proper posterior vector of the medial canthal tendon to allow proper eyelid support for normal function. Suturing the tendon to the periosteum of the posterior lacrimal crest is often a mainstay of treatment. However, if significant boney trauma is also present as in the case of nasoethmoidal fractures, then techniques such as mini-plating or transnasal wiring may be required for proper reconstruction. Reconstruction then addresses any loss of anterior lamellar tissue. Options are varied and depend on the defect size and position but include secondary intention healing, direct closure, local advancement flaps, and full thickness skin grafts.

The ultimate goal of lateral canthal reconstruction is recreation of a lateral canthus with adequate anterior and posterior lamellar structures and a lateral canthal angle, which has a posteriorly directed vector and appropriate tension to allow adequate eyelid support for normal function. In cases of lateral canthal defects which also include full thickness eyelid defects, appropriate tarsal/canthal tendon substitutes must be used and can include free tarsal grafts, tarsal transposition grafts including lid sharing techniques, tarsal substitutes such as hard palate or nasal septum, or local periosteal flaps. Emphasis is on recreation of a lateral canthus with appropriate tension and vector direction (posteriorly directed, hugging the contour of the globe) achieved by ensuring the canthal tendon, or its substitute, is secured to the inner aspect of the lateral orbital rim periosteum in the region of Whitnall's tubercle. In cases with extensive injury, which can include underlying boney injury as well, for example, trimalar fractures which can displace the entire lateral orbital rim, the boney fractures must be repaired to allow adequate canthal reconstruction. If adequate periosteum in the region of Whitnall's tubercle is not present to allow proper lateral canthal tendon fixation, drill holes with wiring may need to be utilized. Anterior lamellar reconstruction can be achieved by various methods; the choice is partly dependent on whether a vascularized flap is required to support posterior lamellar free grafts which may have been used in the reconstruction. Options include direct closure, local rotational flaps (such as rhomboid flaps), local advancement flaps (such as Tenzel semicircular flaps or Mustarde cheek flaps), local transposition flaps including those from the upper or lower eyelids, and full thickness skin grafts.

Outcome

The goals of canthal reconstruction include recreation of a stable canthus and eyelids with adequate eyelid support to allow maximal function, cosmesis, and symmetry.

Complications

Incisions utilized in canthal reconstruction can result in scarring of the canthal region. Failure to achieve accurate canthal vectors can result in eyelid malposition including canthal dystopia, ectropion, and entropion. Secondary rounding and phimosis

of the lateral canthal angle can occur after surgery in this region. Weakening of the orbicularis oculi muscle may occur if there is injury to the zygomatic branch of the facial nerve.

Canthaxanthin, Retinopathy

Hadas Newman
Department of Ophthalmology, Tel-Aviv Sourasky Medical Center, Tel Aviv, Israel

Synonyms

Tanning pills retinopathy; β, β-Carotene-4; 4′-Dione retinopathy

Definition

Canthaxanthin is one of more than 400 naturally occurring carotenoids, which is synthesized by microorganisms and plants. It is found in fruits, vegetables (chanterelle mushrooms), some crustaceans and fish. Canthaxanthin is fat-soluble and accumulates in human tissue through dietary ingestion.

Due to its red-orange hue, canthaxanthin serves as an artificial food-coloring agent. It is associated with E number E161g and is approved for use as a food coloring agent in different countries, including the USA and Europe. The safety of canthaxanthin as a feed and a food additive has been evaluated; acceptable daily intake (ADI) is of 0.03 mg/kg bodyweight.

The bronzing effect of the skin induced by oral ingestion of canthaxanthin has led to therapeutic uses in photosensitivity disorders, such as erythropoietic protoporphyria, but also to its use as an artificial tanning agent, consumed in various tanning pills. Canthaxanthin has been a popular over-the-counter oral tanning agent in Europe, Canada, and Australia since 1979. However, due to related retinopathy, its use as a tanning agent has been banned in the USA by the Food and Drug Administration.

Canthaxanthin retinopathy was first described in 1982 by Cortin et al., after ingestion of high doses of canthaxanthin consumed as tanning pills. The level of canthaxanthin intake in the affected individuals was many times greater than that which could ever be consumed via poultry products. The retinopathy was characterized by accumulation of small (30 μ) birefringent golden crystals in the retina, mainly in the perifoveal area. Fluorescein angiogram demonstrates blocked fluorescence corresponding to the perifoveal crystals.

The described incidence of canthaxanthin retinopathy is 12–14%, although the true incidence may be higher due to the relative asymptomatic course. The risk for retinopathy is dose dependent, seen in 50% of patients consuming a total dose of 37 g and in 100% of patients consuming more than 60 g. Predisposing factors proposed are age, retinal pigment epithelial (RPE) defects, central serous chorioretinopathy, ocular hypertension, retinal vein occlusion, and concomitant use of beta carotene. An extensive reduction in the

number of crystals to complete disappearance has been documented up to several years upon termination of drug consumption.

Polarization microscopy of the retina in cynomolgus monkeys, treated with high and prolonged intake of canthaxanthin, demonstrated birefringent inclusions in the inner layers of the peripheral retina and to some extent, of the central retina. Inclusions were found in the retinal nerve fiber layer, ganglion cell layer, inner plexiform layer and inner nuclear layer, and, in a lesser extent, in the outer plexiform layer (but not in the outer nuclear layer, photoreceptors or RPE). In humans, canthaxanthin deposits were found in the inner layers of the retina using light and electron microscopy. Optical coherence tomography (OCT) has demonstrated crystals in the outer plexiform layer.

Most individuals with canthaxanthin retinopathy are asymptomatic, with normal visual acuity and color perception. Prolonged dark adaptation curve and reduced retinal sensitivity in threshold static perimetry have been described. Normal electroretinography (ERG) and electrooculogram (EOG) were documented in patients with canthaxanthin retinopathy as well as normal ERG in monkeys.

Cantholysis

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Canthoplasty; Inferior cantholysis; Superior cantholysis

Definition

An incision of either the inferior or superior limb of the lateral canthal tendon and lysis of the associated canthal ligamentous fibers.

Indication

Cantholysis is an integral component of multiple surgeries performed in the lateral canthal region. It is usually performed in conjunction with canthotomy. In the emergency management of orbital hemorrhage, canthotomy combined with inferior (and if needed superior) cantholysis allows decompression of the orbital compartment and hematoma evacuation. When combined with canthotomy, cantholysis allows additional horizontal eyelid mobility for closure of eyelid defects. Cantholysis is an integral step in the lateral tarsal strip operation for the management of

horizontal eyelid laxity. Inferior and/or superior cantholysis combined with canthotomy can allow improved access to the lateral anterior orbital space for orbital surgery.

Contraindication

Cantholysis, particularly when combined with horizontal shortening of the eyelid, can result in phimosis and rounding of the lateral canthus. Particularly in previously operated eyelids, weakening of the orbicularis oculi muscle may occur if there is injury to the zygomatic branch of the facial nerve.

Techniques and Principles

Cantholysis involves the incision and lysis of the inferior and/or superior canthal tendon and associated ligamentous fibers. Surgery begins with a canthotomy. Upon completion of the canthotomy, the lateral canthal tendon is composed of inferior and superior canthal tendon limbs. Cantholysis is then performed using Stevens scissors. The tendon, either inferior or superior, is strummed with the scissors and then cut close to the orbital rim. The ligamentous fibers of the canthal tendon are diffuse in their attachments to the orbital rim, and often even after lysis of the main portion of the canthal tendon, additional incision of these ligamentous fibers is needed to completely free the tendon and eyelid. Adequate cantholysis allows easy distraction of the lateral portion of the eyelid.

Outcome

At the completion of the procedure, the eyelid is freely mobile and easily distracted at the lateral canthus in all directions.

Complications

Cantholysis, particularly when combined with horizontal shortening of the eyelid, can result in phimosis and rounding of the lateral canthus, particularly in a multi-operated eyelid. Weakening of the orbicularis oculi muscle may occur if there is injury to the zygomatic branch of the facial nerve. Of particular note, in cases of emergency orbital hemorrhage management, improperly performed canthotomy and cantholysis will not allow adequate orbit decompression, hematoma evacuation, and potential vision preservation.

Canthotomy

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Canthoplasty; Lateral canthotomy

Definition

An incision of the lateral canthal tendon.

Indications

Canthotomy is an integral component of multiple surgeries performed in the lateral canthal region. It is usually performed in conjunction with either an inferior or superior cantholysis. In the emergency management of orbital hemorrhage, canthotomy combined with inferior (and if needed superior) cantholysis allows decompression of the orbital compartment and hematoma evacuation. Canthotomy, particularly when combined with cantholysis, allows horizontal eyelid mobility for closure of eyelid defects. Canthotomy is an integral first step in the lateral tarsal strip operation for the management of horizontal eyelid laxity. Canthotomy combined with inferior and/or superior cantholysis can provide access to the lateral anterior orbital space for orbital surgery.

Contraindication

A large canthotomy incision can result in scarring of the lateral canthal region and possible rounding or phimosis of the lateral canthal angle. Particularly in previously operated eyelids, weakening of the orbicularis oculi muscle may occur if there is injury to the zygomatic branch of the facial nerve.

Techniques and Principles

A scalpel or scissors are used to create a horizontal incision through the horizontal raphe at the lateral canthal angle (the lateral junction between the upper and lower eyelids). The incision is carried down to the lateral orbital rim to ensure the tendon is completely divided into inferior and superior limbs. Hemostasis is obtained with gentle cautery to the wound edges. Alternatively, some authors suggest utilizing a straight hemostat to cause a crush injury at the horizontal raphe prior creating the incision to achieve improved hemostasis.

Outcome

At the completion of the procedure, the lateral canthal tendon is divided into superior and inferior canthal tendon limbs.

Complications

A large canthotomy incision can result in scarring of the lateral canthal region and possible rounding or phimosis of the lateral canthal angle. Weakening of the orbicularis oculi muscle may occur if there is injury to the zygomatic branch of the facial nerve. Of particular note, in cases of emergency orbital hemorrhage management, inferior and/or superior cantholysis must be combined with the canthotomy to allow adequate orbit decompression and hematoma evacuation.

Capsular Bag

Martin Baumeister
Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany

Synonyms

Lens capsule

Definition

The capsular bag is the capsule of the crystalline lens. This term applies especially to the capsule after removal of its content by extracapsular cataract extraction or phacoemulsification, usually through a circular anterior opening (capsulorrhexis). In standard phacoemulsification cataract surgery an artificial intraocular lens is placed into the capsular bag.

Capsular Bag Opacification

Tanja M. Rabsilber and Gerd U. Auffarth
Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Synonyms

After cataract; Anterior capsule opacification (ACO); Posterior capsule opacification (PCO); Secondary cataract

Definition

Lens epithelial cells attached to the lens capsule which have not been removed during cataract surgery (extracapsular cataract extraction) are responsible for the development of capsular bag opacifications. The surgical trauma initiates a wound-healing response provoking changes in signaling potential of lens cells that results in a promotion of proliferation rates, increased cell matrix deposition, transdifferentiation, matrix contraction, and cell differentiation (Wormstone et al. 2009) resulting in pearl formations on or whitening and shrinkage of the capsule (Menapace 2005).

Histology

There are two different kinds of lens epithelial cells. The so-called E-cells can be found at the lens equator. These cells are very active in terms of mitosis, proliferation, and migration along the posterior capsule. The E-cells form the Elschnig's pearl or honey comb pattern of regeneratory posterior capsule opacification (PCO) which can lead to a significant reduction of visual acuity postoperatively (Apple et al. 1992; Pandey et al. 2004). It is considered a long-term complication after extracapsular cataract extraction as it becomes significant predominantly years after surgery.

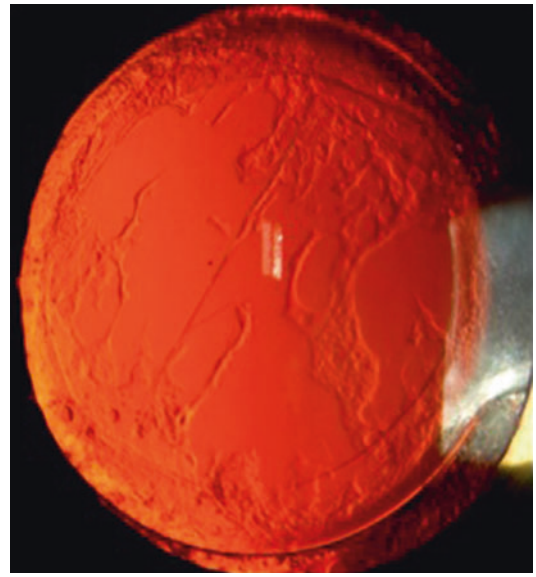
Capsular Bag Opacification, Fig. 2 Retroilluminated image: mild to moderate posterior capsule opacification



Capsular Bag Opacification, Fig. 3 Retroilluminated image: moderate posterior capsule opacification

Anterior capsule opacification (ACO), in contrast, derives from the anterior lens epithelial cells (A-cells) that cause fibrotic changes of the anterior capsule which can lead to shrinkage and whitening of the capsule (Menapace 2005). The A-cells differentiate into spindle-shaped, fibroblast-like cells and become highly contractile (Boulton and Saxby 2004). It can already be seen 3 to 6 months after surgery thus much earlier compared to PCO. Rhexis phimosis (capsule contraction syndrome) is defined as significant capsule contraction due to excessive fibrosis and can lead to secondary intraocular lens decentration (Menapace 2005). Some of these fibroblastic cells tend to migrate onto the posterior capsule as well as where they secrete

Capsular Bend

Tanja M. Rabsilber and Gerd U. Auffarth
Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Definition

Posterior capsule distension around the intraocular lens optic rim and fusion of the anterior and posterior capsule leaves within days to weeks after extracapsular cataract extraction through the production of fibrous tissue (Boulton and Saxby 2004).

Clinical Features

The capsular bending is effective in preventing posterior capsule opacification. The barrier effect is attributed to the mechanical pressure and/or the contact inhibition caused by the capsular bend (Menapace 2005). Residual fibers and epithelial cells are trapped in the space between anterior and posterior capsule. Due to continuous proliferation of lens epithelial cells and differentiation into

lens fibers in this sealed area, a Soemmering's ring formation is possible in the periphery (Boulton and Saxby 2004).

Maximal contact between intraocular lens optic and posterior capsule as well as a complete overlapping of the anterior capsule and the optic seem to be important factors for the bend formation (Menapace 2005). Its speed mainly depends on the intraocular lens design. Experimental studies of Nishi and coauthors showed the importance of the sharp optic edge design in terms of capsular bend formation regardless of the material. The authors concluded that the sharper the truncated optic edge, the sharper the capsular bend and the greater the preventive effect. Nishi et al. introduced the concept of the capsular bend index to quantify the time needed for fusion of the capsular leaves. Compared to hydrophobic and silicone IOL material, polymethyl methacrylate (PMMA) intraocular lenses showed a significant delay in capsular bend formation (Nishi et al. 2002, 2004).

Synonyms

Capsular bag distension syndrome

Definition

Capsular block syndrome (CBS) first described by Davison in 1989 is defined by a postoperative or intraoperative complication after continuous curvilinear capsulorhexis (CCC) with accumulation of fluid (Viscoelasticum Healon5) between the capsular bag and the intraocular lens. A classification of Miyake et al. divides the CBS into intraoperative, early-postoperative, and late postoperative appearance.

Etiology

The groups of the classification by Miyake et al. differ according to their pathogenesis, but they all show the same aspect of an accumulated liquefied substance within a closed chamber. The mentioned substance emerges when the nucleus of the intraocular lens or its optic occludes the anterior capsule opening created by the CCC method.

An intraoperative CBS may result from the shift of capsulorhexis due to the precedently moved nucleus by hydrodissection.

In case of an early-postoperative CBS, a transparent fluid is occurring on the capsule bag, which composes a closed chamber.

The late-postoperative CBS describes the accumulation of proteins produced by remaining lenticular epithelial cells; therefore, the content of capsule bag is milky and fuzzy.

Clinical Presentation

Poor vision by an unexpected overrefractive myopia caused by the anterior IOL movement with a flattening anterior chamber is the main symptom.

Following clinical features include anterior optic displacement, iris diaphragm, anterior chamber flattening, an increasing distance between the posterior capsule and the implant, and accordingly adherence of the anterior capsule to the implant. A persistent uveitis was occasionally described.

Diagnostics

Diagnostic instruments to detect the locked fluid or rather the distance between posterior capsule and intraocular lens are at first primarily the slit lamp or the Scheimpflug camera. A continuative method is the examination with ultrasound or biomicroscopy.

Differential Diagnosis

Differential diagnosis should be considered a secondary cataract, an over- or under-correction, and corneal surface problem.

Also the patients may be mistakenly diagnosed with pupil block glaucoma or endophthalmitis.

Prophylaxis

An efficient intraoperative elimination of viscoelastic material and lens particulates also behind the IOL is important to prevent capsular block syndrome.

An untreated eye may develop glaucoma, posterior synechiae, or posterior capsule opacification with debris in the capsular bag.

Therapy

The main treating principle is to drain the locked fluid by performing a posterior capsulotomy, for example, with the neodymium:YAG (Nd:YAG) laser. Another form of treatment is the intraoperative aspiration of viscoelastic fluid behind the IOL.

Prognosis

The visual prognosis after appropriate treatment is good in the absence of other eye diseases.

Capsular Tension Ring

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

An intraocular implant which allows the support of the capsular bag, maintaining its original contour. The application area comprehends, for example, zonulysis (zonular dehiscence,

generalized zonular weakness), lens subluxation, prophylaxis of lens decentration, pseudoexfoliation, sector kolobomas, aniridia, alleviation of primary posterior capsulorhexis, sulcus suture fixation, and combined cataract and vitreous surgery.

Epidemiology

The idea dates back to Hara et al. in 1991. They presented a closed and flexible ring consisted of silicone, which was not only to stop migration of lens epithelial cells (LEC) but also to antagonize the postoperative deformation of capsular bag.

At about the same time, the capsular tension ring was developed by Legler and Witschel and accordingly Nagamato and Bissen-Miyajima to reduce the contraction and to maintain the circular contour of capsule bag.

This open ring was made of rigid polymethyl methacrylate (PMMA).

Finally Legler et al. reported the first implantation of a capsular tension ring in the human eyes.

Clinical Features

All commercial available implants consist of polymethyl methacrylate and present an oval configuration with two bails on rings end. The caliber of comprimed ring is between 12.5 and 10 mm.

There are modifications of the original capsular tension ring like sulcus suture ring, capsular tension segment, capsular bending rings, and foldable closed ring.

CTRs can be inserted both bimanually, using a forceps and a Y-spatula, or with appropriate injectors.

Tests

Thorough examination of the eyes and workup of the patient's anamnesis is mandatory to rule out several exclusion criteria for cataract surgery or treatment of an after cataract.

Differential Diagnosis

Other implants that are used for indications named above are as follows:

- Sulcus suture rings (Cionni)
- Capsular tension segment (Ahmed)
- Capsular bending rings (Nishi-Menapace)
- Foldable closed ring (Dick)

Etiology

See History section above.

Treatment

A capsular tension ring should be implanted into the evacuated capsular bag following meticulous cleaning. Inserting the ring implant before phacoemulsification induces increased capsular torque and impedes aspiration of cortex fibers.

The use of an injector is more convenient; bimanual implantation minimizes capsular deformation and zonular stress and the risk of capsular entanglement.

Definition

A procedure in cataract surgery or posterior capsular opacification treatment to open the anterior or the posterior portion of the lens capsule.

Epidemiology

See entry "► Cataract Surgery."

History

See entry "► Cataract Surgery."

Clinical Features

According to the method a cystitome, an Nd:YAG laser (neodymium-yttrium-aluminum-garnet) or an vitrector is used.

Tests

Thorough examination of the eyes and workup of the patient's anamnesis is mandatory to rule out several exclusion criteria for cataract surgery or treatment of an after cataract.

Differential Diagnosis

See "Cross-References" section bottom.

Etiology

See "History" section above.

Treatment

The major performed anterior capsulotomy technique today is the continuous curvilinear capsulotomy (CCC) in phacoemulsification surgery. The major performed posterior capsulotomy procedure uses an Nd:Yag laser to clear and disrupt the central portion of the opacified posterior lens capsule.

Carbonic Anhydrase Inhibitors, for Cystoid Macular Edema

Ayala Polack, Efraim Berco and Yoel Greenwald
Department of Ophthalmology, Kaplan Medical Center, Rehovot, Israel

Cystoid Macular Edema

Cystoid macular edema (CME) is retinal thickening of the macula due to disruption of the blood-retinal barrier. Leakage causes accumulation of fluid in the retina, first intracellularly and later in the extracellular spaces leading to a distortion of photoreceptor architecture and decreased vision.

Carbonic Anhydrase Inhibitors

The primary pharmacologic effects of carbonic anhydrase inhibitors (CAIs) occur through the reversible, noncompetitive binding of the drug with the carbonic anhydrase (CA) enzyme. CA catalyzes the conversion of carbon dioxide and water to bicarbonate and protons and vice versa. There are two methods of CAI administration: systemic administration (acetazolamide and methazolamide) and topical administration (dorzolamide and brinzolamide).

Mechanism of Action

The mechanism by which CAIs reduce macular edema is not completely clear. Biologically plausible mechanisms with some experimental support include:

- **Promoting retinal adhesion** – CAIs decrease blood-retinal barrier leakage and stimulate the transport of small molecules such as fluorescein across the blood-retinal barrier.

- **Subretinal fluid absorption** – CAIs stimulate ion and water transport from the retina to the choroid. Animal studies have shown that CAIs increase the absorption of surgically induced subretinal blebs.
- **Subretinal PH changes** – CAIs decrease the pH in the subretinal space. The acidification induces changes in ion and fluid transport leading to a decrease in subretinal fluid (Joussen and Wolgensberger 2012; Salvatore et al. 2013).

Clinical Indications

The treatment response to CAIs seems better when the CME is caused by diffuse injury to the blood-retinal barrier along the retinal pigment epithelium (Wolfensberger 1999). The response of retinal edema to CAIs seems less promising when the damage to the blood-brain barrier is along the retinal vessels as occurs in diseases such as diabetes or retinal vein occlusions.

Clinical evidence supports the role of CAIs as a potential treatment option for CME associated with retinitis pigmentosa and chronic uveitis. Evidence for the use of CAIs for other indications is inconclusive as the present time.

Retinitis pigmentosa (RP) – RP is a clinically and genetically heterogenous group of hereditary retinal disease resulting in a progressive loss of photoreceptors and RPE cells, which leads to impaired night vision and gradual loss of visual fields. The reported prevalence of CME in RP patients varies between 10% and 40% of cases (Salvatore et al. 2013).

Oral CAIs: Multiple studies have shown improvement in vision and decreased retinal thickness with systemic administration of acetazolamide. The most common dose used in these trials is 250 mg twice daily (Rothova 2002).

Topical CAIs: Administration of 2% dorzolamide ophthalmic solution twice daily has also been investigated with conflicting results. Some studies show no significant benefit, while others demonstrate vision improvements in about 20% of participants.

Small trials have also demonstrated efficacy for CAIs in treating CME associated with other hereditary retinal dystrophies including juvenile X-linked retinoschisis, enhanced S-cone syndrome, and choroideremia.

Uveitis – CME is a major cause of visual loss in chronic uveitis. Clinical studies support the effectiveness of short-term (<4 weeks) CAI treatment at doses of up to 1000 mg of acetazolamide daily. Younger patients (< age 55) may be more likely to benefit from treatment.

Studies investigating the long-term effects of low-dose oral acetazolamide are promising and suggest it can be a useful therapeutic option for chronic CME in uveitis. The effect seems better in patients with CME with quiescent uveitis than in patients with concomitant chronic active uveitis (Ossewaarde-van and Rothova 2011).

Side Effects

Significant side effects have been reported with the use of oral CAIs. These include loss of appetite, fatigue, nausea/vomiting, diarrhea, bitter taste in mouth, dizziness, and paresthesias in the arms and legs. Chronic use can also rarely encourage the development of kidney stones. These side effects are caused through the systemic inhibition of carbonic anhydrase isoenzymes. Patients receiving long-term treatment should be monitored closely. Topical CAIs have a significantly better safety profile with mainly local side effects such as eye irritation.

Summary

Carbonic anhydrase inhibitors have a role in the treatment of cystoid macular edema. Treatment success depends largely on patient selection. Patients who respond best present with macular edema caused by fluid leaking diffusely through the retinal pigment epithelium. This may be the

case in hereditary retinal dystrophies such as retinitis pigmentosa and in chronic uveitis especially with quiescent inflammation. Oral treatment is often more efficacious than eye drops but carry a greater risk of systemic side effects. Patients on oral therapy need to be closely monitored, especially with chronic use. The role of CAIs is less clear when the cystoid macular edema is caused primarily by a disorder in the retinal vasculature, such as in diabetes and retinal vein occlusions.

Carcinoma In Situ, of Conjunctiva

Eli B. Moses
Department of Ophthalmology, University of Texas – Southwestern Medical Center, Dallas, USA
Corneal Associates of New Jersey, Fairfield, NJ, USA

Synonyms

Dyskeratosis; Bowen's disease; Conjunctival intraepithelial neoplasia (CIN); Conjunctival squamous dysplasia; Intraepithelial epithelioma

Definition

Defined by abnormal malignant appearing epithelial cells replacing the entire conjunctival stratified squamous epithelial layer. If these malignant appearing stratified squamous epithelial cells extend through the epithelial basement membrane and invade the substantia propria of the conjunctiva, it is characterized as invasive squamous cell carcinoma.

Basic Characteristics

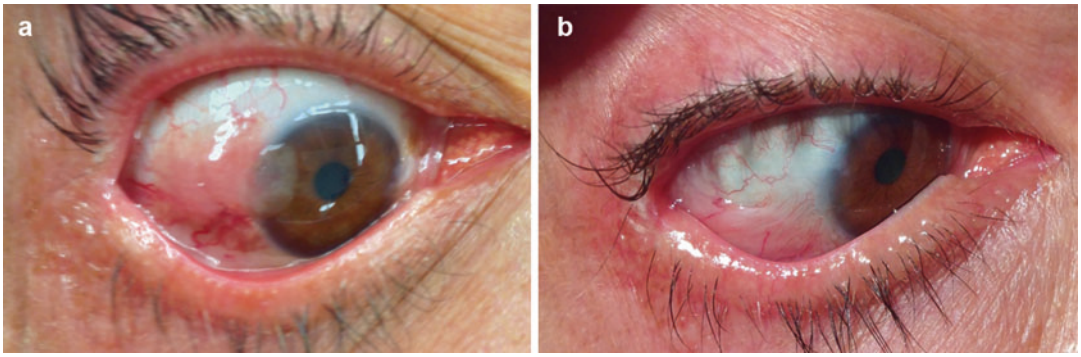
The etiology of CIN is uncertain and possibly multifactorial. The lesion most commonly develops on exposed areas of the bulbar conjunctiva, at the nasal or temporal corneoscleral limbus. Risk factors include male sex, advanced age, cigarette smoking, light complexion, prolonged sunlight exposure, and conjunctival infection by human papillomaviruses 16 and 18. In patients with AIDS, these lesions may undergo rapid growth. Immunosuppressed states seem to have a higher degree of squamous neoplasia (Lee et al. 1994).

Histology

Conjunctival tumors can range from benign hyperplastic and dysplastic lesions to malignant neoplasms. Histologically, CIN represents the presence of conjunctival epithelial dysplasia. The cells display a lack of normal organization and show an abnormal relationship to one another (polarity). In addition, cells do not mature normally as they approach the epithelial surface. If the abnormal, malignant appearing cells completely replace the conjunctival stratified squamous epithelium the term carcinoma in situ is used. If the basement membrane is penetrated, the malignant lesion is termed invasive squamous cell carcinoma.

Ocular Manifestations

Clinically these are slow-growing lesions. There are three common clinical variants. The *gelatinous* lesion consists of translucent thickening



Carcinoma In Situ, of Conjunctiva, Fig. 1 (**a**) Carcinoma in situ with visible feeder vessels and corneal overgrowth. (**b**) Two months after resection with wide margins, cryotherapy, and absolute alcohol debridement of affected cornea

that is usually not well defined. The *leukoplakic* lesion appears as a superficial white plaque pathologically representing hyperkeratosis. Only 10% will appear leukoplakic from surface keratinization. In the *papilliform* variant, a sessile papilloma contains dysplastic cells, clinically seen as a highly vascularized soft tissue mass (Erie et al. 1986). The lesions are generally located in the interpalpebral zone at the limbus. CIN or carcinoma in situ can often spread over the adjacent corneal surface (as seen in Fig. 1a and b). CIN can manifest as a pigmented tumor, resembling melanoma, due to the presence of intratumoral pigmented dendritic melanocytes. The larger the lesion, the greater the likelihood that it may be malignant. Large feeder blood vessels are also indicative of a high chance of epithelial basement membrane invasion (malignancy).

Evaluation

Given the slow growth of these lesions, patients will often be unaware of their existence. Any focal thickening of the conjunctiva, particularly when associated with prominent conjunctival vessels, should be assessed. Lissamine green and rose bengal can be used to help delineate tumor margins. Ultrasound biomicroscopy and more recently high-definition ocular coherence tomography can be used to assess scleral invasion. In any young adult, carcinoma in situ should prompt a serologic test for HIV infection.

Treatment

Suspicious lesions should be biopsied or completely excised. Excision should include 3–4 mm of surrounding benign appearing tissue. To reduce the risk of recurrence, double freeze-thaw cryotherapy to the conjunctiva adjacent to the lesion and to the scleral bed at the site of the excised limbal lesion frequently is performed. Any adjacent growth onto the cornea should be treated with absolute alcohol and removed. Greater than 90% long-term tumor control is achieved by this method (Shields et al. 2002).

Some advocates are using topical chemotherapeutic agents as a treatment or as an adjunct. Mitomycin C (0.02–0.04% solution) and 5- fluorouracil (1%) applied topically as eyedrops appear in some cases to completely eradicate CIN lesions (Shields et al. 2002). More recently, immunotherapy with interferon-a2b (0.5 mL 3 million IU/0.5 mL) has shown success with a far less toxic side effect profile (Karp et al. 2001).

Carotenes

▶ Carotenoids (Xanthophylls)

Carotenoid

▶ Beta Carotene, Use and Dosage of

Carotenoids (Xanthophylls)

Emily Y. Chew
Division of Epidemiology and Clinical Applications, National Eye Institute/National Institutes of Health, Bethesda, MD, USA

Synonyms

Carotenes; Organic pigments; Phytochemicals; Xanthophylls

Definition

Carotenoids, also known as phytochemicals, are fat-soluble plant pigments. They can be further classified as carotenes if they contain only hydrocarbons or xanthophylls if oxygen molecules are present along with the hydrocarbons (Bernstein et al. 2015). There are approximately 700 known carotenoids, while approximately 15–30 carotenoids are found in our bloodstream.

Carotenoids can absorb wavelengths from 400 to 500 nm, allowing them to absorb light energy for photosynthesis to provide protection from photo damage in plants. Carotenoids can also act as antioxidants. These include beta-carotene, alpha-carotene, beta-cryptoxanthin, and gamma-carotene. In the eye, the carotenoids which are also known as xanthophylls, lutein, and zeaxanthin are found in the macular pigment (known as the *macula lutea*). They may play important functions in the eye with their anti-oxidative capabilities and their ability to absorb damaging light from the blue and near ultraviolet spectrum.

Indication

Beta-carotene, a carotene, was tested for the prevention of lung cancer in two large NIH-supported trials in persons who were cigarette smokers or who had exposure to asbestos, both major risk factors for the development of lung cancer. Both studies showed that beta-carotene in fact increased the risk of lung cancer and mortality.

Beta-carotene was also tested in the Age-Related Eye Disease Study (AREDS) as part of a formulation of antioxidants including vitamins C and E along with zinc and copper. AREDS was originally designed as a study of the natural course and prognosis of age-related macular degeneration (AMD) and age-related cataract. The nutritional component was tested with a randomized controlled clinical trial, a 2 × 2 factorial in which the 4,757 participants were enrolled. For those with risk of AMD, they were randomized to vitamins C (500 mg) and E (400 international units), beta-carotene (15 mg) or zinc (80 mg as zinc oxide) with copper (2 mg as cupric oxide), or the combination of the vitamins and minerals. The so-called AREDS formulation was demonstrated to be beneficial for the treatment of age-related macular degeneration with a 25% reduction in the risk of having late

AMD in 5 years (Age-Related Eye Disease Study Research Group 2001).

During the course of AREDS, beta-carotene was found, as previously noted, to increase the risk of lung cancer in those enrolled in 2 NIH-supported trials of lung cancer in persons who are known to be heavy smokers or were previously exposed to asbestos. Lutein was the desired carotenoid to be studied in AREDS, but it was not commercially available when AREDS started. Observational data in AREDS also suggested that dietary lutein reduced the risk of prevalent late AMD, both neovascular and atrophic form. Thus the Age-Related Eye Disease Study 2 was initiated to evaluate the effect of adding lutein/zeaxanthin and/or omega-3 fatty acids to the AREDS formulation. Beta-carotene was found to be deleterious for former smokers in AREDS2, with a doubling of the risk of lung cancer. We have essentially replaced beta-carotene with the xanthophylls, lutein, and zeaxanthin in this formulation (Age-Related Eye Disease Study 2 Research Group 2013b). This makes biological sense as these two xanthophylls are found in the macular pigment. Both lutein and zeaxanthin are thought to be important because of their anti-oxidative capabilities and their ability to absorb damaging wavelengths of the blue and UV spectrum. Addition of lutein and zeaxanthin also resulted in an incremental beneficial effect in reducing the risk of progression to late AMD, especially the neovascular form (Age-Related Eye Disease Study 2 (AREDS2) Research Group et al. 2013a).

Indications: AREDS/AREDS2 formulations are recommended for persons with intermediate AMD (bilateral large drusen) or late AMD in one eye. Those persons with less than intermediate AMD do not benefit as these formulations do not reduce the risk of progression from early to intermediate or along the AMD scale developed from AREDS. Offsprings of those affected with AMD may be better served by having regular dilated eye exams to detect the presence of intermediate AMD. At that point, AREDS/AREDS2 formulation would be recommended.

Recently, investigators have evaluated genetic interaction with the AREDS formulation in a subgroup of AREDS participants who had genetic testing. These investigators have promoted the use of genetic testing to avoid taking zinc with specific *complement factor H* mutations. These results could not be replicated by the AREDS research team. Neither genetic testing nor avoidance of zinc in persons with intermediate AMD or late AMD in one eye is recommended. Such patients should be recommended to take the AREDS/AREDS2 formulation. Zinc alone has never been recommended as a treatment, and only the combination of antioxidant vitamins and zinc should be prescribed for those at risk. The American Academy of Ophthalmology has not recommended genetic testing for AMD, and it is not indicated prior to starting AREDS/AREDS2 formulations. Other experts in the field of genetic, epidemiology, and statistics have also weighed in with the same conclusion (Wittes and Musch 2015). Genetic testing is still reserved for research purposes.

Synonyms

Cavernous-carotid fistula; CC fistula; CCF

Definition

Carotid-cavernous fistulas (CCFs) are pathological vascular shunts where arterial blood flows directly or indirectly from the carotid artery or its branches into the cavernous sinus. CCFs can be broadly classified based on their hemodynamic characteristics, etiology, and anatomy. Hemodynamically, CCFs are divided into high-flow and low-flow fistulas. Etiologically, CCFs can be divided into spontaneous, nontraumatic and traumatic lesions. Anatomically, CCFs may be classified into direct CCFs (those that arise directly from the carotid artery) and indirect CCFs (those that arise from meningeal branches of the carotid artery). Most commonly, CCFs are divided into four types (Barrow classification).

A. Type A CCFs are direct, high-flow lesions in which the internal carotid artery (ICA) is directly connected to the cavernous sinus. Type A CCFs arise from a direct tear in the ICA wall that results from an intracavernous aneurysm rupture or trauma (including iatrogenic surgical trauma).
B. Type B CCFs are indirect, low-flow lesions arising from external carotid artery (ECA) meningeal branches.
C. Type C CCFs are also indirect, low-flow lesions but arise from ICA meningeal branches.
D. Type D CCFs are indirect, low-flow lesions arising from both ECA and ICA meningeal branches.

Etiology

A basic understanding of the cavernous sinus anatomy is required before introducing the etiologies of CCF. The cavernous sinus is a trabeculated venous cavity invested by the dura mater located lateral to the sella turcica. The cavernous sinus contains several vascular and neural structures including the ICA and multiple cranial nerves (CN) III, IV, V1, V2, and VI as well as the ocular sympathetic innervation (producing a Horner syndrome). CN VI (i.e., abducens nerve) runs lateral to the ICA and medial to the dural wall but within the substance of the cavernous sinus while the rest of the CNs (II, IV, V1, and V2) course in the lateral wall of the cavernous sinus between the two dural layers.

The cavernous sinus normally receives drainage from the superficial Sylvian vein, the superior

and inferior ophthalmic veins, and the sphenoparietal sinus. Laterally, the middle meningeal vein drains into the cavernous sinus. The cavernous sinus then drains posteriorly via the superior and inferior petrosal sinuses to the internal jugular vein. Anastomoses connecting the two cavernous sinuses include a basilar plexus of veins and an intercavernous sinus (Moore et al. 2010).

Etiologically, CCFs can be divided into traumatic and spontaneous types.

I. Traumatic CCFs

Traumatic CCFs account for up to 75% of all CCFs and they are the most common type (Type A CCF). Traumatic CCFs are most commonly seen in young male patients due to the male predominance in trauma. Traumatic CCFs can result from craniocerebral trauma and closed head injury-associated basilar skull fracture. However, they could also be a seen in projectile, perforating, or penetrating intracranial injuries. The traumatic bony fracture or shear forces can directly tear the internal carotid artery. Alternatively, a sudden increase in ICA intraluminal pressure and a concurrent distal artery compression lead to vessel wall rupture, resulting in a high-flow communication with the cavernous sinus.

II. Spontaneous CCFs

Spontaneous CCFs account for up to 30% of all CCFs in some series. In contrast to traumatic (direct, high flow) CCFs, spontaneous CCFs are typically found in older female patients, although patients of any gender and age can be affected by spontaneous CCFs. A common source of spontaneous, nontraumatic, high flow, direct CCF is a ruptured cavernous ICA aneurysm. Additionally, many genetic conditions with arterial wall defects predispose patients to spontaneous CCFs, including fibromuscular dysplasia, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum. It is also proposed that microscopic venous thrombosis or increased venous pressure could cause microscopic breaks in dural vessels in the sinus and facilitate fistula formation.

Clinical Presentation

The clinical presentation of direct CCFs is caused by the pooling of highly pressurized arterial blood into the cavernous sinus, leading to venous hypertension. Direct CCFs usually have an acute and dramatic clinical presentation. The classic triad of symptoms consists of exophthalmos; cephalic or orbital bruit; and conjunctival congestion, congestion, and arterialization of vessels. Patients often complain of visual disturbances, most commonly diplopia, blurry vision, and orbital pain. Ophthalmoplegia and other cranial nerve deficits are also commonly seen in these patients. Some patients may experience facial weakness and/or facial pain. Elevated orbital venous pressure, iris and choroid congestion, and forward displacement of iris-lens diaphragm also may lead to angle-closure glaucoma. In some cases, chronic ischemia may produce neovascular glaucoma. Ophthalmoscopic findings might include venous stasis retinopathy with intraretinal hemorrhages, central retinal vein occlusion, proliferative retinopathy, retinal detachment, vitreous hemorrhage, choroidal folds, choroidal effusions, choroidal detachment, or optic disc swelling. The progression of direct CCFs is rapid and patients require urgent treatment.

In contrast, the clinical presentation of indirect CCFs is more insidious and less obvious. Indirect CCFs may not have the complete classic triad of symptoms associated with direct CCFs, and the exact pattern of symptoms depends on the characteristics of the indirect CCF, including the rate of flow, the pressure within the sinus, the location of venous drainage, and the size of the fistula. It is important to note that venous drainage patterns often change with development and resolution of thrombosis.

Anterior draining CCFs drain anteriorly into the orbit via the inferior and superior ophthalmic veins. They are the most common type of indirect CCFs and have similar but less severe symptoms than those of direct Type A CCFs. Patients with anterior draining CCFs usually present with ocular and orbital symptoms (e.g., chemosis, conjunctival injection, ophthalmoplegia, and proptosis). Diplopia may also be present if cranial

nerves or extraocular muscles are involved. A loss of vision may be present from increased intraocular pressure due to orbital venous congestion resulting in glaucoma, venous retinopathy, and ischemic optic neuropathy. However, there is often no objective or subjective bruit, and in the mildest cases there is redness of one or rarely both eyes from arterialization and dilation of conjunctival and episcleral veins. The dilated vessels have a typical tortuous corkscrew appearance of arterialization of the conjunctival/epsicleral vessels that distinguishes indirect CCFs from other diagnoses such as conjunctivitis.

Indirect CCFs that drain posteriorly into the superior and inferior petrosal sinuses may be asymptomatic. Most cases do not have any signs of orbital congestion (i.e., "white eyed shunt"), but in some cases the fistula may produce any combination of ocular motor cranial neuropathy. Patients who have ocular motor nerve paresis caused by posteriorly draining indirect CCF usually only have one affected ocular motor nerve, most commonly the oculomotor nerve (CN III). In most cases, the presentation of paresis is associated with ipsilateral orbital or ocular pain. Furthermore, some cases of posteriorly draining CCFs can cause brainstem congestion and lead to neurologic deficits.

Diagnosis

Cerebral angiography is the gold-standard imaging modality to diagnose CCFs, but patients typically undergo cranial and orbital contrast CT and MRI first. For both direct and indirect CCFs, CT and MRI findings include proptosis, enlargement of the extraocular muscles, enlargement and tortuosity of the superior ophthalmic vein, and enlargement of the ipsilateral cavernous sinus. CT and MRI studies may show dilatation of leptomeningeal and cortical veins in patients with high-flow fistula and retrograde cortical venous reflux. Furthermore, cerebral edema or hemorrhage may be seen in patients with cerebral venous congestion.

Confirmation of the diagnosis of CCF, however, is established by catheter cerebral angiography. Cerebral angiography is also crucial in classifying the CCF, delineating the patterns of venous drainage (including possible cortical venous drainage), and planning the optimal treatment (typically endovascular occlusion). Four-vessel cerebral angiography is done using transfemoral arterial catheterization with imaging of bilateral common carotid arteries (CCAs), ICAs, ECAs, and vertebral arteries.

Differential Diagnosis

1. Chronic conjunctivitis
2. Blepharoconjunctivitis
3. Dysthyroid orbitopathy
4. Orbital inflammatory pseudotumor
5. Orbital cellulitis
6. Episcleritis
7. Sphenoorbital meningioma
8. Tolosa-Hunt syndrome
9. Cavernous sinus thrombosis

Therapy

I. Direct CCF Treatment

The goal of treating direct CCFs is to occlude the fistula while preserving ICA patency if possible. Specific types of treatment will depend on the anatomy of the fistula and the clinician preference. The following are available therapies for direct CCF:

1. Transarterial embolization consists of advancing a catheter and microcatheter in the cervical carotid artery to the cavernous segment of the ICA. Embolic agents include detachable platinum coils, as well as liquid embolic agents such as n-butyl cyanoacrylate (*n*-BCA). Onyx or combinations of these agents can be used to occlude the fistula.
2. Transvenous embolization involves assessing the cavernous sinus from the venous end, such as via the inferior petrosal sinus or superior ophthalmic vein. Once at the site of fistula, detachable platinum coils or liquid embolic agents are used to occlude the site of fistula.

3. Porous stents and coils may be used alone or in combination with other embolization materials to treat large arterial tears. Self-expanding stents can also be used to reconstruct the injured ICA that caused the direct CCF.
4. Covered stents can also be used to obliterate direct CCFs by acting as an impermeable barrier across the fistula while preserving ICA patency.
5. Surgical arterial sacrifices are done for direct CCFs caused by extensive ICA injury not amenable to endovascular occlusion. It is possible that the arterial segment with the fistula might need to be occluded distally and proximally.

II. Indirect ICF Treatment

The treatment goal of indirect CCFs is to decrease the pressure in the cavernous sinus by occluding the fistulous communications. The following are treatment options for indirect CCF:

1. Carotid self-compressions are manual compression of the carotid artery about four to six times per hour for a period of 10 s each. It is particularly effective in patients with low flow fistulas in the anterior cavernous sinus and in patients with short duration of symptoms and low intraocular pressures. Contraindications include patients with declining visual function, high intraocular pressure, intolerable periocular pain, hypertensive carotid sinus syndrome, atherosclerosis stenosis, ulceration of the cervical artery, and history of cerebral ischemia. It is advised to use the contralateral hand so that if ipsilateral cerebral ischemia were to occur from compression of the ICA then the resulting hemiparesis would allow the compressing hand to fall away from the ICA.
2. Transarterial embolization is a good treatment option for indirect CCFs, but distal access into tiny feeder vessels is often difficult and may require multiple sessions.
3. Transvenous embolization is becoming the preferred treatment of indirect CCFs, and the superior ophthalmic vein can be sometimes directly accessed to treat the CCF.

Prognosis

With complete endovascular or other closure of CCF, symptoms such as chemosis and proptosis typically resolve within hours to days, while cranial nerve palsies will resolve over the course of weeks to months. Vision recovery depends on the pathogenesis, severity, and duration of deficits before intervention. Patients who suffer visual loss due to choroidal effusion or choroidal detachment may have recovery of visual function, while patients with visual loss caused by retinal or optic nerve damage may have persistence of their visual loss (Miller 2012). Recurrences of CCFs are uncommon postembolization but could be treated with repeat embolization (Ellis et al. 2012).

Carpenter Syndrome

Rabia Karani
Johns Hopkins School of Medicine, John Hopkins University, Baltimore, MD, USA

Synonyms

Acrocephalopolysyndactyly type II; Carpenter's syndrome

Definition

Carpenter syndrome is a congenital disorder classically characterized by variable syndactyly and polydactyly (particularly preaxial polydactyly of the toes), obesity, and variable craniosynostosis (Gorlin et al. 2001).

Etiology

Carpenter syndrome is a rare, autosomal recessive disorder caused by a homozygous mutation in the RAB23 gene on chromosome 6p11. The Rab23 protein regulates the Hedgehog signaling pathway, and several key features of Carpenter syndrome such as polysyndactyly and brachydactyly are seen in other disorders associated with defective Hedgehog pathway signaling. Craniosynostosis, obesity, and other abnormalities associated with Carpenter syndrome have not shown to be implicated in the Hedgehog pathway, but further research is needed (Jenkins et al. 2007).

Clinical Presentation

Even within families, manifestations of the syndrome are highly variable.

Craniosynostosis and Central Nervous System

Carpenter syndrome patients typically present with craniosynostosis of the metopic, lambdoid, coronal, or sagittal sutures, along with possible acrocephaly. In most forms of congenital craniosynostosis, the coronal sutures are affected. However, in Carpenter syndrome, it is the midline sutures (particularly metopic and sagittal sutures) that are commonly fused. In severe cases, patients can present with cloverleaf skull (Jenkins et al. 2007). The calvaria may also be deformed, and unilateral involvement of the coronal or lambdoid sutures can produce asymmetry. Wormian bones have appeared in the anterior fontanel in a few cases. Mental retardation is a common characteristic of the syndrome, but patients with normal intelligence have been observed (Gorlin et al. 2001).

Hands and Feet

Syndactyly, polydactyly, and brachydactyly of the fingers and toes are typically present, and a characteristic feature of Carpenter syndrome is preaxial polydactyly of the toes (Robinson et al. 1985). Patients may also present with a single palmar crease, brachydactyly, and clinodactyly. Postaxial polydactyly and soft-tissue syndactyly between the third and fourth finger have been observed. Soft-tissue syndactyly may be present in the toes as well (Gorlin et al. 2001). Double toenails and whorls in the bones of the fingers and toes have also been noted (Robinson et al. 1985).

Craniofacial

Facial deformities including ocular, auricular, and mandibular deformities are common features. Ocular deformities include dystopia canthorum and mildly downslanting palpebral fissures, epicanthic folds, ▶ microcornea disease, corneal opacity, slight optic atrophy, and blurring of disk margins. Auricular deformities include preauricular fistula and low-set ears. Mandibular deformities include small mandible and arched or narrow palate, often leading to serious problems with dentition.

Cardiovascular

Congenital heart defects are common and include tetralogy of Fallot, ventral septal defect, atrial septal defect, and patent ductus arteriosus. Deformities of the great vessels and duplication of the superior vena cava have also been noted in a few cases.

Other Abnormalities

Other common features include obesity, hypogenitalism, and umbilical hernia. Common skeletal abnormalities include genua valga, patellar displacement, absent coccyx, spina bifida occulta, flaring of the ilia with poor development

of the acetabula, kyphosis, and scoliosis. Hydronephrosis, hydroureter, inguinal hernia, and accessory spleens have also been reported in a few cases. Patients usually have short necks, and many have short stature (below the 25th percentile), but may in certain cases be above the 60th percentile (Gorlin et al. 2001).

Diagnostics

Clinical observation and genetic testing can be used to confirm the diagnosis. CT scanning and MRI are performed prior to surgery. Fundoscopic examination is necessary to test for papilledema as a result of increased intracranial pressure (Davis et al. 2011).

Differential Diagnosis

Differential diagnoses include Apert syndrome, Bardet-Biedl syndrome, and Sanjad-Sakati syndrome (Gorlin et al. 2001). The critical period of development of Carpenter syndrome occurs between the 30th and 49th day of gestation, usually at a later stage than Apert syndrome but at an earlier stage than Bardet-Biedl syndrome, and therefore has overlap with characteristics of both disorders (Hidestrand et al. 2009). Examples of Carpenter syndrome include Summit syndrome and Goodman syndrome (acrocephalopolysyndactyly type IV) (Gorlin et al. 2001).

Prophylaxis

Unclear.

Therapy

Early surgical correction of craniosynostosis is performed before the 1st year of age to reduce intracranial pressure, enhance appearance, and prevent brain injury (though surgical intervention has not been shown to prevent mental retardation). Surgical intervention may also be necessary for syndactyly and polydactyly, umbilical hernia, and congenital heart defects among other abnormalities. Follow-up support by psychologists, genetic therapists, neurologists, ophthalmologists, otolaryngologists, cardiologists, and physical therapists may be necessary (Gorlin et al. 2001; Davis et al. 2011).

Prognosis

Prognosis of the disease is dependent on the management of associated symptoms. With proper surgical intervention and monitoring of other defects, children can live into adulthood. A single case of survival to adulthood with no surgical intervention has been reported. This case is a representation of the natural progression of Carpenter syndrome. A few of the problems that the patient suffered from included mental retardation, kyphosis, dental problems, congestive heart failure, chronic epiphora which lead to recurrent pneumonia, and optic nerve atrophy due to shallow orbits. The patient died at the age of 26 from complications related to Carpenter syndrome (Robinson et al. 1985; Hidestrand et al. 2009).

Epidemiology

Incidence of the syndrome is 1:1,000,000 of live births, and approximately 50 cases have been reported in the literature. Carpenter syndrome was first described in 1901 by Carpenter and characterized as a separate disorder by Tetamy in 1966 (Gorlin et al. 2001). Ten patients with the disease have been found to have Northern European descent. Both sporadic instances and cases of affected siblings have been reported (Jenkins et al. 2007).

Cat Scratch Disease

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Cat scratch fever; Inoculation lymphoreticulosis; Subacute regional lymphadenitis; Teeny's disease

Definition

Cat scratch disease (CSD) is an infectious disease commonly caused by *Bartonella henselae* (Ormerod and Dailey 1999). It is characterized by self-limited regional lymphadenopathy and can have visceral organ, neurologic, and ocular involvement.

Etiology

Cat scratch disease is primarily caused by *Bartonella henselae* (Cunningham and Koehler 2000). *B. henselae* is a gram-negative, nonmotile, aerobic pleomorphic bacillus (Florin et al. 2008). In the genus *Bartonella*, *B. bacilliformis*, *B. quintana*, *B. elizabethae*, *B. vinsonii*, and *B. koehlerae* may also cause CSD.

Cat exposure has been linked to CSD (Windsor 2001). Domestic cats are the natural reservoir and vectors of transmission of *B. henselae*. Transmission to humans occurs via a cat bite or scratch. Contact with kittens under 1 year of age has been documented in roughly 90–95% of CSD cases. Fleas have also been implicated in transmission of the bacteria and as the cause of CSD. Person-to-person transmission has not been documented.

Clinical Presentation

Individuals with cat scratch disease may present initially with a cutaneous lesion at the site of inoculation of the bacteria (Wear et al. 1983). The lesion usually develops after 3–10 days and generally evolves through vesicular, erythematous, and papular phases. Patients may present with regional, unilateral lymphadenopathy in the head, neck, or upper extremities about 1–7 weeks after animal contact (cat bite/scratch). Over 90% of cases include swollen lymph nodes. Additional symptoms include headache, fever, fatigue, abdominal pain, and possible rash. Very rarely is there extranodal dissemination of the disease.

Ocular involvement of CSD may take many forms, including Parinaud's oculoglandular syndrome, neuroretinitis, optic neuritis, and focal retinochoroiditis (Cunningham and Koehler 2000).

Parinaud's oculoglandular syndrome occurs in 2–8% of patients with CSD (Ormerod and Dailey 1999). Transmission may be directly from cat contact with the eye or hand-to-eye contact. The syndrome includes conjunctivitis, conjunctival granuloma, and adjacent preauricular lymphadenopathy (Lange and Gareis 2007). Eyelid swelling may be associated with severe reactions but

pain is uncommon. The primary granuloma disappears in several weeks, while regional lymphadenopathy resolves more slowly over months. It very rarely results in serious complications.

Neuroretinitis occurs in 1–2% of patients with CSD (Ormerod and Dailey 1999). It is an acute, unilateral visual loss from optic nerve edema associated with macular exudates. Visual acuity may vary from 20/20 to light perception and may worsen over the first several days. A relative afferent pupillary defect and a cecocentral, central, or arcuate visual field defect are typically present. CSD and *B. henselae* are the most common causes of neuroretinitis (Cunningham and Koehler 2000).

Many individuals with ocular manifestations of CSD may also develop retinal white dot syndrome (Ormerod and Dailey 1999). There are retinal infiltrates bilaterally that are round, white, and homogenous. They are a useful indicator of *B. henselae* infection and typically resolve without treatment in 2–3 weeks.

CSD can cause optic neuritis and must be considered on the differential when concerned for causes of optic neuritis.

Retinovascular syndromes are also associated with CSD. Cases of retinal vasculitis, peripapillary angiomatosis, and retinal arteriolar and venular occlusions have been reported in patients with CSD.

Diagnostics (Lab Diagnostics)

CSD is diagnosed typically from clinical findings and laboratory evaluation for confirmation. Exposure to cats is found in roughly 90% of patients with CSD (Cunningham and Koehler 2000).

The primary site of inoculation and regional lymphadenopathy must be determined for appropriate diagnosis (Ormerod and Dailey 1999). Lymph node biopsy and Warthin-Starry silver staining may be conducted if necessary. Further, blood culture samples may be taken to assess for *B. henselae. B. henselae* is a slow-growing, fastidious gram-negative bacterium that requires specific laboratory conditions for optimal growth. Blood culture samples should be collected in tubes containing EDTA to increase the probability of isolating *B. henselae*. Plating onto either chocolate agar or heart infusion agar enhances isolation of organisms.

Two serologic methods, the indirect fluorescence assay (IFA) and enzyme immunosorbent assay (EIA), may be used for diagnosis.

Additional lab tests – transient mild leukocytosis, with increased neutrophils and sometimes eosinophils, and elevated erythrocyte sedimentation rate – may occur.

Differential Diagnosis

Differential diagnosis include infectious and malignant causes of lymphadenopathy; malignant causes including lymphoma, Kaposi's sarcoma, and angiosarcoma; infectious including mycobacterial diseases, Lyme disease, coccidioidomycosis, *Nocardia*, *Bacillus anthracis*, syphilis, leishmaniasis, toxoplasmosis, and viral-associated lymphadenopathy; and noninfectious including cysts and sarcoidosis.

Prophylaxis

Unclear. Care with cats

Therapy

Most immunocompetent patients clear the disease on their own without medical intervention. Symptomatic treatment with analgesics or hot compresses may be recommended in patients with mild/moderate CSD (Windsor 2001).

If antibiotics are required, azithromycin, ciprofloxacin, rifampin, or doxycycline may be used (Ormerod and Dailey 1999). No optimal therapy is known for neuroretinitis.

Prognosis

Outpatient follow-up is recommended for assessing lymphadenopathy resolution. Overall,

there is a positive prognosis expected for patients (Ormerod and Dailey 1999). Depending upon severity of illness, immunocompromised patients may require hospitalization after CSD.

Epidemiology

Cat scratch disease appears to be transmitted primarily from a cat scratch/bite, but may be transmitted by fleabites (Windsor 2001). Cats are the main reservoir for *B. henselae*. Children and adolescents make up the majority of those infected by CSD. Immunosuppressed individuals are at higher risk of CSD and disseminated infection.

There are about 24,000 cases of CSD annually. CSD appears to have a broad international and North American distribution. The incidence is greater in regions with higher temperatures and humidity (e.g., Pacific Northwest, southeastern states). CSD tends to peak during the fall and early winter.

Synonyms

Cat scratch fever

Definition

Flulike illness associated with regional adenopathy and in some cases followed by neuroretinitis or Parinaud's oculoglandular syndrome (POGS). It is usually caused by *Bartonella henselae* which is transmitted by cats.

Background

Bartonella henselae, gram-negative rod, is the principal etiologic agent of cat scratch disease (CSD) and is associated with an expanding spectrum of ocular manifestations. *B. henselae* is 1 of 21 Bartonella species. Of these 21, 8 species have been found to cause human diseases, 4 of which (*B. henselae*, *B. quintana*, *B. grahamii*, and *B. elizabethae*) have been linked to ocular complications. CSD is a feline-associated zoonotic

disease, and cats are the primary mammalian reservoir of *B. henselae*.

Cat-to-cat transmission of *B. henselae* is mediated by the cat flea, but the role of fleas in transmission of infection to humans is unknown. CSD is transmitted to humans by the scratches, licks, and bites of domestic cats, particularly kittens. CSD follows a seasonal pattern, occurring predominantly in the fall and winter. Human-to-human transmission has not been reported.

Epidemiology

CSD is found worldwide and its prevalence has been estimated to be 9.3 per 100,000 persons.

Over 90% of patients report a history of having been scratched by a cat, often a kitten. Children younger than 10 years of age are particularly susceptible to CSD, constituting nearly 80% of cases.

Systemic Involvement

Systemic manifestations of CSD include a mild to moderate flulike illness associated with regional adenopathy that usually precedes the ocular manifestations of the disease. An erythematous papule, vesicle, or pustule usually forms at the primary site of cutaneous injury 3–10 days after primary inoculation and 1–2 weeks before the onset of lymphadenopathy and constitutional symptoms.

Ocular Involvement

Ocular involvement occurs in 5–10% of patients with CSD and occurring 1–4 weeks postinfection.

Anterior Segment

Approximately 4% of patients with symptomatic CSD suffered Parinaud's oculoglandular syndrome (POGS). The typical presentation of POGS includes conjunctival injection, serous discharge, and foreign body sensation. A granulomatous nodule, usually unilateral, develops in the palpebral conjunctiva, surrounded by follicles, intense chemosis, and injection. The nodule may be single, flat and large, or multiple and raised. The fornices and bulbar conjunctiva may also be involved. The granuloma disappears over the period of weeks and leaving no scar.

Corneal involvement usually consists of superficial punctate keratitis (SPK) but rarely causes significant keratitis.

Posterior Segment

Posterior segment involvement occurs in 1–2% of patients with CSD. The presentation is most often unilateral. Visual acuity loss varies between 6/6.5 and 6/60 or worse, 2–3 weeks after the onset of constitutional symptoms. Posterior segment includes neuroretinitis, retinitis, choroiditis, vasculitis, vascular occlusions, intermediate uveitis, panuveitis, and macular hole, and even serous retinal detachments have been reported.

Neuroretinitis

Neuroretinitis is a form of optic neuropathy characterized by optic disk swelling in the presence of a partial or complete macular star. Two to 4 weeks after the optic disk edema, there is an appearance of macular star. The development of the macular star is variable and may be partial or incomplete, usually resolving in approximately 8–12 weeks. When incomplete, a partial macular star is usually seen nasal to the fovea. Macular exudates remain stable for several weeks, after which a gradual regression begins, the most extensive macular exudates may take up to 12 months to resolve. Usually, patients regain most of their visual function; however, some patients suffer from decreased contrast sensitivity and dyschromatopsia.

Multifocal Retinitis and Choroiditis

Several forms of choroiditis and retinitis have been reported in CSD, some of which may mimic other retinochoroidal conditions. Diffuse choroiditis associated with CSD has been reported to cause multiple pinpoint leaks on fluorescein

angiography (FA). Multifocal retinitis in cat scratch disease may also present as bilateral, multiple, intraretinal white infiltrates, 100–300 μm in size, resembling one of the white dot syndromes. The white dots usually clear after 2–3 weeks without a trace. The presence of multifocal retinitis and/or choroiditis can be a clue to the diagnosis of *B. henselae* infection in cases of optic disk edema when associated with peripapillary serous retinal detachment, especially when subretinal or intraretinal exudates are absent.

Vasculitis and Vascular Occlusion

Ocular complications associated with retinochoroiditis in CSD may include vasculitis with arterial and/or venous occlusions causing severe visual loss.

Uveitis

Both intermediate uveitis and panuveitis have been reported in several cases with CSD. It has also been presumed that most patients with focal retinochoroiditis or neuroretinitis associated with CSD have a mild to moderate vitritis and sometimes significant non-granulomatous anterior uveitis.

Diagnosis

The diagnostic criteria for CSD include the following:

1. History of contact with a cat or kitten
2. Primary inoculation site either cutaneous or ocular
3. Positive serological tests – indirect immunofluorescence test (IFA) or enzyme-linked immunoassays (ELISA)

IFA is 88% sensitive and 94% specific for *B. henselae*, with titers of greater than 1:64 being considered positive. ELISA has a sensitivity for IgG of 86–95% and a specificity of 96%. Both IFA and ELISA tests depend on the robust immune response from the host. Because of that, the accuracy of both tests in immunocompromised patients is significantly lower.

Biopsy and Testing

The specimen can be obtained from the granulomatous conjunctival lesion or from infected lymph node. Testing includes:

1. Staining: Direct detection of bacteria by Warthin-Starry silver stain. This stain lacks species specificity.
2. Polymerase chain reaction (PCR): PCR testing for *B. henselae* was successfully used to identify B. henselae infection in specimens from conjunctiva and from lymph node biopsies and aspirates.
3. Cultures: Tissue or blood specimens can take up to 4 weeks before growth is detected on the culture media.

Treatment

In the majority of cases, CSD is a self-limiting illness that resolves completely within 2–4 months, with an overall excellent systemic and visual prognosis, even without treatment. The benign nature of CSD makes the necessity of antibiotic treatment doubtful. A variety of antibiotics, including doxycycline, erythromycin, rifampin, trimethoprim-sulfamethoxazole, ciprofloxacin, and gentamicin, have been used in the treatment of severe systemic or ocular manifestations, despite the fact that their efficacy has not been conclusively demonstrated. The duration of treatment is usually 2–4 weeks in immunocompetent patients and up to 4 months for immunocompromised patients.

Oral corticosteroids have been effective in reducing the inflammation and improving the visual function in cases with systemic and posterior ocular manifestations. However, the necessity of corticosteroids therapy in isolated POGS has not been established.

Differential Diagnosis

Syphilis, Lyme disease, tuberculosis, toxoplasmosis, toxocariasis, leptospirosis, salmonella, chicken pox (varicella), herpes simplex, Rocky

Mountain spotted fever, sarcoidosis, diabetic retinopathy, malignant hypertension, pseudotumor cerebri, and malignancies (especially lymphoma and tumor metastasis).

Synonyms

Cataract eye operation

Definition

An operative treatment for removal of the eye's natural lens with cataract and implantation of an artificial intraocular lens implant (IOL).

Two techniques – phacoemulsification (incision 2–3 mm, foldable IOL) and conventional extracapsular cataract extraction (incision 10–12 mm, non-foldable IOL) – are currently the main types of cataract surgery extraction.

By reason of expense, the phacoemulsification technique is mostly practiced in industrial countries and the extracapsular cataract extraction (ECCE) in developing countries.

Epidemiology

Cataract surgery is the world's most frequently performed surgical treatment. The cataract surgery rate (CSR, the annual number of cataract operations performed per million population) varies in different countries.

The CSR of Europe countries and countries of the United States is 4000–5000 (source WHO). Although the CSR is often according to the economic and social development of countries, the WHO published a CSR about 3000 in India, for example, in the third-world countries up to 200.

Cataract surgery is commonly performed on an outpatient. Today the standard method is the extraction of cataract by phacoemulsification with implantation of a spherical intraocular lens.

History

The history of cataract disease goes back to ancient times. The beginning of surgical treatment was probably 800–600 BC in India: after scleral opening with an edged lancet, an inserted needle pushed the opacified crystalline lens into the vitreous body. This method is known as couching and was in basic principle practiced until the mid-nineteenth century.

The idea of a combined aspirating of cataract was firstly described 850 AC (Rhazes, Ammar).

After a better knowledge about the cataract's pathogenesis, Daviel created a surgical method similar to the established ECCE (extracapsular cataract extraction) in 1753.

Between 1753 and 1862, Pamard of Avignon (placing the surgical incision upper), Himly (introduction of pharmacological mydriasis), and Mooren (iridectomy to combat the complication of papillary block) affected the direction of cataract surgery.

The instrumental development was governed by De La Faye, Beer, and von Graefe.

Koller introduced cocaine as local anesthesia in 1884.

In 1949 Ridley began to implant artificial lenses. A further important step was managed by Barraquer in 1956 to describe the chemical zonulolysis using an enzyme (alpha-chymotrypsin).

Krawicz presented in 1961 a cryoextractor for intracapsular cataract extraction (ICCE). In the following year, Kelman introduced the Kelman phacoemulsification aspiration system in 1962–1967.

In 1980 Miller and Stegman use Healon to stabilize the anterior chamber.

The small incision surgery was developed in 1982 and the following years (Kraft, Sanders, Colvard, Fenzl, Girard).

Finally the last two milestones of the modern era were marked by Nagahara (1993, phaco-chop technique) and Agarwal (1998, bimanual microincisional phacoemulsification).

Clinical Features

It is referred to the articles specifically written that book.

Tests

The most important preoperative tests are listed below: investigation of anamnesis (general, drugs, ophthalmological); efficient examination of both eyes and refraction (including keratometry, uncorrected and best-corrected far and near visual acuity, if necessary retinometer visual acuity); quantification of contrast cognition and glaring, motility, and stereo tests and slit-lamp examination in mydriasis, tonometry, fundus examination (if necessary echography B-scan); and evaluation of the adequate intraocular lens implant (echography A-scan, biometry).

Differential Diagnosis

See "Treatment" section bottom.

Etiology

See "History" section above.

Treatment

The current preferred techniques in developed countries are phacoemulsification or extracapsular cataract extraction (ECCE) with inserting an intraocular lens implant (foldable or non-foldable lenses). In phacoemulsification technique, a small incision size is performed, whereas in ECCE the incision is larger and therefore usually depends on stitching.

The intracapsular cataract extraction (ICCE) is performed less today.

For the precise description of cataract surgery techniques, it is referred to the articles specifically written in that book.

Definition

Cataract is an opacification (clouding) of the crystalline human lens which can affect retinal image formation.

Etiology

Due to the multiplicity of possible causes and phenotypes the disease can be classified in several ways. A basic distinction can be made between congenital and acquired (e.g., senile, traumatic or uveitic, or glaucomatous) cataract.

Congenital cataract is an opacification of the lens which is already present at birth or manifests itself during the first year of life (Kuhli-Hattenbach et al. 2008). Possible causes are intrauterine infections, metabolic diseases, and a large variety of syndromes. The intrauterine infectious diseases most frequently responsible for a congenital cataract are rubella, measles, herpes simplex, varicella, Epstein-Barr virus, influenza, Syphilis, and Toxoplasmosis. Frequent genetic causes are familiar congenital cataract, galactosemia, Down's syndrome, trisomia 13, or Lowe's syndrome. The phenotype of the lenticular opacification is variable according to the part of the lens which is affected. As direct cause of the opacification are assumed oxidative stress and denaturation of lens proteins.

The most common form is, however, the senile cataract which occurs mainly in three manifestations: cortical, nuclear, or posterior subcapsular cataract. Not all types of cataract affect vision in the same way and to the same extent; central nuclear opacification, e.g., causes a reduction in visual acuity while early stages of posterior subcapsular cataract typically result in a strong sensation of glare (Sparrow et al. 1993; Sayegh et al. 2008).

Clinical Presentation

Main symptom of cataract is usually slow progressive loss of visual acuity. Effects of cataract are not limited to high-contrast visual acuity but can also compromise other visual qualities such as contrast sensitivity and glare.

Cataract of the lens nucleus can cause an increase in the optical power of the crystalline lens leading to a change in the overall refraction of the eye in the direction of myopia. Clinically, cataract is detected by slit-lamp examination of the anterior segment of the eye with dilated pupil. In that way, extent and localization of lens clouding and its relationship to the optical axis of the eye can be assessed.

Diagnostics

Cataract is most often diagnosed by slit-lamp examination of the anterior eye segment. For long-term evaluation and in cases of slight to moderate lenticular opacification, additional apparative diagnostics such as wavefront measurement and Scheimpflug photography can be helpful. However, a thorough examination of the anterior and posterior eye segment is mandatory to exclude coexisting other pathologies. In infantile and congenital cataract and those forms associated with extraocular diseases, additional examinations such as enzyme testing may be advisable.

Differential Diagnosis

The symptoms of cataract (loss of visual acuity and contrast sensitivity, glare) can be caused by many other ocular diseases such as corneal opacifications or retinal diseases. Characteristic for cataract are the usually slow onset of the symptoms and the typical findings in slit-lamp microscopy.

Prophylaxis

Among the identified etiological factors of cataract are prominent old age, oxidative stress, and exposure to radiation. Protection from excessive UV radiation and a generally healthy lifestyle (e.g., avoidance of smoking) seem to be beneficial. So far, no drugs have been proven effective for the prevention of cataract.

Therapy

An effective conservative therapy with drugs does not exist. Therefore, standard treatment consists of removal of the lens material from the lens capsule and implantation of an artificial intraocular lens (IOL) (Sayegh et al. 2008). The current state-of-the-art method for removal of the lens is ultrasound phacoemulsification. Special attention is paid to minimally invasive surgical techniques in order to prevent unwanted effects and complications such as surgically induced astigmatism or intraocular microbial (usually bacterial) infections (endophthalmitis). Modern IOL optics can achieve high postoperative optical quality and high patient satisfaction.

Prognosis

If not treated adequately (i.e., surgically), the lenticular opacification will progress with consecutive further deterioration of vision. In cases without additional ocular pathologies, cataract surgery with implantation of an intraocular lens gives excellent results and can fully restore vision.

Epidemiology

Cataract is the most frequent cause of blindness worldwide. In the USA, in 42% of persons between the ages of 52 and 64, 60% of those between the ages 65 and 74, and 91% of those between the ages of 75 and 85 age-related opacifications of the crystalline lens could be detected. The estimated worldwide number of cataract operations per year is six to ten millions. The cataract surgical rate (CSR, the number of cataract surgeries per one million inhabitants) is variable from one country to another. According to the WHO, it is at a very high level of 4000–5000 in the USA and Europe while it is about 3000 in threshold states like India and only 200 in third world countries due to differences in the quality of medical care. The most frequent variant is the age-related cataract which occurs from the sixth decade of life onwards.

Catarrhal (Marginal Corneal) Infiltrates

Jonathan Etter
Krieger Eye Institute, Baltimore, MD, USA

Synonyms

Marginal keratitis; Microulcerative peripheral keratitis; Staphylococcal hypersensitivity keratitis; Staphylococcal marginal disease

Definition

Catarrhal infiltrates are a subtype of peripheral keratitis believed to be secondary to hypersensitivity to staphylococcal antigens.

Etiology

Catarrhal ulceration is thought to be a sterile, type III immune response in which staphylococcal antigens react with antibodies along the limbus, resulting in immune complexes. The limbus is especially prone to such inflammation because of its proximity to vascular arcades that provide the area with additional inflammatory mediators (Stern 2005).

Clinical Presentation

Symptoms of catarrhal ulceration often include pain, photophobia, and history of ocular redness. Because blepharitis often occurs simultaneously, patients may also notice a more chronic history of irritation and crusting. Examination findings are most prominent on the lids, conjunctiva, and cornea. Lids will often show signs of staphylococcal blepharitis which include collarettes surrounding lashes, redness along lid margins, and occasionally microulcerations near lash bases. In marginal keratitis, the conjunctiva is mildly injected. Classic corneal findings in catarrhal ulceration include small white infiltrates adjacent to the limbus with an intervening clear zone. These opacities most commonly occur in clock hours of the cornea with frequent exposure to antigen-rich eyelid margins (2, 4, 8, and 10 o'clock). Corneal epithelium is largely intact over these lesions although variable degrees of staining may be present. Oftentimes, there will be evidence of prior catarrhal ulceration in the fellow eye (Stern 2005; 2013–2014 Basic and clinical science course).

Diagnostics (Lab Diagnostics)

Catarrhal ulceration is usually a clinical diagnosis made by the presence of typical findings. In cases where there is concern for infectious keratitis (cases with more prominent epithelial defect, suppurative inflammation, or other risk factors), one should consider performing corneal cultures to rule out infectious keratitis.

Differential Diagnosis

There are numerous potential causes of microulcerative peripheral keratitis. Certain topical medications may induce a hypersensitivity reaction that may have a similar appearance. Common culprits include topical anesthetics, aminoglycosides, epinephrine, and phenylephrine. Typically hypersensitivity to topical medication will occur in close time proximity to instillation of the offending agent (Stern 2005). Contact lens wear can also initiate small, circumscribed infiltrates adjacent to the limbus in some patients. These lesions are often associated with extended wear soft contact lens usage. Phlyctenulosis is a disorder of the peripheral cornea also thought to be secondary to an exaggerated immune response to staphylococcal antigens along the corneal limbus. Patients with phlyctenule often present with findings of staphylococcal blepharitis and inflamed conjunctiva. Instead of circumscribed infiltrates, these patients possess an elevated white lesion comprised of a mixture of various inflammatory cells. Rosacea blepharitis can induce a peripheral keratitis marked by corneal neovascularization, corneal infiltration along the edges of offending blood vessels, and punctate epitheliopathy.

Eyelids in these patients will often show evidence of posterior blepharitis and meibomian gland dysfunction. Skin changes in rosacea can be helpful in differentiating rosacea keratitis from catarrhal ulceration and often include malar erythema, facial telangiectasias, and corresponding dermatologic lesions. Finally, any area of significant ulceration associated with significant inflammation, purulence, and pain should be evaluated for infectious or peripheral ulcerative keratitis (Stern 2005).

Prophylaxis/Therapy

The mainstay of treatment for catarrhal ulceration is topical steroid. A common regimen includes a low-dose steroid such as loteprednol 0.2% four times daily until disease resolution. A topical antibiotic such as Polytrim is also commonly employed to prevent infection. Treatment for concomitant staphylococcal blepharitis is also important for long-term prophylaxis and may include lid hygiene measures and a topical antibiotic ointment such as bacitracin (Stern 2005; 2013–2014 Basic and clinical science course).

Prognosis

Catarrhal infiltrates often respond quickly to the above treatment regimen. Moreover, if left untreated catarrhal infiltrates will resolve over the course of several weeks. Flares can be recurrent and can involve the fellow eye in patients prone to staphylococcal blepharitis (Stern 2005; 2013–2014 Basic and clinical science course).

Cavernous sinus anatomical boundaries and contents

Definition

The cavernous sinus is a dural venous sinus located lateral to the sella turcica. Venous drainage from the superior and inferior ophthalmic veins empties into the cavernous sinus, and the cavernous sinus itself drains into the superior and inferior petrosal sinuses, as well as the pterygoid plexus. Structures contained within the cavernous sinuses include CN III (and associated parasympathetic fibers), IV, V1, V2, VI, the internal carotid artery (ICA), and associated ocular sympathetic fibers.

One potential danger zone for bacterial spread is formed between the tip of the nose and the two labial angles. Venous drainage from this danger zone leads to the pterygoid plexus through the deep facial veins. Due to the valveless connection between the cavernous sinus and pterygoid plexus, bacterial infection and septic thrombosis of the cavernous sinus may result from a cutaneous infection in this danger zone.

A cavernous sinus syndrome can be due to any lesion in the cavernous sinus (e.g., infectious inflammatory, neoplastic, fistula, aneurysm) producing a multitude of clinical symptoms including ptosis, anisocoria, or diplopia from ocular motor cranial nerve (CN III, IV, VI) involvement, trigeminal pain or numbness (V1, V2), or headache from the resultant inflammation caused by the infection and septic thrombosis.

Definition

Cavernous sinus syndrome (CSS) is defined by signs and symptoms (see cavernous sinus anatomy) related to cavernous sinus pathology and include cranial neuropathies, ophthalmoplegia, proptosis and orbital congestion, orbital or facial pain, trigeminal sensory loss, and ocular sympathetic disturbance such as Horner syndrome. CSS can be caused by multiple conditions resulting in pathology of the cavernous sinus or the structures within. CSS can be divided into four types based on etiology: infection, noninfectious inflammation,

vascular lesion, and neoplasm. Infectious diseases include cavernous sinus thrombophlebitis, actinomycosis, rhinocerebral mucormycosis, and aspergillosis. Noninfectious inflammatory conditions include Tolosa-Hunt syndrome and idiopathic or secondary inflammatory syndromes. Different types of CSS vascular lesions include aneurysm of the internal carotid artery (ICA), carotid-cavernous fistula, and dural arteriovenous fistula. Finally, neoplastic lesions in the cavernous sinus include primary tumors, intracranial tumors directly invading the cavernous sinus, perineural spread of the head and neck tumors, or hematogenous spread of distal tumors.

Etiology

There are several etiologies of CSS and an understanding of the anatomy is critical. Located lateral to the sella turcica, the cavernous sinus is a trabeculated venous cavity invested by the dura mater. It contains several vascular and neural structures, including the ICA and sympathetic fibers that traverse it. The cavernous sinus also contains cranial nerves (CN) III, IV, V1, V2, and VI. CN VI (i.e., abducens nerve) runs lateral to the ICA within the cavernous sinus, while CN III, IV, V1, and V2 course in the lateral wall of the cavernous sinus between the two dural layers.

The cavernous sinus normally receives drainage from the superficial Sylvian vein, the superior and inferior ophthalmic veins, and the sphenoparietal sinus. Laterally, the middle meningeal vein drains into the cavernous sinus. The cavernous sinus then posteriorly drains into the superior and inferior petrosal sinuses. Anastomoses connecting the two cavernous sinuses include a basilar plexus of the veins and an intercavernous sinus and allow the progression of unilateral lesions into a bilateral lesion.

Etiologically cavernous sinus syndrome can be divided into infectious, noninfectious inflammatory, vascular, and neoplastic categories as described previously and are discussed more in depth below:

I. CSS Infectious Diseases
   1. Cavernous sinus thrombophlebitis is caused by bacterial or fungal invasion secondary to paranasal sinus infection, orbital cellulitis, or midface infection. The most common causative organism is *Staphylococcus aureus*, although other organisms including *Pneumococci* and fungi can also be seen. Cavernous sinus thrombophlebitis most frequently occurs in patients with immunosuppression or poorly controlled diabetes.
   2. *Actinomyces* accesses the central nervous system via direct extension from the ear or sinuses, or it may reach the central nervous system via hematogenous spread. Actinomycosis is rare and usually seen in immunocompetent men.
   3. Rhinocerebral mucormycosis fungi usually gains access to the nasal cavity and paranasal sinuses through inhalation and cause necrotizing vasculitis and thrombosis in the nose and sinuses. Infection may then directly extend through the skull base or indirectly access the central nervous system via the ICA and cavernous sinus. Rhinocerebral mucormycosis is seen in immunocompromised and diabetic patients.
   4. Aspergillosis infection usually occurs through hematogenous spread or direct extension of paranasal sinuses, middle ear, or orbital infection. It invades blood vessels and is most commonly seen in immunocompromised patients.

II. CSS Noninfectious Inflammation
   1. Tolosa-Hunt syndrome is characterized by nonspecific granulomatous inflammation in the anterior cavernous sinus, superior orbital fissure region, or orbital apex. However, the exact etiology is unknown.
   2. Inflammatory pseudotumor is characterized by idiopathic inflammatory lesions of the skull base and is characterized by inflammatory cell infiltration and a variety of fibrotic responses.

III. Vascular
    1. Aneurysm of the cavernous segment of the ICA could compress adjacent structures leading to specific symptoms. In adults, they are the most common cause of non-neoplastic parasellar masses.
    2. Carotid cavernous fistula and dural arteriovenous fistula are pathological shunts where the arterial blood flows from the carotid artery into the cavernous sinus, creating a direct communication between arterial and venous blood flow. They are divided into direct and indirect shunts. Direct shunts are most commonly caused by trauma leading to a tear in the ICA, whereas indirect shunts result from tears in the meningeal branches of the carotid artery.
IV. Neoplasm
    1. Intracranial tumor such as pituitary adenoma can directly invade into the cavernous sinus.
    2. Primary tumors can directly arise from the cavernous sinus, such as meningiomas and neurogenic tumors.
    3. Head and neck malignancy can spread to the cavernous sinus via perineural invasion.
    4. Metastatic tumors could originate from distant sites, including the lungs, breasts, and prostate gland.

Clinical Presentation

Clinical presentations of CSS include cranial neuropathies, ophthalmoplegia, proptosis and orbital congestion, orbital or facial pain, trigeminal sensory loss, and sympathetic disturbance such as Horner's syndrome. However, the exact clinical presentation depends on the underlying pathology. For example, cavernous sinus thrombosis may have initial localizing features of unilateral chemosis, periorbital edema, and eyelid swelling. Ophthalmoplegia and exophthalmos may follow as retrobulbar pressure increases, and symptoms may progress to sluggish pupillary reaction, development of extraocular muscle palsies, and diminished acuity.

On the other hand, noninfectious inflammatory causes such as Tolosa-Hunt syndrome (idiopathic granulomatous painful, steroid-responsive CSS) result in painful ophthalmoplegia that is peri- or retro-orbital, severe, and typically lancinating in quality. Meanwhile, vascular causes such as direct carotid-cavernous fistula can present with the classic symptom triad of chemosis, pulsatile exophthalmos, and bruit. But if the underlying vascular defect is an indirect carotid-cavernous fistula, symptoms are insidious in onset and may be variable.

The clinical presentation of neoplastic cavernous sinus syndrome is also variable depending on the type of tumor, location of the tumor, rate of tumor growth, and structures affected by the tumor. Ocular motor cranial neuropathy will be present if the underlying pathology affects CN III, IV, or VI. Trigeminal neuropathy would be present if the ophthalmic (V1) or maxillary (V2) divisions of the trigeminal nerve are affected.

Diagnosis

The diagnosis of CSS is dependent on the underlying etiology, but magnetic resonance (MR) imaging, computed tomography (CT), and cerebral angiography each play a role. The diagnosis of infectious CSS is primarily based on clinical information, although CT and MR imaging can provide direct signs such as changes in signal intensity and size of the cavernous sinus. Imaging could also provide indirect signs including dilation of tributary veins and exophthalmos that clue one to an infectious CSS. Specific bacterial and fungal causes may have different characteristics on imaging.

As another example, the diagnosis of Tolosa-Hunt syndrome is based on exclusion of other traumatic, infective, vascular, neoplastic, metabolic, and inflammatory causes. Further diagnostic criteria include retro-orbital pain that may proceed to ophthalmoplegia and ophthalmoplegia

with or without periarterial sympathetic fiber and optic nerve involvement. Nonspecific inflammatory lesions in the anterior cavernous sinus, the superior orbital fissure, or the orbital apex may also be visualized on MR imaging in Tolosa-Hunt syndrome.

Vascular lesions including thrombosis, aneurysm, and fistula may be well demonstrated using CT angiography initially, but cerebral angiography is the gold standard diagnostic tool for detailed morphology and flow patterns. In addition, endovascular therapy may be directed at the time of cerebral angiography. If mass is suspected, MR imaging is usually the preferred diagnostic method.

Therapy

Treatment must be targeted at the particular underlying cause of CSS. In general, infectious causes require prompt administration of broad-spectrum antibiotics and may require draining of any abscess cavities. Identifying the causative organism is also essential in administering the correct treatment. As for primary cavernous sinus thrombosis, anticoagulant therapy may be beneficial. In Tolosa-Hunt syndrome, patients are universally responsive to corticosteroid treatment. If the underlying cause is vascular as in the cases of fistulas or aneurysms, endovascular therapy may be required. Finally, the management of neoplastic CSS is difficult due to the significant cranial nerve morbidity in surgeries, and exact treatment will be case specific.

Prognosis

Given the broad range of etiologies, the prognosis of CSS is also dependent on the underlying pathology. For example, treatment of septic cavernous sinus thrombophlebitis usually leads to cranial nerve palsy's resolution. However, if visual loss is present, it will likely remain, as it suggests infarction of the retro-orbital portion of the optic nerve. On the other hand, following successful endovascular treatments, patients with carotid-cavernous fistula usually experience a resolution of symptoms. The prognosis of visual loss due to the carotid-cavernous fistula will depend on the underlying pathology of the visual loss. Finally, after corticosteroid treatment, most patients with Tolosa-Hunt syndrome experience a resolution of symptoms, though spontaneous remissions may also occur.

Differential Diagnosis

1. Diabetic ophthalmoplegia
2. Giant cell arteritis
3. Ophthalmoplegic migraine
4. Posterior fossa aneurysm

Cefuroxime

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Second-generation cephalosporin antibiotic.

Indication

Prophylaxis of postoperative endophthalmitis after cataract surgery, therapy of bacterial keratitis.

Contraindication

Allergy against second-generation cephalosporin antibiotics.

Use and Dosage

Cefuroxime disrupts the synthesis of the peptidoglycan layer of bacterial cell walls. Intracameral administration of cefuroxime (1 mg in 0.1 mL normal saline) at the end of cataract surgery was found to be effective in reducing the risk for endophthalmitis after cataract surgery by phacoemulsification. Use of cefuroxime eyedrops (1–5%) has been described in the therapy of bacterial keratitis. However, the formulation is not commercially available.

Adverse Reactions

In systemic use, diarrhea, nausea, vomiting, headaches/migraines, dizziness electrolyte disturbances, and abdominal pain have been described. Excessive doses of intracameral antibiotic agents or inadequate preparation may cause toxic anterior segment syndrome.

Cellophane Maculopathy

Marc D. de Smet
Division of Retina and Ocular Inflammation, MIOS Sa, Lausanne, Switzerland

Synonyms

Epiretinal membrane; Macular pucker; Pseudo macular hole; Preretinal macular fibrosis; Preretinal macular gliosis; Preretinal vitreous membranes; Silk-screen retinopathy; Surface-wrinkling maculopathy

Etiology

Cellophane maculopathy refers to a membrane present at the surface of the retina overlying or surrounding the foveal pit. It is composed of newly formed collagen (mainly types II and IV) and basement membranes, as well as a population of spindle-shaped cells that are GFAP and AE1/AE3 positive, suggesting a glial origin (Fig. 1). The cells have been referred to in the literature as laminocytes, myofibroblasts, or histiocytes. The above description refers to idiopathic membranes with no associated underlying ocular pathology. In cases associated with retinal tears or detachment, retinal pigment cells are invariably present. In membranes associated with diabetes, neovascular stromal tissue is observed. Following trauma, or ocular inflammation, macrophages and inflammatory cells are seen alongside the laminocytes.

Laminocytes are thought to populate the retinal surface prior to a separation of the posterior vitreous, at a time when vitreoretinal traction is causing some mechanical stress to the foveal area. Collagen deposition likely begins at this time. However, when most idiopathic membranes are diagnosed or when therapy is instituted, a posterior vitreous detachment has already occurred. As collagen and extracellular matrix is deposited, the cells cause a contraction of the retinal surface. This in turn causes distortion of the surface vessels that are pulled centripetally toward the center of one or more traction points. With more intense traction, deeper retinal structures are affected leading to loss of retinal integrity and the appearance of cystic structures or edema. Involvement of outer retinal structures, in particular the photoreceptors, will lead to alteration in visual perception.

Clinical Presentation

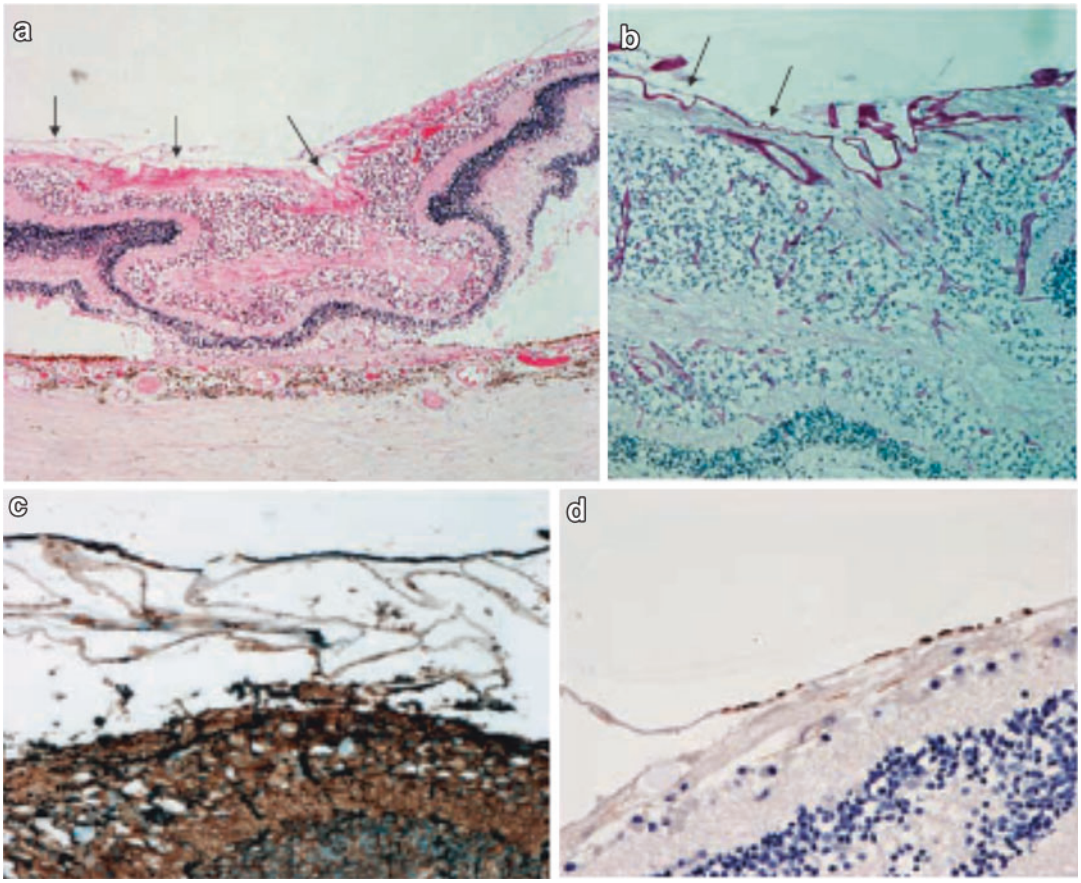
Patients usually complain of distorted lines or images. Straight lines or objects are wavy, while letters have abnormal shapes. Initially, visual acuity remains excellent, but as the distortion worsens, vision begins to decrease. This stage is often associated with the appearance of macular edema as the traction on the retina causes structural retinal changes. These can be seen by biomicroscopy, fluorescein angiography, or optical coherence tomography (OCT).

Diagnostics

The patient can indicate the location of his distortions on an Amsler grid, while an M-chart can help define the severity of the distortion and follow its evolution. On biomicroscopy, a glistening structure is seen at the surface of the macula, while it is absent in the surrounding retina. This glistening caused by the membrane leads to the name cellophane maculopathy. It is often associated with vascular distortion and wrinkling, as vessels in and surrounding the membrane are drawn to traction points within. The membranes can be documented by fundus photography and multispectral scanning laser ophthalmoscopy (Fig. 2). The latter may be particularly useful in identifying subtle membranes.

Fluorescein angiography allows one to document the degree of vascular compromise as affected vessels become permeable leading to the appearance of macular edema.

On longitudinal OCT, above the plane of the retina, a reflective layer of variable thickness and density is observed. It is associated with undulations of the retina, more prominent in superficial layers, involving deeper layers as the membrane causes more centripetal traction (Fig. 3). On



Cellophane Maculopathy, Fig. 1 Sections from post-mortem globes. (**a**–**c**) A case of mascular pucker. The retinal surface can clearly be seen in (**a**) with a typical CM type ERM, including hyperconvoluted ILM present on the retinal surface (arrows) (H&E). The ILM is more clearly demonstrated with the DPAS stain in (**b**), and the GFAP immunocytochemistry stain shows strong positivity in the laminocytes (**c**). (**d**) Another case with a PVD, in which laminocytes are clearly visible on the retinal surface, and staining positively for cytokeratin AE1/AE3. Original magnifications (**a**) ×100; (**b**) ×200; and (**c**, **d**) ×400. (Taken from Eye (2008) 22:1310–1317 Snead DRJ et al.)

transversal OCT scans, the membrane can be seen as a highly reflective surface above the plane of the retina. When looking at the retinal surface, folds are visible radiating out of individual traction points (Fig. 4).

Differential Diagnosis

Cellophane maculopathy is idiopathic. Other etiologies or associations include:

- Retinal detachment or tear
- Proliferative vitreoretinopathy (PVR)
- Proliferative diabetic retinopathy (PDR)
- Retinal vein occlusion
- Diabetic macular edema
- Uveitis
- Ocular trauma

Prophylaxis

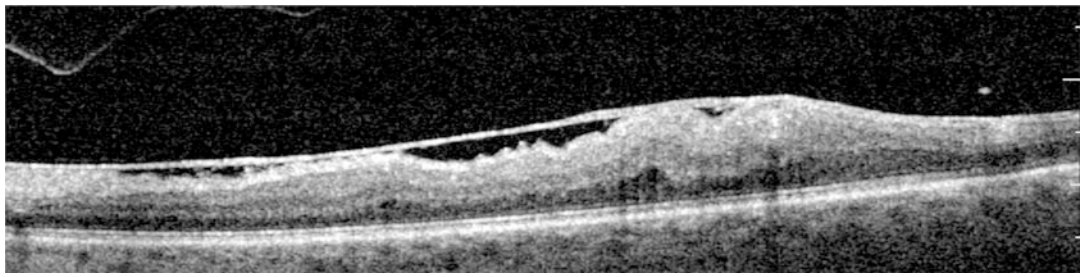
There is no proven prophylaxis. However, the presence of vitreomacular traction is felt to be a major contributor to the formation of preretinal membranes, particularly in pseudophakic patients. A significant increase in the incidence of membranes following cataract surgery has been observed in the 6 months following surgery.

Cellophane Maculopathy, Fig. 2 Multispectral image of an epiretinal membrane. Vessels are tortuous (*arrow*) or drawn toward one another arrowhead. This particular membrane skirts around the fovea forming what is referred to as a pseudohole (*asterik*)

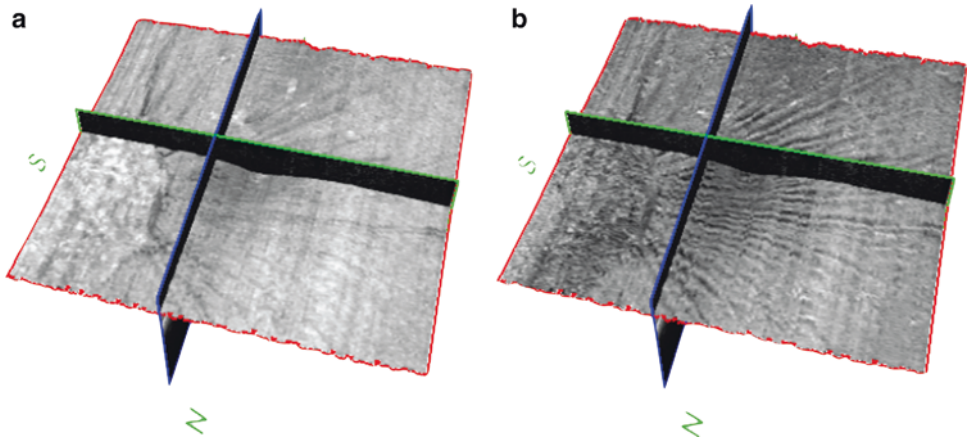
Inducing a medical or surgical release of vitreoretinal traction may limit the appearance of these membranes, but this approach has not so far been proven effective. The growth of membranes can be minimized by limiting or treating any concurrent inflammatory response present in the eye.

Therapy

Not all membranes require therapy. If they do not cause visual loss or distortion, treatment is usually not required. Surgical removal is the only effective therapy. Following removal of the pre-macular vitreous by means of a pars plana vitrectomy, the membrane is peeled from the retinal surface with or without the use of a staining agent (chromovitrectomy).



Cellophane Maculopathy, Fig. 3 Longitudinal OCT scan through the macula showing a thick membrane on the surface of the retina with wrinking of several underlying layers. The posterior surface of a detached vitreous is visible in the upper left corner of the image



Cellophane Maculopathy, Fig. 4 Transversal OCT scan showing in **a** the surface of the membrane above the retinal plan as a highly reflective layer. In **b**, with the scan set at the level of the retina, the radiating folds in the retina are clearly visible, extending a considerable distance from the site of the membrane

Prognosis

Most epiretinal membranes are found incidentally during an ocular exam, as is frequently seen with peri-macular membranes. Only a minority of membranes progress causing more traction on the retinal surface, usually under the influence of an external stimulus as indicated above.

Epidemiology

The prevalence varies with age and is considered to be between 7% and 12% overall. Rarely observed below the age of 40, it is reported to be present in 15% of patients above 70 years of age. Over age 50, in a healthy population, the 5-year incidence is reported to be as high as 5%. Following cataract surgery, the prevalence is said to double over a 6–12-month period.

Cellulitis, Preseptal, *Haemophilus* Causing

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Synonyms

Periorbital cellulitis

Definition

A soft tissue infection of the eyelids that has not extended beyond the septum and into the orbit. Prior to the advent of the *Haemophilus influenzae* type B (HiB) vaccine, this organism caused many pediatric cases of preseptal and orbital cellulitis.

Etiology

A broad variety of insults can lead to the development of preseptal cellulitis. The most common among these in the pediatric population is ethmoid sinusitis. Other causes include hordeola, infectious dacryoadenitis, dacryocystitis, trauma, insect bites, and periocular surgery.

Clinical Presentation

Patients with preseptal cellulitis present with swollen, erythematous eyelids. Depending on the cause of the infection, other classical stigmata may also be seen (e.g., the "S-shaped" upper eyelid deformity of dacryoadenitis). While it may be difficult to examine the eye due to swelling – particularly in uncooperative children – there should be no significant changes in visual acuity, motility deficits, pain with eye movement, proptosis, injection, or chemosis. These signs should prompt the clinician to suspect a true orbital cellulitis.

Diagnosis

Preseptal cellulitis is a clinical diagnosis. Nevertheless, it is often prudent to obtain dedicated orbital imaging in order to assess the condition of the sinuses if the cause of infection is not immediately apparent. In borderline cases or those in which the eye cannot be assessed adequately due to lack of cooperation, imaging is imperative to exclude orbital cellulitis.

If present, secretions or discharge should be cultured. Inpatient treatment with intravenous antibiotics is rarely necessary, but blood cultures are often obtained in this setting. *Haemophilus* bacteremia was often associated with preseptal

and orbital cellulitis prior to introduction of the HiB vaccine, and a high index of suspicion should be maintained in individuals with an uncertain vaccination history.

Differential Diagnosis

Orbital cellulitis
Irritant or allergic contact dermatitis
Herpes simplex or zoster
Blepharochalasis
Secondary inflammation due to ocular pathology
Rhabdomyosarcoma
Metastatic neuroblastoma
Ruptured dermoid

Prophylaxis

No generalized prophylaxis. Patients with chronic sinusitis may benefit from medical or surgical therapy.

Therapy

Preseptal cellulitis is typically treated with oral antibiotics that cover the spectrum of commonly associated microbes (e.g., amoxicillin/clavulanic acid). A lid abscess increases the pretest probability of infection with community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA), and coverage should be adjusted accordingly. Symptomatic relief may be obtained with cold compresses and Tylenol. In borderline cases, or when *Haemophilus influenzae* type B is suspected based on vaccination history, admission for imaging, blood cultures, and intravenous antibiotics may be prudent. Nasal decongestants and saline rinses are often added when sinusitis is the underlying cause. Close follow-up is required to exclude progression to orbital cellulitis.

Prognosis

In general, the prognosis for preseptal cellulitis is excellent with timely and appropriate therapy. *Haemophilus influenzae* type B was frequently associated with childhood bacteremia, epiglottitis, otitis, and meningitis; prognosis is more guarded in such cases and careful management is required.

Epidemiology

Preseptal cellulitis may affect any age group, but is particularly common in younger children. Prior to the advent of the HiB vaccine, *Haemophilus*-related infections were commonly seen in those aged 5 and younger.

Central Corneal Thickness

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

CCT; Central pachymetry; Corneal thickness

Definition

The thickness of the cornea at its center.

Basic Characteristics

The central corneal thickness (CCT) of a normal and healthy cornea ranges from 450 to 650 µm (Doughty and Zaman 2000). It can be thinner in ectatic corneal diseases such as keratoconus, pellucid marginal degeneration, and iatrogenic keratectasia and after surgical tissue ablation. CCT is increased in case of corneal edema (e.g., endothelial dystrophy), in cases of cornea plana, and other corneal dystrophies. Also after lamellar and penetrating keratoplasty, CCT can be increased.

Measurement of the corneal thickness is called pachymetry (*gr.* παχύς: thick). There are different techniques for measuring CCT. The oldest technique uses an optical device of planparallel plates for the slit lamp microscope. CCT could be read indirectly by correctly positioning the two plates relatively to each other. The most widespread used technique and still the gold standard for measuring CCT is ultrasound pachymetry. Optical sections of the cornea could also be done with Scheimpflug photography and optical coherence tomography. Thus, pachymeters based on these principles are available both as standalone unit and integrated in multifunction devices. Advantages of optical pachymeters are their non-invasiveness and the possibility of mapping thickness over the entire cornea.

CCT measurements have clinical relevance in glaucoma detection and refractive surgery. Eyes with thin corneas are more prone to develop glaucoma (Gordon et al. 2002). Moreover, Goldmann applanation tonometry readings are lower than the nominal value if the cornea is thin (Ehlers et al. 1975). In corneal refractive surgery, knowing corneal thickness is essential for treatment planning. In most cases, the CCT is sufficient. Recent studies revealed not only a thinner absolute CCT in keratoconus eyes but also a different ratio between central and peripheral corneal thickness (Ambrósio et al. 2006; Bühren et al. 2010). CCT is not only a limiting parameter for treatments (the residual stromal bed thickness should not be below 250 µm) but also a useful metric for the detection of early keratoconus. However, for keratoconus detection, CCT needs to be always interpreted in conjunction with other data since there is no threshold value below which a cornea is considered a keratoconus cornea.

CRAO

Definition

Sudden, complete, and painless loss of vision in one eye, due to obstruction of normal blood flow in the central retinal artery to the retina. When this obstruction occurs, there is no proper blood supply to the retinal layers, and the retina becomes opaque and edematous, particularly in the posterior pole where the nerve fiber and ganglion cell layers are thickest. The retina appears bright, except the area of the fovea, which will still appear as an orange-red spot, because of the thin retinal layer at this area, and the orange reflex from the intact choroidal vasculature beneath this thin retinal layer. This phenomenon of orange-red spot in the middle of bright, edematous retina is called a cherry-red spot.

Etiology

Several etiologies are associated with the occlusion of retinal artery:

1. Embolic event due to:
   (a) Carotid artery atherosclerosis or dissection
   (b) Cardiac valvular disease
   (c) Cardiac arrhythmia
   (d) Left ventricular hypertrophy and systemic hypertension
   (e) Thrombus after myocardial infarction
   (f) Benign and malignant tumors of the heart
   (g) Organic heart malformation as patent foramen ovale and subsequent venous originated embolus (lipid emboli from pancreatitis, deep vein thrombosis embolus, or intravenous drug use)
   (h) Iatrogentic event as carotid endarterectomy or radiologic studies (carotid or cerebral angiography, cardiac catheterization, lymphography, hysterosalpingography)
2. Trauma due to retrobulbar injection, orbital floor fracture repair, or nasal surgery and penetrating injury
3. Coagulopathies:
   (a) Sickle cell disease
   (b) Genetic mutations of factors in a coagulation cascade (factor V Leiden, protein

C deficiency, protein S deficiency, antithrombin III deficiency, activated protein C resistance)
   (c) Lupus anticoagulant
   (d) Homocystinuria
   (e) Pregnancy or oral contraceptives use
   (f) Platelet abnormalities
   (g) Leukemia or lymphoma
4. Collagen vascular disease (giant cell arteritis, systemic lupus erythematosus, polyarteritis nodosa, Wegener's granolomatosis) and other vasculitis and inflammatory conditions (mucormycosis, toxoplasmosis, *Toxocara canis*, Lyme, Behcet, and cat scratch disease)
5. Ocular conditions as increased intraocular pressure (due to intravitreal injection, gas expansion after vitrectomy, prone intraoperative positioning, retrobulbar hemorrhage, orbital emphysema), optic neuritis, optic disk drusen, and peripapillary arterial loops

Embolization is the most important non-arteritic cause of CRAO, embolus from carotid artery atherosclerosis being the most common one. In patients younger than 40 years old, carotid disease is relatively rare. In these patients, cardiac embolism is the most common etiology.

Cholesterol emboli, which are also called Hollenhorst plaques, stand for 74% of all retinal artery emboli cases. They are seen typically at retinal arterial bifurcations as bright-yellow-colored plaques. These emboli usually suggest a carotid atheromatous origin, but they can also arise from the aortic arch, ophthalmic artery, or proximal central retinal artery. It is worth to note that the presence of a Hollenhorst plaque in the retinal artery occlusion is associated with a low prevalence of carotid atherosclerosis requiring carotid endarterectomy. Furthermore, in contrast to amaurosis fugax, such ocular findings are not associated with a high risk for hemispheric neurological events. However, patients with retinal emboli do have an associated higher mortality rate.

Calcific emboli that account for 15.5% of emboli are typically larger and cause more severe obstruction. They most commonly originate from the cardiac valves.

Another important cause of CRAO is an atherosclerosis-related thrombosis occurring at the level of the lamina cribrosa.

Systemic etiologic considerations, as coagulation disorders, sickle cell disease, infectious diseases, valvular and anatomical malformations of the heart, and arrhythmias, are important and require evaluation.

It is important to note that the leading cause of death in patients with retinal arterial obstruction is cardiovascular disease.

Connective tissue disorders as giant cell arteritis account for approximately 1–2% of cases of CRAO.

Clinical Presentation

The patient may complain of sudden, painless, monocular, severe loss of vision, which occurs acutely (span of a few seconds). Sometimes prior episodes of amaurosis fugax may be reported, and they may suggest an embolic source of the CRAO. Some cases of giant cell arteritis-related CRAO may also be associated with amaurosis fugax. The risk of CRAO after amaurosis fugax is about 1% per year.

Visual acuity is counting fingers to light perception in about 80% of cases. Some patients have a preserved central visual field thanks to a sufficient cilioretinal circulation which supplies some or all of the papillomacular bundle. Visual acuity in CRAO associated to giant cell arteritis is usually better compared to that following an embolic event.

No light perception at presentation is very rare and raises suspicion of patient's concomitant choroidal circulation deficit. Ophthalmic artery occlusion has to be ruled out.

An afferent pupillary defect usually develops within seconds following obstruction of the central retinal artery, regardless of macular sparing. The anterior segment will be quiet in majority of cases, but in about 17% of cases, rubeosis iridis may be seen. If acute rubeosis iridis is present, ocular ischemia secondary to the presence of a concomitant carotid artery obstruction should be considered. On fundoscopy evaluation, the retina

appears pale, except the reddish fovea. No hemorrhages are seen. The presence of hemorrhages may suggest co-occurrence of CRAO with central retinal vein occlusion. Intra-arterial emboli are visible in 20–40% of eyes.

Most classic and earliest signs at presentation are a cherry-red spot (90%) and posterior pole retinal opacity or whitening (58%). Other important fundoscopic signs are optic nerve pallor (39%), retinal arterial attenuation (32%), and optic disk edema (22%). Most of the retinal findings will predominantly be located in the posterior pole, whereas at periphery, it will appear normal. The size of the cherry-red spot is variable and is dependent on the width of the foveola. The classic signs will gradually disappear with time. One month after the CRAO presentation, the cherry-red spot is seen in about 19% and the retinal opacification in 17% of affected patients. Pathologically, this evolution corresponds to resolution of initial acute ischemia-induced intracellular edema with subsequent loss of neuronal cells and the development of an acellular scar of the inner retinal cell layers.

In the acute phase of nonarteritic CRAO, the disk may be normal, hyperemic, edematous, and, rarely, pale.

The optic nerve is acutely edematous in nearly all cases of arteritic (e.g., giant cell arteritis) CRAO as a result of the associated anterior ischemic optic neuropathy that is typically observed in these patients. The pallor of the nerve is due to ischemic opacification of the surface of the nerve fiber layer, which is normally supplied by retinal circulation.

Later on in the course of CRAO, chronic changes may appear on the fundoscopic examination: optic atrophy, retinal arterial attenuation, cilioretinal collaterals, macular RPE changes, and cotton wool spots.

Diagnostics

Finding the proper etiology for CRAO is very important for the treatment strategy and for the prevention of CRAO in the fellow eye, stroke, or other comorbidities.

Blood evaluation: complete blood count, biochemistry and coagulation analysis may yield some information about inflammation, infection, or clotting pathology. A hypercoagulability evaluation should be especially considered for patients younger than 50 years with a suggestive history of prior thrombosis or miscarriage or family history of coagulopathies.

Work-up includes blood tests for factor V Leiden mutation, protein C, protein S, and antithrombin III deficiencies, homocysteine levels, sickle cell disease, and lupus anticoagulant (LAC). Further evaluation of collagen vascular diseases (as antinuclear antibodies, C-ANCA, P-ANCA) may reveal an inflammatory etiology. Other tests for monoclonal gammopathy, cancer, infection, and disseminated intravascular coagulation may be ordered depending on the clinical circumstance.

Carotid Doppler imaging is important to establish the carotid artery origin of the emboli. Most retinal emboli are relatively small. From the ophthalmic point of view, when evaluating the results of carotid Doppler ultrasonography, the presence or absence of plaque is more important than whether a hemodynamically significant stenosis is present. The latter is more important in determining the need for carotid endarterectomy. Carotid Doppler also has its limitations, including the lack of imaging of the thoracic and intracranial portion of the carotid artery and poor resolution for detection of microemboli.

Electrocardiogram (ECG) and Holter ECG are indicated when heart arrhythmia is suspected. Furthermore, a baseline ECG is recommended for almost each patient, since the cardiac morbidity and mortality are significant in patients with retinal artery occlusion.

For heart malformation, valvulopathies, and infectious endocarditis, transthoracic or transesophageal echo is helpful for diagnosis. Transthoracic echo is less sensitive and thus will be performed in patients with low cardioembolic risk. Transesophageal echo is an important diagnostic tool for patients with high cardioembolic risk factors or for patients with suspicious clinical or transthoracic echo findings. A computed tomography angiogram (CTA) or magnetic

resonance imaging angiogram (MRA) should be considered in special cases such as suspected carotid or aortic dissection.

In cases of CRAO in which emboli are not readily visible, giant cell arteritis has to be suspected. For further diagnosis erythrocyte sedimentation rate (ESR) and blood test for C-reactive protein levels, should be obtained. These two tests (if elevated) improve the sensitivity and specificity for giant cell arteritis diagnosis. These two tests improve the sensitivity and specificity for giant cell arteritis diagnosis. Other acute phase reactant markers such as elevated platelet counts are also suggestive of giant cell arteritis. The definitive diagnosis is made with a temporal artery biopsy (although false-negative biopsy results are common).

Autofluorescence (AF)

In the acute phase, the area supplied by an occluded retinal artery shows decreased autofluorescence due to blockage of the normal autofluorescence of the RPE by the thickened inner retina. This blockage resolves over time and may evolve into a window defect with increased autofluorescence in the chronic phase as areas of significant inner retinal thinning develop.

Fluorescein Angiography (FA)

Variable residual retinal circulation is almost always seen in CRAO, but the arterial filling is delayed by 5–20 s and is slower than in normal arteries. Complete absence of retinal filling is rare. The fluorescein dye lines the arterial walls in a pattern similar to the laminar flow filling of normal retinal veins. When intra-arterial emboli are visible, the arteriovenous transit time can be even further delayed. There is a correlation between the severity of arterial obstruction and the initial visual acuity. Staining of the optic disk can be variable.

About 11% of patients may present also with areas of delayed choroidal perfusion. Leakage of fluorescein dye at the level of the RPE is generally not seen in CRAO, unless the choroidal circulation is involved.

In the chronic phase of CRAO, when the retinal circulation is reestablished, the FA may return to an almost normal appearance, but the damage to the infracted retina is irreversible. Therefore, vision loss, optic nerve atrophy, and arterial narrowing will persist.

Normalized FA and normal appearance of the optic nerve may suggest that the reperfusion took place before the irreversible damage has occurred. These cases have much better prognosis.

Optical Coherence Tomography (OCT)

In the acute stage, the macular contour is irregular. There is a hyperreflectivity of inner retinal layers that corresponds to intracellular edema and explains the lack of intraretinal and hyporeflective fluid spaces. Reflectivity of the outer retinal layers and RPE is blocked by the highly reflective inner retinal layer. There is no retinal thickening. At chronic stage, thinning and atrophy of the inner retina is shown, whereas an outer layer is well preserved. Thus, the use of OCT in cases of chronic, not previously diagnosed CRAO with normal fundus features is very important for the definitive diagnosis.

Visual Field (VF)

Central scotoma is the most common defect observed on macular visual field testing followed by paracentral scotoma. Patients with cilioretinal supply to the papillomacular bundle show a preserved central island of vision corresponding to the area perfused by the cilioretinal artery. Peripheral constriction is the most common visual field deficit noted in these patients. Choroidal derived blood supply may perfuse a nasal part of retina; thus, some patients will show a preserved temporal island.

Visual field defects improve in approximately 28% of patients, remain stable in 57%, and worsen in 7%.

Electroretinography (ERG)

Attenuation of the b-wave is more severe than that of the a-wave because the inner retinal layers are more affected by the poor retinal artery perfusion than the outer. This produces a characteristic negative waveform with the scotopic white stimulus.

A significant attenuation of both the a-wave and b-wave suggests a poor perfusion of the choroidal vasculature as well. In this case, ophthalmic artery occlusion has to be suspected.

Differential Diagnosis

Ophthalmic artery occlusion
Optic nerve ischemia

Prophylaxis

Anticoagulants are important for secondary prevention of cerebral and ocular infarction in patients with atrial fibrillation, acute internal carotid artery dissection, or a hypercoagulable condition. Their use for treatment of acute CRAO is doubtful.

Therapy

Treatment options are limited, and their efficacy is uncertain. Treatment should be started within a maximum 24 h of symptoms onset. Treatment strategy consists of dislodging emboli, reducing intraocular pressure and increasing retinal blood flow, vasodilating the ocular blood supply, improving retinal circulation, decreasing retinal edema, maintaining retinal oxygenation until spontaneous reperfusion, and acting on the thrombus.

Lowering the pressure may dislodge the embolus to further smaller division of the retinal artery and thus cause ischemic damage to smaller area of retina. The pressure may be reduced by performing an ocular massage, anterior chamber paracentesis, or use of retrobulbar anesthesia.

A mixture of 95% oxygen and 5% carbon dioxide (carbogen) can be provided to induce vasodilation and improve oxygenation, but efficacy has not been proven. Hyperbaric oxygen provides oxygen at levels of atmospheric pressure. The purpose of hyperbaric oxygen is to preserve the retina in an oxygenated state until recanalization and reperfusion occur, typically at 72 h. The hyperbaric oxygen increases the arterial oxygen pressure and thereby increases nitric oxide synthesis, leading to vasodilation. Case reports of successful treatment have been published, but currently treatment for ocular diseases is an off-label use of hyperbaric oxygen.

Vasodilating medications as pentoxifylline, nitroglycerin, and isosorbide dinitrate that may increase retinal blood flow have been suggested, but their efficacy has never been proven as was isovolemic hemodilution. If giant cell arteritis is suspected as a cause, corticosteroid therapy should be promptly instituted because the second eye can become involved by ischemia within hours to days after the first.

Experimental data have shown that retinal damage may arise not only from the presence of retinal nonperfusion but also from a cascade of events that injure cells after the tissue becomes reperfused. In the future, it may be possible to minimize damage with drugs that block this cascade of oxidative and membrane damage.

Iris neovascularization develops after acute CRAO in approximately 18% of eyes 1–12 weeks (average interval of 4–5 weeks) after the event. Full-scatter laser panretinal photocoagulation (PRP) causes successful regression in approximately 65% of cases.

Prognosis

With time, the central retinal artery may reopen or recanalize, and the retinal edema clears. However, the infarct to the retina usually causes an irreversible damage to the nerve cells; thus, the effect on visual acuity is usually permanent.

Visual acuity tends only to improve within the first week of onset with minimal chance for subsequent significant improvement. Visual recovery after treatment has been shown to correlate with presenting visual acuity and the duration of visual impairment. Although visual acuity may

spontaneously improve in up to 22% of patients with nonarteritic CRAO, less than 10% of patients report a meaningful recovery of vision.

About 66% of the eyes will have final vision worse than 20/400, and only in 18% the visual acuity will be of 20/40 or better. Most cases of 20/40 or better vision occur in the presence of a patent cilioretinal artery, which preserves the central macula. In most cases, the irreversible damage to the sensory retina occurs after 90 min of complete CRAO. Nevertheless, clinical return of vision can be seen in some instances, even if the obstruction has persisted for many hours.

Concomitant rubeosis iridis may occur in the setting of chronic CRAO. The risk of developing iris neovascularization is greater for obstruction lasting more than 1 week compared to those lasting only a few days.

Epidemiology

The estimated incidence of CRAO in general population is about 8.5/100,000. More than 90% of patients are older than 40 years, and the average age is early 60s. It is more common in males than in females. About 1–2% of cases are bilateral.

CRVO

Definition

Blockage of the main vein of the retina (central retinal vein) that can result in macular edema, retinal ischemia, and ocular neovascularization (Figs. 1 and 2).

Etiology

The pathophysiology of CRVO is poorly understood but likely involves hemodynamic alterations resulting in stagnant flow and thrombus formation in the lumen of the central retinal vein. Concurrent systemic vascular disease, most commonly hypertension but including hyperlipidemia, arteriosclerosis, smoking, and diabetes mellitus, is the largest risk factor for CRVO.

Hypercoagulable states and inflammatory conditions may be present in persons with CRVO, particularly if less than 60 years of age. An increased incidence of coagulation cascade abnormalities, including protein C deficiency, protein S deficiency, activated protein C resistance, presence of factor V Leiden, presence of antiphospholipid antibodies, hyperhomocysteinemia, antithrombin III deficiency, prothrombin gene mutations, and abnormal fibrinogen levels, along with hyperviscosity from blood dyscrasias, dysproteinemias, and dehydration, among others, have also been reported with CRVO.

Open-angle glaucoma increases the risk of CRVO. External compression of the globe and optic nerve from thyroid-related ophthalmopathy, mass lesions, or head trauma with orbital fracture may also result in CRVO.

CRVO may result in vision loss through secondary macular edema and neovascularization, which are modulated by growth factors released from the ischemic retina, including vascular endothelial growth factor (VEGF), interleukins (IL) such as IL-6, IL-8, IP-10, MCP-1, and PDGF-AA. Intraocular VEGF levels correlate with severity of macular edema and neovascularization, and VEGF suppression has emerged as the mainstay of CRVO treatment.

Central Retinal Vein, Occlusion of,

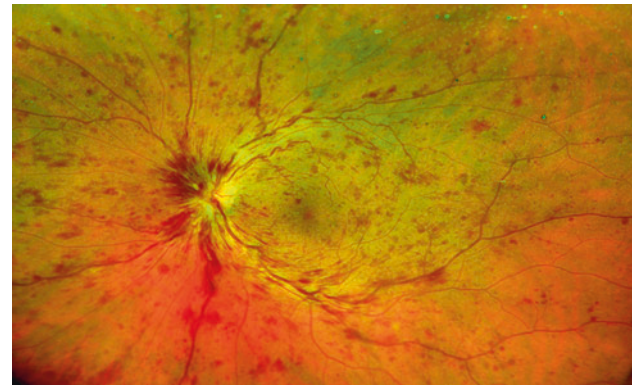

Fig. 1 Classic findings of CRVO include a "blood and thunder appearance" with 360° retinal hemorrhages, venous tortuosity, and macular edema

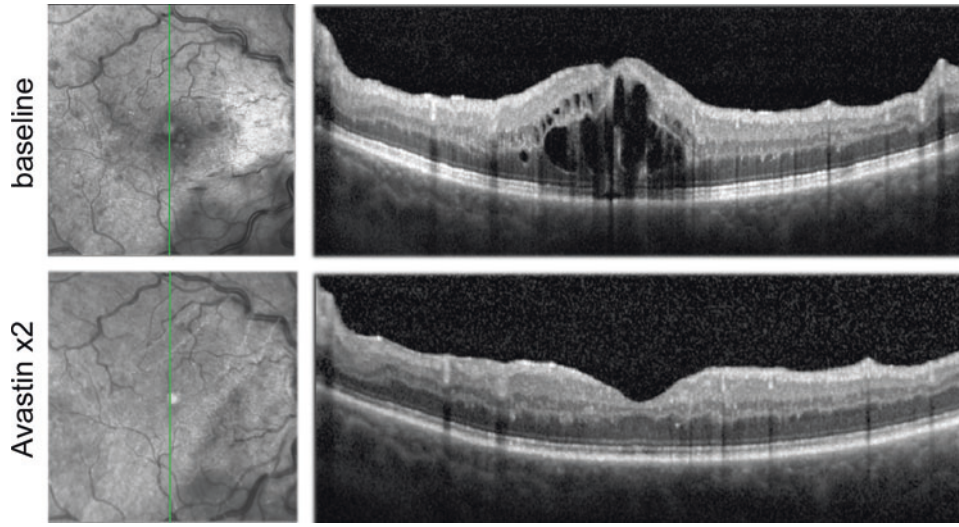

Central Retinal Vein, Occlusion of, Fig. 2 CRVO-associated macular edema at baseline is resolved following intravitreal anti-VEGF pharmacotherapy

Clinical Presentation

Central retinal vein occlusion usually presents with sudden painless loss of vision in one eye. On examination, the retinal venous system is typically engorged and tortuous with superficial nerve fiber layer and intraretinal hemorrhages in all four quadrants. These hemorrhages radiate from the optic nerve head, are variable in quantity, and may result in the classic "blood and thunder" fundus appearance. Optic nerve head swelling, cotton-wool spots, macular edema, and, less commonly, a cilioretinal artery occlusion may also be present.

The extent of retinal hemorrhage may decrease or resolve completely. Persistent macular edema may result in variable degrees of secondary retinal pigment epithelium alterations. Epiretinal membrane formation can also occur. Optociliary shunt vessels, which are collateral vessels to the choroidal vascular system, can develop on the optic nerve head.

In the absence of treatment, macular edema often chronically persists despite resolution of retinal hemorrhages. Neovascularization of the optic disc (NVD), retinal neovascularization elsewhere (NVE), and anterior segment neovascularization

of the iris (NVI) and/or neovascularization of the angle (NVA) may develop as a response to secondary retinal ischemia and may lead to vitreous hemorrhage, tractional retinal detachment, and/or neovascular glaucoma (often within the first 3 months, referred to as "90-day glaucoma"), respectively.

Diagnostics

For the majority of CRVO patients, who are over 65 years of age and have systemic vascular risk factors, a laboratory workup is typically not necessary. The blood pressure may be checked in the ophthalmologist's office, and the patient is referred to his/her internist for timely systemic evaluation and management of vascular risk factors. In persons less than 65 years of age and particularly in younger patients without systemic vascular risk factors, a hypercoagulable workup (protein C, protein S, factor V Leiden, antiphospholipid antibodies, homocysteine, antithrombin III, prothrombin, and fibrinogen) should also be considered.

Differential Diagnosis

The clinical findings in eyes with a CRVO are often pathognomonic but may occasionally be similar to findings seen in diabetic retinopathy, hypertensive retinopathy, ocular ischemic syndrome, radiation retinopathy, and leukemic retinopathy.

The differential diagnoses for underlying factors associated with CRVO include:

- Systemic vascular diseases: hypertension, carotid insufficiency, diabetes mellitus, prior radiation to the head
- Ocular diseases: open-angle glaucoma, ischemic optic neuropathy, pseudotumor cerebri, tilted optic nerve head, optic nerve head drusen
- Hematologic alterations: hyperviscosity syndromes such as dysproteinemias (multiple myeloma), blood dyscrasias (polycythemia vera, lymphoma, leukemia, sickle cell disease or trait), anemia, hypercoagulable states (factor V Leiden, elevated plasma homocysteine, elevated fibrinogen, factor XII deficiency, antithrombin III deficiency, antiphospholipid antibody syndrome, activated protein C resistance, protein C deficiency, protein S deficiency)
- Inflammatory/autoimmune vasculitis: systemic lupus erythematosus
- Medications: oral contraceptives, diuretics, hepatitis B vaccine
- Infectious vasculitis: HIV, syphilis, herpes zoster, sarcoidosis
- Other: dehydration, pregnancy, retrobulbar block

Prophylaxis

Timely identification and treatment of systemic vascular risk factors, such as systemic hypertension and diabetes mellitus, is important in individuals with CRVO. Systemic anticoagulation, such as with aspirin or warfarin, has not been shown to prevent or alter the natural history of CRVO. The prophylactic use of these medications may help prevent non-ocular thrombotic events, especially in individuals with known systemic vascular disease, and their use may be considered in coordination with the patient's internist.

Therapy

Most current treatments for CRVO are directed not toward the underlying thrombus but rather the treatable sequelae of CRVO, particularly macular edema and neovascularization. First-line therapy for CRVO-associated macular edema typically consists of intravitreal administration of anti-VEGF agents or corticosteroids. Anti-VEGF agents used to treat CRVO include ranibizumab 0.5 mg (Lucentis, Genentech, Inc., San Francisco, CA, monthly injections with 14.9 letter mean improvement versus 0.8 letter mean improvement with sham monthly injections after 6 months in the ranibizumab for the treatment of macular edema after Central Retinal Vein Occlusion Study: Evaluation of Efficacy and Safety (CRUISE) trial)

(Brown et al. 2010), aflibercept 2 mg (Eylea, Regeneron, Inc., Tarrytown, NY, monthly injections with 17.3 letter improvement versus 4.0 letter loss with sham monthly injections after 6 months in the Controlled Phase 3 Evaluation of Repeated Intravitreal Administration of VEGF Trap-Eye in Central Retinal Vein Occlusion: Utility and Safety (COPERNICUS) trial Boyer et al. (2012) with equivalent results in the parallel General Assessment Limiting Infiltration of Exudates in Central Retinal Vein Occlusion with VEGF Trap-Eye (GALILEO) study), and bevacizumab 1.25 mg (Avastin, Genentech, Inc., used off-label for treatment of retinal diseases).

Corticosteroids used for treatment of CRVO include a sustained release dexamethasone implant 0.7 mg (Ozurdex, Allergan, Inc., Irvine, CA – single injection with 29% rate of >15 letter gain at day 60 versus 9% with single sham injection in the post hoc analysis of the CRVO subgroup of the Global Evaluation of Implantable Dexamethasone in Retinal Vein Occlusion with Macular Edema (GENEVA) trial) (Haller et al. 2010) and triamcinolone acetate 1 mg (q4 month injections with −1.2 letter mean loss (26% with >15 letter gain) versus −12.1 letter loss (7% with >15 letter gain) with observation in Standard Care versus Corticosteroid for Retinal Vein Occlusion (SCORE)-CRVO trial).

Without data from large trials directly comparing the efficacies of these intravitreal agents, it is not clear if any agent is superior to the other. Because of the side effects, particularly cataract and elevated intraocular pressure, associated with corticosteroid administration, anti-VEGF agents are typically used first-line. In contrast to branch retinal vein occlusions, grid-pattern argon laser photocoagulation was found to reduce macular edema but not improve visual acuity in the Central Retinal Vein Occlusion Study (CVOS) and is therefore not recommended in treatment of CRVO-associated macular edema.

Treatment of CRVO-associated ocular neovascularization consists of panretinal laser photocoagulation (PRP). The CVOS examined optimal timing of PRP treatment. Prophylactic PRP did not significantly decrease the onset of neovascularization and resulted in decreased efficacy of subsequent PRP placement, so the CVOS recommended prompt, but not prophylactic, PRP placement upon development of anterior segment neovascularization. While the use of anti-VEGF therapy may be useful in inducing rapid regression of neovascularization, such therapy is a temporizing adjunct that should be administered in conjunction with PRP treatment if ocular neovascularization is present.

Prior to the development of intravitreal pharmacotherapy for CRVO, various alternative treatments were explored in the absence of robust therapies, including tissue plasminogen activator administration through either a systemic, intravitreal, or direct retinal vein cannulation approach; pars plana vitrectomy with or without internal limiting membrane peeling; laser or surgical chorioretinal anastomosis creation; and radial optic neurotomy. While successes with each approach have been reported, these results have not been consistently reproducible and have been associated with a significant complication profile. These approaches have largely been abandoned since the development of intravitreal pharmacotherapy.

Prognosis

The natural history of CRVO was followed in the Central Vein Occlusion Study. An important prognostic indicator of final visual outcome was visual acuity at the time of presentation. Baseline visual acuity was 20/40 or better in 29% of affected eyes, 20/50–20/200 in 43%, and 20/250 or worse in 28%; median baseline acuity was 20/80. The majority of those with initial visual acuity of 20/40 or better maintained this acuity. Individuals with intermediate visual acuity (20/50–20/200) had a variable outcome: 21% improved to better than 20/50, 41% stayed in the intermediate group, and 38% were worse than 20/200. Persons with poor visual acuity at presentation (less than 20/200) had only a 20% chance of improvement. The development of intravitreal pharmacotherapy for CRVO has provided significant improvements beyond the natural history of disease with a more favorable prognosis for visual rehabilitation.

Epidemiology

Retinal vein occlusions (both central and branch, including hemi) are the second leading cause of vision loss from retinal vascular dysfunction, behind diabetic retinopathy. CRVO accounts for approximately 25% of retinal vein occlusions. Prevalence of CRVO is estimated at <0.1–0.4%, affecting men and women equally and occurring predominantly in persons over the age of 65 years with coexisting systemic vascular comorbidities. CRVO is typically unilateral, but the annual risk of retinal vascular occlusion in the fellow eye is approximately 1% per year, and up to 7% of patients with CRVO may develop CRVO in the fellow eye within 5 years.

Central angiospastic retinopathy; Diffuse retinal pigment epitheliopathy; Idiopathic central serous retinopathy/chorioretinopathy

Definition, Pathogenesis, and Etiology

Central serous chorioretinopathy (CSC) is characterized by a serous detachment of the neurosensory retina that usually affects the macula and the posterior pole (Fig. 1). On fundus fluorescein angiogram (FFA), there is a classic "smokestack" or "ink blot" pattern of choroidal leakage in a proportion of patients. CSC commonly affects young men aged between 30 and 50 years of age. The prevalence of CSC is 9.9 cases per 100,000 in men and 1.7 cases per 100,000 in women.

The pathophysiology of CSC is unknown and has been thought to involve multiple mechanisms such as stasis and ischemia affecting the choroidal circulation (Nicholson et al. 2013). It has been hypothesized that a hyper-dynamic and hyper-permeable choroid causes increased hydrostatic pressure in the choroidal vessels. This leads to both the formation of pigment epithelial detachments (PEDs) (Fig. 2) and the breakdown of the retina pigment epithelium (RPE) barrier causing the leakage of fluid through the RPE cell tight junctions into the subretinal space, leading to the

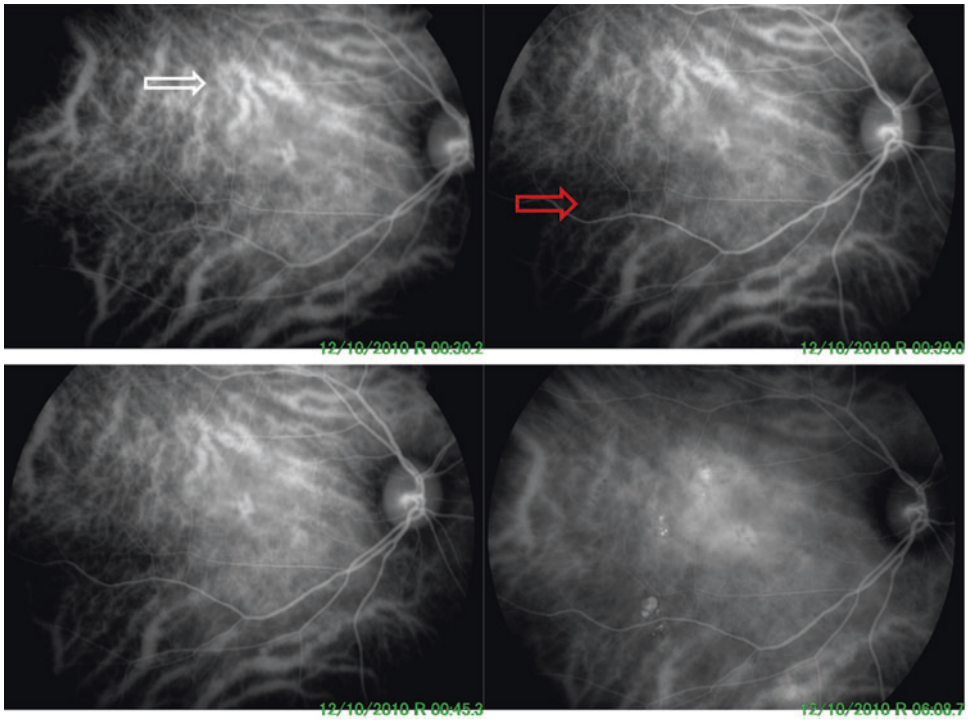
Central Serous Chorioretinopathy/Choroidopathy, Fig. 2 Fundus photo showing *white-gray* discoloration of the fovea due to fibrin deposition and cloudy subretinal fluid. The corresponding spectral domain OCT image (*right*) showing a CSC with an underlying PED (*white arrow*) and hyper-reflective material within the subretinal space due to fibrin deposition (*red arrow*)

classic serous detachment of neurosensory retina seen (Fig. 1) (Ryan 2012).

Animal models of CSC have shown damage to the endothelium of the choriocapillaries and fibrin clots, with leakage of fibrin into Bruch's membrane. Newer studies have also shown increased serum plasminogen activator inhibitor-1 (a fibrinolysis inhibitor) levels in patients with CSC, and this may support an underlying thrombotic mechanism. Another study with aqueous samples showed lower levels of the platelet-derived growth factor (PDGF) in the eyes with CSC than controls, suggesting that abnormal coagulation and platelet aggregation may also be involved in the pathogenesis of CSC (Nicholson et al. 2013).

Indocyanine green angiography (ICG) has shown supporting evidence of choroidal hyper-permeability with increased hyper-fluorescence of the choroidal vessels and areas of choriocapillary non-perfusion corresponding to focal areas of hypo-fluorescence (Fig. 3) (Ryan 2012; Nicholson et al. 2013). Optical coherence tomography (OCT) with enhanced depth imaging (EDI) in patients with CSC has shown a thickened choroid in both the affected and contralateral eyes (Fig. 4). Fibrin deposition in CSC lesions can also be observed clinically and on OCT imaging in humans (Fig. 2) (Agarwal 2012).

For the majority of case, the primary etiology is unknown. However, some secondary etiological agents have been described. Corticosteroids, both exogenous and endogenous, have been strongly associated with the development of CSC. The elevated levels of these compounds activate adrenergic receptors in the sympathetic nervous system and are thought to impair the auto-regulation of the choroidal vasculature (Nicholson et al. 2013). Early reports, which linked exogenous corticosteroid use to the incidence of CSC, include systemic steroids used for the treatment of autoimmune diseases or immunosuppression



Central Serous Chorioretinopathy/Choroidopathy, Fig. 3 ICG images showing areas of hyper-fluorescence (*white arrow*) consistent with choroidal hyper-permeability and areas of hypo-fluorescence (*red arrow*) consistent with areas of choriocapillary non-perfusion

after organ transplantation. In addition, the use of topical, intranasal, intra-articular, intramuscular corticosteroids has been reported to be risk factors for CSC. Excessive endogenous steroids in diseases like Cushing's syndrome and pregnancy are also associated with CSC. A previous study has reported an association of CSC with the type A personality trait (Ryan 2012). Some other

studies have reported an association with psychosocial stressors, in addition to inadequate coping mechanisms and the onset of CSC. Some newer studies have shown that there are also significant mineralocorticoid receptors in the choroid and this may be involved in CSC pathogenesis.

CSC is also associated less commonly with other diseases, such as systemic lupus erythematosus, sarcoidosis, Crohn's disease, paraproteinemia, Goodpasture's syndrome, and thrombotic thrombocytopenic purpura (Agarwal 2012). However it is uncertain whether the disease itself or the subsequent treatment with corticosteroids causes CSC (Liew et al. 2013; Nicholson et al. 2013).

Smaller studies have shown weaker associations of CSC; for example, higher level of basal endogenous catecholamines is thought to explain why obstructive sleep apnea (OSA) is associated with CSC. In one report, the treatment of OSA with continuous positive airway pressure (CPAP) resulted in the rapid resolution of bilateral CSC. An association with *Helicobacter pylori (H. pylori)* infection and CSC has been reported in recent studies. Thrombotic disease is a possible pathogenesis of this association. In one study 40% of CSC patients had *H. pylori* infection versus 25% of controls ($p = 0.0036$). Apart from corticosteroid use, other medications like 5-phosphodiesterase inhibitors (e.g., sildenafil and tadalafil) have been associated with CSC. Some case reports have reported a resolution of CSC after cessation of these medications; however a larger case-control study failed to confirm such an association (Nicholson et al. 2013). Antibiotics, psychopharmacological medications, alcohol, hypertension, and allergic respiratory disease have all been reported in small studies as potential risk factors of CSC.

A genetic basis to the pathogenesis of CSC is still not well established. There are numerous reports of familial CSC, and one study found a 52% rate of CSC-like pathology in families of chronic CSC patients. Despite the clinical findings, only a small percentage reported CSC symptoms. Previous studies have performed analyses on aqueous samples of CSC eyes for various cytokines and growth factors. Vascular endothelial growth factor (VEGF) levels in the aqueous were not found to be elevated in CSC; however this was controversial, as secondary choroidal neovascularization (CNV) that can be a complication of CSC responds well to anti-VEGF therapy. PDGF levels were reported as lower than controls, and this could be a possible mechanism of RPE dysfunction. Other cytokines like IL-6, IL-8, and monocyte chemoattractant protein-1 were found at similar levels in both CSC and control groups (Nicholson et al. 2013).

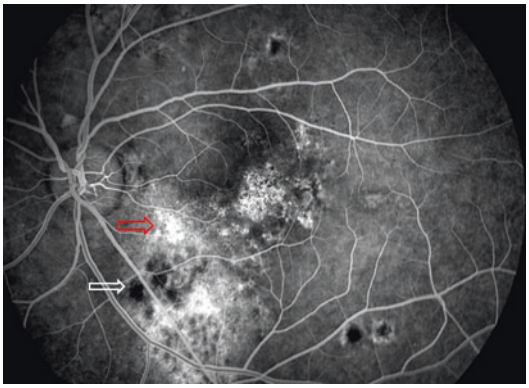
Clinical Presentation

Symptoms

The hallmark characteristics of CSC include blurring of vision, a relative central scotoma, metamorphopsia, and a hyperopic shift. In some patients, where the CSC does not involve the central macula area, they can be asymptomatic. Once the detachment reaches the central macula, it will cause distortion of the photoreceptor arrangement. In areas where there is crowding of the photoreceptors, the patient will experience macropsia; in other areas with a reduction in the number of photoreceptors per unit area, micropsia will result. Dyschromatopsia with a decrease in color saturation, contrast sensitivity, and a delay in retinal recovery time after exposure to light are other symptoms associated with CSC. A hyperopic shift occurs as the neurosensory retinal is pushed forward.

CSC can nominally be classified as acute and chronic; however the definition of the chronic form is not well defined and can range from 3 to 6 months of persistent fluid. Other studies have classified CSC based on the pathology at the level of the RPE. "Classic CSC" has pinpoint leaks at the RPE with minimal focal RPE changes (Fig. 1), while diffuse retinal pigment epitheliopathy (DRPE) has extensive RPE damage and diffuse leakage (Fig. 5) (Nicholson et al. 2013).

The initial episode of acute CSC tends to resolve without serious long-term sequelae. Recurrence of acute CSC, however, is common and has been reported in 15–50% of patients in previous studies. Thirty-three to 50% of CSC



Central Serous Chorioretinopathy/Choroidopathy, Fig. 5 FFA of a patient with chronic CSC showing areas of hypo-fluorescence corresponding to areas of RPE atrophy (*white arrow*) and areas of diffuse hyper-fluorescence consistent with diffuse leakage from the RPE (*red arrow*)

patients experience the first recurrence within the first year of follow-up, while 10% may have three or more recurrences up to 15 years after presentation. The initial presentation of this disease is usually unilateral, but bilateral involvement is reported to affect up to 40% of cases. Recent imaging studies have also documented subclinical structural changes in the contralateral eye of CSC patients (Fig. 4). Risk factors for bilateral involvement include chronic CSC and CSC associated with corticosteroids use (Ryan 2012; Liew et al. 2013).

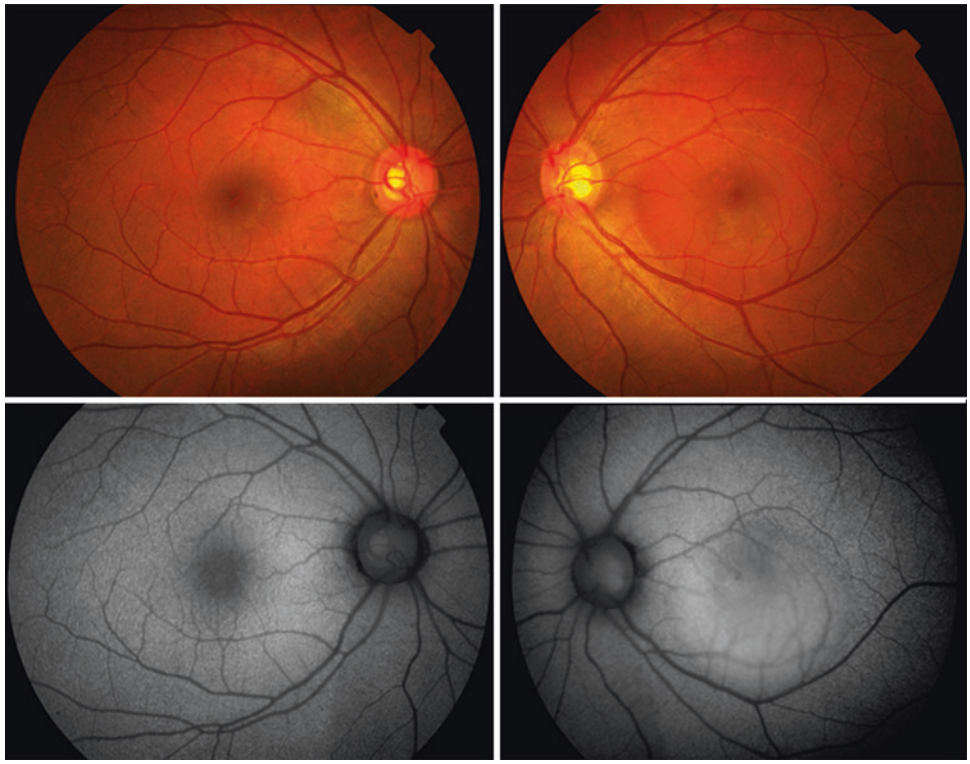
Signs

Clinical findings include a well-demarcated round or oval elevation of the neurosensory retinal, often involving the macula. The foveal reflex is decreased or absent, and the affected area often appears darker than the surrounding area as seen on slit-lamp biomicroscopy (Fig. 6). An associated PED may be present within or adjacent to the neurosensory detachment in 5–63% of all cases. This PED can be solitary or multiple and is typically small (Fig. 2). The areas between the detached and attached RPE appear as a well-circumscribed halo outlining the base of the lesion (Fig. 7). Yellow deposits on the underside of the detached retina are thought to arise from previous phagocytosis of photoreceptor outer segments after shedding. A yellowish discoloration of the foveal region is thought to arise from the increased visibility of the xanthophyll pigment (Fig. 6) (Agarwal 2012; Ryan 2012). The serous fluid within the detachment is mostly clear however in 10% of cases can be cloudy. In these cases, fibrin is deposited in the subretinal space forming a gray-white fibrinous lesion (Fig. 2), which can be misdiagnosed as focal retinitis, a cotton wool spot, or a subretinal neovascular membrane. Some patients develop a bullous serous retinal detachment as the subretinal fluid settles inferiorly (Fig. 8a). In chronic CSC cases, RPE atrophy on the retina can be seen connecting the macula to the inferior bullous detachment (Fig. 8b). The vitreous of a CSC patient is clear with no inflammatory cells.

Diagnostics (Imaging)

Optical Coherence Tomography (OCT)

Recent advances in new high-resolution imaging techniques have enabled better visualization of structures and understanding of the underlying pathophysiology of CSC. Spectral domain OCT (SDOCT) imaging, including enhanced depth imaging (Fig. 4), has enabled imaging of not only the retinal but the choroid. High-definition images of the central serous detachment, serous PEDs, and the underlying choroid have allowed detailed studies of these structures that were not possible using conventional slit biomicroscopy. The choroidal layer in CSC patients has been found to be thickened when compared to controls in both the affected and contralateral eyes (Fig. 4). This suggests a much greater incidence of subclinical bilateral involvement than previously reported. The underlying cause for the thickened choroid is not certain; however this is thought to be related to choroidal vasculature hyperpermeability as seen in ICG angiography (Fig. 3). Choroidal thickness on OCT is a useful parameter, which can be used to monitor disease progression and response to treatment. Visual acuity has been linked with the thickness of the outer nuclear layer (ONL) and the integrity of the inner segment ellipsoid zone (EZ). During chronic CSC, photoreceptor apoptosis and subsequent



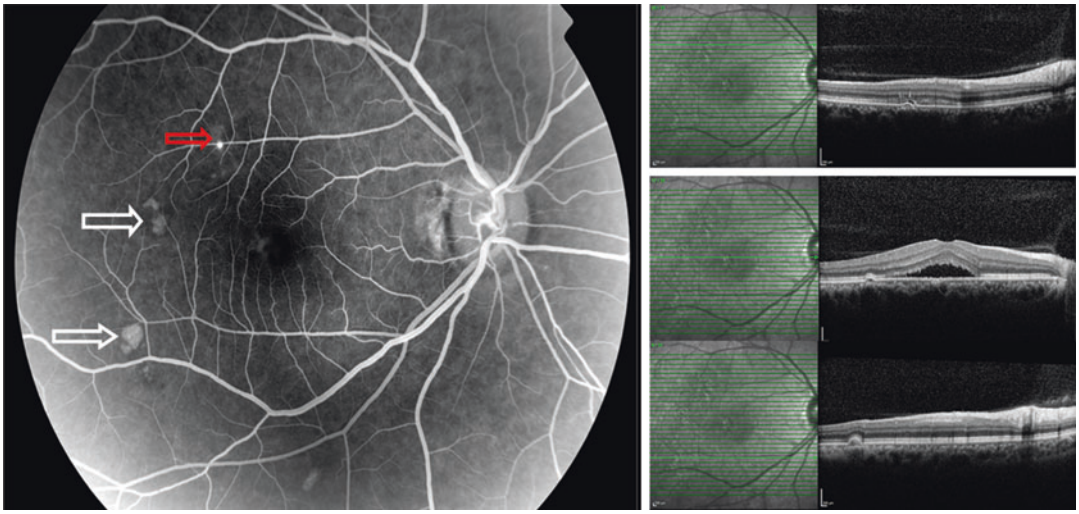
Central Serous Chorioretinopathy/Choroidopathy, Fig. 6 A fundus photo of a patient (*top right*) with CSC involving the macula, as demonstrated by a reduced foveal reflex and a slightly darker elevated region of the neurosensory detachment. The other contralateral eye (*top left*) is unaffected. FAF (*bottom right*) of the CSC shows blocked hypo-fluorescence at the fovea and a mild hyperfluorescent border around the neurosensory detachment more marked inferiorly

atrophy in the foveal region cause thinning of the ONL and disruption of the EZ layer and may result in poorer visual acuity (Fig. 9). In many cases, there is also a corresponding atrophic area of hypo-autofluorescence (AF) seen on autofluorescence (AF) imaging (Fig. 9).

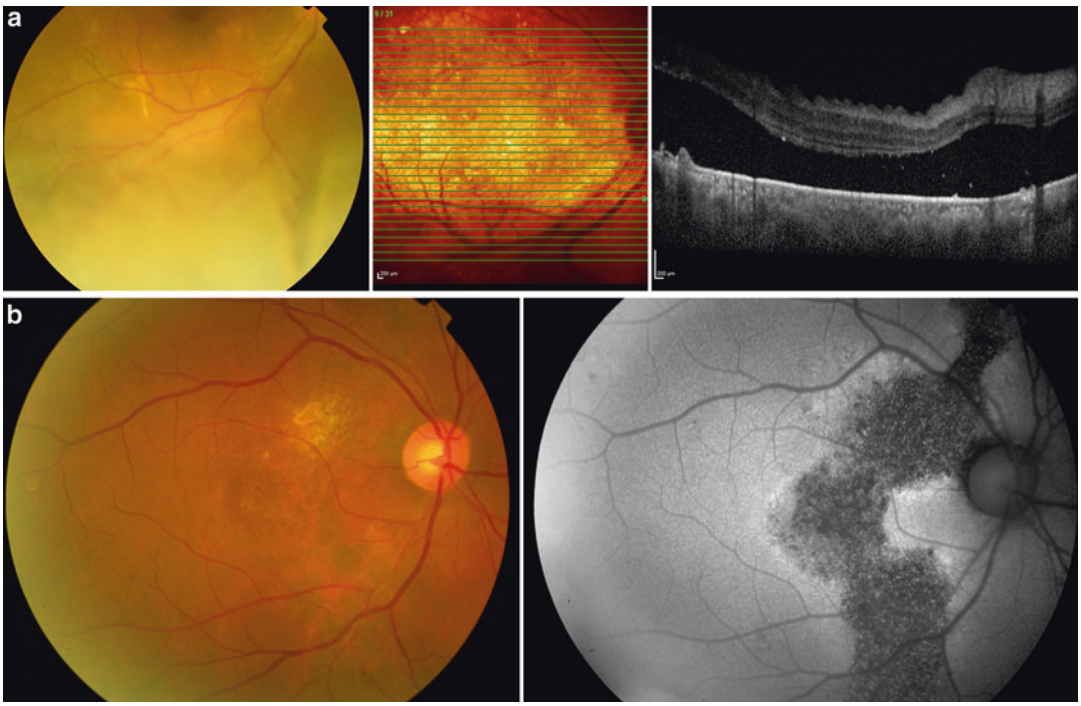
Punctate precipitates and yellow-white material have been observed in 65% of CSC patients and can be seen as hyper-reflective dots on the OCT image both within the retina and in the subretinal space (Figs. 10 and 11). This often correlates with clinical slit-lamp findings and fundus photography. The nature of these substances is still unclear, but possible hypothesis includes shed unphagocytosed photoreceptor outer segments and accumulations of fibrin, lipid, or macrophages clearing the subretinal space from debris (Liew et al. 2013; Nicholson et al. 2013). Focal areas of RPE breaches can be imaged on OCT, and this can correspond with leakage on FFA from the choroid (Fig. 1) (Nicholson et al. 2013). These areas adjacent to the leak on FFA frequently are sites for PED formation. Intraretinal cysts and subretinal fibrosis seen on OCT are also more common in chronic CSC and have a poorer visual prognosis (Liew et al. 2013).

Fundus Fluorescein Angiography (FFA)

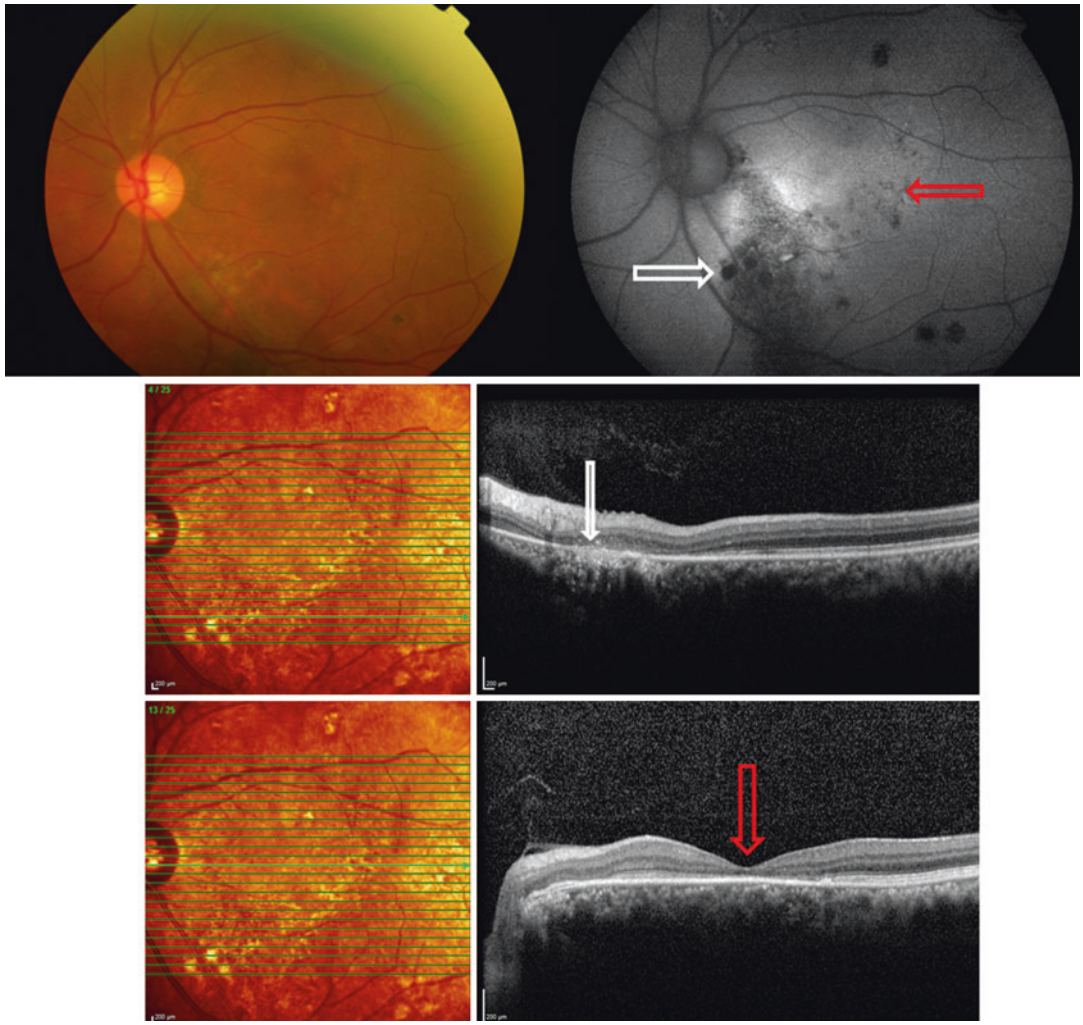
In acute CSC, two distinct patterns of FFA leakage have been described: ink blot or smokestack. The ink blot pattern is caused initially by the fluorescein leaking from the fenestrated choriocapillaries across Bruch's membrane staining the fluid in the sub-RPE space. This round spot of hyperfluorescence enlarges concentrically to fill the area of the PED. In some patients the dye may



Central Serous Chorioretinopathy/Choroidopathy, Fig. 7 FFA (*left*) of a patient with CSR and multiple adjacent PEDs. The superior PED (*red arrow*) is located in the area of leakage causing the neurosensory detachment inferiorly. Corresponding OCT images showing cross sections of the PED is shown – red arrow (*corresponding to top right OCT images*) shows actively leaking PED and the white arrows (*corresponding to the middle right and bottom right OCT images*) show non-leaking PEDs



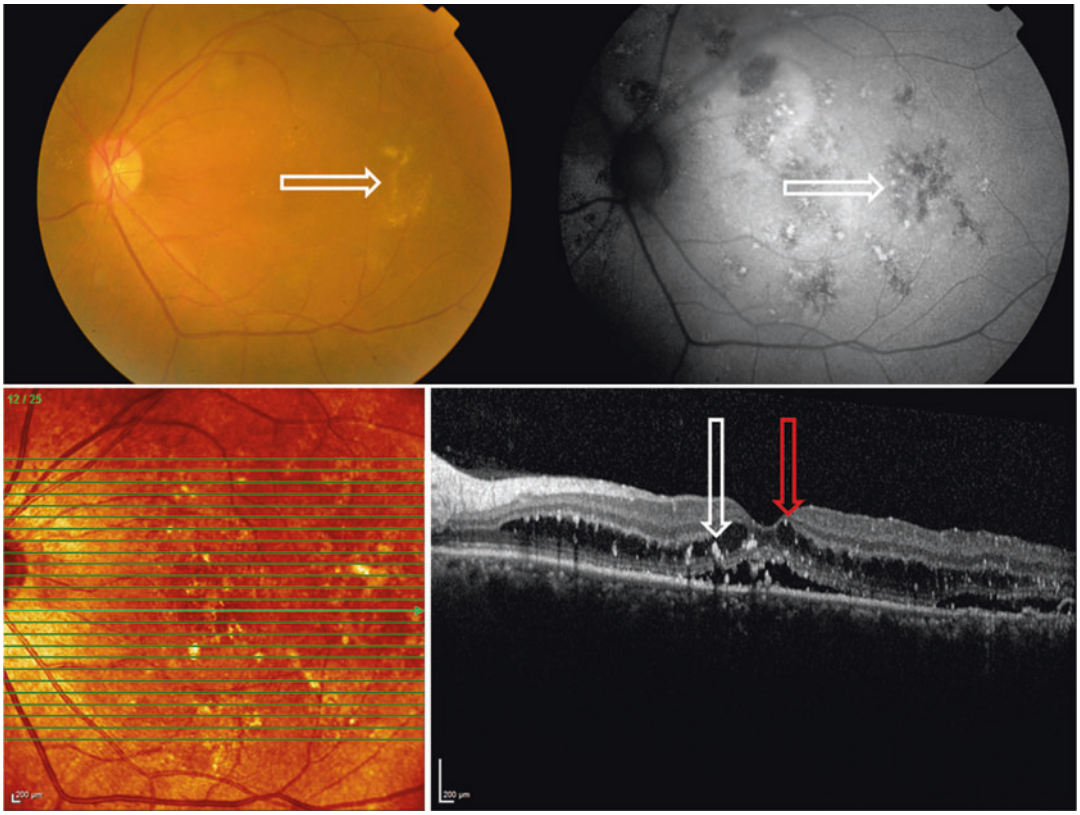
Central Serous Chorioretinopathy/Choroidopathy, Fig. 8 (**a**) Fundus photo (*left*) showing an inferior bullous retinal detachment from a multifocal chronic CSC and the corresponding OCT. (**b**) RPE atrophy tracts connecting the macula to the inferior bullous detachment as seen on color fundus photo (*left*) and hypoautofluorescent area on FAF (*right*)



Central Serous Chorioretinopathy/Choroidopathy, Fig. 9 A fundus photo (*left*) of a patient with resolved CSC showing areas of RPE atrophy corresponding to the areas of hypo-fluorescence on FAF (*right*). The corresponding OCT image shows disruption of the EZ line and thinning of ONL (*red* and *white arrow*). Granular hypo-fluorescence at the fovea region is consistent with a poor visual acuity of 6/90

be confined to the sub-RPE space but in other patients with the dye will diffuse into the subretinal space and cause the subretinal exudate surrounding the PED to be hyper-fluorescent (Fig. 12). The smokestack pattern has only been reported in 10% of cases. It is caused by the dye from the sub-RPE space leaking through a small pinpoint breach in the RPE at the inferior margin of the PED then flowing upward into the subretinal exudate in an umbrellalike or mushroomlike pattern (Fig. 13). It has been proposed that this pattern of leakage is due to the differential specific gravity of the dye and the subretinal exudates, causing convectional currents. In the late stages, all the subretinal exudates will be hyper-fluorescent, except in the foveal region, where it is blocked by luteal retinal pigment (Agarwal 2012; Ryan 2012).

In chronic, extensive CSC with PED and atrophy, RPE window defects may be observed. In multifocal CSC multiple areas of leakage may be observed, and FFA can help differentiate CSC from other inflammatory diseases or secondary choroidal neovascularization (Fig. 14; Agarwal 2012).



Central Serous Chorioretinopathy/Choroidopathy, Fig. 10 Fundus photo and FAF imaging which show yellow-white material, which is also seen as hyper-reflective dots on OCT within the retina and the subretinal space (*white arrows*). Intraretinal cysts and schisis changes (*red arrow*) that can be seen in chronic CSC

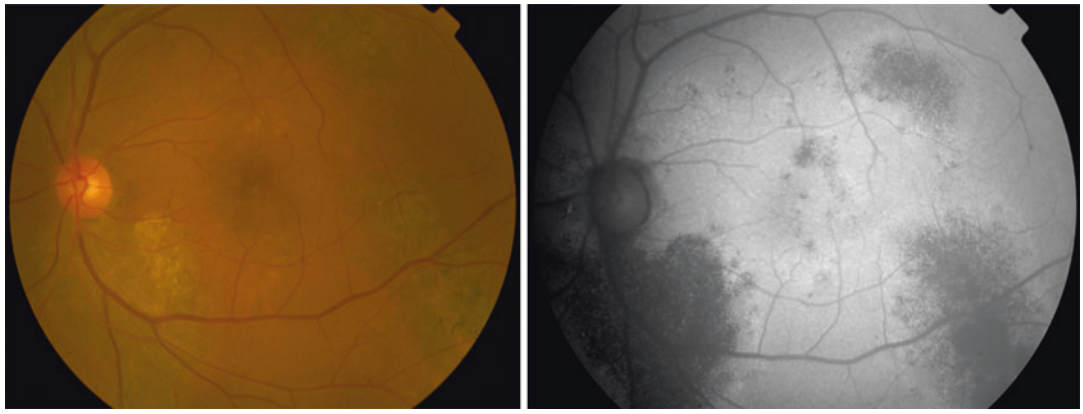
Most often the source of leakage is located in the posterior pole, one disc diameter away from the fovea. During FFA, attention should be focused on the more superior portion of the subretinal detachment as it is commonly the site of the leak due to gravity. About 30% of leakage occurs in the superior nasal quadrant, and 25% occurs in the papillomacular bundle (Agarwal 2012).

Indocyanine Green Angiography (ICG)

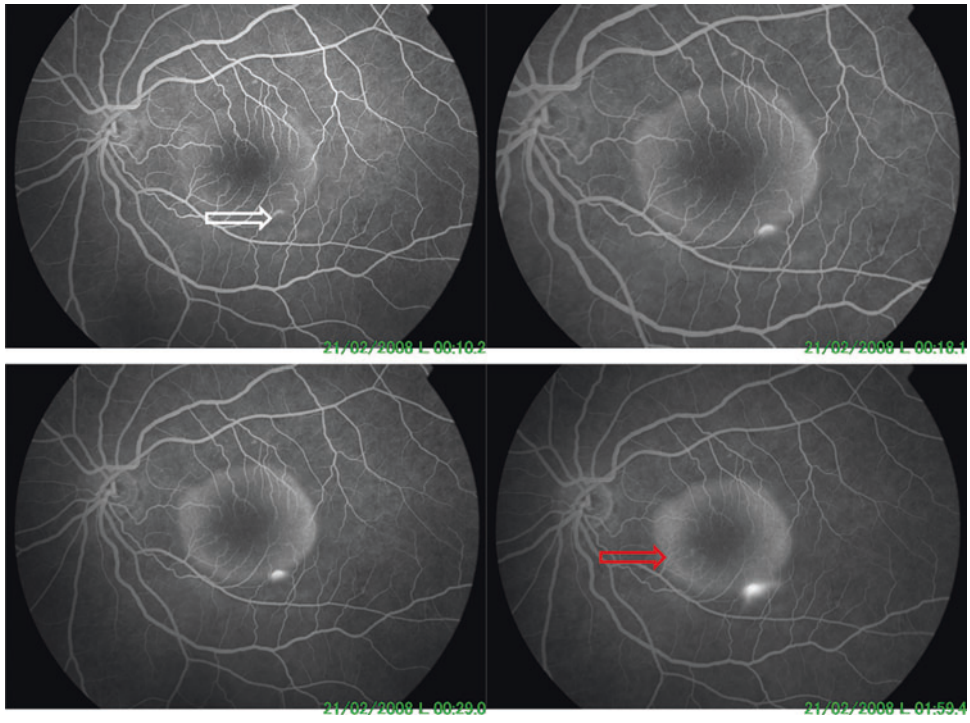
Common findings in CSC include a delay in choroidal filling, abnormal dilated choroidal vessels in the early stage, and choroidal hyperpermeability in the late phase (Fig. 3). The area of abnormality is often much larger than the area affected on FFA and is often observed on the contralateral eye. Patches of hyper-fluorescence in the later stages are caused by leakage into the deeper choroidal layers. Hypo-fluorescent areas on ICG are likely to represent areas of choroidal non-perfusion, a possible pathogenic mechanism for this disease (Fig. 3).

Fundus Autofluorescence Imaging (FAF)

Fundus autofluorescence (FAF) that employs the use of either fundus cameras or confocal systems has also been used to further characterize CSC. Autofluorescent properties such as lipofuscin can release light when stimulated by certain wavelengths. In acute CSC, hyper-autofluorescence develops in the areas of the subretinal fluid due to unphagocytosed photoreceptor outer segments; however this may sometimes be blocked by the macula pigment. A hyper-autofluorescent border around the detachment, which is more marked inferiorly, may disappear on resolution of the CSC (Fig. 6). Other areas of focal hyper-autofluorescence correspond to punctate

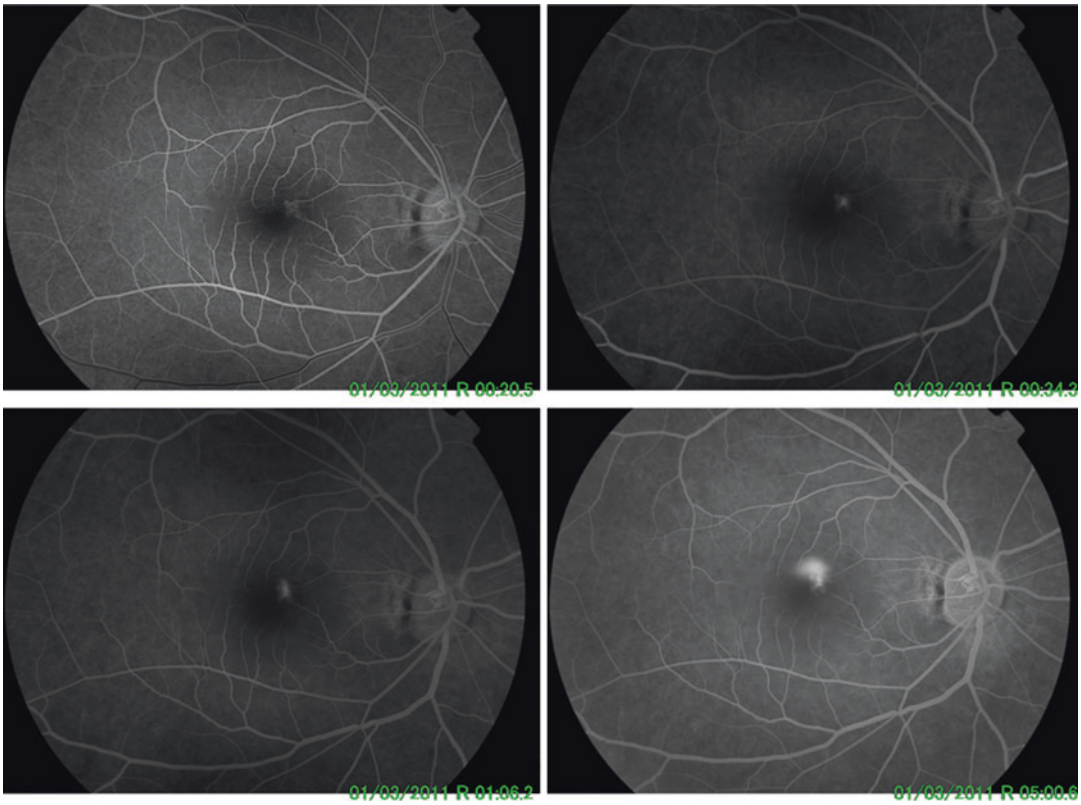


Central Serous Chorioretinopathy/Choroidopathy, Fig. 11 Fundus photo and FAF showing the confluent hypo-autofluorescence pattern in areas of RPE atrophy



Central Serous Chorioretinopathy/Choroidopathy, Fig. 12 FFA showing an "ink blot" pattern of leakage of the CSC. Early phases show the filling of the PED (*white arrow*), and then in the later stages, there is leakage into the subretinal space allowing the neurosensory detachment to be hyperfluorescent (*red arrow*)

precipitates and yellow-white deposits seen clinically and on OCT. In chronic CSC or DRPE, changes on FAF are due to RPE damage as well as areas of active serous detachment. Patterns previously described are granular (Figs. 8b and 9) or confluent hypo- or hyper-autofluorescence (Fig. 11). Descending tracts from the macula and optic nerve caused by the movement of subretinal fluid due to gravity can also be imaged on FAF (Fig. 8b). Correlation of FAF and OCT studies



Central Serous Chorioretinopathy/Choroidopathy, Fig. 13 FFA showing a "smokestack" pattern leakage of the CSC where dye from the sub-RPE space leaks through a breach in the RPE seen in the early phase, then flows upward into the subretinal exudate in an umbrellalike pattern in later phases

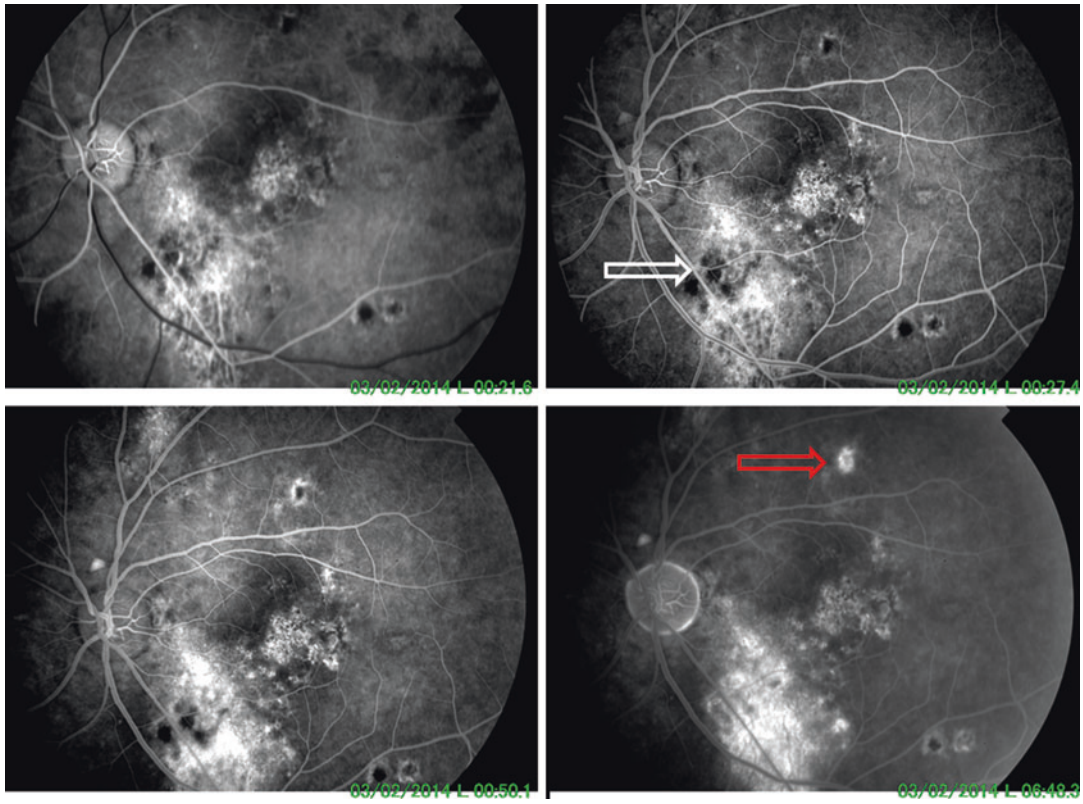
show that the areas of hypo-autofluorescence correspond to the areas of RPE atrophy and can be correlated with visual acuity if the central macula is affected. A granular FAF pattern was suggestive of incomplete RPE loss. Hyper-autofluorescence was not found to correlate significantly with visual acuity (Ryan 2012).

Multifocal Electroretinography (mfERG) and Microperimetry

Functional testing in CSC patients has shown reduction in amplitudes on mfERG with outer retinal dysfunction more marked in the central retina and inner retinal dysfunction more widespread extending into the periphery, and this can be correlated with visual acuity (Agarwal 2012). Implicit times show correlation with OCT findings in the paracentral rings. After subretinal fluid resolution, mfERG amplitudes improve, but do not return to normal. Macula sensitivity as measured by microperimetry correlates with findings on the OCT. Retinal sensitivity decreases with increased disruption of the EZ zone. Microperimetry has also shown a correlation to both mfERG implicit times and visual acuity. Similar to mfERG in CSC patients, retinal sensitivity does not return to normal despite the complete resolution of subretinal fluid and 20/20 visual acuity (Ryan 2012).

Adaptive Optics (AO)

AO allows the imaging of individual photoreceptors and was used in patient with previously spontaneously resolved CSC. There was a significantly lesser cone density in these patients compared to controls, despite most patients having 20/20 vision or better. The cone densities correlated with the visual acuity and with an intact EZ line on OCT (Ryan 2012).



Central Serous Chorioretinopathy/Choroidopathy, Fig. 14 FFA of a chronic recurrent multifocal CSC associated with steroid use, showing a window defect in areas of RPE atrophy (*white arrow*) and a superior area of leakage (*red arrow*)

Differential Diagnosis

In the majority of the time, the diagnosis of CSC can be made through a detailed history, slit-lamp microscopy, and OCT. However other diseases such as a congenital optic disc pit, choroidal tumors (e.g., hemangioma, osteoma, malignant tumors), uveal effusion syndrome, and other inflammatory diseases of the choroid (e.g., Vogt-Koyanagi-Harada disease, sarcoidosis, posterior scleritis) can be associated with serous detachments. Systemic diseases like malignant hypertension, toxemia of pregnancy, and disseminated intravascular coagulopathy can also be associated with a neurosensory detachment. Autoimmune diseases like systemic lupus erythematosus and polyarteritis nodosa can cause serous detachment from the disease itself or the subsequent treatment with corticosteroids. Age-related macular degeneration and polypoidal choroidal vasculopathy can commonly mimic CSC and must be considered in all elderly patients above 50 years old. Ocular contusion from trauma as well as traction from an incomplete posterior vitreous detachment can also resemble a serous detachment. In patients with chronic inferior retinal detachments, the diagnosis of retinoschisis, uveal effusion, or rhegmatogenous retinal detachment should be considered. Occasionally, after scleral buckling procedures, there may be a couple of residual pockets of exudative retinal detachment which may appear similar to CSC, (Agarwal 2012; Ryan 2012).

Therapy

Acute CSC is a self-limiting disease that usually requires no treatment. Risk factors like psychosocial

stressors should be minimized. Patients should be screened for CSC inciting drugs like corticosteroids, catecholamines, and 5-phosphodiesterase inhibitors and discontinue any unnecessary medication. The use of traditional herbal remedies and supplements, which may potentially contain corticosteroids, should also be discontinued. In cases of systemic autoimmune disease requiring immunosuppression, steroid-sparing agents should be considered as an alternative, and a slow tapering off of the steroids should be comanaged with a physician (Agarwal 2012; Ryan 2012; Liew et al. 2013; Nicholson et al. 2013).

In cases with no resolution in 3–4 months, chronic cases, or recurrent cases with progressive vision loss or in patients with high visual demands requiring rapid recovery, treatment can be considered. The main aims of treatment are to improve both structural and functional outcomes. The improvement of symptoms, visual acuity, and the size of the neurosensory detachment on OCT are all parameters used in clinical practice to assess recovery and treatment effect. The visual potential and the degree of swelling should be considered when planning treatment. For example, if there is extensive atrophy in the macula and scarring, there may be limited benefit from treatment; on the other hand, treating to remove chronic subretinal fluid may prevent further deterioration. Throughout the course of treatment, there is a risk of the development of secondary CNV, and this should be diagnosed and treated early to prevent further vision loss. Signs of retinal or subretinal hemorrhages and hard exudates adjacent to the neurosensory detachment or PED may suggest CNV.

Laser Photocoagulation

The best current evidence-based treatment of CSC is laser photocoagulation of extrafoveal areas of leakage or photodynamic therapy (PDT) for areas nearer the fovea. Laser has been thought to hasten the resolution of CSC, but does not affect the final visual acuity in most patients. FFA is required to identify focal areas of leakage, and laser burns are applied accordingly. In general, focal laser is only recommended in cases with an extrafoveal (>375 μm) focal area of leakage on FFA angiography. Diffuse leakage and focal leakage on FFA nearer the fovea should not be treated, due to the risk of scarring and atrophy. The aim of the laser is to stimulate the RPE to absorb to subretinal fluid and to stop further leakage. The exact mechanism of action is unclear. Randomized controls studying focal laser treatment to extramacular leakage sites shows a faster resolution of subretinal fluid but no improvements in visual acuity when compared to controls. There was also no improvement in recurrence rates after focal treatment. Secondary CNV after focal laser treatment was reported as a potential complication, and patients receiving focal laser should receive long-term follow-up.

Photodynamic Therapy

Photodynamic therapy that is directed toward the hyper-permeable choroid vessels has been shown to be safe and effective in the treatment of CSC. This treatment can promote the resolution in acute CSC and also prevent recurrences. The proposed mechanism of action is choroidal remodeling and thinning of the treated choroid. In trials using PDT to treat neovascular age-related macular degeneration, PDT was used to cause vaso-occlusion of the choroidal neovascularization. In contrast for CSC, treatment with PDT is required only for remodeling of the choroidal vasculature. Hence, modifications to the PDT dosage and laser energy aim to adequately treat CSC while reducing potential adverse effects. In a previous randomized controlled trial, half-dose PDT in patients with acute CSC has been shown to reduce the risk of persistent subretinal fluid at 1 year compared to controls. All patients of the treatment group had a visual acuity that was stable or improved in compared to only 78.9% of the control group. Other studies have shown that in some patients, multiple sessions of PDT may be required to achieve complete fluid resolution; however this should be balanced against the risk of chorioretinal atrophy. In one study, the risk of chorioretinal atrophy was found to be greater in the PDT-treated eyes than the eyes treated with focal laser, leading to vision loss in some patients. In addition, secondary CNV, choroidal ischemia, and RPE rips were reported as other potential complications. Hence, reduced fluence treatment that can

be achieved by reducing the laser treatment time, lowering the laser power or increasing the interval between infusion and laser, and reducing the verteporfin dose may be a safer alternative. It is debatable whether PDT should be performed under FFA or ICG guidance. A spot size large enough to cover the area should be applied avoiding areas of significant RPE atrophy (Ryan 2012; Nicholson et al. 2013). In some studies, a significant reduction in the choroidal thickness as seen on enhanced depth OCT is seen in the eyes treated with PDT, but a similar change is not observed in the eyes treated with focal laser.

Anti-VEGF Therapy

VEGF levels were not found to be elevated in the aqueous or plasma in patients with CSC; however small reports of improvements in both anatomical and functional parameters in CSC have been reported after the treatment with anti-VEGF agents. However, anti-VEGF agents did not seem to have better outcomes when compared to PDT. Hence when the two treatments are compared, the efficacy and safety of intravitreal injections are questionable.

Other Therapies

Other forms of laser therapy like diode micropulse laser and transpupillary thermotherapy have been trialed in other smaller studies with a limited follow-up duration. Overall these therapies show a benefit in the resolution rate of CSC but variable improvements in visual acuity and function. However, there is insufficient evidence to support the safety and efficacy of these treatments.

Elevated serum cortisol levels are related to the underlying pathogenesis of CSC. Anti-glucocorticoids, which inhibit the cortisol pathway such as ketoconazole, mifepristone, finasteride, rifampicin, and anti-adrenergics, have been trialed in small studies with variable results. Further studies are needed to confirm a significant benefit. Beta-blockers that cause an adrenergic blockade have been investigated for CSC but have not shown to be effective.

Carbonic anhydrase inhibitors (CAIs) have been used to treat CSC, on the basis that it can increase subretinal fluid reabsorption and retinal adhesion at the level of the RPE. Only one study on CAIs has shown that there was a faster resolution rate of acute CSC but no difference between visual acuity and recurrence rates between treatment group and controls. Similarly, the treatment of *H. pylori* with systemic antibiotics in *H. pylori*-positive CSC patients showed faster resolution of disease but no visual acuity improvement when compared to controls (Ryan 2012). Hypercoagulability has been proposed as another potential mechanism of CSC, and in one study, aspirin was shown to improve the rate of recovery, reduce rate of recurrence, and result in slightly better visual acuity when compared to controls (Ryan 2012; Nicholson et al. 2013).

One small pilot study with no controls has reported an improvement in both central macular thickness and visual acuity in cases of chronic CSC after treatment with eplerenone, a mineralocorticoid receptor antagonist. A few larger randomized control trials are underway to determine the efficacy and safety of this promising medical treatment for chronic CSC (Bousquet et al. 2013).

Prognosis

The natural history of this disease is that 90% of cases will show spontaneous recovery within a few months without significant vision loss. As mentioned before despite visual acuity recovery, subtle changes can still be seen clinically, on FAF, OCT, and mfERG. However in about 5% of CSC patients, visual acuity will not improve to 20/30 or better. Fifty percent of patients recur and this is more common in the first year. Especially in recurrent and chronic forms of CSC, where there is widespread RPE atrophy and scarring, irreversible vision loss with reduction in contrast sensitivity and color vision can occur. Poor prognostic factors for visual acuity include a poor presenting visual acuity and a prolonged duration of the neurosensory detachment. In a small group of patients (up to 6%), a secondary CNV can develop and cause visual loss. Spontaneous resolution of a small PED is more common than in larger lesions; however the visual acuity usually remains preserved despite a large PED. Despite complete resolution of a serous detachment, residual

pigmentary changes and mottling can still be observed. High-resolution imaging shows subclinical structural changes occur despite regaining 20/20 vision; hence CSC should not be considered a benign disease (Agarwal 2012; Ryan 2012).

Epidemiology

The incidence rates of CSC in the largest population-based study in Minnesota, USA, were estimated as 9.9 cases per 100,000 in men and 1.7 cases per 100,000 in women. CSC is thought to have a higher incidence in Asian populations followed by Caucasian populations and affects African-Americans the least (Ryan 2012; Liew et al. 2013). In one study with Chinese Singaporeans, the rates of multifocal and bilateral involvement of CSC were higher than in a similar white population. Another study reported that despite lower rates in African-Americans, these patients have worse visual acuity throughout the course of disease suggesting a greater severity of the disease (Liew et al. 2013).

CSC is more common in males than in females with previous ratio reported as 6:1. The age of onset ranges between 30 and 50 years of age. Older CSC patients tended to have a higher rate of chronic CSC with diffuse RPE loss and sometimes the development of secondary choroidal neovascularization (CNV) (Ryan 2012).

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

History

Cerebral achromatopsia was first reported in the late 1800s and was initially described as the result

of damage to the "color center" of the brain (Danchaivijitr and Kennard 2008).

Definition

Complete achromatopsia is the inability to identify color; everything an individual perceives is monochrome: black, white, and shades of gray. Cerebral achromatopsia is unique because the loss of color vision is due to damage to the cerebral cortex. It may result in complete loss of color vision, or in some cases, patients miss one primary color (Lawton and Wang 2014). Bilateral lesions cause complete cerebral achromatopsia; unilateral lesions cause hemiachromatopsia, which is often unnoticed by patients (Boyd and Matsuba 2011). However, it is perceived when it is tested directly (Paulson et al. 1994). Patients with cerebral achromatopsia generally describe objects as "washed out" or "faded," and they see many shades of gray (Lawton and Wang 2014).

Etiology

Bilateral damage to a relatively small region of the cortex – the inferior surface of the temporal–occipital regions, in particular the lingual and posterior fusiform gyri (Bovier 2006). The most common cause of cerebral achromatopsia is an embolic stroke in the territory of the posterior cerebellar artery. It can also be caused by physical trauma and abnormal tissue growth (tumor). Other conditions such as carbon monoxide poisoning and cerebral metastases have also been reported to cause cerebral achromatopsia (Danchaivijitr and Kennard 2008).

Classification

The two most common classifications for cerebral achromatopsia are complete and hemifield. Complete loss of color vision results from a bilateral lesion, and hemifield is characterized by homonymous hemiachromatopsia, which is contralateral to the single cerebral cortex that is lesioned. In uncommon cases superior or inferior homonymous quadrantachromatopsia has been recorded. In still rarer cases, transient cerebral achromatopsia has been reported due to temporary ischemia (Danchaivijitr and Kennard 2008).

Cerebrohepatorenal (Zellweger) Syndrome

Shiri Zayit-Soudry and Michael Mimouni
Department of Ophthalmology, Rambam Health Care Campus, Haifa, Israel
Department of Ophthalmology, Ruth and Bruce Rappaport Faculty of Medicine, Technion, Haifa, Israel

Synonyms

Cerebrohepatorenal syndrome; Zellweger syndrome

Definition

The peroxisomal biogenesis disorders are autosomal recessive disorders that include cerebrohepatorenal syndrome (Zellweger syndrome), adrenoleukodystrophy, infantile Refsum's disease, and Alagille syndrome. These disorders are characterized by abnormal oxidation and toxic accumulation of very long-chain fatty acids.

Cerebrohepatorenal syndrome is the most severe and most common peroxisomal disorder of early infancy affecting 1 in 50,000 live births. It is characterized by craniofacial dysmorphism and profound neurologic abnormalities with infants rarely surviving beyond the first year of life. Systemic findings include muscular hypotonia, seizures, poor feeding, sensorineural hearing loss, deficient cerebral myelination, renal cysts, and hepatomegaly.

Ocular findings are diverse and include hypertelorism, shallow supraorbital ridges, epicanthal folds, microphthalmia, nystagmus, corneal clouding, cataract, glaucoma, and optic disc atrophy. Brushfield spots, focal areas of stromal hyperplasia on the iris periphery, have also been described in these patients. Retinitis pigmentosa-like retinopathy has also been reported in patients with Zellweger syndrome, characterized by severe, infantile-onset retinal dystrophy with retinal hypopigmentation and vascular attenuation. The electroretinogram is either profoundly abnormal or completely absent, and visual evoked potential (VEP) responses are prolonged. Nystagmus and strabismus are common, secondary to poor vision.

Increase of plasmatic very long-chain fatty acids serves as a biochemical marker for this syndrome. Definitive diagnosis is made via DNA testing.

Currently, no effective treatment is available for Zellweger syndrome. Docosahexaenoic acid supplementation has been suggested as a possible therapy though its benefit is still controversial.

Ceroid Lipofuscinosis

Shiri Zayit-Soudry and Michael Mimouni
Department of Ophthalmology, Rambam Health Care Campus, Haifa, Israel
Department of Ophthalmology, Ruth and Bruce Rappaport Faculty of Medicine, Technion, Haifa, Israel

Synonyms

Batten disease; Neuronal ceroid lipofuscinosis

Definition

The neuronal ceroid lipofuscinoses (NCLs) are a group of autosomal recessive disorders caused by lipofuscin accumulation within the lysosomes of cells leading to cellular dysfunction and cell death. The approximated incidence is 1 per 12,500 live births. The disorders are associated with variable, yet progressive, symptoms including progressive degeneration of the nervous system, cognitive and motor decline, seizures, visual loss, and early death.

Clinically, the childhood-onset disorders have been classified into infantile, late-infantile, and juvenile forms based primarily on the age of symptom onset, rate of disease progression, and pattern of symptoms. The infant and juvenile types are associated with ocular findings in general and pigmentary retinopathies specifically, while the adult forms of NCL are absent ocular manifestation. More recently, following identification of several genetic mutations resulting in this condition, newer classifications have been suggested based on the affected gene.

One of the earliest signs of NCL may be vision loss associated with outer retinal degeneration. Typical ocular findings in infantile NCL include optic disc atrophy, hypopigmentary changes of the retinal pigment epithelium (RPE) in the macular area with mottling of the fundus periphery. The late-infantile and juvenile onset subtypes typically show a macular granularity or a bull's eye maculopathy, with variable degrees of peripheral RPE change, optic disc atrophy, and attenuation of the retinal blood vessels. Fluorescein angiography of juvenile patients demonstrates diffuse RPE atrophy with stippled hyperfluorescence. All NCLs show a profoundly abnormal or absent electroretinogram.

The diagnosis of NCLs is made on clinical grounds and by demonstrating characteristic curvilinear, fingerprint, or granular inclusions on electron microscopy of a peripheral blood smear or conjunctival or other biopsy tissue.

No specific systemic or ocular treatments are currently available for this group of disorders.

Chalazion

Sina Vahedi[1] and Allen O. Eghrari[2,3]
[1]Jefferson Medical College, Philadelphia, PA, USA
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[3]Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Meibomian cyst; Meibomian gland lipogranuloma; Posterior blepharitis; Zeis gland cyst

Definition

A chalazion is a noninfectious, lipogranulomatous reaction within the eyelid sebaceous glands (Cohen et al. 2001; Canninga-Van Dijk 2006; Friedman and Kaiser 2007; Lambreghts and Melore 2008; Shields and Shields 2008).

Etiology

A chalazion results from a noninfectious obstruction of the sebaceous gland ducts. Sebum accumulates and leaks into the surrounding tissue resulting in acute inflammation that leads to a chronic lipogranulomatous reaction. Chalazion can also result from an internal hordeolum (Lambreghts and Melore 2008). It is associated with poor lid hygiene, chronic blepharitis, and acne rosacea (Friedman and Kaiser 2007).

Histopathological evaluation demonstrates fatty cells within a granulomatous reaction (Canninga-Van Dijk 2006). A connective tissue pseudocapsule is often seen around the lesion. Causative organisms are usually not found, as the reaction is by definition a sterile inflammation, but secondary infections may occur.

Clinical Presentation

Chalazia initially present with tender, erythematous swelling of the eyelid and in late stages develop into a firm, painless nodule palpable to the patient and examiner (Lambreghts and Melore 2008). Patients may present at any stage; slit-lamp examination demonstrates meibomian gland disease and a papillary reaction with hyperemia of the palpebral and tarsal conjunctiva. Manual pressure on the eyelid margins may result in expression of thick, toothpaste-like secretions from meibomian glands. Patients often describe a history of previous chalazia (Cohen et al. 2001).

Diagnosis

Diagnosis of chalazion is based on a combination of history and clinical examination. Recurrent chalazia should raise suspicion for sebaceous cell carcinoma and require biopsy of the eyelid and conjunctiva (Cohen et al. 2001).

Differential Diagnosis

A stye, or external hordeolum, differs from a chalazion in its location in the anterior eyelid and an infectious etiology, often staphylococcal in origin (Friedman and Kaiser 2007). Patients with stye typically experience greater tenderness, erythema, and discharge compared to chalazion, although both find benefit from hot compresses (Cohen et al. 2001).

Sebaceous cell carcinoma often mimics chalazion, and recurrent chalazia in the same location should be biopsied to rule out this potentially lethal eyelid malignancy. Multiple conjunctival map biopsies will be required due to its pagetiod spread through the conjunctival epithelium, and such patients should be referred to an oculoplastic specialist (Shields and Shields 2008).

Prophylaxis

Conservative treatment with hot compresses, lid scrubs, and mild lid massage may be helpful to reduce recurrence in most patients. In those with frequent recurrences, low-dose oral tetracyclines may assist with both infection and inflammation.

Therapy

Initial therapy includes hot compresses, lid scrubs, and eyelid massage to dilate gland orifices and assist in secretion of solidified meibum (Cohen et al. 2001). Topical steroids reduce inflammation and a short course can be given with appropriate follow-up to prevent a steroid response; intralesional steroid injection, such as triamcinolone, can be effective but may cause hypopigmentation of overlying skin (Lambreghts and Melore 2008). At the slit-lamp, secretions and miniscule soft, distal obstructions can be expressed through meibomian gland orifices with pressure at the eyelid margin from a cotton-tipped applicator; once inflammation has resolved, incision and curettage may be utilized to remove remaining granulomatous material.

Prognosis

Chalazia generally resolve medically or surgically without detriment to vision. However, large, central, upper-eyelid chalazia overlying the cornea in children may induce ptosis and astigmatism and should be addressed to reduce risk of amblyopia (Friedman and Kaiser 2007). Recurrence in multiple locations is not uncommon and patients should be counseled on good eyelid hygiene practices (Friedman and Kaiser 2007). Sebaceous cell carcinoma is potentially lethal and recurrent chalazia should be biopsied to exclude its presence.

Epidemiology

Men and women are equally affected. Chalazia are more commonly found in adults than children.

Chandler Syndrome

Allen O. Eghrari
Johns Hopkins University School of Medicine, Baltimore, MD, USA
Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Iridocorneal endothelial (ICE) syndrome

Definition

The most common variant of ICE syndrome, which includes essential/progressive iris atrophy and Cogan-Reese syndrome, Chandler syndrome is characterized by proliferation of endothelial cells with subsequent microcystic corneal edema and beaten bronze appearance to the corneal endothelium. Notably, corneal edema is present despite normal or slightly elevated intraocular pressure and may be present early in disease. Iris nodules, which form early in Cogan-Reese syndrome, may appear late in Chandler syndrome. High peripheral anterior synechiae and glaucoma are characteristic of this disease.

Hereditary motor-sensory neuropathy retinal degeneration

Definition

Charcot-Marie-Tooth (CMT) disease is the most common inherited peripheral neuropathy with an

incidence of 1 in 2,500 live births. CMT is a demyelinating disorder comprised seven different major types with types 1 and 2 being the most common involving over 30 different identified genes. Patients typically present during early adulthood with motor and sensory peripheral polyneuropathy leading to distal leg weakness, foot deformities such as pes cavus or hammer toes, and sensory deficits. Ambulation is usually maintained throughout life, and life expectancy is not affected. The management of CMT is primarily supportive as specific disease-modifying therapy is not yet available.

Ocular symptoms are not invariably present. The most common ophthalmic symptoms are bilateral subacute deterioration of visual acuity accompanied by a central or paracentral *scotoma* and color vision abnormalities usually affecting the red-green axis. Ocular manifestations such as pupillary reflex abnormalities, premature *presbyopia*, *retinitis pigmentosa*, *optic atrophy,* and nystagmus have all been previously described in CMT. Fundus examination, depending on the precise genotype and phenotype, may demonstrate optic atrophy, attenuation of peripapillary blood vessels, thinning of the retinal nerve fiber layer, and signs of pigmentary retinopathy. Pathological reports indicate a pattern of retinal ganglion cell loss similar to Leber's hereditary optic neuropathy with preferential involvement of the papillomacular bundle, while the outer retina is usually not involved.

Visual field testing may demonstrate a central or paracentral scotoma. Fluorescein angiography may show signs of central tapetoretinal degeneration with macular pigmentary changes. Visual-evoked potentials usually show markedly reduced amplitude and delayed patterns. Electroretinographic recordings are usually within normal limits.

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Complex visual hallucination; Visual release hallucinations; Visual release phenomena; Vivid visual hallucinations

Definition

Charles Bonnet syndrome (CBS) is a common cause of complex visual hallucination occurring in patients with variable degrees of visual impairment and in the absence of alternative secondary causes (e.g., hallucinogenic drug use, delirium, mental illness). Its prevalence varies from 10% to 15% in visually impaired patients and is probably under recognized. It was named after the Swiss naturalist and philosopher Charles Bonnet (1720–1792) whose grandfather experienced these types of formed visual hallucinations (e.g., people, birds, and buildings).

Etiology

Although numerous theories have been suggested to explain CBS, its pathophysiology

remains poorly understood. It has been hypothesized however that reduced or absent visual stimulation causes an increased excitability of the sensory cells that continue to generate perceptual visions that had been already stored in the brain visual cortex (deafferentation theory). CBS release phenomenon is possibly analogous to "phantom limb" symptoms after an amputation in which a person might perceive pain and sensation of the amputated limb. CBS predominantly affects patients with moderate or severe visual impairment particularly with bilateral and central vision loss and can be precipitated by or associated with simultaneous illness infections or older age. Multiple etiologies have been associated with the visual loss in CBS including diabetes, optic nerve damage, macular degeneration, and glaucoma.

Clinical Presentation

Although there are no universally accepted diagnostic criteria for CBS, patients typically report formed, vivid, and frequently stereotyped visual hallucinations in the setting of prior visual impartment. Patients typically have some or total insight that the visual hallucinations are imaginary and unreal. An alternative diagnosis to CBS however should be considered first if any of the following is present: psychosis, dementia, intoxication, altered mental status, focal neurological signs, auditory hallucinations, or underlying metabolic derangements. CBS most commonly affects elderly people with visual impairment (most commonly age-related macular degeneration, glaucoma, and cataract).

The descriptions of the visual hallucinations vary from groups of people or animals, figures, or forms, and usually they have no personal meaning, underlying context, or symbolic interpretations. Each episode may last from few seconds to days. Many patients have chronic symptoms that may wax and wane or even improve after several months. Interestingly, some patients with progressive visual loss might even improve after the vision is totally lost.

Diagnostics

CBS is a diagnosis of exclusion. Gold and Rabins recommended the following diagnostic criteria of CBS: (1) formed, repetitive, complex, and stereotyped visual hallucinations, (2) the retained insight into the unreal nature of the visual hallucinations, (3) the absence of delusions, and (4) the absence of other modalities of hallucinations. Degree of visual impairment was not included within their diagnostic criteria, but most of studies report some relation between the severity of visual impairment and the risk of CBS.

Differential Diagnosis

1. Schizophrenia
2. Delirium tremens
3. Dementia
4. Complex partial seizures
5. Recreational drug abuse
6. Parkinson disease or other neurodegenerative disease (e.g., Lewy body) with visual hallucinations
7. Hypnagogic and hypnopompic hallucinations
8. Migraine aura
9. "Alice in Wonderland" syndrome

Prophylaxis

Not applicable

Therapy

Although there is no treatment with proven benefit for CBS, it is crucial to appropriately make the diagnosis and exclude treatable or alternative conditions. Most patients only wish to have reassurance that it is not an underlying psychiatric disorder. Treating comorbidities and lifestyle modifications may also be helpful (e.g., reducing social isolation and encouraging interpersonal contact).

Treatments with antipsychotics, antimigraine agents, and anticonvulsants may be helpful in

selected cases (e.g., risperidone, valproate, carbamazepine, clonazepam, gabapentin, olanzapine, and selective serotonin reuptake inhibitors).

Prognosis

The prognosis of CBS is variable and may remit spontaneously or with treatment. Treatment of the visual impairment if possible is recommended, and there have been cases where cataract extraction and recovery of vision lead to improvement in CBS.

Epidemiology

Patients with visual hallucinations due CBS often fail to report their symptoms to their physician or their family members because of the fear that they represent a psychiatric disease. The prevalence of CBS varies from 12% to 15% of visually impaired patients. The mean age is between 70 and 85 years.

Partial oculocutaneous albinism

Definition

Chédiak-Higashi syndrome (CHS) is an autosomal recessive disorder among the spectrum of partial oculocutaneous albinism, in which hypopigmentation of the skin and eyes is associated with immunodeficiency. Clinical findings include increased susceptibility to infection, especially bacterial, coagulation defects, and progressive peripheral neuropathy. Ultimately, a severe disease stage occurs in which massive lymphohistiocytic infiltration of organs termed "accelerated phase" results in death in the first decade of life. CHS is a rare disorder, with less than 500 reported cases in the past two decades, caused by a fundamental defect in granule genesis, leading to abnormally large granules in multiple tissues. Mutations in the CHS1/LYST gene, encoding a family of proteins thought to regulate lysosomal trafficking and degranulation, have been identified in CHS patients.

The pigmentary dilution involving the hair, skin, iris, and ocular fundus is the result of a pathologic aggregation of oversized melanosomes that fail to disperse to the target organs. Patients typically have silvery gray hair and blue irides. Ocular symptoms include photophobia and decreased visual acuity which may result from high refractive error, iris transillumination defects, retinal pigment epithelium (RPE) degeneration, and foveal hypoplasia. Rotary nystagmus and strabismus, often present at birth, may be related to abnormal decussation

of the optic nerve fibers from the temporal retina to the contralateral cerebral hemisphere and may also correlate with the degree of foveal hypoplasia.

Clinical diagnosis is supported by the presence of peroxidase-positive giant inclusions in white blood cells, by detection of pigment clumping in the light microscopy analysis of hair, and eventually by studies revealing abnormal platelet aggregation. A definitive diagnosis requires genetic testing for mutations in the CHS1/LYST gene on chromosome 1.

No specific ocular treatment is available. Refractive errors should be corrected, and some patients benefit from bifocal lenses. If visual acuity is severely impaired, these patients can be helped with telescopic and other low-vision devices. Strabismus surgery for esotropia or exotropia can be considered for better ocular alignment.

The most effective treatment for the hematological and immune defects of CHS is hematopoietic stem cell transplantation, although little evidence of efficacy in delaying or preventing neurological dysfunction exists.

Cheek Elevation, in Eyelid Repair

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Midface lift; Preperiosteal midface lift; SOOF lift; Subperiosteal midface lift

Definition

Elevation of cheek and midface tissues with the goal of anterior lamellar recruitment (skin and muscle) for lower eyelid repair when anterior lamellar shortage is present.

Indication

Posttraumatic or post-cancer excision (including Mohs surgery) defects of the lower eyelid with resultant anterior lamellar shortage requiring skin recruitment to repair the defect can be addressed with midface/cheek lift surgery. Other options include local myocutaneous advancement flaps and full-thickness skin grafts. In addition to its utility in reconstructive surgery, cheek/midface lift surgery is sometimes performed as an aesthetic procedure to improve the youthfulness of the cheek and midface region.

Contraindication

Cheek/midface elevation adds to surgical operating time as well as surgical complexity. Adequate skin recruitment may not be achievable with cheek/midface elevation alone in cases of large defects.

Techniques and Principles

When utilized in eyelid repair surgery, the goal of cheek/midface lifting is to recruit anterior lamellar tissues (skin and muscle) for lower eyelid reconstruction. There are a variety of techniques utilized in cheek/midface lift surgery, which can be broadly categorized based on the plane of dissection and the incisional approach. The plane of dissection of the cheek/midface lift can be either subperiosteal or preperiosteal. A variety of incisional approaches to the midface exist including transconjunctival, subciliary, sublabial, and temporal approaches. Endoscopic guidance can also be used to improve visualization, particularly when using a temporal approach.

Preperiosteal cheek/midface lift begins with the desired incisional approach; a transconjunctival

approach is most common. A preperiosteal plane is then carried inferiorly until adequate freeing and superior mobilization of the cheek/midface is achieved to allow for eyelid reconstruction. Care is taken to spare the infraorbital neurovascular bundle and to avoid the branches of the facial nerve, which lie just above this preperiosteal plane. The midface tissues are then lifted and secured to the periosteum of the infraorbital rim with sutures.

The subperiosteal cheek/midface lift can often provide a more robust superior lift as compared to a preperiosteal cheek/midface lift. The subperiosteal cheek/midface lift begins with the desired incisional approach; a transconjunctival approach is most common. Dissection is carried down to the arcus marginalis of the inferior orbital rim, and an incision is then created through the periosteum to gain access to the subperiosteal space. Freeing of the entire midface is then performed in this plane. Care is taken to avoid injury to the infraorbital neurovascular bundle. A periosteotomy is created medially along the piriform aperture, inferiorly along the alveolar ridge, and laterally along the masseter muscle to allow complete midface mobility. The midface is then lifted superiorly and secured to the arcus marginalis of the infraorbital rim with sutures.

Regardless of the plane chosen or the incisional approach, the goal of cheek/midface lift surgery in eyelid repair remains the same, recruitment of anterior lamellar tissues superiorly to allow for eyelid reconstruction.

Outcome

Elevation of the cheek/midface tissues results in recruitment of vascularized anterior lamellar tissues, particularly the skin and muscle, for use in eyelid reconstruction.

Complications

Injury to sensory and/or motor nerves within the midface is possible. Secondary ectropion of the reconstructed lower eyelid can result if inadequate skin has been recruited or if downward tension on the lifted cheek/midface is present.

Chelation Therapy, for Calcific Band Keratopathy

Mona Kaleem
Department of Ophthalmology, Euclid Hospital, Cole Eye Institute, Cleveland Clinic Foundation, Cleveland, OH, USA

Synonyms

Disodium ethylenediaminetetraacetic acid; EDTA chelation therapy

Definition

Procedure for the removal of calcium phosphate crystals from the superficial corneal layers

Indication

EDTA chelation therapy is the most commonly practiced method in the treatment of band keratopathy. Band keratopathy is characterized by deposition of calcium phosphate salts in the epithelial basement membrane, Bowman's membrane, and anterior stroma. It commonly occurs in the eyes with chronic diseases such as uveitis, keratitis, trauma, exposure to chemical toxins, intraocular silicone oil, sarcoidosis, glaucoma, and conditions associated with elevated serum calcium or phosphate.

Contraindication

Limbal stem cell deficiency and neurotrophic keratopathy (relative contraindications)

Use and Dosage

EDTA is prepared as a 3% solution by diluting disodium EDTA 15% (150 mg/ml) 1:4 with normal saline. A drop of topical anesthetic is instilled into the eye at the beginning of the procedure. Epithelial debridement is performed with a surgical blade. EDTA solution is then applied with a saturated cellulose sponge or cotton-tipped spatula. The solution forms chelation complexes with the calcium deposits and can then be removed with a surgical blade or a diamond burr. The procedure is repeated several times until the

Chemical Burns

▶ Chemical Injury (Burns)

Chemical Injury (Burns)

Ahmara G. Ross
Department of Ophthalmology, UPMC - The University of Pittsburgh Medical Center, Pittsburgh, PA, USA

Synonyms

Chemical burns

Definition

Exposure to acid or alkali whose severity of damage and ease of treatment are related to chemical toxicity, time of contact, depth of penetration, and area of involvement.

Acidic burns have a pH <7.4 and precipitate protein which acts as a potential barrier to deeper penetration and tissue destruction (Singh et al. 2013). Alkali burns have a pH >7.4 which causes saponification within cells of the ocular structure. An inflammatory response causes deeper tissue damage and limbal ischemia (Singh et al. 2013).

Etiology

Most acidic injuries are from household items, while alkali injuries in households and industry (Singh et al. 2013).

Clinical Presentation

The type of agent, toxicity of the agent, mechanism of injury, duration of contact, depth, and area of involvement should be collected. Use of protective eyewear should be carefully documented. Elevations in IOP should prompt immediate treatment (Wagoner 1997).

Clinical course is divided into immediate, acute, early, and late repair phase. The area of involvement is assessed by extent of fluorescein staining, depth of tissue injury, loss of stromal clarity, visual acuity, and observation of vascular ischemic and limbal necrosis. The immediate phase immediately follows chemical injury (Singh et al. 2013).

Acute phase of injury (day 1–7) is when epithelial migration occurs. The early repair phase (day 7–21 of injury) is marked by epithelialization. Limbal stem cell loss is evident by dysfunctional epithelialization. The late repair phase (day 21) is where conjunctivalization of the cornea occurs (Gupta et al. 2011).

Diagnosis

pH in the immediate phase of injury (Wagoner 1997).

Differential Diagnosis

Differential should include an open globe, local contact, thermal or radiant burns, or projectile tissue damage.

Prophylaxis

Use of protective eyewear and proper storage when handling corrosive or high-temperature substances.

Therapy

Obtain information from www.aapcc.org or by contacting poison control (Wagoner 1997). Immediate irrigation of the abnormal pH unless concern for an open globe exists. Copious irrigation with balanced solution using a Morgan Lens before clinical examination to return ocular structures to neutral pH. There is no difference between isotonic saline, lactated Ringer's, and saline with BSS; however, eyes irrigated with saline plus BSS have less pain. Once pH has been normalized, visual acuity, intraocular pressure, extent of perilimbal ischemia, and health of the corneal epithelium should be evaluated and treated (Wagoner 1997).

Treatment is based on grading with Roper-Hall or Dua classification (Gupta et al. 2011). Grade

I injuries are treated with a topical antibiotic with prednisolone acetate (QID). Grade II injuries are treated with antibiotics and more frequent use of prednisolone acetate. Oral supplementation with doxycycline 50 mg BID is also recommended. Placing punctual plugs might be considered and epithelial debridement might be required. Grade III is often treated with amniotic membrane transplantation within the first week of injury. More severe injuries classified as grade IV are treated with surgical intervention aimed at restoring limbal vascularity (Clare et al. 2012). The importance of serum drops at reducing inflammation can be tried. Injuries should be followed daily initially in the immediate and acute stage of healing with subsequent visits tapered to every few days until normal reepithelialization has occurred (Singh et al. 2013).

Prognosis

Clinical examination and visual prognosis is evaluated using the same Roper-Hall grade or Dua classification. While the Roper-Hall grading system is commonly studied and used to develop a standardized form of treatment, the Dua classification system is better aimed at determining visual prognosis.

Visual prognosis for RH grades I and II is good; however, visual prognosis for higher grades should remain guarded (Singh et al. 2013). The Dua classification is graded on a scale from I to VI involving clock hours of limbal involvement and percent of conjunctiva damaged with visual prognosis ranging from good to poor (Dua et al. 2001).

Roper-Hall (RH) grade of ocular surface burns is graded on a scale from I to IV. RH grade I injuries are described as eyes with corneal epithelial damage and no limbal ischemia. RH grade II includes eyes with corneal haze (with visible iris details) and $<1/3$ limbal ischemia. RH grade III includes total epithelial loss and stromal haze with iris details obscured with 1/3–1/2 limbal ischemia. RH grade IV involves an opaque cornea with iris and pupil obscured and $>1/2$ limbal ischemia. Generally, visual prognosis for grades I and II is good; however, visual prognosis for higher grades should remain guarded (Singh et al. 2013).

The Dua classification is graded on a scale from I to VI involving clock hours of limbal involvement and percent of conjunctiva damaged. Prognosis from classification I to VI is very good to very poor. Classification I involves no limbal or conjunctival involvement, with a visual prognosis that is "very good." Classifications II and III involve less than 3 clock hours of limbal involvement and $<30\%$ of conjunctiva or between 3 and 6 clock hours of the limbus with 30–50% of conjunctiva with a "good" visual prognosis. Classification IV involves a good to guarded prognosis in eyes presenting with between 6 and 9 clock hours of limbal involvement and 50–75% of the conjunctiva. Classification V involves between 9 and 12 clock hours of limbal involvement and 75–100% of the conjunctiva with a guarded to poor prognosis. Finally, classification VI has a very poor prognosis involving total limbus and total conjunctiva (Dua et al. 2001).

While the Roper-Hall grading system is commonly studied and used to develop a standardized form of treatment, the Dua classification system is better aimed at determining visual prognosis.

Epidemiology

Chemical injury represents 11–21% of total ocular traumas, mostly in young men between the ages of 20 and 40 years. Sixty-one percent of all chemical burns are industrial accidents in the workplace and 37% have been reported to occur in the home and in association with criminal assaults. Alkali injuries appear to occur more frequently than acidic (Clare et al. 2012).

Chemical-Induced Optic Neuropathy

► Toxic/Nutritional and Hereditary Optic Neuropathy
► Toxic Optic Neuropathy

Chemosis

Kathleen Jee
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Conjunctival edema

Definition

Chemosis is the swelling of the conjunctiva as a result of abnormal leaky conjunctival capillaries. It is typically a nonspecific indication of conjunctival irritation.

Etiology

In chemosis, the integrity of conjunctival capillaries is compromised, leading to increased permeability and leakage of serous fluid. Causes include conjunctival irritation, infection, inflammation, trauma, and severe intraorbital inflammation. The acute onset of chemosis is most commonly due to a hypersensitivity reaction, whereby an allergen irritates the conjunctiva and may lead to profuse rubbing of the eye. Chronic chemosis may indicate orbital outflow obstruction.

Causes include:

- Acute allergic conjunctivitis
- Conjunctivitis (viral or bacterial)
- Thyroid eye disease
- Orbital cellulitis
- Ocular trauma
- Carotid-cavernous fistula
- Cavernous sinus thrombosis
- Superior vena cava obstruction
- Post-ocular surgery
- Acute glaucoma
- Angioedema

Occurrence

Patients with chemosis frequently present with itchy or irritated eyes, particularly if caused by allergies. Other symptoms include tearing, blurry vision, and diplopia. The presentation may be asymptomatic in some cases. Chemosis appears as a localized or diffuse swelling of the conjunctiva. Depending on the severity, there can be incomplete eyelid closure. Conjunctival injection can also be present. Chemosis may cause corneal abnormalities, including exposure keratitis, superficial punctate keratitis, and Dellen formation.

Classification

In thyroid eye disease, the Vision, Inflammation, Strabismus, Appearance (VISA) inflammatory score incorporates a grading scale for chemosis:

0 – No conjunctival swelling present.
1 – Conjunctiva lies behind the gray line of the eyelid.
2 – Conjunctiva extends anterior to the gray line of the eyelid.

[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Lesions of the optic chiasm; Parasellar lesions; Suprasellar mass lesions

Definition

A chiasmal disorder defined as any lesion that causes a disruption in the optic chiasm.

Etiology

The majority of optic chiasmal lesions in adults are caused by compressive suprasellar or parasellar lesions, such as:

1. Pituitary adenomas.
2. Craniopharyngiomas.
3. Meningiomas.
4. Internal carotid suprasellar aneurysm.
5. Dysgerminoma and hypothalamic/optic chiasmal glioma in younger patients.
6. Other infrequent causes of chiasmal disorders are demyelination (chiasmal neuritis), metabolic, toxic, traumatic, ischemic, infiltrative, inflammatory, or infectious.

The anatomical location of the optic chiasm (superior in relation to the sellae and inferior to the third ventricle) often determines the affected visual fibers and the visual defects. For example, a prefixed chiasm over the tuberculum occurs in 9%, the central body of the chiasm is directly above the pituitary in 80% (leading to the typical bitemporal hemianopsia), and is postfixed chiasm over the dorsum sellae 11%.

Clinical Presentation

The most common presenting symptom of chiasmal compressive lesions is a gradual, painless, progressive vision loss. Other less common symptoms are headache, diplopia from lateral extension of the lesion to the cavernous sinus, and concomitant ocular motor cranial neuropathies; endocrine dysfunction (from hypothalamic or pituitary lesions) may precede the visual symptoms (e.g., amenorrhea/galactorrhea, acromegaly, thyroid abnormalities, decreased libido, etc.).

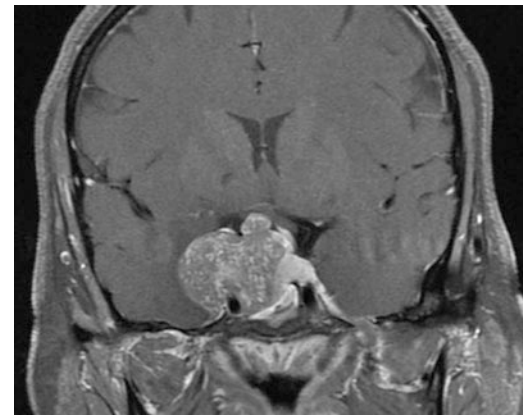
The most common visual field defect is bitemporal hemianopsia (complete, incomplete, symmetrical or asymmetrical) which accounts for 67% of the visual field defects due to compression of the crossing fibers of the chiasm and nasal fiber susceptibility at this location. Central scotoma (from concomitant unilateral or bilateral optic neuropathy), junctional visual field defect

(e.g., junctional scotoma and junctional scotoma of Traquair), or homonymous hemianopsia (optic tract) may occur but with less frequency.

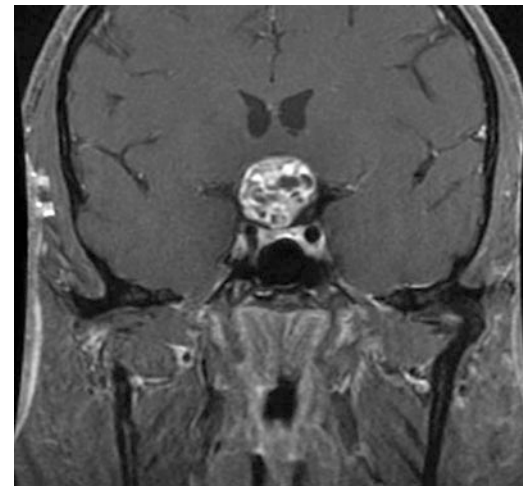
Although typically compressive chiasmal lesions produce subacute or chronic visual loss, an acute onset of bitemporal hemianopsia from chiasmal lesions may implicate a life-threatening emergency from a pituitary apoplexy or suprasellar aneurysm. Less commonly, demyelination or trauma can occur acutely. Pituitary apoplexy and suprasellar aneurysm are medical and neurosurgical emergencies that require prompt diagnosis and treatment. Apoplexy is typically characterized by an acute onset of severe headache, visual symptoms (impairment visual acuity and visual field), double vision (from cavernous sinus involvement), altered mental status, and hormonal dysfunction which is often associated with a life-threatening cortisol deficiency. Patients with chiasmal syndromes may have a relative afferent pupillary defect if a concomitant optic neuropathy or optic tract involvement is present. Slit lamp examination in patients with optic chiasmal glioma might show Lisch nodules in patients with neurofibromatosis 1. Motility exam might show ophthalmoplegia due to concomitant cavernous sinus involvement. Ophthalmoscopy may be normal or show optic atrophy depending on the etiology and duration of symptoms.

Diagnostics

Magnetic resonance imaging (MRI) of the brain with and without gadolinium (pituitary gland protocol) is the study of choice for the diagnosis of chiasmal disorders and can assist to distinguish between different lesions. The typical MRI features of a pituitary adenoma are hypointense to the brain on T1 and hyperintense on T2 with variable enhancement after gadolinium contrast (see Fig. 1). Craniopharyngioma is typically a cystic and solid heterogeneous mass in the suprasellar space that is isointense to lightly hypointense to the brain on T1 and shows variable/mixed on T2 and vivid enhancement on T1 post-gadolinium (see Fig. 2). Meningioma is typically isointense to the brain on T1 and T2 with vigorous, homogenous contrast enhancement with a dural tail.



Chiasmal Disorders, Fig. 1 Coronal MRI showing suprasellar pituitary mass hypointense to the brain on T1 and hyperintense on T2



Chiasmal Disorders, Fig. 2 Coronal MRI showing craniopharyngioma lightly hypointense to the brain on T1 and shows variable/mixed on T2

Computed tomography (CT) scan might be an adjunctive study to MRI in suprasellar lesions, hyperostosis or calcification (e.g., meningioma or craniopharyngioma) or might be the initial study in acute lesions or emergent settings like hemorrhage (e.g., pituitary apoplexy or aneurysm). Computed tomography angiography (CTA), magnetic resonance angiogram (MRA), and/or catheter angiography could still be

considered in case of radiographic findings suggestive of an aneurysm (e.g., a round lesion adjacent to the internal carotid artery with a flow void). Endocrinologic evaluation might be necessary in patients with suprasellar lesions.

Differential Diagnosis

The differential diagnosis of chiasmal lesions as mentioned in the etiologies section.

There are several conditions that mimic bitemporal hemianopsia:

1. Bilateral enlarged blind spot from peripapillary atrophy, the idiopathic big blind spot syndrome, papilledema, or posterior myopic staphyloma
2. The tilted optic disk syndrome

Prophylaxis

Non-applicable

Therapy

The treatment of the chiasmal lesion depends on the nature of the lesion. For instance, prolactin-secreting pituitary adenomas (i.e., prolactinoma) might be best treated medically with dopamine agonists (e.g., bromocriptine, cabergoline); demyelinating optic chiasmal neuritis might benefit from systemic corticosteroids; the most compressive lesions (e.g., pituitary adenoma, craniopharyngioma, and meningioma) require surgical intervention, but the approach and adjuvant or other chemotherapies or radiotherapies might be required. Transsphenoidal surgery has emerged as the best initial surgical treatment for symptomatic nonsecreting pituitary adenoma, but the surgical approach depends on the lesion type and location.

Radiation therapy (fractionated or by Gamma Knife) is reserved as an adjunctive therapeutic option for patients with non-resectable pituitary lesions (e.g., extensive cavernous sinus involvement), subtotal resections with risk of recurrence, or in patients who refuse or cannot tolerate a neurosurgical procedure. Craniotomy is generally not needed for most pituitary adenomas but may be necessary for other suprasellar lesions (e.g., craniopharyngioma, meningioma).

Pituitary apoplexy is a life-threatening emergency that typically requires admission to the hospital and emergent hormonal (corticosteroid) replacement.

Prognosis

The prognosis of a chiasmal lesion depends on the type of the lesion, size, and extension to adjacent structures and the duration of symptoms. Visually symptomatic pituitary adenoma may show stabilization or improvement after surgery in up to 94% of patients. In one series, authors noted that 25% had complete vision recovery and 50% had useful but incomplete vision recovery. Prognosis is correlated with the type of the tumor, patient age, duration of symptoms, size of the tumor, and presence or absence of optic atrophy. Optical coherence tomography (OCT) has arisen as a possible adjunctive tool for providing an objective prediction of visual prognosis and recovery.

Epidemiology

Pituitary tumors (pituitary adenomas) are the most common cause of chiasmal disorders with a prevalence as high as 75.7 per 100,000, and 47% were prolactinomas and 34% were nonfunctioning pituitary adenomas. There is no sexual predilection. Affected adults range in age from 30 to 40 years, but these tumors may occur at any age. Meningioma is typically a disorder of older-aged females but can occur in any age and either gender. Dysgerminoma and optic pathway glioma tend to affect younger individuals and aneurysms tend to affect older patients.

▶ Pediatric Glaucoma

Chlamydia

Mithaq Vahedi
Department of Ophthalmology, William Beaumont Hospital, Royal Oak, MI, USA

Synonyms

Chronic follicular conjunctivitis; Inclusion conjunctivitis; Trachoma

Definition

As an obligate intracellular bacterium and the most common cause of infectious blindness worldwide, the *Chlamydia* genus is comprised of *C. trachomatis*, *C. pneumoniae*, *C. psittaci*, and *C. trachomatis*, responsible for the majority of ocular chlamydial infections, and is further classified into three biovars, ocular (A-C), genital (D-K), and and lymphogranuloma venereum (L1-3), although all immunotypes may cause ocular symptoms. Clinical presentation with trachomatous infection includes a follicular conjunctivitis with conjunctival injection, irritation, and discharge. Characteristic features of trachoma include Herbert's pits, localized depressions following necrosis of limbal follicles; Arlt's line, linear scarring of the upper tarsus; trichiasis, which occurs in late stages of disease; and subsequent secondary corneal opacification. Treatment with tetracyclines or macrolide antibiotics can eliminate the organism.

Chloasma, of Eyelids

Pete Setabutr
Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA

Synonyms

Melasma

Definition

Dark brown, well-demarcated patches of hyperpigmentation.

Etiology

Common acquired hyperpigmentary disorder with unknown pathogenesis.

Clinical Presentation

Irregular light-to-gray-brown macules seen on sun-exposed areas of the face (cheek, forehead, nose, upper lip, and chin).

Diagnostics

Clinical examination, epidermal pigmentation enhanced with Wood's lamp, biopsy may be performed to determine diagnosis and to determine if dermal hyperpigmentation is present. In vivo reflectance confocal microscopy (RCM) may also be used.

Differential Diagnosis

Nevus, melanoma, pigmentary lesions of the eyelid, and posttraumatic hyperpigmentation.

Therapy

Numerous chemical peeling and hydroquinone- or tretinoin-based creams available.

Prognosis

Lasts longer in darkly pigmented peoples. Epidermal pigmentation may respond to treatment better than dermal involvement.

Epidemiology

More common in women. Associated with oral contraceptive use, chronic atopic eczema, rosacea, or family history.

Chloroquine Toxicity, Cornea Verticillata

Sana Idrees
The George Washington University, Washington, DC, USA

Synonyms

Cornea verticillata; Vertex keratopathy

Definition

Chloroquine toxicity is characterized by whorl-like corneal epithelial deposits.

Etiology

Medications of the chloroquine family, including chloroquine (Nivaquine, Avloclor), hydroxychloroquine (Plaquenil), and amodiaquine, have been associated with keratopathy (Srinivasan et al. 2011). Quinolone antimalarial drugs are used in the prophylaxis and treatment of malaria as well as in the treatment of certain rheumatological disorders (e.g., rheumatoid arthritis, juvenile chronic arthritis, systemic lupus erythematosus). The use of chloroquine has also been advocated in the treatment of calcium abnormalities associated with sarcoidosis (Kanski and Bowling 2011). The use of these drugs have led to multiple ocular manifestations, including vortex keratopathy, decreased corneal sensation, accommodative weakness, posterior subcapsular cataracts, and bull's eye maculopathy (Srinivasan et al. 2011). The corneal deposits in cornea verticillata

associated with chloroquine are composed of unchanged antimalarial salts (Yam and Kwok 2006).

Clinical Presentation

The initial signs of chloroquine toxicity include the development of bilateral, fine gray or golden-brown opacities seen in the inferior corneal epithelium (Kanski and Bowling 2011). The deposits are limited to the corneal epithelium and may vary in pattern (Yam and Kwok 2006). They tend to progress into branching horizontal lines and then into a whorl-like pattern that begins below the pupil, but spares the limbus (Kanski and Bowling 2011). The corneal deposits are concentrated in the central corneal epithelium, with decreased density of deposits in the periphery of the cornea. Corneal deposits are harmless and can develop at doses ranging from 100 mg/day over several years to 1000 mg over only 3 weeks (Srinivasan et al. 2011).

Bilateral keratopathy develops within 2–3 weeks of beginning therapy with chloroquine. While the deposits may involve the visual axis, patients are usually asymptomatic (Srinivasan et al. 2011). Visual acuity is not reduced by corneal deposits secondary to chloroquine (Yam and Kwok 2006). However, they may complain of blurry vision or halos around lights, even without detectable retinopathy or change in visual acuity. Patients may also report diminished corneal sensation with the use of chloroquine (Srinivasan et al. 2011).

Long-term use of antimalarial drugs may lead to disturbances in accommodation on rare occasions. This manifests as an inability to change focus quickly and may occur soon after administration of chloroquine. If the symptoms are bothersome, the dose of chloroquine may be reduced. Another complication of chloroquine toxicity is cataract development. Cataracts have been described in over 20% of patients receiving chloroquine therapy. However, no cataracts have been described in patients receiving hydroxychloroquine. The cataracts associated with chloroquine therapy develop as tiny white flakes axially placed under the posterior lens capsule. The most serious complication of chloroquine therapy is retinal toxicity. Retinal toxicity manifests as a bull's eye maculopathy. Retinal toxicity can affect visual acuity and color vision in its advanced stages (Yam and Kwok 2006).

Diagnosis

Ultrastructural examination reveals concentrically lamellated cytoplasmic inclusions in basal epithelial cells of the conjunctiva and cornea. Confocal microscopy may reveal corneal alterations before they are detectable with slit lamp biomicroscopy. On exam, these patients will have no detectable retinopathy or changes in visual acuity (Srinivasan et al. 2011).

Differential Diagnosis

There are several categories of diseases that may result in crystalline deposits in the cornea:

1. Lipid keratopathies, such as Schnyder's crystalline dystrophy, Tangier disease, and familial lipoprotein disorders
2. Errors of protein metabolism, such as tyrosinemia, cystinosis, hyperuricemia, and gout
3. Acquired immunoprotein keratopathies, such as multiple myeloma, cryoglobulinemia, benign monoclonal gammopathy, and rheumatoid arthritis
4. Infectious crystalline keratopathies
5. Miscellaneous dystrophies and metabolic abnormalities, such as posterior crystalline corneal dystrophy, Bietti's corneal dystrophy, porphyria, and calcium deposition
6. Drug deposition, such as chrysiasis, chlorpromazine, and chloroquine deposits

The diagnosis can be differentiated based upon histopathology of the crystalline deposits, clinical appearance of the deposits, and systemic evaluation (Grimmett 2011).

Prophylaxis

The hydroxychloroquine dose for therapy has decreased over the past thirty years, resulting in a decreased incidence of corneal toxicity (Yam and Kwok 2006).

Therapy

Corneal deposits are completely reversible with discontinuation of the offending chloroquine derivative. Regardless of the duration of chloroquine exposure, no residual corneal damage ensues. The development of corneal toxicity is not an indication to discontinue therapy. However, these patients should be carefully evaluated for maculopathy, which is a serious complication of chloroquine toxicity and would be an indication for discontinuation of the drug (Yam and Kwok 2006).

Prognosis

The development of keratopathy has no correlation with the dose or duration of therapy with quinolone medications. Discontinuation of quinolone drugs typically results in gradual elimination of the subepithelial deposits. They may clear despite continued therapy with the implicated drug (Kanski and Bowling 2011). Thus, development of keratopathy is not an indication for discontinuing therapy. However, the development of keratopathy is associated with an increased incidence of chloroquine-associated retinopathy (Srinivasan et al. 2011).

Epidemiology

Bilateral keratopathy affects 28–95% of patients on treatment with chloroquine. Hydroxychloroquine has a decreased incidence of bilateral keratopathy compared to chloroquine, approximating 1–28% (Srinivasan et al. 2011). This difference may reflect a lower degree of hydroxychloroquine accumulation in the cornea compared to chloroquine or differing tendencies of the two drugs to bind to corneal tissue (Yam and Kwok 2006).

Chlorpromazine Retinopathy

▶ Chlorpromazine, Retinal Degeneration

Chlorpromazine, Cornea Verticillata

Atif Mohiuddin
Department of Ophthalmology, George Washington University, Washington, DC, USA

Synonyms

Chlorpromazine keratopathy

Definition

Chlorpromazine is a sedating antipsychotic medication that with long-term use can result in corneal verticillata, or whorls.

Etiology

Chrysiasis generally results from medical treatment of disorders such as rheumatoid arthritis with injection or oral therapy with gold.

Clinical Presentation

Patients may present with subtle, diffuse yellowish-brown granular deposits in the posterior stroma, Descemet membrane, and endothelium. These deposits generally only occur in the exposed cornea of the interpalpebral fissure. Patients may also develop fine, stellate yellowish-brown deposits on the anterior lens capsule. In the retina, chlorpromazine usage may result in a pigmentary granularity and clumping.

Diagnosis

Chlorpromazine verticillata would be diagnosed with careful examination of the cornea under slit-lamp examination.

Differential Diagnosis

Other causes of a vortex keratopathy include chloroquine, hydroxychloroquine, amiodarone, silver, gold, and amantadine toxicity.

Prophylaxis

Preventing ingestion of chlorpromazine would prevent this process from occurring.

Therapy

Chlorpromazine verticillata is visually asymptomatic; there is no therapy for this entity.

Prognosis

Prognosis is good as chlorpromazine verticillata will remain visually asymptomatic requiring no treatment. In some cases, the depositions may clear after the cessation of therapy, while in others the depositions never disappear.

Epidemiology

Chlorpromazine verticillata occur after long-term ingestion of chlorpromazine. Lens deposits occur in 50% of patient who ingest over 1,000 g of the drug. The normal daily dose of chlorpromazine is 75–300 mg.

Chlorpromazine, Retinal Degeneration

Michael Mimouni and Shiri Zayit-Soudry
Department of Ophthalmology, Rambam Health Care Campus, Haifa, Israel
Department of Ophthalmology, Ruth and Bruce Rappaport Faculty of Medicine, Technion, Haifa, Israel

Synonyms

Chlorpromazine retinopathy; Phenothiazine retinopathy; Thorazine-induced retinal degeneration; Thorazine retinopathy

Definition

Chlorpromazine-induced pigmentary retinopathy.

Etiology

Phenothiazines are a group of tranquilizing drugs with antipsychotic actions that are thought to act by blocking synaptic transmission of the neurotransmitter dopamine within the brain. Chlorpromazine (Thorazine) and thioridazine (Mellaril), phenothiazine drugs commonly used for schizophrenia and other psychotic disorders, are known to be associated with several adverse effects, including ocular and dermatological complications (Yanoff and Duker 2008). These drugs can bind to melanin granules in the uveal tissue and when used in high dosages can cause abnormal pigmentation of the eyelids, conjunctiva, cornea, and lens (Regillo 2012). These side effects usually do not cause visual impairment (Agarwal 2012) and are at least partially reversible upon cessation of the drugs (Chern and Saidel 2011).

A more serious and vision-threatening complication of phenothiazine medications involves the cone and rod photoreceptors in the neurosensory retina and the retinal pigment epithelial (RPE) cells. Most cases have been reported in association with thioridazine and chlorpromazine use (Chern and Saidel 2011). It is possible that retinal functions mediated by the neurotransmitter dopamine are being compromised by phenothiazines, leading to formation of retinal abnormalities. Further, these drugs are photosensitizers and can produce light-induced damage to cells and tissues, with resultant pigmentary retinopathy and outer retinal degeneration (Ryan 2012). In contrast to thioridazine which may cause severe subacute retinopathy after a few weeks of dosages above 800 mg/day (standard dose range 150–600 mg/day), chlorpromazine retinopathy is typically milder and is seen at higher dosages of 2,400 mg/day (standard dose range 75–300 mg/day) taken throughout months to years (Chern and Saidel 2011).

Clinical Presentation

The early pigmentary changes in the retina are rarely associated with visual or functional deficits. Massive doses of chlorpromazine may lead to peripheral visual field loss, night blindness (nyctalopia), color vision disorders (dyschromatopsia), and, eventually, loss of central vision (Chern and Saidel 2011). Initially, the fundus examination may be normal, and a high index of suspicion may be needed before coarse RPE stippling in the posterior pole and other pigmentary abnormalities become evident. Further toxicity may lead to retinal granularity, pigment clumping, and widespread but patchy atrophy of the RPE and choriocapillaris, with a characteristic nummular pattern of involvement extending centrally from the peripheral retina. It has been reported that chlorpromazine-associated pigmentary retinopathy is usually irreversible even with cessation of the drug (Yannof and Duker 2008).

Diagnosis

Obtaining extended anamnestic data is paramount in order to identify chlorpromazine or other phenothiazine drug as the cause of the patient's complaints. Clinical observation, photographic documentation, and periodic follow-up to assess recovery or progression are warranted. Visual field changes are nonspecific, and most characteristically show paracentral scotomas or peripheral ring scotomas. Intravenous fluorescein angiography may reveal a wide spectrum of RPE abnormalities ranging from mild alterations to extensive areas of window defects and staining consistent with atrophy of the RPE and choriocapillaris. Though in early phases of the disease electroretinographic (ERG) testing may be within normal limits, an attenuated ERG is an indication of severe toxicity (Chern and Saidel 2011).

Differential Diagnosis

Because patients receiving chlorpromazine have often received other medications that may have

included potentially retinotoxic drugs, assignment of the exact cause of the retinopathy may be difficult.

Differential diagnosis includes pigmentary retinopathy associated with other phenothiazine medications, inherited retinal degenerations such as retinitis pigmentosa, and cancer-associated retinopathy (Chern and Saidel 2011).

Prophylaxis

The deleterious effects of thioridazine appear much sooner than those of other phenothiazines, but chlorpromazine-associated adverse effects are also related to the dose and duration of the treatment. Patients using chlorpromazine are generally not monitored with routine ophthalmoscopy because toxicity is rare at standard doses. However, suspected cases or patients who have taken the drug at high doses should undergo full ocular evaluation and regular monitoring, as toxic side effects of progressive phenothiazine-induced retinopathy can ensue within weeks. Subsequently, atrophy of the RPE can become manifest, and severe visual loss can occur (Yanoff and Duker 2008).

Therapy

Immediate discontinuation of phenothiazine and periodic ocular assessments should be performed, including examinations to document recovery or progression after cessation of the drug (Chern and Saidel 2011).

Prognosis

In cases of early toxicity, immediate cessation of medication may result in reversal of both the functional visual and morphological abnormalities. In most cases, despite slow improvement in visual function, the pigmentary changes of the RPE are irreversible. In some cases, however, the severity of retinopathy may progress, and visual the deterioration may actually continue despite cessation of the medication. It is not known whether these late atrophic changes after discontinuation of the drug represent continued toxicity or a decompensation of cells that were injured when the drugs were used initially (Chern and Saidel 2011).

Epidemiology

Even though chlorpromazine and thioridazine have been largely replaced by newer antipsychotic drugs, awareness to their potential side effects is warranted, and cautious periodic observation of patients treated with these medications is recommended to lessen the frequency of phenothiazine-induced serious visual loss. Of note, the massive doses which were once given and led to these findings are rarely prescribed currently. As such, chlorpromazine-induced retinal toxicity is becoming an extremely rare entity (Agarwal 2012).

Cholesterol Emboli (Hollenhorst Plaques)

Mordechai Rosner
Goldschleger Eye Research Institute, Sheba Medical Center, Tel Hashomer, Israel
Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel

Small, solitary or multiple, discrete oval or rhomboid-shaped, bright, refractile, yellowish plaques lodged in the lumen of retinal arteriolar bifurcations, usually originating from atheromatous plaque within the carotid arteries. They may indicate severe atherosclerosis and previous ischemic episode in the eye.

Retinal cholesterol emboli can cause a visual field defect when they block the vascular flow or remain asymptomatic. They may move in the arterioles and finally disappear. They can be associated with the rare entity – cholesterol crystal embolism.

Retinal cholesterol emboli are called also Hollenhorst plaques after the American ophthalmologist Dr. Robert Hollenhorst (1913–2008) who first described their significance in 1961.

Chorioretinal Coloboma

► Ectasia, Retinal

Choristoma

► Epidermoid Cysts

Choristomas

Rasha Ali
Department of Ophthalmology, Wohl Eye Center, University of Minnesota, Bloomingdale, IL, USA

Synonyms

Ectopic lacrimal gland; Epibulbar osseous choristoma; Limbal or epibulbar dermoid

Definition

A choristoma is defined as a group of histologically normal cells in an abnormal location. A simple choristoma consists of one type of tissue, whereas a complex choristoma is comprised of multiple types of tissues.

Etiology

Epibulbar choristomas are thought to occur as congenital anomalies in utero at 5–10 weeks gestation. The exact pathogenesis is not clearly understood. Limbal dermoids are not typically inherited except in the case of Goldenhar's syndrome, where inheritance patterns are variable, and ring dermoid syndrome, where inheritance is autosomal dominant.

Clinical Presentation

Choristomas of the anterior segment are comprised of the skin, bone, lacrimal gland, and/or cartilage.

Limbal or epibulbar dermoids typically present in the inferotemporal cornea and conjunctival epibulbar regions as tan or white elevated masses. They can range from very small, minimal growths to large protuberant masses. They often have protruding hairs. A yellow white lipid demarcation line may be seen in the corneal stroma.

Rarely, limbal dermoids present bilaterally as 360 conjunctivoscleral rings around the cornea, such as seen with ring dermoid syndrome.

Mann's grading system for limbal dermoids stratifies lesions into one of three grades based on anatomic involvement. Grade one lesions are the most common and consistent of epibulbar limbal lesions with superficial corneal involvement. Grade two lesions affect the full-thickness cornea, with potential Descemet's and endothelial sparing. Grade three lesions involve the entire cornea and all anterior chamber structures. The latter are the most rare.

Ectopic lacrimal gland choristomas tend to present as vascularized, pink nodules in the perilimbal region. These ectopic lacrimal glands are thought to represent the ectopic palpebral lobe due to the presence of smooth muscle on histopathologic examination. Care must be taken to distinguish a true ectopic lacrimal gland choristoma from a prolapsed lacrimal gland, because excision of the latter would result in permanent dry eye. Ectopic lacrimal glands usually extend deep into the cornea and sclera and may only be partially excised. They have been associated with encephalocraniocutaneous lipomatosis.

Epibulbar osseous choristomas are the least common type of choristoma and tend to appear as fleshy yellow subconjunctival nodules in the supertemporal quadrant. They seldom involve the cornea, are well circumscribed, and are usually located 5–10 mm behind the limbus. These lesions are comprised of compact bony tissue. Epibulbar osseous choristomas not demonstrate growth.

All of these lesions are present at birth, but tend to be detected in the first or second decade of life. There is no racial or sexual predilection for developing them. Choristomas may or may not be associated with systemic conditions such as Goldenhar's syndrome and epidermal nevus syndrome.

Diagnosis

Clinical, biopsy.

Differential Diagnosis

The differential diagnosis of a limbal dermoid includes epidermal cyst, foreign body granuloma, atypical pterygium, sclerocornea, Peter's anomaly, juvenile xanthogranuloma, and hemangioma. The differential diagnosis of a dermolipoma includes prolapsed orbital fat, lymphoma, or a herniated lacrimal gland. The differential diagnosis of an osseous choristoma includes prolapsed orbital fat and extraorbital tumor extension.

Therapy

Therapy involves observation, lubrication if ocular irritation occurs, or surgical resection if lesions induce astigmatism and amblyopia or are cosmetically unacceptable. Surgery may involve lamellar sclerectomy, sclerokeratectomy, or penetrating keratoplasty depending on the location of the lesion. Amniotic membrane may be used to cover conjunctival defects. All remnants of dermoids and dermolipomas should be meticulously excised because residual material may cause a large inflammatory response. Total excision is particularly difficult to accomplish with dermolipomas, because these choristomas usually extend into the fornices and become enmeshed with orbital fat and extraocular muscles.

Complications of surgical resection include extraocular motility limitation from scarring, worsening astigmatism, and globe penetration.

Prognosis

The overall prognosis is good. These congenital lesions tend to have limited postnatal growth which mirrors the patient's growth. They do not undergo malignant transformation. If the lesions are large and straddle the cornea, prognosis is less favorable due to the likelihood of induced astigmatism and amblyopia.

Epidemiology

Worldwide incidence of limbal dermoids is estimated to be 1–3 per 10,000. Dermolipoma tends to be the most common epibulbar choristoma, followed by dermoid.

Choroid, Gyrate Atrophy of

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Gyrate atrophy of the retina and choroid; Hyperornithinemia with gyrate atrophy (HOGA); Ornithine aminotransferase (OAT) deficiency

Definition

Gyrate atrophy is an autosomal recessive, slowly progressive chorioretinal dystrophy caused by mutations in the gene encoding ornithine

aminotransferase. Patients generally start to notice nyctalopia and peripheral field loss in the second to fourth decades of life. This eventually evolves into tunnel vision and ultimately central vision loss. Considerable variability exists in age of first symptoms, legal blindness, and loss of central vision. Patients characteristically will have elevated serum ornithine levels 10–20 times normal, hyperornithinuria, and hypolysinemia due to a deficiency in ornithine aminotransferase.

Clinical exam shows bilateral distinct circular areas of chorioretinal atrophy in the retinal periphery and mid-periphery. With time, these lesions coalesce into larger areas of chorioretinal atrophy with scalloped edges and eventually progress to involve the macular region. Pigmentation in and around the lesions can also be present. Patients may also be myopic and posterior subcapsular cataracts are common. Visual field testing confirms restriction in peripheral fields. Full-field electroretinogram (ERG) shows severe reduction in rod and cone responses that eventually become non-detectable with time.

Ornithine aminotransferase is an enzyme localized to the mitochondria matrix in most tissues. Systemic findings can be seen with gyrate atrophy, but most of these changes are subclinical and asymptomatic. Systemic changes include thinning of hair, subclinical proximal skeletal muscle atrophy, abnormal electroencephalogram (EEG), abnormal electrocardiogram (ECG), and MRI findings of premature atrophy and white matter changes in the brain.

No treatment currently exists to halt or reverse the ocular changes seen with gyrate atrophy. Diet supplementation with vitamin B6 and/or diets low in arginine, the precursor to ornithine, may slow disease progression.

Etiology

Gyrate atrophy is caused by mutations occurring in the ornithine aminotransferase gene on chromosome 10q26. This gene encodes the vitamin B6-dependent mitochondrial enzyme, ornithine aminotransferase, which converts ornithine to glutamate and proline. Significant heterogeneity exists with more than 60 different known mutations.

Occurrence

Gyrate atrophy is a rare autosomal recessive disease. Males and females are equally affected. Patients from Finland, Western Europe, Israel, Japan, and the United States have been reported in the literature.

Classification

Two different subtypes of gyrate atrophy exist, likely due to variation in the genotypic mutations. These subtypes are distinguished by response to treatment with supplementation of vitamin B6, a cofactor necessary for normal ornithine metabolism. Those that respond to vitamin B6 supplementation have a significant drop in serum ornithine levels to near normal levels. Nonresponsiveness to vitamin B6 supplementation is more common. These patients may benefit by a low arginine diet to lower serum ornithine levels. However, the effect of dietary changes on progression of ocular disease is variable and again may be due to the heterogeneity of mutations causing gyrate atrophy.

Choroidal Hemangioma

Jacob Pe'er and Shahar Frenkel
Department of Ophthalmology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel

Definition

A benign vascular hamartoma of the choroid. (Iris and ciliary body hemangiomas are extremely rare.)

Etiology

Circumscribed choroidal hemangioma (CCH) is a hamartoma. It occurs sporadically without any associated ocular or systemic anomalies. There is no evidence of genetic etiology. It is composed of vascular spaces lined by endothelial cells and involves the full thickness of the choroid.

Clinical Presentation

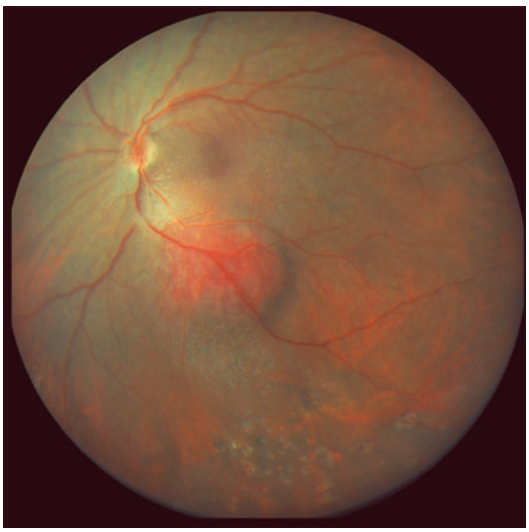
CCH appears ophthalmoscopically as a red-orange choroidal mass with indistinct margins that blend with the surrounding choroid. It is usually located in the posterior choroid, in the proximity of the optic nerve head or temporal to it, with no evident intrinsic tumor vessels or feeder vessels. CCH becomes symptomatic not before the third decade of life. Symptoms are due to associated subretinal fluid/exudative retinal detachment or cystoid macular edema that cause decreased visual acuity or other visual disturbances such as metamorphopsia. The presence of the tumor mass itself can also affect visual acuity (Naseripour and Singh 2014).

Diagnostics

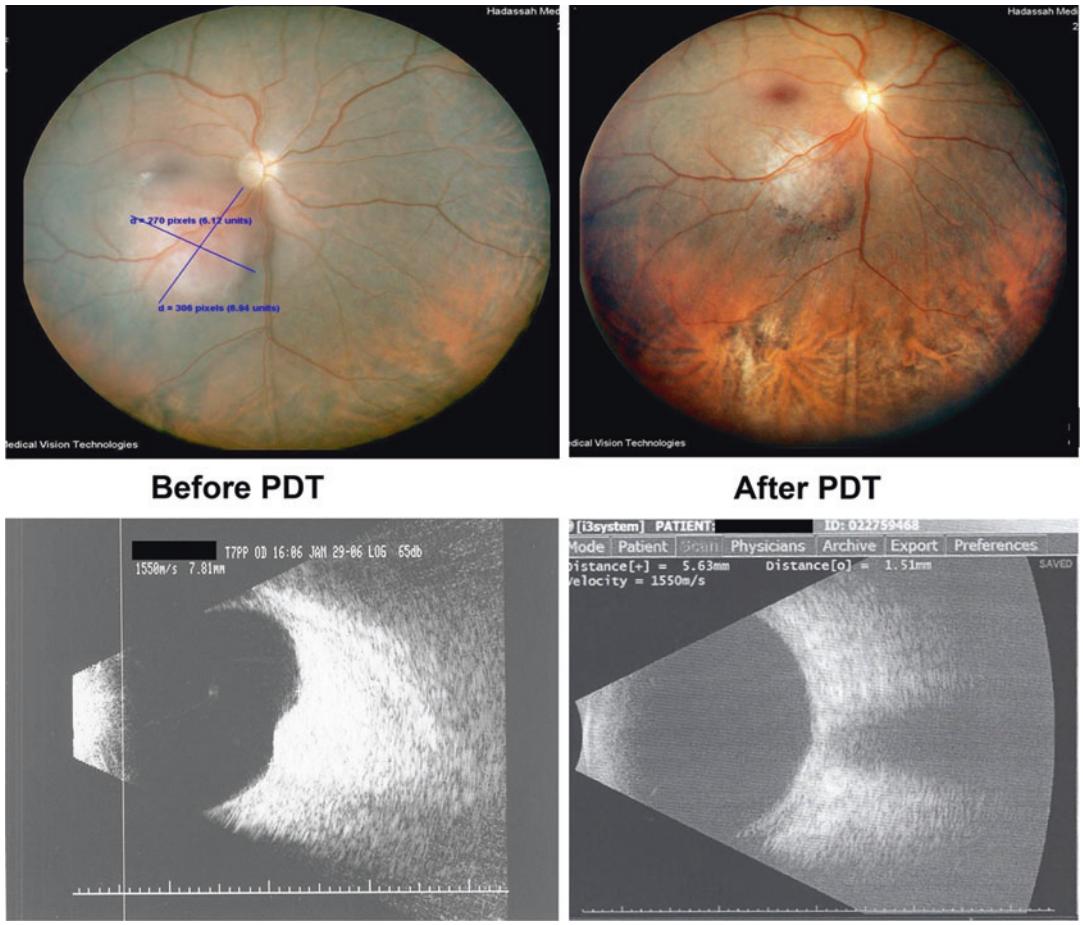
The clinical features of CCH are essential for the diagnosis of CCH and should be documented by fundus photography. Ultrasonographic and angiographic studies are helpful in establishing the correct diagnosis. By B-scan ultrasonography CCH appears as a dome-shaped choroidal mass with a smooth contour, and A-scan demonstrates high internal reflectivity. On fluorescein angiography, the CCH shows early hyperfluorescence that increases with lacy network of intrinsic vessels. These intrinsic vascular patterns are better displayed with indocyanine green (ICG) angiography. Optical coherence tomography is used to show the retinal changes over and around the CCH.

Differential Diagnosis

Differential diagnosis includes → amelanotic choroidal melanoma → choroidal metastasis →



Choroidal Hemangioma, Fig. 1 A red-orange choroidal hemangioma with indistinct borders under the lower temporal retinal vascular arcade



Choroidal Hemangioma, Fig. 2 Fundus and ultrasound pictures of choroidal hemangioma touching the inferior-temporal margin of the optic nerve head before treatment (*left*) and after treatment by PDT (*right*)

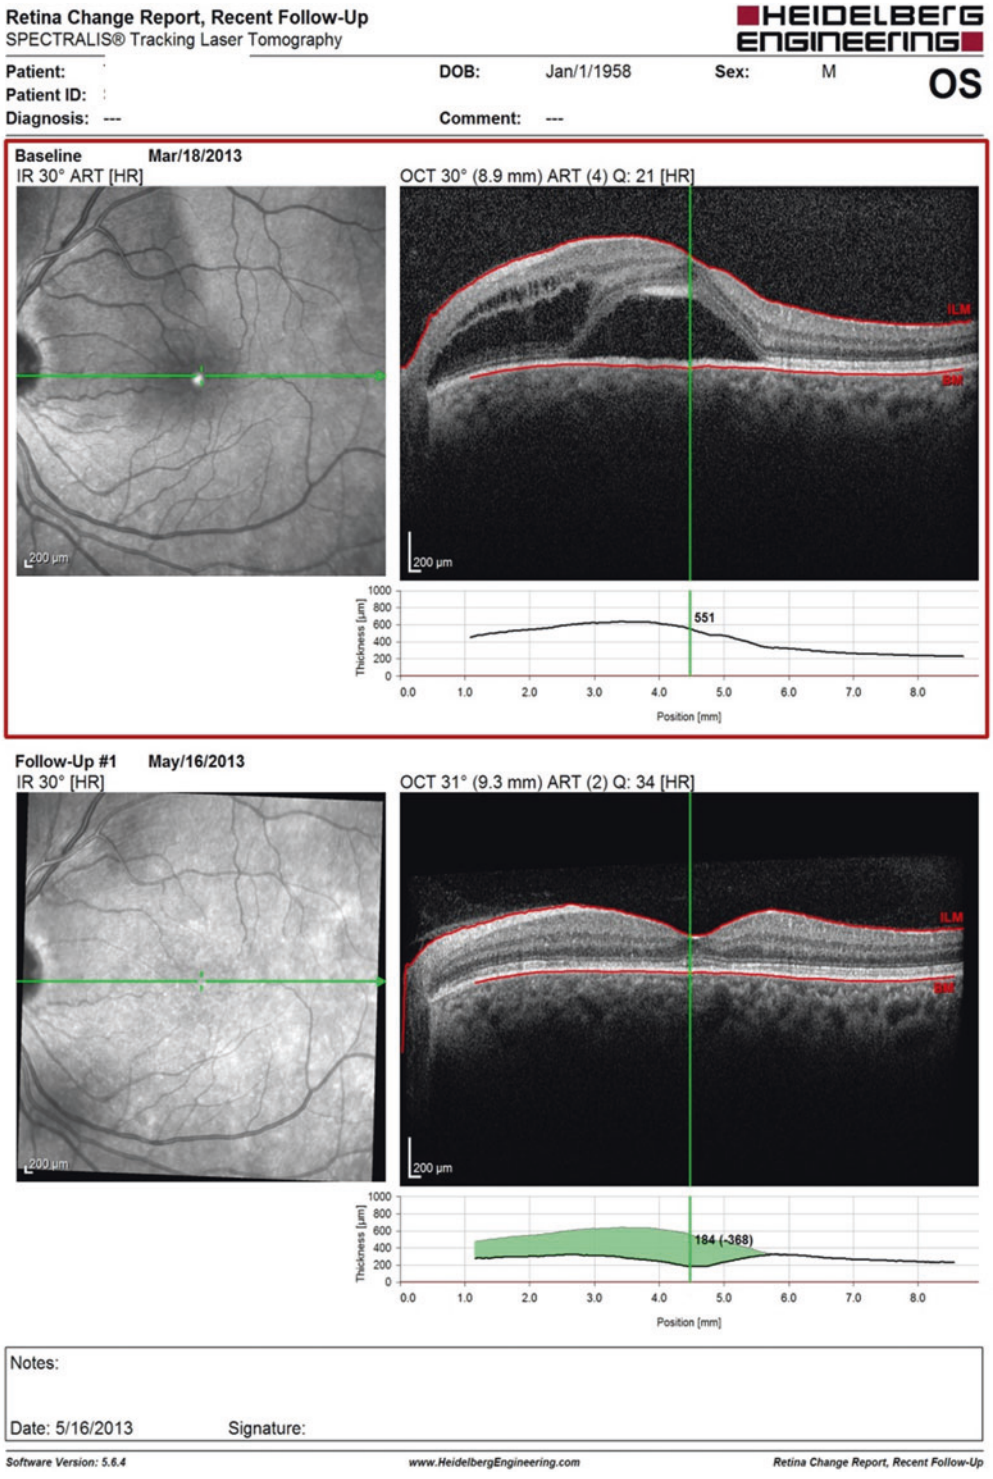
posterior scleritis → choroidal granuloma → atypical central serous retinopathy.

Prophylaxis

None. Asymptomatic CCH should be followed for early changes that can lead to visual disturbances.

Therapy

Asymptomatic CCH does not need treatment and should be observed. Symptomatic CCH must be treated in order to preserve vision. Radiation therapy, usually of low dose, has been applied in treating CCH via various methods: external beam radiotherapy, episcleral plaque brachytherapy (Co-60, Ru-106, I-125, Pd-103), proton beam radiotherapy, and stereotactic and gamma knife radiosurgery. Transpupillary thermotherapy (TTT) has been used, but because of visually significant complications it is not suitable for CCH located in the subfoveal or juxtapapillary regions. Photodynamic therapy (PDT) using verteporfin has been proven to be a very effective method and is currently the most popular way of treating CCH. It can be applied using the standard protocol (which is used in



Choroidal Hemangioma, Fig. 3 Optical coherence tomography of the retina in an eye with choroidal hemangioma located superior to the optic nerve head, showing subretinal and intraretinal fluid in the macular area (*above*), returning to normal after treatment of the hemangioma by PDT (*below*)

treating AMD), but modified protocols have been used (Schmidt-Erfurth et al. 2002). Intravitreal injections of anti-VEGF drugs (bevacizumab and ranibizumab) with or without PDT or TTT and oral propranolol have been used for reducing subretinal and intraretinal fluid.

Prognosis

CCH is a benign lesion that does not threaten life. Visual loss caused mainly by subretinal and intraretinal fluid can improve with treatment. However, when treatment is late or when the macula or papillomacular area is involved, the long-term prognosis for vision is poor. The use of PDT in recent years has improved the visual prognosis (Figs. 1, 2, and 3) (Shields et al. 2001).

Epidemiology

CCH is rare and no epidemiological data are available.

Definition

Choroidal neovascularization (CNV) is defined as the pathological growth of new blood vessels that originate from preexisting choroidal vessels and proliferate in either the subretinal (between the retina and RPE) or subretinal pigment epithelial (between Bruch's membrane and the RPE) space via a break in Bruch's membrane. This process is commonly associated with severe visual loss and may eventually lead to blindness.

Classification

Choroidal neovascularization is generally classified into two main categories depending on the location of the new blood vessel growth. Proliferation in classic CNV occurs in the subretinal space, whereas occult CNV is characterized by the proliferation of blood vessels under the RPE. In classic CNV there are typically one or few breaks in the Bruch's membrane, and the vessels then proliferate in the subretinal space. Occult CNV, on the other hand, tends to occur with multiple breaks in Bruch's membrane and thus multiple growth sites. The vessels tend to grow laterally under the RPE between lipids accumulated in Bruch's membrane and the basal laminar deposits (Grossniklaus and Green 2004). There can also be CNV that is a combination of these two types.

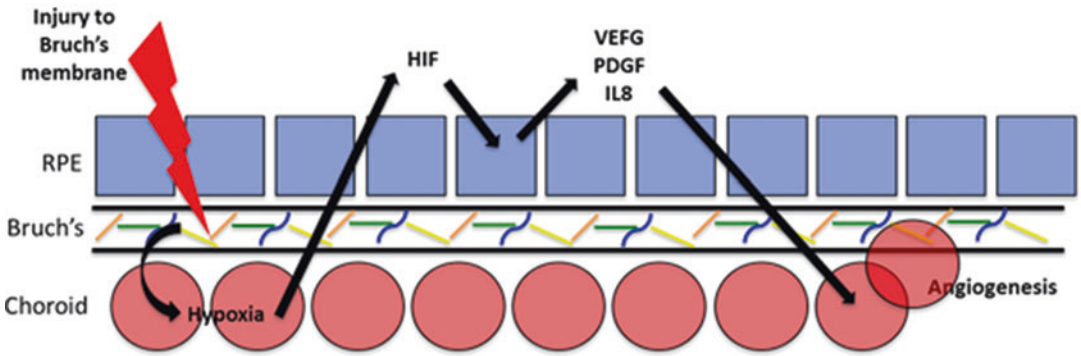
Etiology

Pathogenesis

The development of CNV is a dynamic process which may develop secondary to virtually any form of injury or inflammation at or around Bruch's membrane or the RPE. Bruch's membrane plays an important role in choroidal homeostasis, RPE attachment, and transport of nutrients and waste products between the RPE and choroid (Gliem et al. 2014). It also serves as a physical barrier between the choroid and the RPE and thus prevents the invasion of vessels. Once the disease process is initiated with injury to Bruch's membrane, the choroid becomes hypoxic and releases hypoxia inducible factor (HIF) (D'Ambrosio et al. 2014). The release of HIF then leads to the production of several angiogenic and inflammatory factors by the retinal photoreceptors and RPE which in turn disrupts the normal balance of these factors and thus leads to inflammation and neovascularization (Fig. 1).

These angiogenic and inflammatory factors include vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), as well as the inflammatory cytokine IL8 which are produced by retinal photoreceptors and the RPE (Grossniklaus and Green 2004). It has also been found that macrophages accumulate around breaks in Bruch's membrane and produce TNFα which then stimulates further production of VEGF, PDGF, and IL8 (Grossniklaus and Green 2004). The concentration of VEGF is the highest near Bruch's membrane which allows vascular endothelial proliferation to and through the membrane (D'Ambrosio et al. 2014). PDGF allows for stabilization and maturation of the new vessels by allowing pericytes to coat the endothelial cells (Kaiser 2013). IL8 causes inflammation that increases the permeability of the new vessels and allows leakage of serum into the subretinal or sub-RPE space. The macrophages found near the breaks in Bruch's membrane also produce tissue factor (TF) and matrix metalloproteinases (MMPs). TF causes fibrogenesis and the formation of a scaffold onto which the newly formed blood vessels can grow and proliferate (Grossniklaus and Green 2004). The MMPs digest tissue in the eye and allow for neovascularization to occur in and through the different planes in the eye. The combination of angiogenesis and edema in the subretinal or sub-RPE space causes damage to the RPE and photoreceptors and thus can result in focal retinal detachment and vision loss (van Lookeren Campagne et al. 2014).

As CNV progresses, the retinal photoreceptors and RPE increase production of anti-inflammatory



Choroidal Neovascularization, Fig. 1 Injury to Bruch's membrane leads to hypoxia of the choroid and its release of HIF followed by release of angiogenic and inflammatory factors from the RPE which thus causes neovascularization

and anti-angiogenic factors. Specifically TGF-β is released in increasing amounts throughout the process (Grossniklaus and Green 2004). Eventually, there is enough TGF-β to fully inhibit the inflammation and angiogenesis in CNV. Continued activity of the disease leads to proliferation of RPE cells, fibroblasts, and glial cells which leads to the formation of fibrovascular scar tissue known as a disciform scar in the subretinal or sub-RPE space (Grossniklaus and Green 2004).

Risk Factors/Underlying Disease

The etiology of CNV varies widely with age. In the younger population, traumatic damage to Bruch's membrane is most common. In individuals older than 50 years of age, however, age-related macular degeneration (ARMD) is typically seen. Inflammatory diseases and pathologic myopia may lead to CNV in any age group (Yanoff & Duker: Ophthalmology 2008).

The most common etiology of CNV is ARMD (Cohen et al. 1996). ARMD is a progressive degenerative disease that increases in frequency with age. The most severe manifestation of ARMD is CNV. It is hypothesized that injury to Bruch's membrane occurs secondary to oxidative damage and drusen (lipid and protein waste droplets) deposition. Oxidative damage leads to an increase in VEGF production and therefore causes an imbalance between angiogenic and anti-angiogenic factors which leads to new vessel formation (van Lookeren Campagne et al. 2014).

ARMD is the most common etiology in the elderly; however, in patients less than 50 years old, pathologic myopia is the most common cause. Patients with pathologic myopia have refractive errors of −6 diopters or more. Fractures of Bruch's membrane, commonly known as lacquer cracks, are commonly found in these patients. They have been shown to be a predisposing factor for the development of CNV. The fundus may also show peripapillary chorioretinal atrophy, gyrate atrophy of the RPE, or a posterior staphyloma which may lead to damage to Bruch's membrane and development of CNV (Cohen et al. 1996).

Other, rarer diseases may lead to the development of CNV. Infectious causes include ocular histoplasmosis syndrome (OHS) in which infection of the eye with *Histoplasma capsulatum* leads to antigen deposition in Bruch's membrane. A reactive inflammatory response to the antigen deposition causes a break in the membrane and the initiation of the development of CNV (Grossniklaus and Green 2004).

Certain genetic factors may also predispose patients to CNV. Pseudoxanthoma elasticum, a genetic disease with an autosomal recessive mutation of adenosine triphosphate-binding cassette subfamily C member 6 (ABCC6) gene, may manifest as thickening and calcification of Bruch's membrane. These alterations in Bruch's membrane cause thinning of the choroid which leads to hypoxia and release of HIF (Gliem et al. 2014). Similarly, pathological myopia is also inherited as an autosomal recessive disorder in many cases. Ocular histoplasmosis syndrome is also more frequently seen in HLA-B27 and HLA-DR2. CNV may also manifest as an uncommon complication of uveitis, especially posterior uveitis (D'Ambrosio et al. 2014).

Idiopathic CNV is defined as CNV in individuals less than 50 years old that do not have any evidence of trauma, pathological myopia, or any other intraocular inflammation.

Clinical Presentation

The presentation of CNV varies from patient to patient and may be found before the patient complains of severe symptoms. The most common presentations of CNV include metamorphopsia (distorted vision) and central scotomas. Patients will also complain of decreased visual acuity. Importantly, patients with CNV will not complain of any eye pain (Wong et al. 2014).

Diagnosis

Clinical Exam

When a patient presents with symptoms of metamorphopsia and central scotomas, it is important to keep CNV high on the differential diagnosis list. On slit-lamp biomicroscopy, fundus changes can be seen. Retinal changes may include

localized elevation due to detachment of the RPE and retinal edema. The macula may show gray-green discoloration, and exudates may be present in or around the macula. Subretinal hemorrhage may also be visible.

Fluorescein Angiography (FA)

Fluorescein angiography (FA) is used to diagnose and classify CNV. Two major patterns of CNV are seen: classic and occult CNV.

Classic CNV

Classic CNV is characterized by hyperfluorescence initially after injecting the dye followed by progressive leakage throughout the course of the angiogram. This pattern is seen in only 10% of patients with CNV due to ARMD but is seen more frequently in other causes of CNV (Wong et al. 2014; Bressler 2012).

Occult CNV

Occult CNV can be further subdivided into two types:

1. Fibrovascular pigment epithelial detachment (PED): vessel and fibrous tissue infiltration leads to RPE elevation and thus a fibrovascular PED. In this type, fluorescence within the fibrous PED slowly increases after injection of the dye followed by a unique staining pattern late in the angiogram.
2. Late leakage from an undetermined source: lack of fluorescence early in the angiogram is followed by areas of fluorescence seen later during the test.

CNV lesions are described based on the proportion of classic component in the CNV lesion. Predominantly classic lesions are described as having more than 50% classic component in the lesion, minimally classic lesions are described as having between 1% and 49% of classic component, whereas occult with no classic CNV suggests there is no classic component in the CNV lesion.

Identification of classic and occult components used to be critical in the management of CNV, since treatment strategies such as photodynamic therapy (PDT) and focal laser treatment varied depending on the portion of classic CNV. However more recently, the use of anti-VEGF treatment agents has reduced the need for this distinction since treatment doesn't change based on this criterion.

Optical Coherence Tomography (OCT)

OCT plays a critical role in evaluating the progression of CNV and response to treatment in patients with CNV (Cavalcante et al. 2014). OCT provides high-resolution images of posterior eye structures and can demonstrate vascular activity. Frequently seen findings in such patients include intraretinal and subretinal fluid, intraretinal cystic spaces, RPE elevation, neurosensory detachment, and intraretinal hyperreflective flecks (Giani et al. 2011).

Fundus Photography

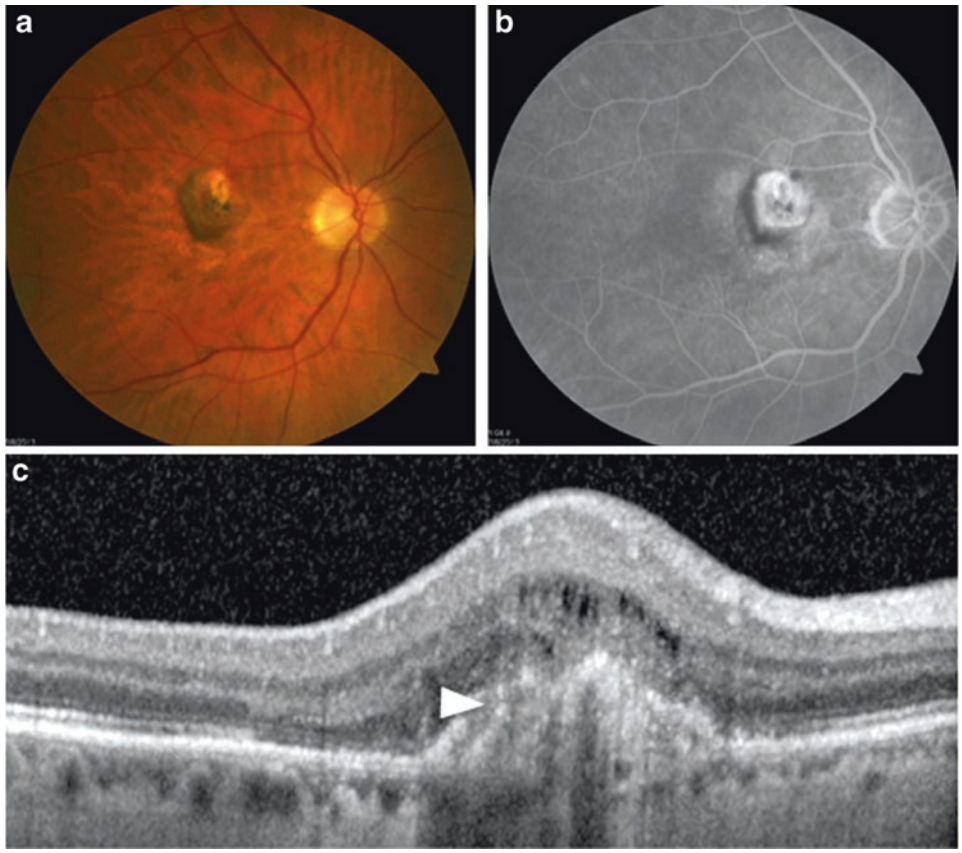
Fundus photography can be used as an adjunct when diagnosing and classifying CNV. It may also help determine the underlying cause of CNV. Color fundus photography allows visualization of the macula and the retina. It can show subretinal hemorrhages, geographic atrophy, exudates, and blood vessels. Fundus photography is not used in every patient to diagnose CNV (Fig. 2).

Differential Diagnosis

The symptoms of metamorphopsia and central scotomas are found in most patients with CNV; however, it is important to exclude other pathology. Other conditions that may present like CNV include angioid streaks, central serous chorioretinopathy, and macular edema.

Prophylaxis

The AREDS trial was a randomized multicenter clinical trial that evaluated the effect of high-dose vitamin regimens on the progression of AMD. It was shown that in patients with intermediate AMD a combination of both antioxidants (500 mg vitamin C, 400 IU vitamin E, and



Choroidal Neovascularization, Fig. 2 A 67-year-old patient with neovascular AMD. (**a**) Color fundus photograph shows a *greenish brown* lesion, approximately one disk diameter in size within the macula. (**b**) Fluorescein angiogram showing hyperfluorescence of the lesion. (**c**) Optical coherence tomogram of the same patient showing a hyperreflective neovascular lesion (*arrow head*) disrupting the RPE-choriocapillaris complex with accompanying intraretinal fluid

15 mg β-carotene) and zinc (80 mg zinc oxide plus 2 mg copper) leads to a 25% reduction in progression to advanced AMD and a 19% reduction in rates of moderate visual loss. Patients without AMD or in the early stages of AMD did not seem to benefit from this formulation. Antioxidants or zinc alone, however, were not shown to prevent the progression of AMD (Eter et al. 2006).

This trial was followed up by the AREDS2 trial in which beta-carotene was substituted with lutein and zeaxanthin, since beta-carotene had previously been associated with increased risk of lung cancer in previous smokers. Omega-3 fatty acids were also added to the formulation. The study found that while omega-3 fatty acids had no effect on the formulation, lutein and zeaxanthin appeared to be a safe replacement to beta-carotene (Eter et al. 2006).

Therapy

Laser Photocoagulation

The first surgical treatment of CNV was laser photocoagulation. The principle behind laser treatment was to cauterize the feeder vessels of subfoveal CNV to prevent further hemorrhage and edema (Hanout et al. 2013). In the Macular Photocoagulation Study (MPS) it was shown that severe visual loss was significantly decreased in treated eyes. Although visual loss was decreased,

patients who were treated had an increased risk of vision loss during the early stages of the treatment. Therefore, laser photocoagulation is no longer recommended for the treatment of subfoveal CNV (Hanout et al. 2013).

Verteporfin Photodynamic Therapy (PDT)

Verteporfin photodynamic therapy uses light-activated verteporfin to induce occlusion of new vessels (Hanout et al. 2013). Patients treated with PDT demonstrated better visual acuity benefits compared with the placebo after 12 months of treatment. The response to treatment was not stable after 24 months (Wolf et al. 2014). PDT was thus used to help prevent visual acuity loss while other treatments were being developed.

Anti-VEGF Agents

Pegaptanib Sodium Pegaptanib sodium is an aptamer that binds specifically to VEGF165, the most prevalent isoform in neovascular AMD, to block its activity and therefore prevent the proliferation of new vessels (Eter et al. 2006; Hanout et al. 2013; Bressler 2009). The VISION trial was a randomized controlled trial that studied the efficacy of intravitreal pegaptanib intravitreal injections for the treatment of CNV (Eter et al. 2006). Three different doses (0.3, 1.0, and 3.0 mg) given at 6-week intervals for a total of 48 weeks were compared to a sham treatment (Bressler 2009). All doses were shown to stabilize visual acuity in patients with all types of CNV after 1 year of treatment and beyond if treatment is continued (Eter et al. 2006). The side effects of pegaptanib sodium included eye pain, vitreous floaters, punctate keratitis, increased intraocular pressure, endophthalmitis, retinal detachment, and traumatic cataract (Eter et al. 2006; Hanout et al. 2013). Pegaptanib was thus approved by the US Food and Drug Administration (FDA) as a treatment for CNV in December 2004.

Ranibizumab Ranibizumab is the antigen binding fragment of a humanized murine monoclonal anti-VEGF antibody that blocks all forms of VEGF-A (Eter et al. 2006). Initial trials compared ranibizumab intravitreal injections to verteporfin photodynamic therapy. The Minimally Classic/Occult Trial of Neovascular Age-Related Macular Degeneration (MARINA) and Anti-VEGF Antibody for the Treatment of Predominately Classic Neovascularization in Age-Related Macular Degeneration (ANCHOR) studies were two pivotal phase three trials that demonstrated the critical role of ranibizumab in patients with AMD. Both of these trials compared 0.3 mg and 0.5 mg intravitreal ranibizumab injection with either a placebo arm (MARINA) or with PDT treatment (ANCHOR). Approximately 40% of patients in both trials showed a three-line improvement in vision at month 24 (Hanout et al. 2013). Ninety-five percent of eyes treated with ranibizumab showed improvements in both studies (Eter et al. 2006). The side effects of ranibizumab include endophthalmitis (1%) and stroke (1.3%) (Eter et al. 2006; Hanout et al. 2013). Ranibizumab was thereafter approved by the FDA for the treatment of wet AMD in June 2006.

The HARBOR study is currently comparing the approved dose of ranibizumab (0.5 mg) with a higher dose (2.0 mg) for AMD.

Bevacizumab Bevacizumab is recombinant humanized murine monoclonal anti-VEGF antibody that was originally approved in humans for the treatment of metastatic colorectal cancer (Eter et al. 2006). Off-label treatments for CNV have been studied thoroughly. The SANA (Systemic Avastin for Neovascular AMD) study treated nine patients with bevacizumab infusion and found that after 12 weeks of treatment visual acuity improved by 12 letters and OCT showed decreased central retinal thickness (Eter et al. 2006). The bevacizumab for neovascular age-related macular degeneration (ABC) trial demonstrated visual acuity gain of more than 15 letters in 33% of patients treated with intravitreal injections of bevacizumab compared to only 3% of patients treated with PDT and in the placebo group (Hanout et al. 2013). Only 3% of patients experienced ocular inflammation after intravitreal bevacizumab injections. The CATT (Comparison of AMD Treatment Trial) and IVAN (Inhibit VEGF in Age-related choroidal Neovascularisation) studies both determined that

treatment outcomes with monthly intravitreal injections of bevacizumab were not statistically different from monthly treatments with ranibizumab (Hanout et al. 2013). Although the IVAN study found that bevacizumab and ranibizumab had similar safety profiles, the CATT study found that more systemic side effects were encountered in patients treated with bevacizumab versus ranibizumab (Hanout et al. 2013). To date, bevacizumab is not FDA approved for the treatment of CNV; however, many clinicians use intravitreal injections of bevacizumab off-label in the treatment of CNV due to its proven efficacy.

Aflibercept Aflibercept is a recombinant fusion protein made of the Fc portion of IgG1 (Immunoglobulin G1) and the extracellular domains of human VEGF receptors 1 and 2. It binds to both VEGF-A and VEGF-B with high affinity (Browning et al. 2012). The VIEW1 and VIEW2 phase three trials showed that aflibercept intravitreal injections were non-inferior and clinically equivalent to monthly ranibizumab injections (Hanout et al. 2013; Browning et al. 2012). Interestingly, one treatment method tested included three monthly loading doses and doses every other month thereafter. This treatment method was also shown to be as efficacious as monthly ranibizumab (Browning et al. 2012). As this treatment regimen requires fewer injections, owing to its longer proposed half-life, it may be beneficial to patients in terms of reducing treatment frequency and therefore any risks associated with the intravitreal injection. Aflibercept was approved by the FDA for the treatment of wet AMD in November of 2011.

Future

Anti-PDGF-β

The Ophthotech company has developed the pegylated aptamer E10030 which is an anti-PDGF-β agent. It is thought that adding an anti-PDGF-β agent to an anti-VEGF agent could improve the treatment of CNV by inhibiting the initiation, growth, maturation, and stabilization of the nascent blood vessels. A phase two study has recently demonstrated that a combination of ranibizumab and E10030 resulted in better visual improvement and visual acuity stabilization (Hanout et al. 2013). The combination therapy also increases the frequency of regression of CNV (Campochiaro 2013). The Ophthotech agent is thus a promising new agent that, when added to currently available treatments, may further improve visual acuity in patients suffering from CNV. Two phase three studies have therefore been recently initiated to further explore the potential of this new agent.

Prognosis

Untreated CNV has a poor prognosis with most patients progressing to complete loss of vision. With treatment, however, many patients are able to maintain or improve their visual acuity for improved quality of life. Response to treatment does vary from patient to patient and the best predictors of response are clinical. Patients with superior responses to treatment include those who present with earlier stage disease, at a younger age, with smaller CNV lesions and better baseline visual acuity (Finger et al. 2014). Poor prognoses even with treatment are associated with delayed treatment, subfoveal CNV, lower baseline visual acuity, lengthier duration of disease, and older age (Wang and Kang 2012). Interestingly, the effect of smoking on the prognosis of CNV is currently unknown (Finger et al. 2014). Three different studies showed different effects of smoking on CNV (good, bad, and inconclusive), and therefore more research is needed to determine the true effect.

Genetic factors may also affect anti-VEGF treatment response (Finger et al. 2014). Several studies suggest that patients with AMD who have known risk genes (complement factor H (CFH), AMS2/HTRA1) or VEGF polymorphisms tend to have poorer outcomes than AMD patients without the risk genes (Finger et al. 2014). Additional genetic studies are required to determine its role in predicting a patient's response to treatment and prognosis of CNV.

Choroidal Neovascularization: Myopia

Salomon Y. Cohen
Department of Ophthalmology, Centre Ophtalmologique d'Imagerie et de Laser, Paris, France

Choroidal neovascularization (CNV) is a common cause of visual loss in pathologic myopia. Among patients aged less than 50, myopia accounted for 62% of cases of CNV (Cohen et al. 1996). CNV was initially described as Forster-Fuchs' spots corresponding to the fibrotic evolution of the CNV associated with a hyperpigmentation of the lesion. CNV was considered as one of the most severe complication of pathologic myopia. However, its prognosis was radically changed and improved by intravitreal injections of anti-VEGF agents.

Epidemiology, Risk Factors

CNV was reported to affect 5–12% of the eyes with pathologic myopia. Different studies, especially performed in Japanese patients, tried to recognize risk factors for the development of CNV in myopic eyes (Ohno-Matsui et al. 2003; Hayashi et al. 2005, 2010; Ikuno et al. 2010; Wakabayashi and Ikuno 2010). The only

recognized general factors are female gender, with two-thirds of patients being women, and older age. Presence of CNV in the fellow eye is also considered as a significant increase of risk. Local fundus risk factors are lacquer cracks and presence of patchy atrophy. The incidence of lacquer cracks in eyes with myopic CNV was found to be at least 75%. OCT and angiographies also helped to recognize choroidal filling delay and thin choroidal thickness as important risk factors. Both findings may explain the role of aging in the occurrence of myopic CNV. On the contrary, axial length or refractive error does not seem to constitute significant risk factors (Neelam et al. 2012).

Pathogenesis

While still discussed, pathogenesis of myopic CNV may involve an attempt of choroidal vessels to supply retinal oxygen to the outer retina, because choroidal thinning may result in outer retinal hypoxic changes with increase in VEGF production. Lacquer cracks may promote the extension of choroidal vessels into the sub-RPE space. Mechanical stretching may also enhance the choroidal thinning and production of VEGF. In summary, there are many anatomical and physiological changes attributable to myopia that could explain the occurrence of CNV in these eyes, but the exact role of each of these changes remains speculative (Spaide 2014).

Clinical Description

Symptoms of CNV in myopic eyes do not differ from those occurring in other conditions. Patients usually complain from visual loss, metamorphopsia, central scotoma, less frequently micropsia, or dyschromatopsia. The most typical myopic CNV present as small (<1 disk area) grayish subfoveal lesions. Subfoveal location of CNV was found in 58–70% of cases. Small hemorrhages are frequent. A dark border, corresponding to hyperpigmentation, may be observed, but usually in relatively ancient lesions. Large hemorrhages or lipid exudates are very uncommon (Soubrane and Coscas 2001).

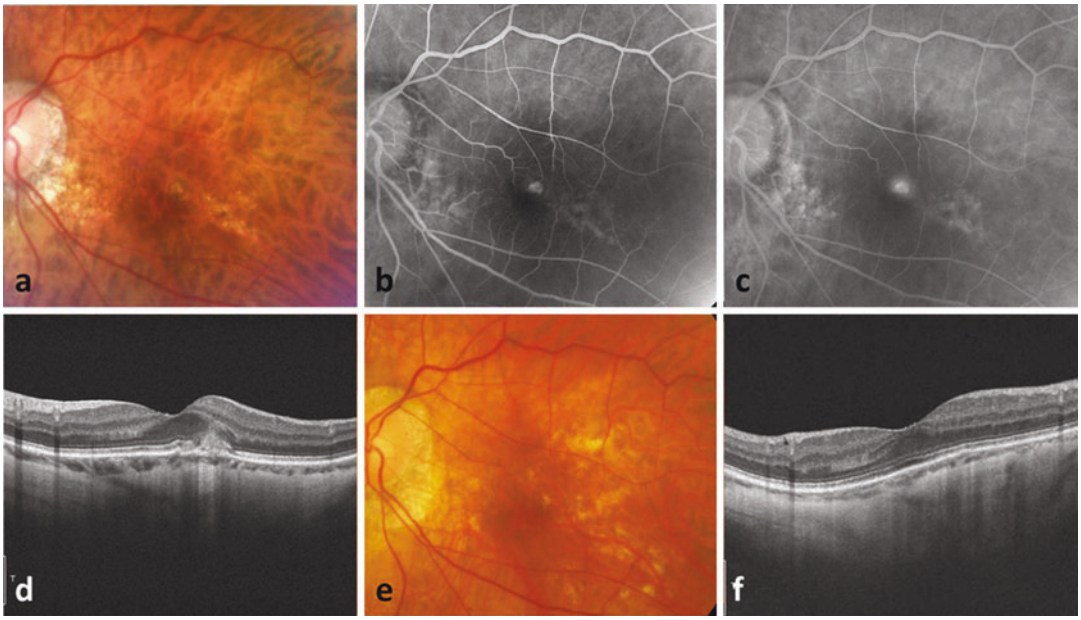
Fluorescein angiography demonstrates the CNV as "classic" or "type 2," characterized as an early hyperfluorescence associated with leakage of dye. This leakage may be minimal, especially in small lesions (Fig. 1). But, in other cases, it could be obvious. Indocyanine green angiography may be useful when the CNV is masked by hemorrhages and help to differentiate hemorrhages related to CNV from those that accompany the lacquer cracks formation. ICG angiography shows the CNV as a faint hyperfluorescent lesion. OCT usually shows the CNV as a localized thickening at the level of the subretinal space and the outer retina, giving a grayish appearance. This subretinal hyperreflective lesion may be accompanied by usually small amounts of intra- or subretinal fluid (Fig. 1).

Natural History

The natural history of myopic subfoveal CNV has been evaluated in various studies. Overall, less than one third of the eyes in the series reported retained visual acuity of more than 20/200, both in these studies and in the control group of one interventional prospective study (Chan et al. 2005; Soubrane 2008; Silva 2012).

Previous Therapeutic Options

Before the anti-VEGF era, treatment options were limited to laser photocoagulation for extra- and juxtafoveal CNV (Soubrane et al. 1986) and verteporfin (Visudyne, Novartis Pharma AG, Basel, Switzerland) photodynamic therapy (PDT) for subfoveal CNV (VIP-myopia). In the past, several alternative treatments were also advocated, including macular translocation (Mateo et al. 2004), surgical removal of CNV (Uemura and Thomas 2000), radiotherapy (Kobayashi and Kobayashi 2000), indocyanine green-mediated photothrombosis (Costa et al. 2003), transpupillary thermotherapy (Wu et al. 2008), and PDT combined with intravitreal triamcinolone (Chan et al. 2007a).



Choroidal Neovascularization: Myopia, Fig. 1 Subfoveal choroidal neovascularization. (**a**) Color photography: typical myopic fundus with tessellation and macular pigmentary changes. (**b**, **c**) Fluorescein angiography: early central hyperfluorescence with subtle leakage of dye in the late frame. (**d**) Horizontal scan of the OCT: *grayish* appearance of the outer retina, without significant thickening of the retina. (**e**, **f**) Color photograph and horizontal scan of the OCT after one intravitreal injection of ranibizumab: no scarring process of the retina, *restitutio ad integrum* of the foveal morphology

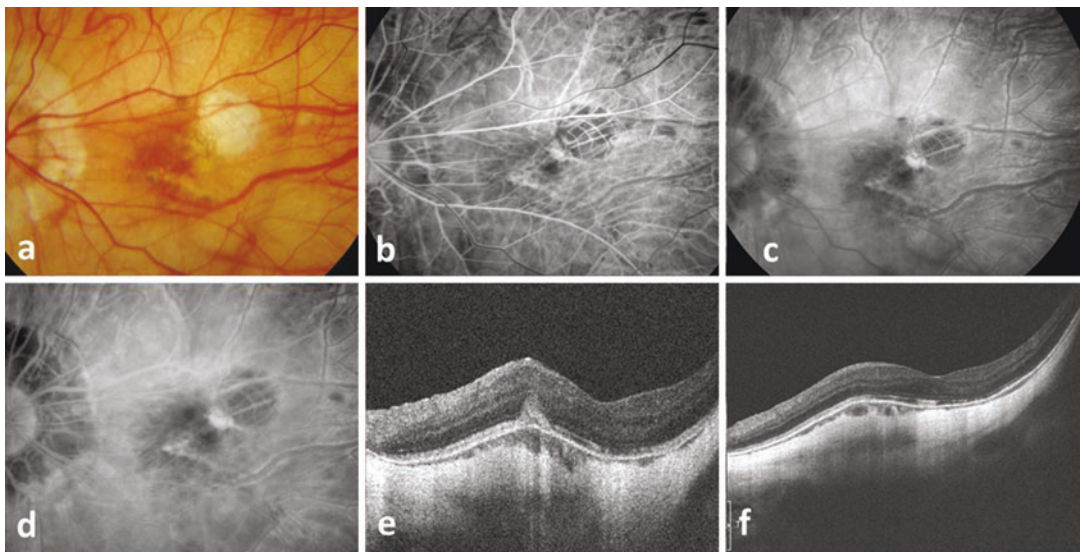
After laser photocoagulation, the first important step was the development of verteporfin therapy because it meant that patients with subfoveal CNV could now be treated. In most cases, the location of myopic CNV is indeed subfoveal. The results of a randomized, double-masked, placebo-controlled VIP study showed that at 1 year, visual loss of eight or more ETDRS chart letters occurred in 28% of treated eyes versus 56% of untreated eyes (Vip-Group 2001). However, at 2 years, the difference between these groups was no longer significant (Blinder et al. 2003). This limited long-term visual outcome was confirmed in subsequent studies (Schnurrbusch et al. 2005; Pece et al. 2006). In all these studies, final VA was found to be less than 0.3, in decimal equivalents, except for patients aged less than 55 (Lam et al. 2004) or treated only once (Chen et al. 2007). In clinical practice, verteporfin PDT was usually performed in subfoveal CNV because it was the only possible treatment. Its indications have been extended to juxtafoveal CNV and, even, to extrafoveal CNV.

Anti-VEGF Therapy

The development of anti-VEGF therapy over the past few years has revolutionized the management of exudative age-related macular degeneration, because for the first time, treatment with intravitreal ranibizumab (Lucentis, Genentech, Ca) proved effective in improving the mean VA of patients with subfoveal CNV. Bevacizumab, an inexpensive anti-VEGF agent whose structure is very close to that of ranibizumab, also became available and was widely used to treat this condition. As observed earlier for verteporfin PDT, the indication for intravitreal injections of anti-VEGF agents was rapidly extended to other diseases complicated by CNV. However, unlike what was done with verteporfin PDT, no manufacturer-sponsored randomized planned clinical trial of ranibizumab in myopic eyes was performed before 2012. So that use of anti-VEGF agents was discussed or controversial during many years (Rosenfeld 2007). However, data available

for pilot, monocentric, nonrandomized clinical studies all achieved similar results, including, in particular, significant improvement of VA (Laud et al. 2006; Chan et al. 2007b; Hernández-Rojas et al. 2007; Sakaguchi et al. 2007; Yamamoto et al. 2007; Arias et al. 2008; Rensch et al. 2008; Rhéaume and Sebag 2008; Silva et al. 2008; Dithmar et al. 2009; Gharbiya et al. 2009; Ikuno et al. 2009; Konstantinidis et al. 2009). In almost all series investigated, the gain in VA was important, usually more than three lines on ETDRS charts, after only a few injections. In all the series, safety was excellent, with no adverse events related to the drugs or to the procedure. Then, anti-VEGFs were rapidly considered as the first-line therapeutic option for management of myopic CNV (Cohen 2009). Recently, results of the RADIANCE study that compared verteporfin PDT with intravitreal ranibizumab have been recently reported (Wolf et al. 2014) and confirmed the excellent 1-year results obtained in another clinical study, named REPAIR (Tufail et al. 2013). The protocol of the RADIANCE trial has also compared two arms of patients treated with ranibizumab depending on their retreatment basis: one based on changes in VA and the other based on the disease activity. After 3 months, the eyes treated with ranibizumab gained 10.5 and 10.6 letters versus 2.2 letters, respectively, in the PDT arm. After 12 months, VA gains were of 13.8 and 14.4 letters, respectively, in the ranibizumab arms.

Anti-VEGF therapy is now the first-line treatment of myopic CNV. However, some questions remain. The first question concerns the choice of drug (ranibizumab, bevacizumab, or aflibercept). In AMD, clinical trials did not allow to observe differences in efficacy between ranibizumab and bevacizumab. The choice between the two drugs probably depends on the availability of anti-VEGF drugs, which may differ greatly from one country to another, on safety considerations and regulatory recommendations, and cost. There are no data in the literature concerning aflibercept. However, the results of the Phase 3 MYRROR study in myopic choroidal neovascularization (mCNV) have been reported in different meetings. In this trial, patients receiving aflibercept at an initial dose of 2 mg, followed by treatment on an as-needed (PRN) basis, had a mean



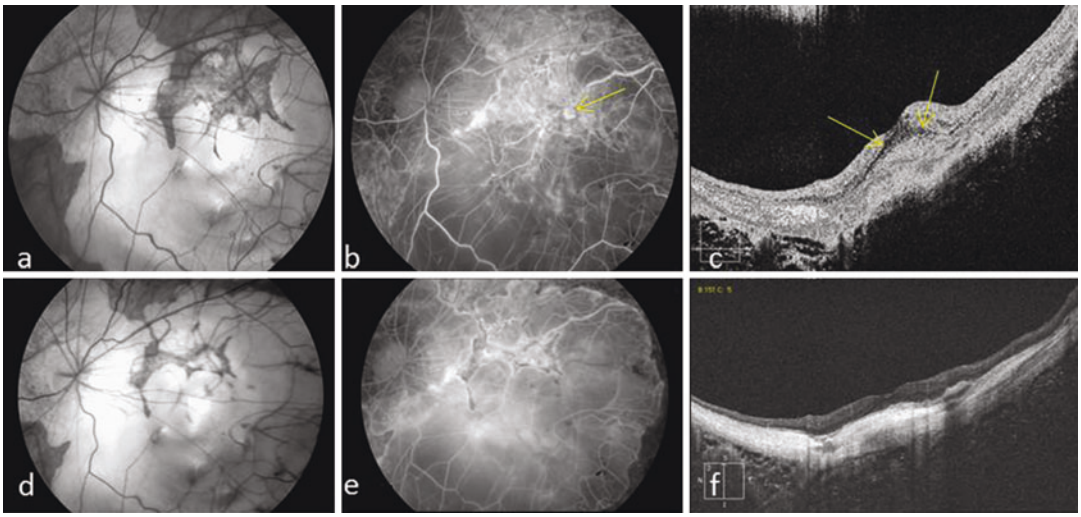
Choroidal Neovascularization: Myopia, Fig. 2 (**a**) Color photography: typical myopic fundus pallor, with an atrophic roundish lesion corresponding to a previous photocoagulation scar of a myopic CNV. (**b**–**d**) Fluorescein angiography: juxtafoveal recurrence of the CNV with moderate leakage of dye. (**e**) Horizontal scan of the OCT: *grayish* appearance of the outer retina, without significant thickening of the retina. (**e**, **f**) Color photograph and horizontal scan of the OCT after a single intravitreal injection of ranibizumab: restitution ad integrum of the foveal morphology

improvement in best-corrected visual acuity (BCVA) from baseline at week 24 of 12.1 letters, compared to a loss of 2.0 letters in patients receiving sham injections ($p < 0.0001$). There was no comparison with verteporfin or other anti-VEGF agents.

The second question is the protocol that should be used for treating myopic CNV with anti-VEGF drugs. The radiance trial results suggested the use of a PRN dosing after a single injection, with further treatment depending on the resulting VA and on fluorescein angiography and/or OCT findings. Indeed, one injection may be sufficient to allow the disappearance of the CNV (Figs. 1 and 2).

The third question is that of defining the follow-up protocol and the indications for reinjection during that period. An initial monthly follow-up is advised, but in absence of recurrence, the follow-up may be less strict than in AMD patients. Concerning detection of recurrences, the extent of the perfusion of the CNV may be difficult to evaluate without fluorescein angiography (FA). Furthermore, OCT is not easy to perform in myopic eyes and only gives a measurement of macular thickness, which is no more than an indirect index of leakage due to perfusion of the CNV. There is no formal recommendation for the follow-up of patients with myopic CNV treated with anti-VEGF agents. However, it could be advised to use all clinical parameters (visual loss, reoccurrence of metamorphopsia, appearance of hemorrhages) and perform OCT and/or fluorescein angiography in order to detect any sign of neovascular activity and decide re-treatments.

The last question is the long-term results of anti-VEGF in myopic CNV. In AMD, the long-term studies have shown a progressive decline of visual acuity with loss of the initial visual gain. Some studies addressed this question in myopic eyes with CNV. Extension of myopic atrophic changes may obviate the initial good visual results of anti-VEGF therapy (Fig. 3). Most of studies showed a small decline over time of the mean visual acuity of treated eyes attributable to occurrence of atrophic changes (or extension of pre-existing myopic atrophic changes) or, less frequently, to fibrosis or persistence of subretinal fluid. The decline was, however, relative. Indeed, all studies showed significant improvement



Choroidal Neovascularization: Myopia, Fig. 3 (**a**) Red-free photography: typical myopic atrophic changes. (**b**) Fluorescein angiography: subfoveal CNV (*arrow*). (**c**) Horizontal scan of the OCT: *grayish* appearance of the outer retina (*arrows*), with thickening of the retina. (**d**–**f**) Corresponding images 2 years after three intravitreal injections of ranibizumab: the CNV is no more present, but the initial gain in visual acuity was lost because of extension of the atrophic myopic changes

compared to baseline at 2, 3, or 4 years of follow-up (Franqueira et al. 2012; Lai et al. 2012; Peiretti et al. 2012; Oishi et al. 2013; Cohen et al. 2015). Thus, myopic CNV may be considered as a serious but usually treatable complication of pathologic myopia.

C

Choroidal Osteoma

Shahar Frenkel and Jacob Pe'er
Department of Ophthalmology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel

Synonyms

Osseous choristoma

Definition

Benign choroidal tumor consisting of many osteocytes, osteoblasts, and a few osteoclasts that form interconnected bony trabeculae with large blood vessels.

Etiology

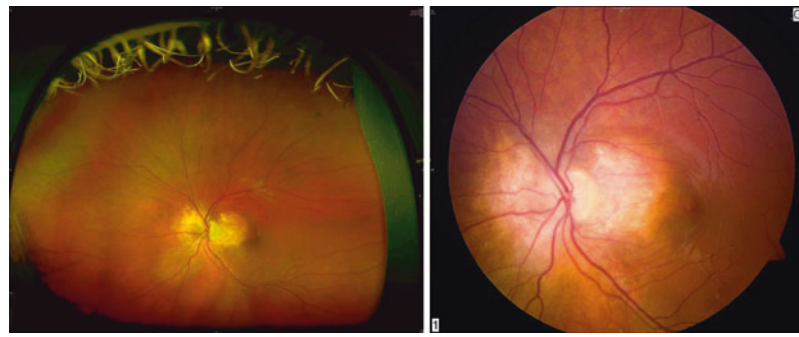
These tumors are usually choristomas in origin. There is some evidence to support both a genetic etiology, with some families having several members with the disease over several generations, and an inflammatory etiology following cases of choroiditis, posterior scleritis, and idiopathic orbital inflammation. The lesion is most common in women in their second to third decade and may be complicated by choroidal neovascularization (CNV) (Trimble and Schatz 1983; Horgan and Singh 2014).

Clinical Presentation

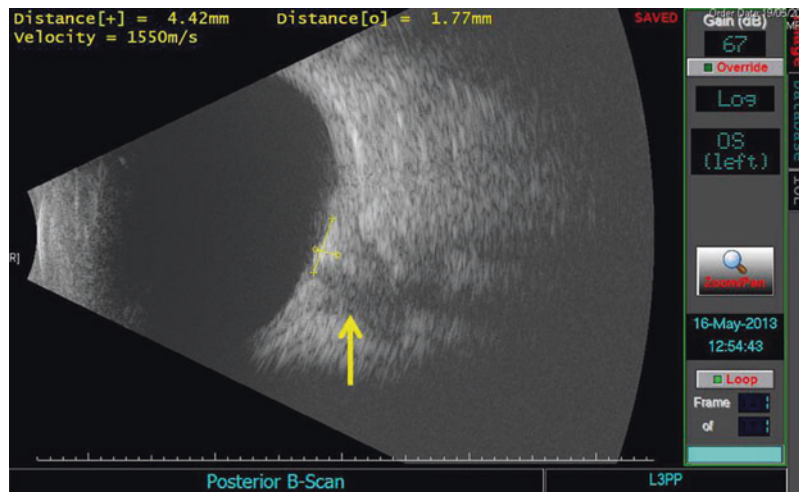
In most cases choroidal osteomas are unilateral, although bilateral cases have been reported. Choroidal osteomas appear as a flat yellow-white lesion with overlying retinal pigment epithelium (RPE) changes. The lesions are usually oval and have a clear irregular margin. The typical size is 1.5–2 disc diameters, although larger lesions have been reported. Lesions are usually located around the optic disc and may extend into the macula (Fig. 1). Calcifications are apparent on ultrasonography (Fig. 2). The osteomas usually grow slowly, but there have been rare reports of rapid growth on the one hand and of spontaneous regression on the other hand. The main complication, appearing in about half of the cases in the first decade after diagnosis, is choroidal neovascularization. Visual loss may result from the tumor itself, from neovascularization, or from damage to the optic nerve (Horgan and Singh 2014).

Diagnostics

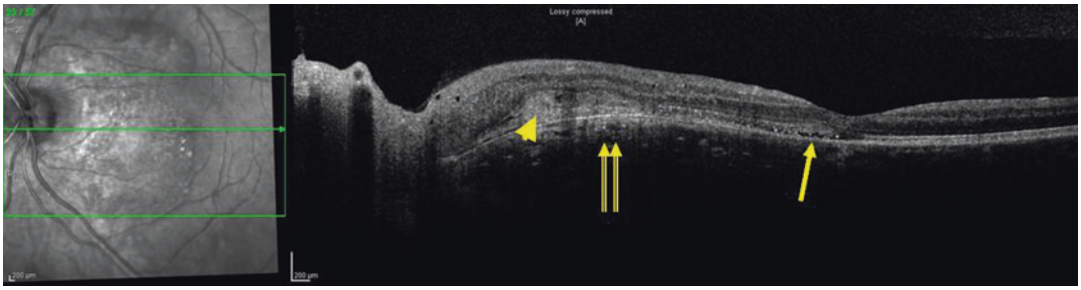
Clinical examination should be complimented by ultrasonography and fundus photography, along with optical coherence tomography (OCT) imaging to detect leakage from choroidal neovascularization (Fig. 3). B-scan ultrasonography is very sensitive in detecting the shadowing effect created by calcifications within the osteoma (Fig. 2). OCT can detect both subretinal and intraretinal fluids. If these fluids do not extend into the central macular area, they should not cause a visual disturbance and can remain untreated. There are typical angiographic signs of



Choroidal Osteoma, Fig. 1 Peripapillary and macular choroidal osteoma with an elevated *white-yellow* appearance (*left panel*, wide angle; *right panel*, 30° fundus picture)



Choroidal Osteoma, Fig. 2 B-scan ultrasonography demonstrates the shadowing effect (*arrow*) of the internal calcification



Choroidal Osteoma, Fig. 3 Optical coherence tomography (OCT) shows the sub-foveal fluid (*arrow*), the subretinal exudate (*arrowhead*), and the irregular shape of the choroid (*double arrow*) at the location of the osteoma

choroidal osteoma in both fluorescein angiography (FA) (early patchy hyperfluorescence and late staining) and in indocyanine green (ICG) angiography (early hypofluorescence and late diffuse staining). Angiography can also detect abnormal choroidal vessels with a lacy network with late leakage in FA. However, the clinical significance of finding non-leaking vessels is low, since standard treatments for CNV have limited success. Other forms of imaging, such as computed tomography (CT), can also detect the calcifications but are uncalled for when ultrasound is available.

Differential Diagnosis

Differential diagnosis includes ▶ malignant choroidal melanoma (amelanotic), ▶ choroidal hemangioma, choroidal metastasis from a distant primary malignancy, ▶ choroidal lymphoma, and ▶ posterior scleritis.

Clinically, the light-colored appearance of the osteoma may be seen in the lesions in the abovementioned list. The typical ultrasonic picture of internal calcification can also occur in a long-standing untreated choroidal hemangioma. However, posterior scleritis will also show a retrobulbar edema on ultrasound. Choroidal lymphoma has a similar clinical appearance and is usually a metastasis from systemic lymphoma with rare cases of primary choroidal lymphoma, which are hard to diagnose. It is the clinical combination of all the information that leads to the correct diagnosis, although follow-up may sometimes be the determining factor.

Prophylaxis

There are currently no methods to avoid development of a choroidal osteoma, or prevent the formation of CNV in this tumor.

Therapy

Replacement of normal choroidal vasculature by the osteoma cannot be reverted. Thus, the damage to the overlying RPE and retina is irreversible, and damaged areas will remain as a scotoma (blind spot). Similarly, if the osteoma grows around the optic nerve head and compresses it, treatment is of no avail. One can try and treat damage caused by leaking CNV. Sealing of the leaking vessels by laser photocoagulation has been replaced by PDT. Recent studies report on reducing the fluid via use of intravitreal injections of anti-vascular endothelial growth factor (anti-VEGF) (Bevacizumab, "Avastin") (Khan et al. 2014). However, the origin of the leaking vessels from an osteoma may render some protection, and only some of the patients benefit from any treatment in terms of improvement in visual acuity, whether there is any remaining sub- or intraretinal fluid or not. Therefore, stable amounts of sub- and/or intraretinal fluid that do not disturb vision can be left untreated.

Prognosis

As a benign tumor, choroidal osteoma does not threaten patients' lives, but after a decade most patients will lose vision down to 20/200 or less.

Epidemiology

This is a rare condition with an unknown incidence.

Choroidal Perfusion Abnormalities in the Preeclampsia, Eclampsia, and HELLP Syndrome Complex

Elona Dhrami-Gavazi[1,2] and Michael Engelbert[2,3]

Definition

Pregnancy complicated with the abnormalities encompassed by the multisystemic spectrum of preeclampsia, eclampsia, or HELLP syndrome may be accompanied by segmental or generalized arteriolar spasm, arterial and venous occlusive disease, serous retinal detachments, and yellow, placoid discolorations of the retinal pigment epithelium. These manifestations are due to vascular compromise in the retinal and choroidal circulations and are predominantly transient.

Preeclampsia is an obstetrical complication that typically develops after the 20th week of pregnancy and is characterized by hypertension, proteinuria, and generalized edema. It is subclassified as mild and severe and upgraded to eclampsia when it is superimposed by seizures. The Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy released in November 2013 recommended that the presence of alternative systemic findings observed with new-onset hypertension can fulfill the diagnosis of preeclampsia even in the absence of proteinuria, defining as one of the alternative systemic findings the "cerebral or visual symptoms." The HELLP syndrome, on the other hand, consists of hemolysis, elevated liver enzymes, and low platelets and is generally associated with severe preeclampsia or eclampsia.

Etiology

Preeclampsia is a syndromic condition that affects all organ systems, with repercussions that go far beyond hypertension and renal dysfunction and with placental dysfunction at its genesis. The latter is generally understood as an immunologically altered function of trophoblasts, which impairs vascular remodeling of the maternal spiral arteries that perfuse the placenta, with resultant placental hypoperfusion and increased blood velocity. This derangement of placental perfusion is believed to, in turn, cause a multisystemic maternal disease via a series of mediators, which include modifiers of angiogenesis and vascular endothelial function. The fetus is endangered due to placental vascular insufficiency. It is common knowledge that preexisting chronic hypertension in an expecting mother can manifest as severely increased blood pressure and this chronic hypertension, defined as

"hypertension that predates pregnancy," can be associated with fetal morbidity, expressed as intrauterine growth restriction. One of the main challenges in the care of pregnant women with chronic hypertension is to be able to distinguish whether chronic hypertension has worsened or preeclampsia has settled in, as the maternal and fetal morbidity are significantly augmented in case preeclampsia superimposes.

The choroidal perfusion abnormalities precipitated by preeclampsia's cascade of events range from a focal necrosis of the choriocapillaris to a fibrinoid necrosis of the larger caliber arterioles. The preeclampsia-induced choroidopathy is upheld to be ischemic in nature based on the features observed on clinical examination (small choroidal infarcts, ultimately manifesting as foci of atrophy and pigmentary hyperplasia, namely, the Elschnig spots), as well as the fluorescein and indocyanine green angiography findings. Areas of choroidal non-filling in angiograms can be differentiated from patchy choroidal filling, by an absence of choroidal fluorescence that persists for over 5 s and correspond to the serous retinal detachment areas. In the context of severe, generalized vasospasms that occur in preeclampsia, it has been noted that the posterior ciliary artery blood flow velocity is also increased in this disease, suggesting a vasospasm. Despite the rich circulation of the choroid, its vessels lack autoregulative defenses to hypertensive spikes. Also, a rapid deceleration of the arteriolar flow occurs in the choroid, as the blood flows in a terminal fashion from a functional perspective, given that its arterioles run a short course and undergo minimal branching. This enables damage to occur when acute, severe attacks of hypertensive spasms are swiftly transmitted downstream, causing focal choroidal edema and ischemia. After a focal occlusion occurs in the choroid, there is negligible collateral flow. Furthermore, preeclampsia may be associated with a perfusion dysfunction that goes beyond mere hypertensive spasms, as vascular endothelial function may be altered by a variety of putative mediators, activating intravascular coagulation with consecutive microcirculatory blockage. The microemboli are more likely to lodge at the choroidal capillaries given the large volumetric arteriolar flow that decelerates rapidly.

The putative mechanism of the development of serous retinal detachments and yellow, opaque areas of discoloration in the retinal pigment epithelium is that the ischemia at the choriocapillaris level may lead to retinal pigment epithelium ischemia, which causes malfunction of its fluid pump, leading to the accumulation of the subretinal fluid associated with ischemic damage at the retinal pigment epithelium level, manifested as deep, yellow lesions.

Clinical Presentation

The preeclamptic syndrome has been associated with a spectrum of posterior segment findings that include a retinopathy similar to hypertensive retinopathy, consisting of severe, segmental, or generalized arteriolar spasms, arterial occlusions, and venous occlusive disease. However, serous retinal detachments and yellow, placoid discolorations of the retinal pigment epithelium are features not commonly encountered in hypertensive retinopathy. Retinal manifestations may be more common in expecting mothers with preexisting hypertension. Acutely severe hypertension is associated with spasm of the central retinal artery, as suggested by the increased central retinal artery blood flow velocity. Saito et al. have suggested that while retinopathy is more frequently seen in preeclampsia superimposed on preexisting hypertension, the presence of serous retinal detachments and yellow deep retinal pigment epithelium discolorations are more specific to preeclampsia and eclampsia.

Symptomatically, preeclamptic patients may present with blurry vision, scotomata, and photopsia. However, choroidal perfusion abnormalities may be observed funduscopically in the absence of significant retinal vascular abnormalities and are associated with yellow, placoid areas of retinal pigment epithelium change. The neurosensory detachments are typically bilateral and bullous.

Diagnostics

Fluorescein angiography (FA) and indocyanine green angiography (ICG) are helpful in assessing the perfusion abnormalities seen in eclampsia. Aside from visualizing the degree of retinal nonperfusion, areas of choroidal nonperfusion in the FA can be differentiated from patchy choroidal filling by an absence of choroidal fluorescence that persists for over 5 s and correspond to the serous retinal detachment areas. In the context of severe, generalized vasospasms that occur in preeclampsia, it has been noted that the posterior ciliary artery blood flow velocity is also increased in this disease, suggesting a vasospasm. ICG demonstrates areas of ischemia accompanied by staining and hyperpermeability of the choroidal vessels.

Differential Diagnosis

The incidence of central serous chorioretinopathy (CSC) may be increased in pregnancy and shares characteristics with the choroidopathy in eclampsia. Both can have bullous elevation of the retina; however, central serous chorioretinopathy tends to be unilateral. FA in CSC shows a focal RPE leak and possibly the classic smokestack pattern of dye accumulation in the subretinal space. Choroidal vascular dilatation, leakage, and staining may be seen on ICG. Neither FA nor ICG will show ischemia in CSC.

Prophylaxis

Prenatal care includes monitoring for, and early treatment of, preeclampsia. Close follow-up is of paramount importance for women who have had a previous pregnancy complicated by preeclampsia. There is no specific ophthalmic prophylaxis.

Treatment

Early detection and treatment of preeclampsia and careful management of eclampsia and HELLP syndrome are crucial in preventing the development or treating the manifested ocular complications of this syndrome complex, since no specific ophthalmic treatment exists for them.

Prognosis

All serous retinal detachments and retinal pigment epithelium discolorations observed in a series of 40 eyes studied by Saito et al. came to a resolution with the delivery, except for three eyes with a large, geographic pattern of retinal pigment epithelium lesions that went on to develop significant chorioretinal atrophy.

Epidemiology

Preeclampsia affects an estimated 3–7% of all pregnancies. Risk factors include nulliparity, extremes of mother's age, African-American ancestry, multi-fetal gestations, preexistence of hypertension, or renal pathology. Serous retinal detachment secondary to choroidal hypoperfusion is a relatively rare yet well-reported cause of vision loss in this multisystemic perfusion and metabolic derangement. In the previously mentioned study by Saito et al., 65% of the eyes (40 out of 62 eyes of 31 patients with preeclampsia or eclampsia) was found to have serous retinal detachments, and 58% (36 of 62 eyes) had retinal pigment epithelium lesions that were located in the peripapillary or macular regions.

The choroidopathy manifested as serous retinal detachments does not appear to be an additional risk factor in potential adverse neonatal outcomes. The detachments generally resolve with complete restoration of visual acuity within a few weeks. However, there are a few reports of persisting changes for over a year after pregnancy or chronic changes that were later in life thought to represent tapetoretinal degenerations.

Chromatic Aberration: Definition

Len Zheleznyak
Center for Visual Science, The Institute of Optics, University of Rochester, Rochester, NY, USA

Synonyms

Axial chromatic aberration; Lateral chromatic aberration; Longitudinal chromatic aberration; Transverse chromatic aberration

Definition

Due to the dispersion of refractive materials (i.e., glass, water, ocular media, etc.), the focusing properties of a lens depend on the wavelength of light. Chromatic aberration is generally manifested in two ways: focusing error and magnification error. Dispersion-induced focusing error is known as *axial* or *longitudinal chromatic aberration* and is illustrated in Fig. 1. The axial chromatic aberration of the eye over the visible spectrum is approximately 2 diopters (Thibos et al. 1992), as shown in Fig. 2. Due to the positive Abbe number of the ocular media, shorter wavelengths (blue colors) are relatively hyperopic to the longer wavelengths (red colors).

Dispersion-induced error in magnification is known as *transverse* or *lateral chromatic aberration*. Both types of chromatic aberration increase as the pupil size increases; however, only transverse chromatic aberration increases with retinal eccentricity.

Chrysiasis, Corneal Pigmentation

Atif Mohiuddin
Department of Ophthalmology, George Washington University, Washington, DC, USA

Synonyms

Ocular chrysiasis

Definition

Chrysiasis is the deposition of gold in bodily tissues after the long-term administration of gold therapy, most commonly in the treatment of rheumatoid arthritis.

Etiology

Chrysiasis generally results from medical treatment of disorders such as rheumatoid arthritis with injection or oral therapy with gold.

Clinical Presentation

Gold deposits are visually asymptomatic, but may be seen in both the cornea and the conjunctiva. In the cornea, the deposits are at the level of the posterior stroma and Descemet's membrane. They consist of yellow-brown granules which may have a metallic sheen. Gold deposits may very rarely also appear in the lens.

Diagnosis

Chrysiasis would be diagnosed with careful examination of the cornea and conjunctiva under slit-lamp exam.

Differential Diagnosis

Other causes of pigmented deposits of the posterior stroma include copper deposits or a mottled cyan opacification associated with long-term soft contact lens wear. The cause of this opacification is unclear. Copper deposition has been associated with most commonly Wilson's disease. Non-pigmented deposits can be caused by cornea farinata, pre-Descemet's corneal dystrophy, X-linked ichthyosis, and ocular argyrosis. Crystalline dystrophies or keratopathies may also be confused with this disease process.

Prophylaxis

Preventing ingestion of gold would prevent this process from occurring.

Therapy

As chrysiasis is visually asymptomatic, there is no therapy for this entity.

Prognosis

Prognosis is good as chrysiasis will remain visually asymptomatic requiring no treatment. In some cases, the depositions may clear after the cessation of therapy, while in others the depositions never disappear.

Epidemiology

Chrysiasis is found in individuals undergoing medical treatment of disorders such as rheumatoid arthritis who may get gold injections or gold oral therapy. Almost all patients who have received greater than 1,500 mg of gold therapy develop gold deposits.

Ciliary Arteries

Tara Uhler
Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Definition

Branches of the ophthalmic artery, these arteries or their subsequent branches supply the anterior optic nerve, choroid, choriocapillaris, rectus muscles, iris, and ciliary body.

Basic Characteristics

Variable numbers and branches of the ciliary arteries have been reported. Typically, however, a medial and lateral posterior ciliary artery arise from the ophthalmic artery and penetrate the globe a few millimeters to either side of the optic nerve. Each of these divides into one long posterior ciliary artery and 7–10 short posterior ciliary arteries. The former course along the horizontal meridians, branch at the ora serrata, and help supply the anterior choriocapillaris and ciliary muscle; the latter supply the posterior choriocapillaris, peripapillary choroid, and anterior optic nerve.

Cilioretinal arteries arising from the ciliary arteries are present in 20–25% of eyes; by perfusing certain portions of the macula, they may afford preservation of vision after central artery occlusion.

The muscular branches of the ophthalmic artery supply the rectus muscles and form the anterior ciliary arteries. Each rectus muscle has two arteries except the lateral rectus, which only has one. Further anteriorly, the anterior ciliary arteries penetrate the sclera posterior to the limbus and supply the iris (major arterial circle), ciliary body, and anterior choroid. Branches which do not penetrate the sclera, but continue toward the limbus, merge with subconjunctival vessels to form the episcleral plexus.

Anterior segment ischemia may occur following extraocular muscle surgery. The horizontal muscles have collateral circulation between the long posterior ciliary arteries and the anterior ciliary arteries; however, the vertical muscles do not. Therefore, anterior segment ischemia usually is seen only when multiple muscles and at least one vertical rectus muscle have been involved.

Ciliary Block (Malignant) Glaucoma, Muscarinic Antagonists for

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Synonyms

Aqueous misdirection; Direct lens block angle closure; Malignant glaucoma

Definition

In ciliary block glaucoma, there is an accumulation of aqueous humor in or behind the vitreous (rather than flowing normally from the posterior chamber into the anterior chamber), causing a forward shift of the vitreous and forward movement of the lens-iris diaphragm resulting in a shallow anterior chamber.

Etiology

The mechanism of ciliary block glaucoma is not clearly understood. The ciliary body may form a seal around the lens or anterior hyaloid preventing the anterior flow of aqueous. The anterior hyaloid may contribute to this blockage by pushing forward against the ciliary body as fluid collects posteriorly. As intraocular pressure increases, flow of fluid through the vitreous decreases, contributing further to the vicious cycle of elevated intraocular pressure and collection of fluid in the vitreous. Lastly, laxity of lens zonules allowing anterior movement of the lens may also contribute. Ciliary block glaucoma occurs after intraocular surgery, especially after glaucoma surgery on patients with angle-closure glaucoma.

Clinical Presentation

On exam, the anterior chamber is shallow peripherally and centrally. Intraocular pressure is normal to elevated. Clear pockets of fluid may be seen within the vitreous. On ultrasound biomicroscopy, ciliary processes can be seen rotated anteriorly.

Diagnostics (Lab Diagnostics)

It is important to rule out suprachoroidal hemorrhage by exam or echograpy and rule out pupillary block glaucoma by creating an iridotomy.

Differential Diagnosis

1. Pupillary block glaucoma. Often associated with peripheral iris bombe and deeper central anterior chamber; can be eliminated by iridectomy or iridotomy

2. Choroidal detachment. Usually associated with low intraocular pressure
3. Suprachoroidal hemorrhage. Often associated with pain and elevated intraocular pressure

Prophylaxis

Cycloplegic therapy at the time of glaucoma surgery may be helpful.

Therapy: The two main components of therapy are cycloplegia and intraocular pressure management. Atropine can be used daily to four times per day and may act to tighten the zonules to break ciliary block. Intraocular pressure can be controlled with hyperosmotics such as oral glycerol or intravenous mannitol, as well as topical agents including carbonic anhydrase inhibitors, -blockers, and α_2-agonists, or oral agents including methazolamide or acetazolamide.

If medical management is not effective, surgery is considered. If the individual is aphakic or pseudophakic, the Nd:YAG laser can be used to rupture the anterior hyaloid face(thereby allowing trapped fluid behind hyaloid face to come forward) or the argon laser can be used to shrink ciliary processes if they are visible through an iridectomy (this can break the seal between the ciliary body and lens). If these attempts fail, pars plana tap of the vitreous or pars plana vitrectomy with removal of the anterior hyaloid may be needed.

Prognosis

Fifty percent of individuals are effectively treated within 5 days with medical therapy alone. Sometimes long-term use of cycloplegic-mydriatic therapy is necessary.

Epidemiology

Occurs in 0.6–4% of incisional surgeries for angle-closure glaucoma.

Aqueous misdirection syndrome

Definition

The term malignant glaucoma was coined by von Graefe in 1869. He noted that following peripheral iridectomy for acute angle-closure glaucoma, a number of patients developed shallowing of the anterior chamber together with high intraocular pressure. The subsequent prognostic outlook for such eyes was typically poor, hence the term "malignant."

Classically, malignant glaucoma is characterized by a shallow anterior chamber associated with raised intraocular pressure and in the presence of a patent iridotomy (Ruben et al. 1997).

Etiology

Malignant glaucoma occurs in 2–4% of eyes undergoing surgery for angle-closure glaucoma and may occur at any time following surgery, from the first postoperative day to many years later. Usually it occurs after filtering surgery in eyes with angle closure but has also been described after surgical iridectomy and after cataract surgery. There are also reports of the condition after laser iridotomy, Nd-YAG laser cyclophotocoagulation, or holmium laser sclerostomy.

The exact mechanism of malignant glaucoma remains unclear. Shaffer proposed misdirection of aqueous either into or around the vitreous, but recently Quigley questioned that mechanism and proposed that malignant glaucoma involves a vicious cycle in the behavior of the vitreous gel, but without a one-way valve or aqueous misdirection (Quigley 2009). Acute choroidal expansion induced by the sudden surgical decompression of the eye causes immediately postoperative IOP elevation and leads to increased aqueous outflow and development of a substantial posterior-anterior pressure gradient. This differential leads water to move from the posterior vitreous cavity toward the posterior chamber. Since most adult eyes have a posterior vitreous detachment to some degree, fluid from behind the vitreous must pass through the gel to equalize this pressure difference. Normal vitreous does, however, limit the free passage of water, and its fluid conductivity decreases under an increased pressure differential. In persons with extremely poor vitreous conductivity, this leads to a vicious cycle. The vitreous is unable to equalize the pressure difference, and it compresses. The vitreous and the iris and lens move together toward the cornea as aqueous leaves the trabecular meshwork (or the fistula).

Clinical Presentation

Following filtration surgery malignant glaucoma presents as a shallow anterior chamber with a normal or high intraocular pressure in the presence of a patent peripheral iridectomy. There is axial shallowing of the anterior chamber, and, unlike pupil block, the iris is not typically bowed forward.

Diagnostics

The configuration of the anterior segment structures shows iridocorneal touch and appositional angle closure in the presence of a patent iridotomy or iridectomy. A pooling of aqueous between the posterior capsule and the anterior hyaloid face may be visible especially in the cases of pseudophakic malignant glaucoma. Using high-resolution ultrasound, anterior rotation of the ciliary body with apposition to the iris should be detectable.

Differential Diagnosis

Angle closure caused by pupil block may be distinguished by the typical bowing of the iris. If the patency of the iridotomy is in doubt, a repeat laser iridotomy should be performed (Rauscher and Parrish 2008). A shallow anterior chamber associated with a wound leak should be easily detectable and will usually be associated with hypotony. If the iridotomy is patent and the intraocular pressure high, choroidal hemorrhage must be excluded either clinically or by ultrasound examination. In the absence of a history of surgery, other causes of secondary angle closure including intumescent lens, choroidal neoplasm, central retinal vein occlusion, and secondary pupil block must be excluded.

Prophylaxis

Filtering surgery in eyes with angle-closure glaucoma should only be performed when all other therapeutic modalities have failed to adequately lower IOP. Treating angle-closure glaucoma (after

iridotomy) with cyclophotocoagulation may not only lower IOP but also be preventive for malignant glaucoma by shrinking ciliary processes. If filtering surgery has become mandatory, a two-stage procedure with previous cataract extraction by phacoemulsification or one-stage combined procedures (phacotrab) should be preferred. Tight closure of the flap and a large-sized iridectomy should be performed. Leaving some viscoelastics in the anterior chamber at the end of surgery may be of some use to prevent anterior chamber shallowing. In small eyes prone to pseudophakic malignant glaucoma, the size of IOL optics should not exceed 6 mm.

Therapy

Management of ciliary block glaucoma is in the first instance medical. This consists of cycloplegic drops, topical beta-blockers, apraclonidine, oral carbonic anhydrase inhibitors, and, if necessary, oral glycerol or intravenous mannitol. This combination reduces choroidal expansion, shrinks the vitreous, decreases aqueous production, and encourages backward displacement of the lens-iris diaphragm. Fifty percent of cases will be relieved within 5 days. If high pressure continues after this time, or if lens-corneal touch occurs, surgical intervention should be considered. Once the anterior chamber deepens and the IOP has been normalized, medical treatment can be gradually withdrawn. The patient may be maintained on atropine alone, but may require indefinite treatment with atropine to prevent recurrence.

Direct argon laser treatment through a peripheral iridectomy to shrink the ciliary processes may be used. In aphakic or pseudophakic eyes, Nd-YAG laser may be used to perform posterior capsulotomy/hyaloidotomy. Recently, diode laser cyclophotocoagulation has been shown to be very effective in treating malignant glaucoma (Bresson Dumont et al. 2006).

If none of the above is enough to maintain anterior chamber depth and to lower IOP, surgery must be considered. In phakic eyes, phacoemulsification and in the bag IOL is the first step or is performed as combined procedure with vitrectomy (Sharma et al. 2006). Usually a vitreous tap has to be performed first to adequately lower the IOP and enable safe phacoemulsification. When phacoemulsification is finished, a core vitrectomy is performed either via an anterior approach using a posterior capsulorhexis or a pars plana approach. Excision of posterior capsule and partial zonulectomy must be included in the procedure creating a direct communication between vitreous cavity and the anterior chamber through an iridectomy.

Prognosis

Approximately 50% of cases will be permanently under control with medical treatment alone. Long-term treatment with atropine carries however a substantial risk of allergic reactions. Surgical treatment has a high success rate of up to 90% if combined procedures (i.e., phacoemulsification and vitrectomy) are used in cases of pseudophakic malignant glaucoma. In the majority of cases, however, the IOP-lowering success of the filtering surgery is lost, and the patient may require further glaucoma treatment.

Epidemiology

Malignant glaucoma occurs in 2–4% of eyes undergoing surgery for angle-closure glaucoma. Pseudophakic malignant glaucoma is rare (less than 0.1%).

Ciliary Body

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Definition

A structure containing muscle, vessels, epithelium, and autonomic neural tissue that is attached at the scleral spur and is composed of the pars plicata (with its ciliary processes) and pars plana, that has several functions, including creating the supraciliary space adjacent to the sclera, producing aqueous humor, maintaining a portion of the blood-aqueous barrier, and allowing accommodation and uveoscleral outflow. It is considered to be part of the uveal tract (along with the choroid and iris).

Definition

The ciliary ganglion (CG) is a parasympathetic ganglion responsible for miosis (pupil constriction) in response to light and accommodation. Parasympathetic, sympathetic, and sensory fibers run through the CG but only the parasympathetic fibers synapse in the CG. It is located in the posterior orbit.

Anatomy

The parasympathetic fibers originate from the parasympathetic brainstem nuclei then travel with the oculomotor nerve (cranial nerve III) which then enters the posterior orbit through the superior orbital fissure. After synapsing in the CG, the parasympathetic fibers continue to the eye via the short ciliary nerves. These postganglionic fibers control miosis by innervating sphincter pupillae, and they

control accommodation by innervating the ciliary body muscle. Disruption of the parasympathetic fibers can result in anisocoria.

In contrast, postganglionic sympathetic fibers, which originate from superior cervical ganglia, branch off of the carotid plexus surrounding the internal carotid artery, pass through the superior orbital fissure, and then continue through the CG on the way to the eye. Upon exiting the CG, these sympathetic fibers travel with parasympathetic fibers in the short ciliary nerves. These sympathetic fibers are responsible for mydriasis (pupil dilation) in response to dark ambient lighting conditions by innervating the dilator muscle.

General sensory fibers, the ophthalmic branch of the trigeminal nerve (cranial nerve V_1), also enter the orbit through the superior orbital fissure. V_1 provides innervation for general ocular, orbital, and periorbital sensation, including nasociliary, frontal, and lacrimal branches. Some fibers from V_1 pass through the CG and travel along the short ciliary nerves to the eye. These fibers provide sensation to the cornea and can be tested with the corneal reflex. Other fibers from V_1 travel along the nasociliary nerve and become a part of the long ciliary nerves.

Clinical

Disruption of the parasympathetic fibers to the eye can result in anisocoria that is greater in the light. Disruption of sympathetic innervation to the eye can result in an ipsilateral Horner syndrome, characterized by ptosis, miosis, and anisocoria in the dark, and anhidrosis, but typically damage to the CG results in parasympathetic dysfunction-related anisocoria worse in the light. Most cases of CG damage are idiopathic (e.g., Adie tonic pupil), but some occur after orbital infection, surgery, or trauma to the CG. Disruption of V_1 fibers to the eye can result in loss of sensation to the cornea and will result in a negative corneal flex test. Depending on the location of the lesion along these nerves, facial sensation can be lost as well.

Ciliary Muscle

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The ciliary muscle is a ring muscle located within the ciliary body which controls by its contraction and relaxation the tension of the zonular fibers and thereby the shape of the crystalline lens with accommodation.

Anatomy

The ciliary muscle is a smooth muscle with some peculiarities in its structure and function (fast contraction and relaxation, tendons at the origin and point of insertion, parallel orientation of myofibrils). Its cross-sectional shape is triangular. It consists of three groups of muscular fibers differing in situation and orientation within the ciliary body. These groups are the longitudinal, radial, and equatorial or circular fibers. It is found in the outer part of the ciliary body where its fibers originate from a ring-shaped tendon which is fixated at the scleral spur. Neighboring structures are the sclera and the collagen fibers, fibroblasts, and melanocytes of the outer face of the ciliary body. The inner surface of the ciliary muscle borders anteriorly to the pars plicata and posteriorly to the pars plana of the ciliary body. The anterior insertion is at the scleral spur and the trabecular meshwork. Posteriorly it is fixated to the stroma of the choroid by elastic tendons.

Neural and Blood Supply

The mesodermal smooth muscle is supplied by the short ciliary nerves carrying postganglionic parasympathetic fibers from the ciliary ganglion. Preganglionic fibers originate in the Edinger-Westphal nucleus in the midbrain and run to the ciliary ganglion in the inferior portion of the third cranial nerve. There is also a weak reciprocal sympathetic innervation of the ciliary muscle inserting the orbit from the carotid plexus together with the first branch of the fifth cranial nerve where they join the long and short ciliary nerves. The blood supply of the ciliary muscle comes from the anterior and posterior ciliary arteries. Venous drainage is posteriorly to the vortex veins.

Function

Contraction of the ciliary muscle pulls the suspension of the lens which causes relaxation of the zonular fibers. As a consequence, the crystalline lens is molded into a more convex shape by its elastic capsule and the eye is focused to a nearer distance (Glasser et al. 2003).

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Definition

Claude syndrome refers to the set of signs and symptoms associated with unilateral tegmental lesions of the dorsomedial midbrain. Named after Henri Charles Jules Claude, who described the condition in 1912, this particular intramedullary brainstem syndrome most commonly involves unilateral infarction of the medial half of the red nucleus and superior cerebellar peduncles after decussation.

Etiology

Infarction of the dorsomedial midbrain may arise secondary to occlusion of a branch of the posterior cerebral artery. These events are most commonly caused by preexisting cerebrovascular disease or malignancy. Large artery disease producing emboli or in situ thrombosis account for the majority of mesencephalic infarct mechanisms, while cardioembolism and small-vessel disease are associated with 25% of cases.

Disruption of blood flow in the posterior cerebral artery may compromise the following neuronal tracts within the midbrain tegmentum, thus yielding the characteristic signs and symptoms of this stroke syndrome: red nucleus, superior cerebellar peduncles after decussation, dentatorubro fibers, oculomotor nerve nucleus, and fibers. Insult to fourth nerve fascicles, the medial lemniscus and the medial longitudinal fasciculus have been observed.

Clinical Presentation

Patients with *Claude syndrome* present with ipsilateral oculomotor nerve palsy and contralateral cerebellar hemiataxia and tremor. The third nerve palsy is usually a partial palsy characterized by ptosis, a dilated pupil, and downward (hypotropia) and lateral deviation (exotropia) of the involved eye. Features of cerebellar hemiataxia involve asynergy of upper and lower limbs, poor gait, and dysdiadochokinesia. Cerebellar tremor may be referred to as a rubral tremor or intention tremor and presents with dysmetria or the lack of coordination of a limb to move accurately to an intended position.

Patients may also have a dissociated horizontal nystagmus of the abducting eye due to internuclear ophthalmoplegia when medial longitudinal fasciculus axons are injured. Further, due to the proximity of fourth nerve fibers to the posterior cerebral artery in the midbrain, patients may concurrently present with a fourth nerve palsy.

Diagnostics

Appropriate neuroimaging (i.e., magnetic resonance imaging, computed tomography) should

be directed to the dorsomedial midbrain in patients presenting with *Claude syndrome*.

Differential Diagnosis

Differential diagnoses for *Claude syndrome* generally include other intramedullary brainstem syndromes (e.g., Benedikt, Wallenberg, Weber, Nothnagel, Parinaud, von Monakow, Millard-Gubler, Avellis, and Jackson syndromes).

Prophylaxis

Evaluation and management of underlying risk factors for cerebrovascular disease should be considered.

Therapy

Treatment is directed toward the underlying etiology.

Prognosis

Prognosis for *Claude syndrome* is variable and dependent upon the severity and extent of the underlying disease process affecting the dorsal midbrain.

Epidemiology

Ischemic cerebrovascular disease increases with age, but other underlying risk factors for ischemia can occur in younger patients, in either gender and in any ethnic group.

Synonyms

Tunneling

Definition

A surgical technique of small-incision cataract surgery. The incision affects only the cornea and therefore does not depend on a conjunctival dissection. There are three forms of clear corneal incisions: uniplanar, biplanar, and triplanar.

The advantages are an easier access of the phacoemulsification tip and the self-sealing occlusion of the incision, so that sutures are not necessary. The incision is favorable to foldable intraocular lens implants and frequently used after or with fistulation operations from the temporal. Furthermore, this technique reduces the possibility of bleeding and allows a local noninvasive anesthesia. Anticoagulants should not be discontinued.

History

The idea dates back to 1992 when Fine first described a new concept of a planar temporal clear corneal sutureless and self-sealing incision (single-plane clear corneal incision). The position of incision was chosen by picking the point with the largest distance to the corneal center on the temporal median. Fine affirmed this incision was easier, quicker to realize, and astigmatically neutral. Other authors modified the description. Kellar favored a "sclera-less" clear corneal incision beneath a short conjunctival flap. Williamson and Langerman introduced hinged clear corneal incisions (shallow-groove two-plane incision and deep-groove two-plane incision). Ernest ascertained that corneal healing proceeded faster when the fibroblastic healing response was allowed to start at the conjunctival limbus (7 days compared with 1 month with other techniques). Neuhann and Ernest described in 1996 the posterior limbal incision as equal in aesthetics and surgical efficiency, slightly superior in patient comfort, and far more stable.

Clinical Features

Tunneling is conducted by using a diamond keratome (corneatome), 90° tip, 45°shoulders, and double-beveled edges. The line of intersection should be drawn obliquely, immediately anteriorly to the limbal vascular arcade. During this process, a limbal fixation ring may stabilize the eyeball. The slit knife cuts at a depth of 1, 5–2 mm; its tip is turned posteriorly to perforate Descemet's membrane. The resulting incision is 3 mm and thus sufficient for emulsification and implantation of foldable intraocular lenses. A biplanar incision may be performed by modifying the angle of penetration.

Tests

In advance to prepare for the clear corneal incision, an efficient examination of the eyes and the acquisition of the patient's anamnesis with possible past eye surgeries are elementary to determine any exclusion criteria.

Differential Diagnosis

Other cataract wound incision techniques:

- Sclera tunnel incision (traditional curvilinear, straight and frown incisions)
- Posterior limbal incision

Etiology

See "History" section above.

Treatment

See sections "Differential Diagnosis" and "Clinical Features" above.

Synonyms

Many different names have been applied to the different manifestations of what may be a single pathological response in the cornea (Gray et al. 1992). These names were based on race, geography, occupation, clinical appearance, presumed etiology, presumed nature of the corneal deposits, and eponyms, including:

- The blindness of Dahalach
- Tropical corneal dystrophy
- Nodular band-shaped dystrophy of tropical countries of arid soil
- Fisherman's keratopathy
- Labrador keratopathy
- Nama keratopathy
- Eskimo keratopathy
- Bietti's nodular corneal dystrophy
- Degeneratio corneae sphaerularis elaioides
- Degeneratio primaria oleoguttata centrale et superficiale
- Band-shaped nodular dystrophy
- Nodular band-shaped hyaline keratopathy
- Spheroidal degeneration
- Spheroidal keratopathy
- Gelatinous dystrophy
- Droplet keratopathy
- Droplet degeneration of the cornea
- Colloid degeneration of the cornea
- Hyaline corneal degeneration
- Keratinoid corneal degeneration
- Keratoid corneal degeneration
- Proteinaceous corneal degeneration
- Elastotic degeneration of cornea
- Elastoid degeneration
- Corneal elastosis
- Chronic actinic keratopathy
- Band-shaped climatological degeneration

Chronic actinic keratopathy describes a condition associated with conjunctival elastosis and typified by characteristic extracellular concretions (Klintworth 1972). A later publication found this entity and others, including Labrador keratopathy, to fit the classification of the clinical term "spheroidal degeneration" (Fraunfelder and Hanna 1973). Several other reported clinical entities describe globular deposits of the cornea that may represent the same condition, with geographic variations or subtypes:

- Spheroidal keratopathy
- Spheroid degeneration
- Hyaline corneal degeneration
- Colloid degeneration of the cornea
- Sphaerularis elaiodes
- Superficial central primary degeneration oleogutta
- Degeneratio hyaloidea grannuliformis corneae
- Bietti corneal degeneration
- Nodular corneal dystrophy in tropical arid countries
- Nodular hyaline, band-shaped keratopathy
- The blindness of Dahalach
- Fisherman's keratopathy
- Band-shaped nodular dystrophy of the cornea
- Labrador keratopathy
- Keratoid corneal degeneration
- Climatic droplet keratopathy
- Chronic actinic keratopathy
- Proteinaceous corneal degeneration
- Elastoid degeneration
- Elastotic degeneration
- Eskimo corneal degeneration

Definition

A degeneration of the cornea and/or conjunctiva characterized by the appearance of fine, golden yellow, spherules or globules of varying size at or beneath the epithelium. A degeneration characterized by the appearance of yellow or golden globules of varying size in the superficial cornea or conjunctiva.

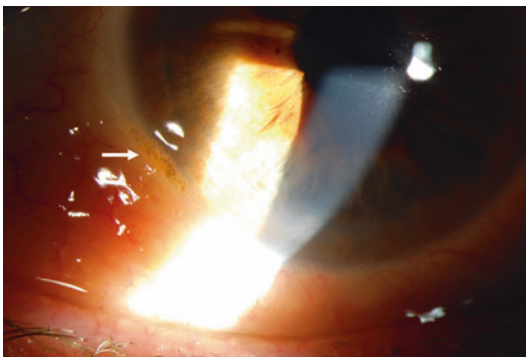
Etiology

The exact source of the protein material forming the droplets is unknown. It has been postulated that the material may result from the actions of ultraviolet light on serum proteins that diffuse into the cornea from limbal vessels (Farjo and Sugar 2009). Increasing age and exposure to ultraviolet light are the most common associated factors. Other proposed risk factors include dry eyes, malnutrition, corneal trauma or microtrauma (wind, sand, ice), low humidity, and extremes of temperature. Associated ocular diseases include keratitis, lattice corneal dystrophy, and glaucoma (Fraunfelder and Hanna 1973).

Clinical Presentation

The clinical appearance is characterized by the presence of yellow or golden spherules or "droplets" at or beneath the corneal or conjunctival epithelium (Fig. 1). The spherules, or globules, are generally clear but may become more opaque over time and range in size from approximately 0.1–0.6 mm in diameter. These lesions are located in the superficial corneal stroma, Bowman's membrane, subepithelium, and occasionally in the epithelium in advanced degeneration (Magovern et al. 2004).

The clinical presentation has been classified as primary corneal, secondary corneal, and conjunctival forms (Gray et al. 1992). In the primary form, the lesions are typically seen at the horizontal limbus within the palpebral fissure, and there is no evidence of other corneal pathology. With progression, the spherules enlarge and spread toward the central cornea. In the secondary corneal form, the lesions are less likely to assume a band-shaped configuration and may be concentrated around areas of prior scarring, neovascularization, or inflammation. The lesions are generally bilateral except in secondary cases where there is associated unilateral pathology such as scars, trauma, or



Climatic Droplet Keratopathy (Spheroidal Degeneration), Fig. 1 Multiple golden spherules are visible along the limbus (white arrow)

keratitis. In the conjunctival form, lesions occur interpalpebrally at the 3 and 9 o'clock positions and are frequently found in association with pinguecula.

A modified grading system has been used to describe the distribution and visual effects of the globular deposits (Johnson and Ghosh 1975).

Trace: Deposits seen in very small numbers. One eye only affected or only one end of interpalpebral strip in each eye if bilateral.

Grade 1: Involvement of medial and lateral interpalpebral strips, with sparing of central cornea.

Grade 2: Central cornea affected, but not enough to affect visual acuity.

Grade 3: Central cornea affected, and vision reduced.

Grade 4: Elevated nodules present in addition to findings of Grade 3.

Diagnosis

Diagnosis is made clinically based on the characteristic appearance. Biopsy with histologic examination can support or confirm the diagnosis but is not typically required. Histologically, deposits appear as extracellular amorphous globules, which may coalesce to form larger masses in Bowman's membrane (Farjo and Sugar 2009).

Differential Diagnosis

Similar appearing clinical entities include corneal amyloid degeneration, gelatinous drop-like corneal dystrophy (familial subepithelial amyloidosis), band keratopathy, climatic proteoglycan stromal keratopathy, primary lipoidal degeneration of the cornea, Salzmann nodular degeneration, and limbal girdle of Vogt (type II).

Prophylaxis

Unknown. Based on the recognized association with sunlight exposure, it is plausible that methods to reduce sunlight exposure could potentially reduce the development or progression of climatic droplet keratopathy.

Therapy

Treatment is rarely required since the majority of individuals are asymptomatic. In patients with loss of vision from central corneal lesions, treatment can be considered. Possible treatment options include superficial keratectomy, phototherapeutic keratectomy, lamellar keratoplasty, or penetrating keratoplasty depending on the depth and density of the lesions.

Prognosis

The majority of individuals do not develop any symptoms and progression is slow in the primary form. However, progression may result in loss of vision, particularly in areas of the world where climatic exposure is severe. Visual acuity may be affected due to involvement of the visual axis of the cornea or from irregular astigmatism. In advanced disease, accumulation of globular masses or plaques may cause heaping up of the corneal surface, epithelial defects, and recurrent corneal erosions. Corneal sensation may be reduced, and sterile ulceration may rapidly progress to microbial keratitis or perforation (Ormerod et al. 1994).

Epidemiology

The prevalence varies based on geographic location with rates of 6% in England and over 60% in males in Labrador (Farjo and Sugar 2009). It is approximately three times more common in males and increases with age, being found in roughly 50% of patients over 70 years of age (Fraunfelder and Hanna 1973). It is most frequently seen in areas with high sunlight exposure. While the primary form is generally considered a degeneration, there are rare reported cases describing a more dystrophic form that may be familial and occurs in relatively young patients without a history of other ocular disease or environmental exposure.

Coats' White Ring

Tiago Lansini
Department of Ophthalmology, Bruno Born Hospital, Lajeado, RS, Brazil

Synonyms

Corneal white dot

Definition

Coats' white ring is a superficial ring of iron deposition that occurs after a metallic foreign body is removed.

Etiology

It appears as a tiny ring of white dots, most often inferiorly. It is thought to result from previous iron deposition by a corneal foreign body and occurs long after resolution of the corneal iron ring. It has no symptoms and it represents an incidental finding. The ring may be oval and incomplete, and small white opacities may be seen inside. Epithelium remains intact, and it has been localized just deep to the corneal epithelium in the anterior portion of Bowman's membrane.

Classification

1. Trauma.
2. Occupational: when working with limestone, there may be deposition of some of the substance's components, especially calcium oxide, in the cornea.

Synonyms

Nonsyphilitic interstitial keratitis

Definition

Rare multisystem disease that affects the cornea by causing stromal interstitial keratitis and the vestibuloauditory system by causing vertigo and deafness.

Etiology

An autoimmune disorder but the exact etiology is unknown, possible immune reaction to a common autoantigen in the cornea and middle ear (Kanski and Bowling 2011). The disease also shares some clinicopathologic features with polyarteritis nodosa (Skuta et al. 2011–2012).

Clinical Presentation

Usually affect young adults. The majority of the patients report an upper respiratory tract infection few weeks before the onset of ocular or vestibuloauditory symptoms (Snow and Wackym 2009). The most common eye finding is a chronic bilateral interstitial keratitis; it begins with faint paralimbal (peripheral) subepithelial infiltrate of the cornea, and the patient may complain of irritation, photophobia, redness, and decreased vision. Later those lesions may progress centrally associated with deep stromal vascularization that may eventually regress leaving ghost vessels. Rarely, anterior uveitis, episcleritis, scleritis, and retinal vasculitis may develop, and these signs represent atypical Cogan syndrome (Yanoff and Duker 2004). The vestibuloauditory symptoms include tinnitus and vertigo followed by progressive sensorineural hearing loss mostly bilateral but can start in one ear and quickly (within days) progress to the other ear. Other systems (heart, gastrointestinal, renal, respiratory) may be involved as well. Small percentage of patients (10%) may develop severe vasculitis similar to polyarteritis nodosa (Yanoff and Duker 2004).

Diagnosis

Mainly clinical and after other causes of interstitial keratitis especially syphilis (by obtaining VDRL/FTA-ABS) has ruled out. Audiologic test could be helpful to look for typical sensorineural hearing loss.

Differential Diagnosis

It includes other causes of keratitis with vestibuloauditory symptoms:

- Syphilis (congenital or acquired)
- Sarcoidosis
- Polyarteritis nodosa
- Wegener's granulomatosis
- Vogt-Koyanagi-Harada disease
- Sympathetic ophthalmia

Prophylaxis

Unclear.

Therapy

It is important to have high index of suspicion for this disease as it usually leads to permanent hearing loss within months if not treated. Treatment consists of high-dose oral corticosteroid with the possibility of adding immunomodulatory therapy if response to corticosteroid was not sufficient. Keratitis is treated with topical corticosteroids. A multidisciplinary approach that involves an ophthalmologist, otolaryngologist, and an internist is advised.

Prognosis

With adequate treatment and early recognition, the prognosis of ocular and auditory symptoms is usually good.

Epidemiology

Affect young adults (peak incidence in third decade of life) with both sexes affected equally, and it is more common in Caucasians (Snow and Wackym 2009).

Collamer Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

ICL; Implantable collamer lens; Implantable contact lens; Posterior chamber phakic intraocular lens

Definition

A phakic IOL that is placed between the iris and the crystalline lens fixated in the ciliary sulcus (Kohnen and Koch 2006).

Epidemiology

Today, the number of implanted ICL is higher than implanted PRL, but lower than the lastest anterior chamber angle (AcrySof) and iris-supported phakic IOL models (Artisan/Verisyse and Artiflex/Veriflex).

History

Complications from anterior chamber angle-supported implants led to the idea of moving toward the posterior chamber. This location theoretically provided lower incidence of halos and glare as the margins of the pupil cover the border of the optical zones. Additionally, the risk of corneal endothelial damage was also theoretically minimized, due to the greater distance between the implant and the corneal endothelium. One of the first posterior chamber phakic IOL designs, the "collar-button" or "mushroom" configuration, is attributed to Fyodorov in 1986 (Fechner and Alpor 1986). He developed a one-piece silicone lens, with a 3.2-mm optic and a concave anterior surface that projected anteriorly through the pupil. The lens was fixated behind the iris plane by two haptics and had a total length of 8.0 mm. Initial complications included corneal touch, decentration, pupillary block glaucoma, iridocyclitis, and cataract formation. Since then, evolution in design and materials has led to the emergence of several different models, including the Adatomed lens. However, cortical opacities and decentration frequently occurred after surgery, and this lens was also withdrawn from the market. Currently, there are only two posterior chamber models available on the market: the "Implantable Contact Lens" (ICL, STAAR Surgical, Monrovia, USA) and the "Phakic Refractive Lens" (PRL, Carl Zeiss Meditec, Jena, Germany) (Hardten et al. 2003).

Clinical Features

This lens is made of collamer which is a mixture of 0.2% collagen and 60% HEMA copolymer. This material attracts deposition of a monolayer

of fibronectin on the lens surface that inhibits aqueous protein binding and makes the lens invisible to the immune system. ICL's design and materials were refined through a series of prototypes in different clinical trials. For models V (Version) 2 and 3, complications reported were small percentages of pupillary block and pigment dispersion glaucoma. However, late anterior subcapsular opacities of the crystalline lens occurred and were attributed to intermittent contact between the ICL and the crystalline lens. The current model, Visian ICL V4, is a rectangular single-piece lens, 7.5–8 mm wide, available in four overall lengths: 11.5–13.0 mm in 0.5-mm steps for myopic and 11.0–12.5 mm in 0.5-mm steps for hyperopic lenses. Optic diameter ranges from 4.65 to 5.5 mm in myopic IOL, depending on the dioptric power. In hyperopic ICLs, optic diameter is always 5.5 mm. Available powers for myopic lenses range from −0.5 to −18.0 D, for hyperopic lenses from +0.5 to +10.0 D, and for toric ICLs correcting myopia with added positive cylinder of +1.0 to +6.0 D. ICL thickness is less than 50 μm at the optic zone, 500–600 μm at the haptic zone, and 100 μm at the haptic footplates.

Tests

Anterior chamber depth for ICL implantation must be at least 2.8 mm for myopic and at least 3 mm for hyperopic lenses. Other inclusion criteria for phakic IOL implantation must be considered (see also "▶ Phakic Intraocular Lens").

Differential Diagnosis

The other posterior chamber phakic IOL is the PRL that floats freely between the iris and the crystalline lens.

Etiology

Other currently available types of phakic IOLs are anterior chamber angle (AcrySof) or iris-supported phakic IOLs (Artisan/Verisyse and Artiflex/Veriflex) (Güell et al. 2010).

Treatment

Correct loading of the ICL in the cartridge and the injector is essential for easy implantation. The ICL has two tiny holes on the footplates (distal right and proximal left) that allow anterior-posterior orientation of the lens. The cartridge is filled with viscoelastic substance. The lens is loaded with dome up, taking special care of a correct haptic position avoiding their rupturing. A piece of soft material, the Staar Foam-tip, is positioned to protect the ICL from contact with the plunger of the shooter. Broad mydriasis is essential for uneventful implantation. The ICL may be inserted through a sub-3 mm incision. One or two side-port incisions of about 1 mm and 90° separated from the main incision are created. The anterior chamber is filled with viscoelastic. The cartridge is inserted bevel-down, and ICL is carefully injected. It is essential to control unfolding of the lens, so as to twist the bevel right or left to assure a correct orientation of the lens. Finally, the haptics are gently pushed under the iris with a blunt spatula. As correct centration of the ICL and position of the haptics in the ciliary sulcus is checked, acetylcholine is injected in the anterior chamber to induce pupil constriction. In hyperopes a peripheral iridectomy should be performed to prevent pupillary block situation. Alternatively, one or two Nd:YAG laser iridotomies are performed in the peripheral iris one week preoperatively. In myopes, the lastest Version of the ICL implements a central hole (aquaport) in the optic of the lens so that an iridectomy/iridotomy is not necessary any more.

[8]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Collier tucked lid sign; Posterior fossa stare

Definition

Retraction of the upper eyelids in primary gaze or upgaze, resulting in a "staring" expression, can be due to the Collier lid retraction sign. Unlike the typical lid retraction seen with thyroid eye disease, downgaze is usually normal and usually no lid lag occurs (Lee and Brazis 2011), but patients with the full dorsal midbrain syndrome may have ophthalmoplegia (e.g., bilateral upgaze palsy) that might mimic thyroid eye disease.

Etiology

The etiology varies based on the patient's age group, but is usually due to damage to the pretectal area or dorsal midbrain (Parinaud syndrome). The lid retraction is thought to be due to disinhibition of the central caudal nucleus and excess activation of the levator palpebrae superioris muscle, which raises the eyelid. There is often an associated bilateral upgaze palsy, and lid retraction can worsen with attempted upgaze (Campbell 2013), but other features of the dorsal midbrain syndrome may also be present (e.g., convergence-retraction nystagmus and light near dissociation of the pupils). Any lesion in the dorsal midbrain may produce the Collier sign including infectious, inflammatory, vascular, neoplastic, demyelinating, traumatic, toxic, and shunt malfunction or hydrocephalus.

Occurrence

Although there is no gender or racial predilection for the Collier sign, age at onset may be helpful in the differential diagnosis. In children, neoplastic (e.g., pinealoma), congenital (e.g., aqueductal stenosis, hydrocephalus), or infectious etiologies (e.g., postviral) predominate. In contrast in adults, demyelinating (e.g., multiple sclerosis), traumatic, neoplastic (e.g., dysgerminoma), or vascular etiologies (e.g., arteriovenous malformation) are more common. In the elderly, ischemic (e.g., midbrain stroke), neoplastic, or, less likely,

vascular (e.g., posterior fossa aneurysm) can result in the Collier sign (Kanski 2010).

The Collier lid retraction sign may or may not be associated with other features of the dorsal midbrain syndrome (e.g., upgaze palsy, light near dissociation of the pupils, convergence-retraction nystagmus).

Color Blindness

Ido Perlman and Shadi Safuri
Ruth and Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel

C

Synonyms

Color vision deficiency; Dyschromatopsia

Definition

Color blindness is an inaccurate term that is used by many in reference to a wide range of deficiencies in color vision. Color vision disorders range from a very mild deviation from normalcy that can be identified only under laboratory condition to a very severe condition expressed as complete loss of ability to separate between different colors. Therefore, it is preferable to define disturbances in color vision as color vision deficiency or disorders in color visions, terms that cover the entire spectrum of color vision defects.

Etiology

Color vision disorders can be inherited or acquired, and it can arise from different pathological mechanisms, some are specific to color vision, and others are more general. Normal color vision depends upon undisturbed transmission of colored visual images from the outside world to the retina. The retina contains rod photoreceptors and three populations of cone photoreceptors, each containing a visual pigment of unique absorbance spectrum. Rod photoreceptors do not participate in color vision except under mesopic conditions. Under photopic conditions, light-induced electrical activities in the three populations of cone photoreceptors interact in post-receptoral neurons of the retina and are

transmitted to the brain as color-coded electrical signals. These color-coded messages reach specific regions in the brain, where further processing occurs, leading eventually to color perception.

Primary inherited color vision deficiency is present from birth and is similar in the two eyes, reflecting a mutation in one, two, or even three genes coding the protein part of the cone visual pigments. In one specific case, primary inherited complete color blindness arises from a mutation not associated with the genes coding the cones' visual pigments, but with the genes coding proteins specific for the cone phototransduction process, including transducin, PDE, or the cGMP-dependent cationic channels in the cone's outer segment.

Secondary color vision deficiency starts after birth and results from diseases of the visual system that can be inherited or acquired. Any abnormality in the ocular media, the functional integrity of the cone photoreceptors, the neural connections within the retinal cone systems, or color information processing in the brain can lead to disturbances in color vision. (i) Selective absorbance of certain wavelengths by the ocular media due to cornea opacity, cataract, or vitreous hemorrhage can lead to color vision disorder. This type of color vision defect worsens as the underlying cause develops, but disappears when the underlying cause is treated by corneal transplant, cataract extraction, or vitrectomy, respectively. (ii) Any disorder in the integrity of the cone photoreceptors, like cone dystrophy or cone-rod dystrophy, is expected to cause non-specific color vision disorders that worsen with time as the cone dystrophy progresses. (iii) In retinitis pigmentosa, a cone-rod dystrophic disease that affects primarily rod photoreceptors, a transient color vision disorder along the blue-yellow axis (tritanopia-like), can develop; the patient behaves as if the functional integrity of the short-wavelength cone photoreceptors is reduced compared to the function of medium- and long-wavelength cone photoreceptors. (iv) Patients with inherited or acquired disorders of the central retina, the macula, such as central serous retinopathy or Stargardt's disease suffer from color vision deficiency as well, starting usually as tritanopia-like defect, but can develop with time to a more general, unspecified color vision disorder. However, in these cases the color vision defect is limited to objects illuminating the macula. The color of large objects illuminating large retinal regions can be perceived correctly because peripheral cone photoreceptors are not damaged. (v) Glaucoma is a very common ocular condition associated with optic nerve damage and dropout of ganglion cells. In review of patients with open-angle glaucoma, only 20–40% of patients had normal color discrimination, 30–50% had tritanopia-like defects, and 5% showed red-green defects (Pacheo-Cutillas et al. 1999). (vi) Optic neuritis, an inflammatory disease of the optic nerve, causes reduction in visual acuity and specific effect on the perception of colors. Patients usually report on desaturation of colors, especially of red colors. (vii) A lesion along the visual cortical pathways may result in different degrees of acquired color vision deficiency, even to complete loss of color vision (achromatopsia). Notably, some reports describe patients suffering from cerebral achromatopsia, but normal visual acuity and normal visual fields (Hart 1987; Celesia and Brigell 2005).

Occurrence

Primary inherited color vision deficiency is one of the most common inherited visual disorders, with prevalence of up to 8% in males and 0.5% in females (Simunovic 2010). This gender-wise difference in prevalence is explained by the localization of two out of three cone opsin genes (the long and medium wavelengths) on the X-chromosome.

Anomalous red/green trichromacy and red/green dichromacy constitute the majority of cases of primary inherited color vision deficiency. Other forms, tritanomaly and tritanopia, are very rare and affect males and females alike at an occurrence of about 1 out of 500. Rod monochromacy (achromatopsia) or cone monochromacy (incomplete achromatopsia), which is usually accompanied with visual defects beyond color discrimination, is much more rare. Rod monochromacy occurs in 1 out of 50,000, and blue-cone monochromacy occurs in 1 out of

100,000, while green-cone or red-cone monochromacy occurs in 1 out of 1,000,000 or may be even 1 out of 100,000,000.

The prevalence of secondary color deficiency depends on the prevalence of the primary disorder itself. In contrast to primary inherited color vision deficiency, the prevalence is similar among males and females.

Classification

Color vision deficiency can be divided into two major classes: primary inherited color vision deficiency and secondary color vision deficiency.

1. *Primary inherited color vision deficiency* (Simunovic 2010): In a normal observer, there are three types of cone photoreceptors, each containing a different visual pigment with a different absorption spectrum – long-wavelength, medium-wavelength, and short-wavelength visual pigments. Therefore, a normal observer is characterized by trichromatic color vision.

   Three major types of primary color vision deficiency exist:

   (i) Anomalous trichromat: Subjects possess three classes of cone photoreceptors, but the visual pigment in one cone population is of abnormal structure, and therefore, its absorption spectrum differs slightly from that of the normal.

   (ii) Dichromat: One of the three cone visual pigments is missing or is not functional, and the remaining two cone visual pigments are normal. Therefore, color vision depends upon two populations of cones with different visual pigments instead of three, as in individual with normal trichromatic color vision.

   (iii) Monochromat: These can come in two forms – cone monochromat and rod monochromat. Cone monochromats in which only one spectral type of cone population is present are usually blue-cone monochromat, but cases of red-cone monochromat and green-cone monochromat have also been reported. Since, under mesopic condition, rods and cones can interact to give some degree of color vision, cone monochromats are also referred to as incomplete achromats. Rod monochromats, also known as achromats, possess no functioning cones; correspondingly, they suffer also from photophobia and reduced visual acuity.

2. *Secondary color vision deficiency*: The type of secondary color vision defect is not easy to classify, and its severity can progress with age as the underlying disease progresses. However, if the underlying defect is treated, the resulting color vision defect may disappear or at least weakens in severity. Diseases of the visual system causing color vision defects may affect any level of the visual system from the optical system to the brain. Köllner's rule, stating that patients with retinal disease develop blue-yellow discrimination loss, while optic nerve disease causes red-green discrimination loss, was historically used to classify acquired deficiencies. Exceptions to this rule include glaucoma, a disease of the ganglion cells and nerve fiber layer, which is primarily associated with blue-yellow defects, and also some retinal disorders such as central cone degeneration, which may start with blue-yellow defect but progresses to red-green defects and eventually to a general defect in color vision. Currently, the most widely used classification of secondary color vision disorders is Verriest's classification, which largely divides acquired color disorders into three types (Pinckers 1982):

   Type I – protanopia-like, with mild to severe confusion of red-green hues, little or no loss of blue-yellow color discrimination, and severe reduction visual acuity.

   Type II – deuteranopia-like, with mild to severe confusion of red-green hues with a concomitant mild loss of blue-yellow color discrimination and moderate to severe reduction in visual acuity.

   Type III – tritanopia-like, with mild to moderate confusion of blue-yellow hues with a lesser impairment of red-green color discrimination. Vision acuity in this type may be normal or moderately reduced.

It should be noted that the color tests used routinely in the ophthalmic clinic, e.g., pseudo-isochromatic plates (like Ishihara plates), Farnsworth D-15, and Farnsworth-Munsell 100-Hue tests, were designed to diagnose specifically the primary inherited color vision deficiencies that are defined physiologically. These tests are also used to define the color vision deficiency in disorders of the visual system that interfere with color vision. In the initial stages, a definition of disorder type according to Verriest is possible. However, at later stages the color vision defect is quite general and more difficult to define.

Color Vision, Three Cone Opsins

Joseph J. Carroll
Department of Ophthalmology, Eye Institute-Medical College of WI, Milwaukee, WI, USA

Definition

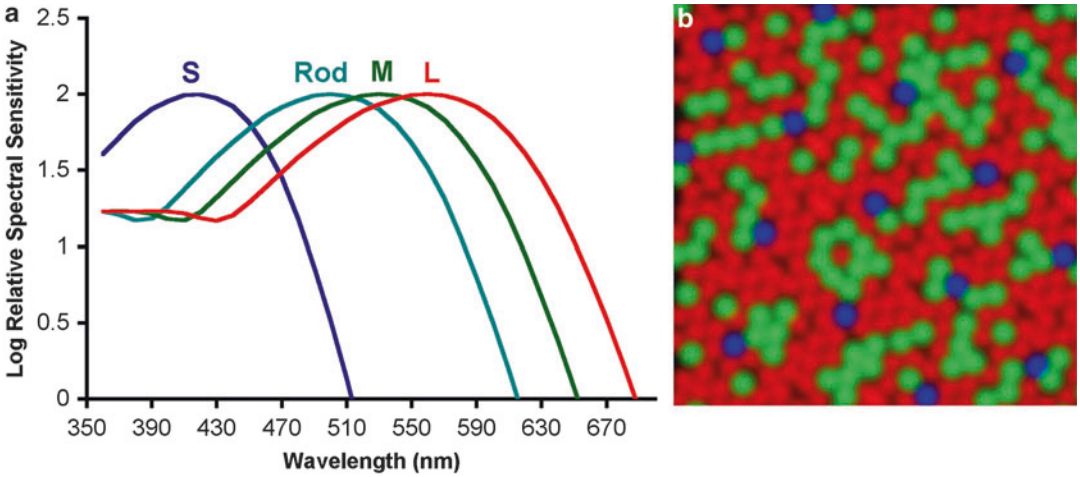
Color vision refers to the ability to discriminate objects based solely on the wavelength they reflect/emit. The presence of three distinct types of cone opsins provides humans with trichromatic color vision.

Basic Characteristics

Photoreceptor Basis of Human Color Vision

Humans with normal color vision can discriminate some two million hues. The retinal substrate for this exquisite color perception is the cone photoreceptor mosaic. While the highly sensitive rods outnumber cones nearly 20:1 and subserve vision at low (scotopic) light levels, it is the cones that underlie the majority of the visual experience at high light levels (photopic), including high spatial acuity and color vision.

There are three types of cone photoreceptors, each having a distinct spectral sensitivity (Fig. 1). The spectral sensitivity of the photopigment simply reflects the probability of it absorbing a photon of light and is determined by the particular photopigment present in the cone cell. Retinal photopigments consist of two parts: a protein (opsin) and a chromophore (in humans, 11-*cis*-retinal). The chromophore is covalently bound via a protonated Schiff base linkage with a specific lysine



Color Vision, Three Cone Opsins, Fig. 1 Photopigment basis for trichromatic color vision. (**a**) Photopigment absorption spectra. The human photopigments have different, but overlapping, spectral sensitivities. The cone photopigments, which dominate the photopic (daytime) vision are named based on the region of maximal absorption in the visible spectrum – short (*S*), middle (*M*), or long-wavelength sensitive (*L*). Rods serve scotopic vision and are maximally sensitive at about 500 nm. (**b**) Simulation of the organization of the L (*red*), M (*green*), and S (*blue*) cones within the cone photoreceptor mosaic. Note the relative paucity of S cones in the mosaic, and the random arrangement of the L & M cones, with L cones outnumbering M cones by about 2:1 in individuals with normal color vision, though this is variable

residue in the opsin (apoprotein) molecule. Opsins belong to the protein superfamily of G protein-coupled receptors (GPCR).

Three Cone Opsins

Photopigments (and their associated cones) are classified according to the region of the visible spectrum they are most sensitive to – either short-, middle-, or long-wavelength sensitive (abbreviated S, M, and L). All humans with normal color vision have the same S-cone pigment, with peak absorption around 417 nanometers (nm). The M-cone pigment varies slightly among individuals, with an average peak at about 530 nm. There is variability in the peak sensitivity of the L-cone pigment among humans with normal color vision, though there are two main variants that peak at 555 and 559 nm. Trichromatic color vision relies on the presence of one cone type from each of these three spectral classes, and these cone types appear to be randomly arranged within the cone mosaic (Fig. 1). While the human retina contains some 100 million photoreceptors, only about five million of them are cones, and of the cones, about 95% are of the L/M type. If the function of one or more of the cone classes is disrupted or absent, the result is a color vision defect.

At the protein level the L and M pigments are about 96% homologous, though they show only 43% identity with the S pigment. Since all cone photopigments employ the same chromophore (11-*cis*-retinal), the difference in spectral sensitivity between photopigments is linked directly to the opsin protein. A small number of amino acid positions within the opsin molecule are involved in spectrally *tuning* the pigment – generating the spectral difference between the S, M, and L opsins as well as the spectral variation within the M and the L pigment class.

Colvard Pupillometer

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Hand-held infrared pupillometer

Definition

A hand-held device for measuring pupil diameter.

Purpose

Measurement of pupil diameter prior to refractive surgery or for neuro-ophthalmological purposes.

Principle

The Colvard pupillometer is a hand-held view-through residual light amplification device developed by Michael Colvard (1998). An infrared LED serves as light source that leaves the pupil diameter unaffected. The anterior segment of the patient is viewed on a light amplification screen. A ruler with a millimeter scale is superimposed over the image of the subject's eye. The examiner can measure/estimate the subject's pupil diameter directly using the ruler. A rubber cup avoids disturbing light falling into the subject's eye and affecting the pupil diameter.

Indication

Measurements of the mesopic pupil diameter are part of the preparing examinations prior to refractive surgery. Also quantification of anisocoria and measurement of pupil diameters after pilocarpine, cocaine, or pholedrine application in neuro-ophthalmology require a pupillometer.

Contraindication

Measurements with the Colvard pupillometer are noninvasive. There are no contraindications.

Advantage/Disadvantage

The Colvard pupillometer is a rather simple, handy, easy-to-use, and cost-efficient device (Schnitzler et al. 2000). Therefore, it became very popular among refractive surgeons. Main disadvantages are the dependence from the surround illuminance and from the observer. If pupil behavior should be determined under standardized, controlled illuminance conditions and if simultaneous measurements in neuro-ophthalmology are required, a binocular pupillometer with a controlled background illuminance such as the Procyon pupillometer is superior to the Colvard device (Kohnen et al. 2003).

Comatic Aberrations

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Coma

Definition

A type of monochromatic aberration with asymmetry of refractive power along an axis through the pupil center.

Basic Characteristics

Coma (*gr.* κώμη: hair, tail) typically occurs if optical systems with spherical aberration undergo decentration or if an object is imaged off-axis through such an optical system. The result is an asymmetric wedge-shaped blur figure resembling a comet or a ghost image (Chalita et al. 2004). Comatic aberrations are higher-order aberrations and cannot be corrected with sphero-cylindrical lenses. In the set of Zernike polynomials, comatic aberrations are represented by polynomials of odd order ≥ 3 with an angular frequency of -1 or 1 (e.g., Z_3^{-1} for primary vertical coma). While a small amount of vertical coma is present in the healthy eye (Salmon and van de Pol 2006), coma is elevated beyond physiological levels in eyes with keratoconus, corneal scars, cataract, pterygium, after keratoplasty, and in case of decentration of excimer laser ablations and intraocular lenses. If coma originates from the cornea, it can be corrected by rigid gas-permeable contact lenses. Also objects that are imaged off-axis in an eye with spherical aberration are distorted by comatic aberrations.

Comma Sign, in Sickle Cell Hemoglobinopathies

Gilad Rabina[1,2] and Michaella Goldstein[3]
[1]Department of Ophthalmology, Tel Aviv Medical Center, Tel Aviv, Israel
[2]Department of Ophthalmology, Oculoplastic and Orbital Institute, Tel Aviv University, Tel Aviv, Israel
[3]Department of Ophthalmology, Tel Aviv Medical Center and Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Synonyms

Sickle cell anemia; Sickle cell disease; SCD

Definition

A hereditary form of hemoglobinopathy in which a mutated form of hemoglobin distorts the red blood cells (RBC) into a rigid crescent shape that causes small blood vessel occlusion and low tissue oxygen levels.

Genetics

In a normal red blood cell, two α-globin subunits, two β-globin subunits, and a central heme molecule combine to form adult hemoglobin (Hb A). The β-globin gene, an oxygen transport gene, is found on the short arm of chromosome 11. Hemoglobin S (Hb S) results from a single amino acid point mutation in which valine substitutes for glutamic acid within the β-globin chain, and hemoglobin C (Hb C) results from a single amino acid point mutation in which lysine substitutes for glutamic acid in the β-globin molecule. Sickle cell disease (SCD) is transmitted through an autosomal recessive mode of inheritance. Two copies of Hb S may combine with one another (SS disease), or one copy of Hb S and another β-globin variant, such as Hb C, may combine (double heterozygous SC disease). Individuals with one copy of Hb A and one copy of Hb S are described as having the sickle cell trait, the carrier state for SCD.

Ophthalmic Clinical Features

Anterior-Segment Involvement

A clinical finding in many patients is segmentation of blood in the conjunctival blood vessels. A pathognomonic sign for sickle cell hemoglobinopathies is the comma sign, which has the clinical appearance of short, truncated, isolated, dark vascular segments. Also, segmental iris atrophy and pupil abnormalities can be seen in individuals with SCD. Iris atrophy is thought to result from sectoral ischemic necrosis resulting from occluded radial iris vessels. Hyphema in a patient with SCD and in those with sickle cell trait represents a sight-threatening emergency, as even modest elevations of intraocular pressure (IOP) have resulted in vision loss from central retinal artery occlusion or macular branch retinal artery occlusion. This is likely a mechanical phenomenon, as sickled red blood cells clog the trabecular meshwork, causing elevation in IOP.

Posterior-Segment Involvement

Optic Nerve

The optic nerve in patients with SCD may exhibit vascular changes. Dark, dilated capillaries at the optic nerve head appear as small red dots and represent precapillary arterioles plugged with sickled erythrocytes.

Macula

The macula is also susceptible to infarction from vaso-occlusive disease. The "macular depression sign" has been described as an oval depression of the bright foveal or parafoveal reflex as a result of macular thinning due to ischemic atrophy.

Angioid Streaks

Angioid streaks, breaks in Bruch's membrane, have an association with SCD, occurring in 1–2% of patients. These irregular, reddish subretinal bands are most commonly found in patients with the Hb SS genotype.

Nonproliferative Sickle Cell Retinopathy (NPSR)

The retinal findings seen in NPSR are caused by arteriolar and capillary occlusion. Anastomosis and remodeling occur in the periphery, as does the resorption of the blood in the area of the infarct.

Retinal findings of NPSR include:

- Salmon patch hemorrhages – Pinkish orange hemorrhages located beneath the internal limiting membrane (ILM), occurring after a peripheral retinal arteriolar occlusion.
- Iridescent spots – After arteriolar occlusion causes retinal hemorrhage, a small schisis cavity may develop after the intraretinal portion of the hemorrhage resolves. The cavity may contain hemosiderin-laden macrophages.
- Black sunburst lesions – Flat, stellate, or round areas of hyperpigmentation. Result when intraretinal hemorrhage tracks into the subretinal space. On histopathologic examination, black sunbursts appear as focal hypertrophy of the RPE.

Proliferative Sickle Cell Retinopathy (PSR)

PSR is one of many retinal vascular diseases in which extraretinal fibrovascular proliferation occurs in response to retinal ischemia. Whereas the neovascularization in proliferative diabetic retinopathy (PDR) generally begins postequatorially, that in PSR is located more peripherally.

PSR has been classified into five pathogenic stages:

1. Stage 1: Defined by peripheral vascular occlusion. The peripheral retina may show multiple simultaneous arteriolar occlusions.
2. Stage 2: Peripheral arteriovenular anastomoses, which appear to be dilated, preexisting capillary channels.
3. Stage 3: Preretinal sea fan neovascularization, probably the most recognizable trademark lesion of sickle retinopathy. These lesions are most commonly found in the superotemporal retina, followed by the inferotemporal, superonasal, and inferonasal quadrants. Sea fans represent true neovascularization, most of them are found at the border of perfused and nonperfused retina, and they grow toward the ora serrata.
4. Stage 4: Vitreous hemorrhage. Sea fans grow or are pulled into the vitreous chamber, and vitreous traction on the delicate neovascular fronds may cause bleeding into the vitreous.
5. Stage 5: Tractional retinal detachment (TRD). TRD develops as the result of chronic vitreous hemorrhage or chronic transudation from neovascular tissue and resultant vitreous membrane formation.

Diagnosis

Fluorescein angiography (FA) is the gold-standard imaging tool for assessment of retinal perfusion status. A potential limitation of conventional fluorescein angiography is the inability to image the pathology of the far peripheral retina in some eyes with sickle retinopathy.

Ultrawide-field fundus photography and angiography have become useful in the evaluation of the retinal periphery in eyes with sickle cell retinopathy.

Indocyanine green (ICG) angiography has been studied as a way to assess choroidal perfusion, but the utility of ICG in sickle retinopathy is as yet undetermined.

Optical coherence tomography (OCT) may provide important details about foveal anatomy, which may aid in the diagnosis and management of sickle retinopathy even in asymptomatic patients.

Therapy

Treatment of PSR may be considered in the eye of an individual with significant visual loss from PSR or vision impairment in the contralateral eye. Treatment may also be required in cases of rapid growth of a sea fan, presence of large, elevated sea fans, spontaneous hemorrhage, or bilateral proliferative disease. The goal of intervention is to prevent the progression of stage III to stages IV and V.

Scatter laser photocoagulation is the current mainstay of treatment in PSR. The objective of scatter laser treatment is similar to that employed in the management of PDR. Anti-VEGF agents have been reported to cause complete regression of retinal neovascularization and resolution of vitreous hemorrhage following intravitreal injection in eyes with PSR, but further study is warranted to assess its role in treating PSR. Vitrectomy may be considered for nonclearing vitreous hemorrhage or TRD. Exchange transfusion, erythropheresis, and hyperbaric oxygen have been attempted to minimize complications from surgically induced anterior-segment ischemia. These methods were without clear benefit and were associated with systemic complications.

Epidemiology

Sickle cell disease (SCD) is the most common inherited blood disorder and affects nearly 80,000 people of African-American and Hispanic descent. SCD occurs in 0.2% of African American births and in 0.0027% of Hispanic-American births. Approximately 8% of African Americans possess sickle cell trait, which is not associated with increased mortality or morbidity. At-risk genotypes for SCD are also observed in people of Mediterranean, Caribbean, South and Central American, Arab, and East Indian descent.

Commotio Retinae (Berlin Disease/Edema)

Oded Ohana, Eyal Cohen and Adiel Barak
Tel Aviv Sourasky Medical Center,
Tel Aviv-Yafo, Israel

Synonyms

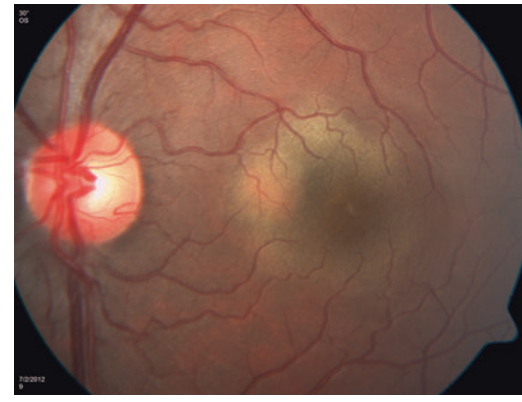
Berlin's edema; Retinal concussion; Retinal contusion; Traumatic retinopathy

Definition

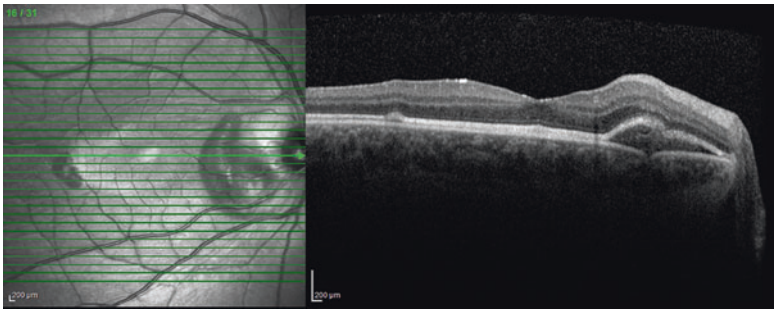
A gray-white change in color of the retina following a blunt contusion. The pathology affects primarily the outer retinal layers. When confined to the macular area, the condition is called Berlin's edema, a term first introduced by Berlin in 1873 (Agarwal 2012) (Figs. 1 and 2).

Etiology

After a blunt trauma to the globe, swelling and disorganization of the outer retinal layers ensue, causing an opaque and whitened look to the retina area involved. Retinal whitening usually appears a



Commotio Retinae (Berlin Disease/Edema), Fig. 1 Color fundus image of Berlin's edema macular commotio retina



Commotio Retinae (Berlin Disease/Edema), Fig. 2 OCT image of a combined Berlin's edema and choroidal rupture case. Sub-foveally there is hyperreflectivity of the IS-OS junction. Nasally there is an elevation of the RPE and a focal defect in Bruch's membrane, corresponding to the choroidal rupture seen on the infrared picture

few hours after the insult. The swelling occurs at the outer retinal layers.

The injury is presumably mechanical, with deformation of the vitreous and hydraulic forces shift as a result of the injury, traversing the globe and damaging the retina. Commotio retina is presumably a contrecoup injury to the retina, i.e., occurs at the side opposite that of the impact site. There are also reports of a hemodynamic component to the injury, but these are less prominent.

Histopathologic studies showed that the whitening is caused by fragmentation of the photoreceptor outer segments and acute damage to the photoreceptor cells. Other histopathological features include edema of Muller cell processes and of the retinal ganglion cell axons and retinal pigment epithelium (RPE) damage. Commotio retina is not a "true" edema, as little extracellular fluid accumulation occurs.

Whitening of the retina is believed to occur because of the loss of the vertically oriented configuration of the photoreceptor tips, into a disarrayed mesh and consequent loss of regular light scatter.

Clinical Presentation

Patients present after blunt ocular trauma, with a decrease in vision which varies between 20/20 and 20/400, depending on the region of the retina involved and the extent of the damage. The severity of the decrease in vision does not always correlate with the degree of retinal opaqueness.

When presenting early after injury, the retinal examination may appear normal although the patient complains of decreased vision. A period of spontaneous resolution follows; its duration depends on the extent and severity of the initial damage. Mild commotio retina usually resolves after a few days, while more severe cases can show a prolonged course of a few months, some with residual non-resolving sequelae.

Diagnosis

No laboratory tests are contributory to the diagnosis, as the diagnosis is mainly made following a suggestive history and careful clinical examination.

Different imaging modalities aid in better categorizing and assessing the insult: visual field testing, especially microperimetry testing, is useful in demonstrating small visual field defects which might develop after photoreceptor cell death.

Fluorescein angiography (FA) shows in cases of mild commotio retina areas of hypofluorescence in the areas of opaque retina; mild RPE staining is sometimes seen, and no leakage from the retinal vessels. In more severe cases, FA demonstrates a more intense staining and occasional leakage of retinal vessels, corresponding to the more extensive damage at the RPE level.

Multifocal electroretinogram (mfERG) demonstrated reduced sensitivity in involved areas, which improves with resolution of the commotio retina. Some studies show reduced retinal

sensitivity even after complete OCT resolution and restored visual acuity, suggesting lasting damage despite complete functional resolution.

OCT imaging aids in better visualization of mainly macular commotio retina (Ahn et al. 2013). Several features are visible upon imaging and include, with escalating severity:

1. Inner segment–outer segment (IS-OS) junction hyper-reflectivity
2. Cone outer segment tip (COST) defects
3. COST and IS-OS junction defects
4. COST, IS-OS junction, and external limiting membrane (ELM) defects

Prognosis seems to worsen with increasing severity of OCT findings.

Differential Diagnosis

In the absence of adequate history, retinal whitening in certain configurations can resemble branch retinal artery occlusion or cilioretinal artery occlusion. The retinal thickening however occurs at different retinal levels and is mainly affecting the inner retinal layers in vascular occlusions as opposed to affecting the outer retinal layers in commotio retina.

Prophylaxis

The main prophylactic measure is the prevention of ocular trauma, by either using a protective eye wear or by avoiding harmful circumstances.

Therapy

No known intervention is currently known to alter commotio retina course or prognosis. Common pathologies occurring in conjunction with commotio retina need to be actively sought out in order to administer appropriate therapy and readily convey prognosis. These include retinal tears, dialysis, choroidal rupture, retinal detachment, and traumatic optic neuropathy.

Prognosis

When uncomplicated, commotio retina is usually a self-limited disease (Blanch et al. 2013). In patients presenting with an extramacular commotio retina, the visual prognosis is excellent, with resolution of the retinal whitening after a few days. Macular commotio retina cases present with a more varied prognosis, and while the majority shows an improvement in visual acuity to pre-injury levels, some cases show prolonged recovery over 3 months, a decrease from pre-injury visual function, and persistent scotoma. As mentioned above, several OCT features visible soon after injury are helpful in better assessing future visual recovery. Injury limited to the IS-OS junction and COST usually holds good visual rehabilitation and visual acuity restoration to pre-injury or near pre-injury levels. A more severe macular commotio retina showing ELM defects can later show RPE atrophy and photoreceptor defects leading to decreased visual outcomes and visual field defects.

Cases complicated by subfoveolar hemorrhage, macular hole, or choroidal rupture may show poorer visual acuity outcomes, determined mainly by the extent of the additional pathology and resultant complications.

Epidemiology

Commotio retina is a relatively common disease, accounting for 0.4% of civilian (Weichel et al. 2008) and 15% of military eye injuries. It is more common in young men, as with other trauma-related injuries.

Synonyms

Anterior communicating artery

Definition

The anterior communicating artery is a very short artery in the circle of Willis, a hexagon of vessels that anastomoses the major blood supplies of the brain. The anterior communicating artery connects the left and right anterior cerebral arteries, allowing for communication to both hemispheres of the brain. This is particularly important should the internal carotid artery become occluded on either side.

Synonyms

Acquired melanocytic nevus; Melanocytic nevus

Definition

A benign neoplasm composed of nests of melanocytes located on the dermoepidermal junction and dermis layers of the skin (Albert and Jakobiec 2008; Shields and Shields 2008).

Etiology

Unknown. A genetic factor is likely in many families, working together with sun exposure. They may occur on the eyelid skin and on the eyelid margins. Lesions typically present in childhood as small, flat, tan macules that increase in size on the basal epithelium. As the lesion increases in diameter, a nest of cells drops of into the dermis; later, the cells migrate entirely in the dermis (intradermal nevus). Therefore, the natural progression from junctional nevus to compound nevus, then to intradermal nevus is consensus.

Clinical Presentation

Domed pigmented (light or dark brown) nodules are of up to 1 cm in diameter (Fig. 1). The borders of the lesion are irregular but symmetric. Most lesions are smooth, but larger ones may be cerebriform, or hyperkeratotic and papillomatous; hairs may be present.

Compound Nevus, Fig. 1 Pigmented melanocytic nevis involving the periocular region

Diagnostics

Clinical presentation. Histopathologic evaluation is confirmatory to compound nevus.

Differential Diagnosis

Differential Diagnosis includes ▶ melanoma, ▶ seborrheic keratosis, ▶ neurofibroma, and ▶ atypical nevus.

Prophylaxis

Avoidance of sun exposure and sun education.

Therapy

The majority do not require treatment and can be observed periodically. Indications for removal include cosmetic concerns, chronic irritation

(itching and/or bleeding), and changes in appearance (color, size, or shape) that are suspicious for melanoma. Options of surgical therapy when the lesion involves eyelids include shave biopsy, excisional biopsy, or full thickness eyelid biopsy.

Prognosis

Most are benign with little malignant potential. The most active nevus is the junctional nevus. As nevi descend further into the dermis (compound and intradermal nevi), they decrease in potential to malignant transformation.

Epidemiology

The prevalence of melanocytic nevus varies with age and race. They increase in number gradually during childhood and adolescence, reaching a peak during adult life and declining with increasing age. These lesions are common in patients with light or fair skin (Albert and Jakobiec 2008; Shields and Shields 2008).

Computerized Corneal Topography

Rachel Song and Wuqaas M. Munir
Department of Ophthalmology, Boston Medical Center, Boston University School of Medicine, Boston, MA, USA

Synonyms

Anterior segment optical coherence tomography; Corneal mapping; Corneal tomography; Photokeratoscopy; Photovideokeratoscopy; Posterior corneal mapping; Scheimpflug imaging; Videokeratography

Definition

Noninvasive medical imaging technique of the cornea to determine corneal power.

Purpose

To map the curvature of the cornea.

Principle

Corneal topographic measurements can be either derived from the slope of the cornea or directly measured from elevation data (Swartz et al. 2007). Most commonly, slope data is examined through the use of a pattern of illuminated, concentric rings focused onto the anterior surface of the patient's cornea with the concentric rings and then reflected back to a digital camera. Several thousand data points are generated via the reflected pattern allowing for corneal curvature to be calculated based on the spacing between rings. The topographical map is then produced and color-coded based on steepness or dioptric power of the cornea. These measurements,

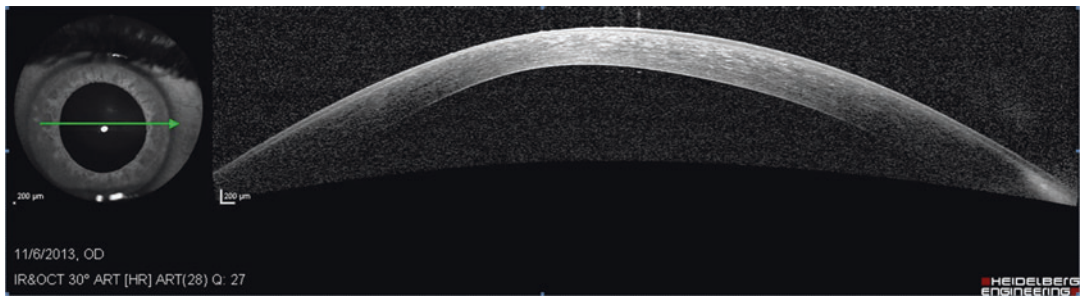
however, assume a normal posterior corneal curvature and, therefore, power (Fowler and Dave 1994; Martinez and Klyce 2010). Newer techniques, such as the slit scanning technology used in the Orbscan (Bausch & Lomb, Rochester NY) and Scheimpflug imaging used in the Pentacam (Oculus, Arlington WA), more directly measure elevation data (Martinez and Klyce 2010). The techniques use a series of slit beams at regular intervals but variable angles to measure the curvature and regularity of the anterior and posterior corneal surface, as well as corneal thickness to generate a complete reconstruction of corneal anatomy. Pentacam technology, in particular, uses Scheimpflug optics to vary the depth of focus, generating thousands of elevation points and 25 or 50 images to create a three-dimensional representation of the cornea. There are many different indices used to aid calculation of corneal surface regularity. Direct imaging of the anterior and posterior cornea is also possible using anterior segment optical coherence tomography (ASOCT). ASOCT uses the emission and reflection of light, similar to ultrasound technology, to build a cross-sectional image of the cornea, including corneal thickness (Heur et al. 2010).

Indication

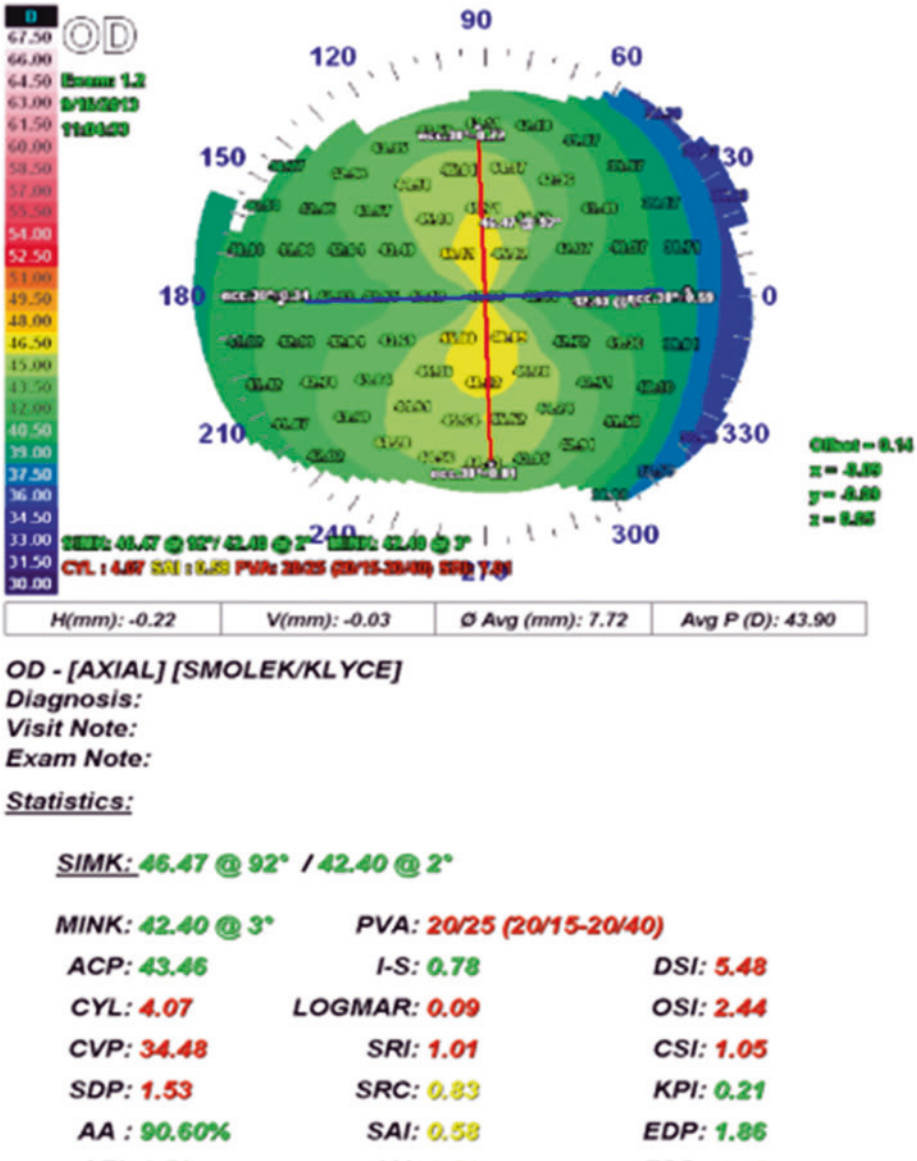
Computerized corneal topography can be a useful diagnostic procedure when evaluating for corneal ectatic disease including keratoconus or pellucid marginal degeneration (Martinez and Klyce 2010) (Fig. 1). Topography can also provide useful preoperative measurements for any patient requiring refractive surgery or cataract surgery patients to aid in intraocular lens implant selection. Any patient with a significant degree of astigmatism postoperatively can also benefit from topography to guide further management (Fig. 2). Finally, patients who require rigid gas permeable contact lens can benefit from topographical measurements to ensure optimal contact lens fit.

Advantage/Disadvantage

Computerized corneal topography is a noninvasive, quick measurement with results that are generally operator and patient independent. Patients with both "forme fruste" (i.e., subclinical) and clinical keratoconus can benefit from corneal topography to evaluate severity of disease as well as to guide future management. ASOCT can be quite useful in managing patients with corneal opacities since pachymetry can be more readily acquired versus slit scanning technology (Heur et al. 2010). Topography and ASOCT are less affected by the microsaccadic movements of the eye secondary to rapid acquisition time, whereas scanning slit technology and Scheimpflug imaging can produce inconsistent results given longer acquisition times. A disadvantage of corneal topography is that data points are based on patterns of reflection from the surface of the eye; therefore, a smooth, healthy ocular surface is necessary. Surface eye disease, e.g., dry eye syndrome, epithelial defect



Computerized Corneal Topography, Fig. 1 Anterior segment OCT of the right eye of a patient with keratoconus shows paracentral thinning



Computerized Corneal Topography, Fig. 2 Topography of the right eye of a patient displays the classic "bow tie"-shaped pattern of regular, with-the-rule astigmatism

can result in unreliable and inaccurate results (Swartz et al. 2007).

Concretions

► Conjunctival Degenerations

Concretions, Conjunctival

Farhan I. Merali
Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Conjunctival lithiasis

Definition

Small, superficial, subepithelial deposits white to yellow in color found in the palpebral conjunctiva, usually in elderly patients or those with chronic conjunctivitis. Histopathologically, they are epithelial inclusion cysts filled with epithelial and keratin debris. Secondary calcification of concretions can occur, in which case they are referred to as conjunctival lithiasis. Usually asymptomatic, concretions may cause foreign-body sensation if they lead to erosion of the overlying epithelium, in which case they can be removed at the slit lamp under topical anesthesia.

Concussion

► Concussive Trauma

Concussive Trauma

Katherine Giuliano
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Concussion; Mild head trauma; Mild traumatic brain injury (MTBI); Minor closed head injury

Definition

A concussive trauma, or mild traumatic brain injury (MTBI), is caused either by non-penetrating contact injuries to the head or neck or by the force of rapid acceleration or deceleration. While there is no clear consensus on the clinical definition of a concussive trauma, several organizations, including the World Health Organization (WHO) and the American Congress of Rehabilitation Medicine, have published MTBI definitions. They agree that concussion results in a transient impairment in neurologic functions that occurs shortly after a traumatic incident. Neurologic impairments include loss of consciousness, posttraumatic amnesia, altered mental status, and focal neurological deficits, including neuro-ophthalmologic deficits such as pupil dysfunction, traumatic optic neuropathy, ocular motility dysfunction, and visual disturbances. To be considered a mild traumatic brain injury, the loss of consciousness cannot exceed 30 min, and the posttraumatic

amnesia cannot exceed 24 h (Bodin et al. 2012). The WHO further defines an MTBI by a Glasgow Coma Scale score of between 13 and 15 at approximately 30 min post-injury.

Etiology

Concussive trauma results from blunt force to the head, with either the head colliding with an object or an object forcibly hitting the head. Common causes include falls, sporting injuries, and motor vehicle accidents. Concussive trauma can also result from acceleration or deceleration forces, when the head moves or stops suddenly and rapidly, as in a car accident. Blast injuries from military explosions are another cause of concussive trauma. The most common causes of MTBI are motor vehicle accidents (Albert et al. 2008). In all cases, concussion depends upon the sudden motion of a stationary head or the halting of a moving head. As the cranium and its overlying structures move, so too does the brain, suspended in cerebrospinal fluid. Depending on the location and angle of the trauma upon the head, the brain can undergo linear acceleration, rotational acceleration, angular acceleration, or a combination. The exact mechanism of the resultant clinical syndrome – loss of consciousness, posttraumatic amnesia, altered mental status, and focal neurological deficits – is widely debated. Interference with the reticular activating system is postulated to account for the loss of consciousness often seen in concussive trauma. Other hypotheses for the pathophysiology of MTBI include interference with the cholinergic reticular inhibitory system and neuronal paroxysmal depolarization shifts resulting in a convulsive process (Moore et al. 2012).

Clinical Presentation

The four primary presentations of concussive trauma patients are loss of consciousness, posttraumatic amnesia, altered mental status, and focal neurological deficits. Patients may present with one, some, or all of these conditions. Some, but not all, of concussion patients experience loss of consciousness, and in MTBI, this loss of consciousness is short-lived. Patients rapidly transported to a hospital emergency department following a closed head trauma may present unconscious, or EMS and/or accompanying family or friends may report a history of loss of consciousness. Posttraumatic amnesia is a state of confusion and an inability to store new memories in the moments after a concussive trauma. This amnesia, combined with altered mental status and loss of consciousness, can make it difficult to obtain information from the patient, such as identifying information, a medical history, and a narrative of what occurred during the actual trauma. Altered mental status includes confusion, disorientation, and attention deficits. This can manifest as incoherent or repetitive speech, mental sluggishness, or inability to respond to questions. Focal neurological deficits refer to impairments of specific nervous system functions and include disordered movement, paralysis, cognitive impairment, and sensory impairment. Patients also commonly experience headache following a concussive trauma; other potential symptoms include difficulty with balance and coordination and concussive convulsions (brief tonic-clonic movements).

The sensory impairments that can occur following a concussive trauma include a variety of neuroophthalmic manifestations. Traumatic mydriasis is dilation of the pupil that occurs as a result of injury to the iris sphincter. It is usually unilateral, and the affected eye will constrict poorly to light and accommodation.

If the trauma damages the sympathetic nervous system pathway anywhere from the hypothalamus to the eye, the patient will present with Horner syndrome, which includes miosis and ptosis on the affected side. Depending on where in the pathway the lesion is, the patient may also present with anhidrosis and dilated conjunctival blood vessels on the affected side.

Traumatic optic neuropathy (TON) results when the optic nerve is damaged, most commonly when the force of a blunt head trauma is transmitted to and damages the optic nerve. Patients with TON present with unilateral visual loss, defects in

color vision, and/or a relative afferent pupillary defect (RAPD). In some patients, the RAPD is the only presenting sign of TON, highlighting the importance of a complete opthalmic examination in head trauma patients (Kanski 2009).

Damage to any part of the visual pathway will result in accompanying visual field defects. As one example, traumatic chiasmal injury typically produces bitemporal hemianopia. Any traumatic lesion of the anterior visual pathway (retina, optic nerve, chiasm, or optic tract) will also cause an RAPD.

Although more common in severe head trauma, mild head trauma can also damage the cranial nerves. When the third, fourth, or sixth nerves are injured, opthalmic symptomatology results. A patient with damage to the oculomotor nerve (third nerve palsy) will present with diplopia, ptosis of the affected eyelid, mydriasis, and motility deficits. Due to loss of innervation of the superior, medial, and inferior rectus, as well as the inferior oblique, adduction, depression, and elevation of the affected eye will be impaired on physical exam. Due to its long length, the trochlear nerve is particularly susceptible to traumatic injury. Patients with fourth nerve palsy often present with a head tilt to the contralateral side as well as diplopia that is worsened by looking downward. On exam, they have impaired ability to depress the eye in adduction. The head tilting occurs to compensate for the loss of superior oblique muscle function in the affected eye. Injury to the abducens nerve is uncommon except in serious head trauma. Sixth nerve palsy presents with diplopia, impaired abduction due to the loss of function of the lateral rectus muscle, and esotropia (Schiefer et al. 2007).

Diagnosis

The diagnosis of MTBI is largely a clinical one. A history of trauma to the head or neck, combined with the clinical presentation of loss of consciousness, altered mental status, posttraumatic amnesia, and/or focal neurologic deficits, is highly suggestive of a concussion. In the acute setting following injury, computed tomography is the imaging modality of choice for most patients in order to evaluate for the presence of fracture or hemorrhage.

In order to evaluate for any opthalmic manifestations, a full examination of the eyes should be performed, including assessment of the size and shape of the pupils, symmetry between bilateral pupils, pupillary response to light and accommodation, and assessment for a potential RAPD. Eye examination should also include assessment of the patient's visual acuity, visual fields, color vision, and ocular range of motion.

Unilateral mydriasis can result from pupillary sphincter injury, such as small tears to the sphincter muscle caused by the traumatic injury, or from trauma-induced damage to the oculomotor nerve (CN III). Unilateral miosis suggests that there is a lesion somewhere in the sympathetic nervous system pathway, causing Horner syndrome. A patient with Horner syndrome will additionally present with diplopia, ptosis of the affected eyelid, impaired adduction, depression, and elevation of the affected eye and may present with anhidrosis and dilated conjunctival blood vessels on the affected side.

Injury to the trochlear nerve (CN IV) and the abducens nerve (CN VI) will also cause diplopia and ocular motility dysfunction. Specifically, a patient with trochlear nerve damage will have difficulty depressing the affected eye in adduction, and the diplopia is worsened by looking downward. Fourth nerve palsy also presents with a compensatory head tilt toward the unaffected side in order to compensate for the lost ocular motility. A patient with abducens nerve injury will have impaired ability to abduct the affected eye and may present with esotropia, with the eye turning medially.

A relative afferent pupillary defect (RAPD), during which both pupils constrict when light is shone into the unaffected eye and both pupils dilate when the light is swung into the damaged eye, reflects a lesion anywhere in the anterior visual pathway or traumatic optic neuropathy (TON). Changes in visual acuity or visual fields that accompany an RAPD are suggestive of TON, while isolated visual changes are caused by lesions of the visual pathway. In TON,

fundoscopic examination is initially normal following the traumatic injury, so a patient presenting immediately or shortly after a concussive trauma will have a normal-appearing fundus even if traumatic optic neuropathy has occurred. Optic atrophy and optic disc pallor are not visualized on fundoscopic examination until approximately 3–6 weeks after the inciting trauma.

Differential Diagnosis

A history of trauma, such as a motor vehicle accident, a sports injury, or a witnessed fall, is highly suggestive of an MTBI as the cause of the presenting symptoms of loss of consciousness, posttraumatic amnesia, altered mental status, and/or focal neurological deficits. If a traumatic injury cannot be confirmed by either the patient or a witness and there is no physical evidence of a trauma (such as contusions, lacerations, ecchymosis, or edema), toxicology should be performed to rule out drug or alcohol overdose as the causative agent of the symptoms. Even if drug and alcohol toxicology is positive, MTBI remains on the differential, as an intoxicated patient could have suffered a concussive trauma and the symptomatology of intoxication and MTBI may be overlayed.

Unilateral mydriasis can be caused either by pupillary sphincter injury or by oculomotor nerve damage, both of which can result from a concussive trauma. If the patient also presents with ipsilateral ptosis and ocular misalignment, the unilateral mydriasis is likely to be a result of a third cranial nerve lesion. Isolated unilateral mydriasis without other opthalmic manifestations is more likely to be caused by tears in the pupillary sphincter muscle. The diagnosis can be confirmed using pharmacologic testing with 1% pilocarpine, as a pupil with sphincter damage typically fails to constrict in response to pilocarpine.

Unilateral miosis is suggestive of Horner syndrome (damage to the sympathetic nervous system pathway), but bilateral miotic pupils are more commonly caused by narcotic use and further point to the value of obtaining toxicology.

Prophylaxis

The primary prophylactic measure to prevent concussive traumas is accident prevention. As motor vehicle accidents are a common cause of mild traumatic brain injury, automotive safety interventions such as seat belts and air bags are key to preventing such injuries. These interventions can be enacted on the federal and state governmental level, including the drafting of laws that govern speed limits and safe driving, the regulation of the safety features of automotives, and the enforcement of vehicular laws by police officers. Safety interventions are also enacted by the motor vehicle industry in the manufacturing of safety interventions such as seat belts, alarms that indicate a driver or passenger is not buckled, air bags, and roll-over prevention mechanisms. Finally, individual drivers should be educated on the importance of practicing safe driving habits such as using a safety belt, obeying the speed limit, and obeying traffic laws to prevent motor vehicle accidents.

Sports injuries are another common cause of MTBI. Concussive traumas to the head can be mitigated by the use of helmets and/or protective gear as well as by the enforcement of rules that limit contact forces to the head and neck. Falls, especially in the elderly population, also commonly result in MTBIs. Elderly individuals, as well as anyone else at increased risk of falls, can reduce fall risk by wearing supportive shoes, eliminating clutter in hallways and passageways, and assuring adequate lighting. Hospitalized patients are particularly at risk for falls, so patients should be assessed for their fall risk upon admission to the hospital. If a patient is at risk for fall, interventions such as coiling excess electrical wires, ensuring the call button is easily accessible, and clearing the pathway to the bathroom can be employed to reduce the risk of a fall and thus an MTBI or other injuries.

Therapy

MTBIs are generally managed conservatively, with observation and rest as the cornerstones of

treatment. The symptoms of a concussive trauma (altered mental status, amnesia, focal deficits) should abate on their own over the course of approximately 1–2 weeks. Patients are monitored to ensure that symptoms do indeed resolve, but worsening or persistence of symptoms merits additional workup and care. During the 1–2 weeks post-concussion, patients should rest both physically and cognitively, avoiding any strenuous physical or mental activity and especially avoiding any activities, such as contact sports, that could predispose the patient to suffering another head injury.

If the concussive trauma causes a traumatic optic neuropathy (TON), potential therapies include observation, corticosteroids, and surgical decompression of the optic canal, although therapeutic management of TON is controversial. Current treatment protocol begins with high-dose intravenous methylprednisolone therapy: a 30 mg/kg loading dose infused over a minimum of 30 min and followed by a maintenance dose of 5.4 mg/kg/h for 48 h (Albert et al. 2008). The therapeutic response to corticosteroids is then monitored by continually retesting for the presence of an RAPD and assessing the patient's visual acuity and visual fields. If the intravenous methylprednisolone results in improved function for the patient after 48 h, therapy should be switched to oral prednisone therapy and should be tapered. If there is no improvement after 48 h, corticosteroids should be continued for up to 72 h. If there is no improvement after 72 h, surgical decompression of the optic canal should be considered.

Third, fourth, and sixth cranial nerve palsies caused by concussive trauma oftentimes recover spontaneously over weeks to months, so patients' symptoms of diplopia, ocular motility dysfunction, and, in the case of third nerve palsy, ptosis should be monitored over the course of several months. If deficits are still present 6 months after the inciting injury, they are more likely to persist and become comitant deviations, in which the distance between the double images of the diplopia is little affected by the direction of gaze. In the short term while the patient is being observed, patching one eye can help alleviate diplopia. If symptoms persist after 6 months, prism therapy (whereby a prism is ground into a spectacle lens) can be used to mitigate visual symptoms. For patients who fail prism therapy, the next therapeutic option is surgery to correct strabismus. Surgery is also considered to correct the ptosis of persistent third nerve palsies.

Prognosis

The prognosis for concussive traumas is generally very good. MTBI has an extremely low mortality rate, and most of the symptoms of MTBI resolve spontaneously over the course of approximately 1–2 weeks. Problems may persist beyond this 2-week period, which reinforces the importance of observation and follow-up for patients who suffer a concussive trauma, but even in these patients, the problems are rarely permanent. Patients who have suffered an MTBI are, however, at an increased risk of suffering another concussion, most especially in the time period when they are recovering from the initial event, underscoring the importance of avoiding situations where another traumatic incident is likely to occur in the period following the concussion. The neuroophthalmic manifestations of concussive trauma also oftentimes resolve spontaneously, although these symptoms can last for longer periods of time, up to 6 months.

Epidemiology

Concussive traumas are extremely common, with an estimate of approximately 1.6 million head injuries occurring annually in the United States alone (Albert et al. 2008). There is a male preponderance in the incidence of MTBI. Concussive traumas affect people of all ages, ranging from birth to death. The most common cause of concussive trauma is motor vehicle accidents, but other common etiologies include sports injuries, falls, and assaults. Sports injuries are a particularly common cause of concussion in children, accounting for more than half of pediatric cases (Bodin et al. 2012).

Conductive Keratoplasty

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Surgical technique for the correction of hyperopia and hyperopic astigmatism and management of presbyopia by delivering radio-frequency current directly into the corneal stroma.

Purpose

Conductive keratoplasty is a non-laser treatment for presbyopia and spherical hyperopia.

Principle

Conductive keratoplasty is performed by transferring radio-frequency energy through the corneal stroma. The result is a localized heating of collagen and shrinking of collagen fibers. The curvature of the central cornea is increased and hyperopia decreased.

Indication

Patients 40 years of age or older, treatment of spherical hyperopia +0.75 to +3.25 D, temporary induction of myopia to improve near vision in the nondominant eye and presbyopic hyperopes.

Contraindication

Patients under the age of 40 and patients with myopia are not suited for conductive keratoplasty.

Advantage/Disadvantage

Conductive keratoplasty preserves the central cornea and has no flap-related complications. So far no disadvantages of the procedure have been reported.

Cone Degeneration

► Cone Dystrophies/Degeneration

Cone Dystrophies/Degeneration

Hadas Newman
Department of Ophthalmology, Tel-Aviv Sourasky Medical Center, Tel Aviv, Israel

Synonyms

Cone degeneration; Inherited cone dysfunction

Definition

The cone dystrophies are a heterogeneous group of inherited retinal disorders, characterized by the abnormal function of the cone cells – the photoreceptors responsible for day and color vision.

They are all characterized by bilateral visual loss, color vision abnormalities, central scotomata, variable degrees of nystagmus, and photophobia, with electrophysiological or psychophysical evidence of abnormal cone function. Electroretinography (ERG) demonstrates generalized cone system dysfunction with either no (cone dystrophy) or mild rod system involvement (cone-rod dystrophy).

Disorders of cone function can be divided into stationary (cone dysfunction syndromes) and progressive disorders (cone and cone – rod dystrophies). In progressive cone dystrophies, onset is usually in childhood or early adult life, and patients often develop rod photoreceptor dysfunction in later life, thereby leading to considerable overlap between progressive cone and cone-rod dystrophies.

The stationary subtypes (such as "blue cone monochromatism" and "rod monochromatism" (achromatopsia)) which are congenital with normal rod function are described in other chapters. This chapter will focus on the progressive cone dystrophies.

Etiology

There is considerable clinical and genetic heterogeneity. Cone dystrophies (CDs) showing autosomal dominant (AD), autosomal recessive (AR), and X-linked recessive (XL) inheritance have all been reported, but the AR form is by far the most common. The genetic causes of the AD and XL inheritance have been largely clarified, but the genetic causes of the AR form are mostly unknown.

Autosomal dominant cone or cone-rod dystrophy identified and mapped genes are AIPL1, CRX, GUCA1A, GUCY2D, PITPNM3, PROM1, PRPH2, RIMS1, SEMA4A, and UNC119. While mapped loci, still unidentified, are CORD4, CORD17, and RCD1.

Autosomal recessive cone or cone-rod dystrophy identified and mapped genes are ABCA4, ADAM9, C21orf2, C8orf37, CACNA2D4, CDHR1, CERKL, CNGA3, CNGB3, CNNM4, KCNV2, PDE6C, PDE6H, RAB28, RAX2, RDH5, RPGRIP1, and TTLL5, with an unidentified locus CORD8.

X-linked cone or cone-rod dystrophy identified and mapped genes are CACNA1F and RPGR, with an unidentified locus COD2.

Findings

The progressive cone dystrophies are not usually symptomatic until late childhood or early adult

life. The age of onset of visual loss and the rate of progression show wide variability in the different families, but visual acuity usually deteriorates over time to the level of 6/60 or counting fingers.

Patients usually complain of light sensitivity and tend to see better at dusk or in the dark. Most have subnormal vision, dark to light adaptation problems, and loss of hues and color saturation. Some patients may have "urban night blindness"; in a city environment, there is usually enough light at night so the rods are unable to undergo full dark adaptation, while cones do not function as well. Congenital or early cases will typically have nystagmus.

Common fundus findings include bull's eye maculopathy and profound macular atrophy with a "cookie cutter" shape, while some cases show only subtle atrophic RPE changes and granularity or a normal looking macula.

In most patients the atrophy is confined to the fovea and usually is symmetric between eyes. Temporal optic pallor or atrophy is common. The retinal periphery is usually normal in pure cone dystrophies, although rarely white flecks similar to those seen in fundus flavimaculatus may be seen. Some X-linked cone dystrophy patients have confluent retinal areas of tapetal-like sheen, and rare patients have crystal deposits in the macula. Abnormal retinal blood vessel crossings of the macula have been described.

Specific Cone Dystrophies

CD Associated with GUCA1A

Onset is between the third and fifth decade with mild photophobia and reduced central vision. There is a generalized dyschromatopsia with no evidence of nystagmus. The mode of inheritance is AD. Ophthalmoscopy reveals a range of macular phenotypes, from mild RPE changes to frank macular atrophy with a normal peripheral retina. In full-field ERG, cone single-flash and flicker amplitudes are markedly subnormal, but there is minimal implicit time-shift (which is unusual in most CDs). There is usually no abnormality of the rod system, but forms of cone-rod dystrophy have been described. The gene GUCA1A encodes the phototransduction protein guanylate cyclase-activating protein-1 (GCAP1).

X-Linked CD

A genetically heterogeneous disorder has been mapped to loci on Xp21.1 (COD1, OMIM 304020) and Xq27 (COD2, OMIM 300085). COD1 maps to a region that harbors the RPGR gene, mutations in which account for more than 70% of patients with XL retinitis pigmentosa. The majority of these mutations reside in one purine-rich exon, ORF15, encoding 567 amino acids with a repetitive domain rich in glutamic acid residues. Two families with XLPCD linked to Xp21.1 (COD1) have been identified with two different mutations in ORF15 in RPGR. In both families clinical findings were typical of CD with photophobia, reduced central vision, progressive macular atrophy, and reduced cone ERGs with normal rod responses in affected males. However, they were unusual in having a late onset of reduced vision in the fifth decade.

Diagnosis

The diagnosis of cone dystrophy is confirmed by full-field electroretinogram (ERG), demonstrating generalized cone system dysfunction. Under light-adapted conditions, the photopic ERG responses to bright flash and flickering bright stimulus with a frequency of 30 cycles per second (Hz) stimulate the cone system. In cone dystrophies, the photopic ERG is severely abnormal to nonrecordable, while the dark adapted rod ERG is normal to subnormal. While the rod tracing might not have normal amplitude, it is well formed and usually stable over time. The cone ERG progressively worsens over time and may become nonrecordable.

Visual fields will show central scotomata, while the peripheral field is usually normal.

Psychophysical testing of color vision demonstrates color abnormalities. Because all three classes of cone photoreceptor are usually affected, the color vision defects seen are along all three color axes, not infrequently progressing to complete loss of color vision over time.

A recent study of 15 patients with cone dystrophy examined the morphological characteristics of the outer retina on spectral-domain optical coherence tomography (SD-OCT). Four out of 15 patients showed no definite structural changes

on OCT, while 11 out of 15 patients had symmetric changes in the outer retinal layers in both eyes. These changes were categorized into (1) irregular foveal loss of the ellipsoid portion of the photoreceptor inner segment (ISe) band and obscurity of the border between the ISe band and the external limiting membrane (ELM), (2) central retinal thinning and segmental foveal loss of the ISe band, and (3) central foveal thickening of the ISe band and irregular perifoveal loss of the ISe band. The outer segment (OS) contact cylinder layer was not discernible and the RPE layer was thickened in all 11 patients.

Differential Diagnosis

Stationary congenital cone dysfunction syndromes – mainly achromatopsia (rod monochromatism) and blue cone monochromatism. These are usually characterized by absence of photopic cone responses in ERG and usually do not progress.

Cone-rod dystrophies involve the rod system as well, but to a lesser degree than the cone system.

Prophylaxis

Prenatal diagnosis can be performed in families in which the responsible gene has been identified.

Therapy

There is currently no specific treatment for CDs.

Patients' management includes correction of refractive errors and wearing of tinted lenses to ease symptoms of glare and low visual aids.

Prognosis

Cone dysfunction usually progresses over time. The rate of progression shows wide variability in the different families, but visual acuity usually deteriorates over time to the level of 6/60 or counting fingers.

A recent longitudinal, multicenter study examined 98 consecutive probands with cone dystrophy. Average duration of follow-up was 19 years. The mean age onset for CD was 16 years (standard deviation, 11). Ten years after diagnosis, 35% of patients had a bull's eye maculopathy, and 37% developed rod involvement on ERG. The mean age of legal blindness was 48 (standard error, 3.1) years.

Epidemiology

Cone dystrophy (CD) and cone-rod dystrophy (CRD) are the most common hereditary cone disorders with a frequency of 1:30,000–40,000 worldwide.

Cone-rod degeneration

Definition

The cone-rod dystrophies are a heterogeneous group of inherited progressive retinal degenerative disorders, characterized by the primary progressive loss of cone photoreceptor function, with later or sometimes concomitant loss of rod photoreceptor function. Electroretinography (ERG) demonstrates generalized cone system dysfunction with milder rod system involvement.

There is considerable overlap between progressive cone (CD) and cone-rod dystrophies (CRDs), since cone dystrophies usually present in childhood or early adult life, with many patients developing rod photoreceptor involvement in later life.

Symptoms resemble those of CD, and include reduced visual acuity, color vision abnormalities and photophobia, but are followed later by night blindness due to rod involvement. Visual fields show a relative central scotoma with variable loss of peripheral fields.

Etiology

CRDs are most frequently non-syndromic, but they may also be part of several syndromes, such as Bardet-Biedl syndrome and spinocerebellar ataxia type 7 (SCA7).

Non-syndromic CRDs are genetically heterogeneous, inherited by autosomal dominant (AD), autosomal recessive (AR), or X-linked recessive (XL) inheritance. Most cases of progressive CD and CRDs are sporadic and probably represent autosomal recessive inheritance, but some may represent new AD mutations and, in severely affected males, XL disease.

Autosomal dominant cone-rod or cone dystrophy identified and mapped genes are AIPL1, CRX, GUCA1A, GUCY2D, PITPNM3, PROM1, PRPH2, RIMS1, SEMA4A, and UNC119, while mapped loci, still unidentified, are CORD4, CORD17, and RCD1.

Autosomal recessive cone-rod or cone dystrophy identified and mapped genes are ABCA4, ADAM9, C21orf2, C8orf37, CACNA2D4, CDHR1, CERKL, CNGA3, CNGB3, CNNM4, KCNV2, PDE6C, PDE6H, RAB28, RAX2, RDH5, RPGRIP1, and TTLL5, with an unidentified locus CORD8.

X-linked cone-rod or cone dystrophy identified and mapped genes are CACNA1F and RPGR, with an unidentified locus COD2.

The four major causative genes involved in the pathogenesis of CRDs are *ABCA4* (which causes Stargardt disease and also 30–60% of autosomal recessive CRDs), *CRX* and *GUCY2D* (which cause autosomal dominant CRDs), and *RPGR* (which causes about two-thirds of X-linked retinitis pigmentosa (RP) and also an undetermined percentage of X-linked CRDs). ABCA4 seems to be the most prominent causal gene of CRD, but a large proportion of AR-CRD cases are still with an unknown etiology.

The genes involved in CRD can be classified in four categories. The first category includes genes mostly responsible for CRDs cases. A predominant gene encodes the homeobox protein CRX, which controls rod and cone photoreceptor cell differentiation and survival. Most *CRX* mutations cause AD- CRD, with a prevalence estimated at 5–10% of dominant CRDs. The severity of the disease is highly variable, from mild to very severe cases. There are a few reports of dominant Leber congenital amaurosis (LCA) caused by *CRX* mutations, a condition which is usually recessive, as well as a few RP cases.

The second category includes genes mostly found in macular dystrophies, mainly the *ABCA4*, which is involved in the retinoid metabolism and causes the Stargardt disease. Mutations in the *ABCA4* gene are responsible for 30–60% of the cases with autosomal recessive CRDs. In some cases, the disease begins as a Stargardt macular dystrophy phenotype, which soon extends to the periphery. In other cases, the disease starts as a diffuse retinopathy with predominance of macular involvement. The *ABCA4* mutations linked to CRDs are truncating mutations, often on both alleles, whereas amino acid change mutations are more frequently found in Stargardt disease. Belonging to this second category, mutations of *GUCA1A* have been described in autosomal dominant CRD as well as in cone dystrophies. The *GUCA1A* gene encodes a protein that activates the guanylate cyclase (GC).

The third category includes two genes mostly found in RP cases. The RDS (PRPH2) gene encodes the outer segment protein peripherin/RDS. RDS mutations are involved in autosomal dominant RP, dominant CRD, and dominant macular dystrophy. CRDs due to mutations in the *RDS* gene are relatively moderate in comparison with autosomal recessive CRDs. The second gene codes for RPGR, which is involved in opsin trafficking. *RPGR* is the major causative gene for X-linked RPs, but it also accounts for some X-linked CRD with its locus referred as *COD1* or *CORDX1* and cone dystrophies. As for RPs, CRDs caused by mutations in the *RPGR* gene are severe and diagnosed early in life.

The 4th category includes genes found in LCA. CRD families with mutations in the *RPGRIP1* gene (AR inheritance) and *AIPL1* (AD) have been described. There are also several CRD families reported with mutations in *GUCY2D*, which is the major causative gene for LCA. In contrast to LCA patients, CRD patients with *GUCY2D* mutations have a dominant condition, the mutations being restricted to exon 13 encoding the dimerization domain of the guanylate cyclase.

Findings

The clinical signs of CRDs reflect the predominant involvement of cones, leading to decreased visual acuity and loss of sensitivity in the central visual field. Decrease in the visual acuity is the earliest symptom, with early photophobia and frequent dyschromatopsia, while evidence of rod involvement with associated night blindness occurs later. This fits the original description of the CRD entity in which cone loss precedes rod degeneration. However, in some cases, diffuse retinopathy affects simultaneously cones and rods, resulting in both night blindness and loss of visual acuity.

CRDs present first as a macular disease or as a diffuse retinopathy with predominance of the macular involvement. Typically, the age of clinical onset in humans is in the first decade of life or early adulthood, but milder cases are not recognized until later in life.

Fundus examination shows macular atrophy or a bull's-eye maculopathy in the early stages. Peripheral RPE atrophy, retinal pigmentation in the periphery and macula, arteriolar attenuation, and optic disc pallor can be seen in the late stages. The dark choroid sign may be seen on fluorescein angiography. A tapetal-like sheen that may change in appearance on dark adaptation (Mizuo-Nakamura phenomenon) has been described in association with X-linked CRD.

Diagnosis

Clinical diagnosis is based on the early decrease of visual acuity and photophobia, fundus findings,

subnormal photopic and scotopic ERG responses with predominant cone involvement, and progressive worsening of these signs.

The photopic ERG responses to bright flash and flickering bright stimulus are severely reduced and delayed, in keeping with generalized cone dysfunction. The dark-adapted (DA) ERG shows subnormal rod response to dim light and subnormal amplitudes of a and b waves to stronger flashes. There is predominant involvement of photopic (cones) over scotopic (rods) responses. The cone and rod ERG progressively worsens over time and may become nonrecordable.

Visual fields: a central scotoma appears first, followed by a variable degree of peripheral involvement.

Psychophysical testing of color vision demonstrates color abnormalities.

Spectral domain optical coherence tomography (SD-OCT) can be used to evaluate the retinal morphological changes in CRDs. A normal outer retina structure includes four bands in SD-OCT: the inner most band is the external limiting membrane (ELM), the second is the ellipsoid zone (EZ) of the inner segments, the third is the interdigitation zone (IZ) between the outer segments and the apical processes of the RPE, and the fourth is the RPE complex. A recent study described the outer retina structure in 24 eyes of 12 patients with CRD. SD-OCT scans demonstrated complete absence of the interdigitation zone in the entire length of SD-OCT scan in all 24 study eyes. Outside the foveal area, the external limiting membrane and ellipsoid zone were intact in all study eyes. The intensity of the ellipsoid zone was decreased in the entire length of SD-OCT scan in all study eyes. Within the foveal area, there was loss of the external limiting membrane and ellipsoid zone in 20 (83%) and 22 eyes (92%), respectively. The retinal pigment epithelium complex was identified in all study eyes.

Cone Dystrophy with Supernormal Rod Electroretinogram

It is a recessively inherited disorder, which was first reported by Gouras et al. in 1983. It is related to mutations in KCNV2, which encodes a subunit of a voltage-gated potassium channel expressed in both rod and cone photoreceptors.

Patients typically present in the first two decades of life with reduced visual acuity, photophobia, and color vision abnormalities, with some experiencing nyctalopia. Most patients are myopic. The fundus appearance may be normal in the early stages, but later there may be pigmentary disturbance at the macula and macular atrophy. Rings of parafoveal hyperautofluorescence can develop with age, and in older individuals, it may surround central areas of atrophy. Spectral domain optical coherence tomography characteristics are variable; disruption of photoreceptor inner-outer segment junction, optical gap at the foveola, and central retinal thinning are variably observed. The ERGs in cone dystrophy with supernormal rod ERG are diagnostic. The light-adapted ERGs are reduced and delayed, as in other cone dystrophies. The dark-adapted (DA) ERG has no detectable response to a very dim white, and to a stronger ISCEV standard dim flash (DA 0.01), the ERG shows extraordinary delay and is usually of subnormal amplitude. There is then a disproportionate increase in b-wave amplitude with relatively small increases in stimulus intensity. The DA 11.0 ERG has a normal a-wave slope and a broadened "squared" shape often with a late negative "peak" to the a-wave, which appears pathognomonic of the disorder when combined with the large increase in b-wave amplitude after relative small increase in stimulus intensity from the DA 0.01 ERG.

Differential Diagnosis

Cone dystrophies – CRD can be distinguished from CD by the early involvement of rod photoreceptors.

The main clinical signs in CD are loss of visual acuity, photophobia, dyschromatopsia, and cone involvement at ERG. However, in some cone dystrophies, there may be some rod involvement, particularly in late stage. In contrast to CRDs, rods remain at least partly spared at these late stages, whereas they are usually nonrecordable in late-stage CRD.

Rod-cone dystrophies, retinitis pigmentosa – A disease history characterized by predominant night blindness with prominent rod involvement on ERG. In RP rod function is lost faster than cone function, versus CRD, in which the rate of cone and rod loss is similar.

Maculopathies – in Stargardt disease, some advanced cases will show peripheral retinal involvement with cone-rod dysfunction in ERG.

Prophylaxis

Prenatal diagnosis can be performed in families in which the responsible gene has been identified.

Therapy

There is currently no specific treatment.

Patients' management includes correction of refractive errors, wearing of tinted lenses to ease symptoms of glare, and low visual aids.

Prognosis

The clinical course of CRDs is generally more severe and rapid than that of rod-cone dystrophies, leading to earlier legal blindness and disability. Patients are often severely visually disabled or legally blind by the end of the second decade of life.

A recent longitudinal, multicenter study examined 83 consecutive probands with CRD. Average duration of follow-up was 19 years. The mean age onset for CRD was 12 years (standard deviation, 11). Ten years after diagnosis, 51% of CRD patients had a bull's-eye maculopathy, and 70% showed absolute peripheral visual field defects. The mean age of legal blindness was 35 (standard error, 1.1) years.

Epidemiology

Estimated prevalence 1/40,000

Subtypes: Confocal fluorescence microscopy; Confocal in vivo microscopy

Definition

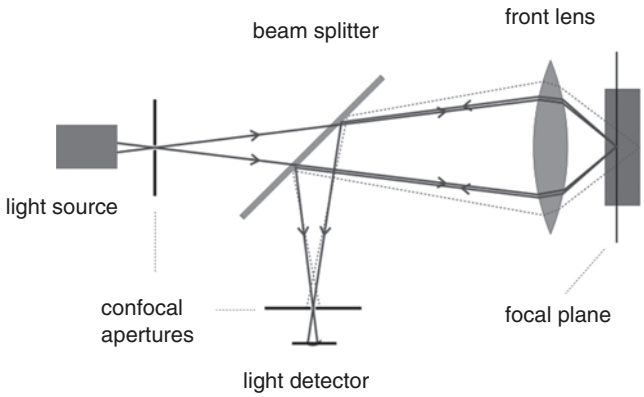
Method for imaging tissue (e.g., the cornea) on a cellular level with high resolution and magnification (ca. 200-fold). In contrast to optical coherence tomography, confocal microscopy produces optical sections in the frontal plane. In ophthalmology, confocal microscopy is used for both imaging tissue in vivo and ex vivo.

Purpose

Confocal microscopy is used to image the living cornea, conjunctiva, and sclera on a cellular level. Ex vivo virtually every type of tissue can be imaged with confocal fluorescence microscopy.

Principle

The principle of confocal imaging was described and patented by Marvin Minsky and aims to overcome the limitations of conventional wide-field microscopes. In a conventional microscope (e.g., light microscope or slit lamp), the entire tissue sample is flooded evenly in light. All parts of the specimen in the optical path reflect the light at the same time, and stray light scattered back from these out-of-focus layers blurs the in-focus image. In contrast, a confocal microscope uses a focused illumination (point or slit) and a pinhole in an optically conjugate plane in front of the detector to eliminate the out-of-focus light – hence the name "confocal" (Fig. 1). Because of the steep light gradient with maximum in the focal plane and the confocal pinhole, resolution is much better than that of conventional microscopes. Only details in the focal plane are imaged. As only one point (or slit) in the sample is illuminated at a time, imaging requires scanning over a raster in the specimen. The achievable thickness of the focal plane is defined mostly by the wavelength of the used light divided by the numerical aperture of the objective lens, but also by the optical properties of the specimen. For use in ophthalmology, two types of confocal in vivo microscopes are commercially available: A white-light slit-scanning microscope (ConfoScan, Nidek) and a laser scanning microscope (HRT RCM, Heidelberg Engineering) (Guthoff et al. 2006). There are numerous types of confocal



Confocal Microscopy, Fig. 1 The principle of confocal microscopy

fluorescence microscopes commercially available for examination of tissue samples ex vivo.

Indication

Confocal in vivo microscopy generates optical sections of the imaged tissue in the frontal plane similar to histological flat sections. The technique is particularly useful if conventional slit-lamp microscopy does not provide clear results, e.g., for differentiation of corneal opacities. One classical clinical indication is the search for trophozoites of *Acanthamoeba* spp. in case of keratitis (Winchester et al. 1995). With the laser scanning microscope, also the conjuctiva and sclera can be imaged. This can be helpful for the assessment of conjunctival neoplasias and filtering blebs after glaucoma surgery (Messmer et al. 2006a, b). Confocal in vivo microscopy is an important tool for monitoring corneal wound healing after corneal refractive laser surgery, particularly for scientific purposes.

Confocal fluorescence microscopy is an important technique in life sciences. In ophthalmology, this method is particularly useful for imaging corneal, retinal, and optic nerve tissue.

Contraindication

Confocal in vivo microscopy is a semi-invasive examination method, comparable to applanation or impression tonometry. Like in tonometry, there is potential danger of infection. If the cornea is applanated (HRT RCM), there can be mechanical irritation. The method must not be used in any case of open globe situation (e.g., injuries, early after intraocular surgery). Relative contraindications are keratitis and uncooperative, highly irritable patients. The cornea needs to be anesthetized with a local anesthetic. Therefore, allergy against local anesthetics is another contraindication.

Advantage/Disadvantage

Confocal in vivo microscopy provides unique information on a cellular level similar to histological sections far beyond magnification and resolution of the slit lamp. In some clinical cases, tissue biopsies can be avoided. In animal studies, intermediate results can be obtained during the time course without taking specimens. Because of their monochromatic nature, images obtained with the confocal in vivo microscope need a lot of experience to be interpreted. The technique is more invasive than a simple slit-lamp examination.

Confocal Scanning Laser Ophthalmoscopy, in Retinal Examination

Adiel Barak and Oded Ohana
Tel Aviv Sourasky Medical Center,
Tel Aviv-Yafo, Israel

Confocal Scanning Laser Ophthalmoscopy

Confocal scanning laser ophthalmoscopy (cSLO) is an ophthalmic imaging technology that scans an object point by point by a focused laser beam and then capturing the reflected light through a small aperture (a confocal pinhole). As opposed to conventional imaging technology which uses a bright flash of white light to

illuminate the retina, confocal technology requires the use of laser light instead of white light. The confocal pinhole, which is the core hallmark of the technology, suppresses light reflected or scattered from outside of the focal plane, which otherwise would blur the image. The result is a sharp, high-contrast image of the object layer located at the focal plane.

The advantages of using cSLO over traditional fundus photography include improved image quality as compare to standard photo, small depth of focus, and suppression of scattered light which eliminates image noise and patient comfort through less bright light. Because of the digital nature of the imaging process, 3D imaging capability and video capability are available. Due to the use of laser light which needs smaller capturing area, effective imaging is possible of patients who do not dilate well. This is especially valuable in diabetic patients, glaucoma patients and in elderly patients who typically do not dilate well. The cSLO also can penetrate hazy media as blood or opaque cataract due to the ability to increase the laser emission if needed.

Disadvantages of the use of cSLO imaging are the unnatural color images obtain as compare to white light. The cSLO scans the retina using several laser beams of different wavelength to produce color image and then superimpose the images obtain from each wavelength to construct a composite color image, but compare to the full spectrum of white light obtained from standard retinal photography and from clinical examination, the colors obtained look unnatural.

[2]Department of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Definition

Congenital hereditary endothelial dystrophy (CHED) is a rare corneal dystrophy characterized by bilateral, noninflammatory corneal clouding. There are two main forms of the disease, CHED 1 and CHED 2.

Etiology

CHED 1 is an autosomal dominant dystrophy with the gene locus on 20p11.2-q11.2.

CHED 2 is an autosomal recessive dystrophy with the gene locus on 20p13.

Clinical Presentation

In CHED 1, patients typically present within the first or second year of life with photophobia and tearing; then corneal clouding might follow. Corneal clouding might be asymmetrical and appears as a ground-glass milky appearance with significant corneal thickening. The photophobia and tearing seem to resolve by the time corneal clouding develops.

While in the CHED 2, the presentation is a diffused corneal coloring with a gray-blue ground-glass haziness of the corneal stroma within the first 6 months of age. Typically there is no or very slow progression; however, occasionally the corneal opacity might progress rapidly within the first year of life. Sometime stromal dots and flakes in deep cornea might be seen. Because of the severity of vision loss, some patients develop fine nystagmus.

Corneal thickness in CHED might be two to three times thicker than normal, with a central thickness more the 1 mm. The intraocular pressure and corneal diameters are normal which help in differentiating it from congenital glaucoma. The rest of the ocular structures are normal.

Diagnostics

There is no definitive diagnostic modality for CHED, which makes it a diagnosis of exclusion. However, when examination of a patient under general anesthesia shows the typical bilateral stromal opacification, gross corneal thickening, normal horizontal diameter, normal IOP, and the absence of brakes in Descemet's membrane, a provisional diagnosis of CHED can be made.

Histopathologically the corneal epithelium is thin or atrophic due to the corneal edema. Loss of Bowman's membrane is common and Descemet's membrane is usually thickened. The endothelial cells are either absent, reduced, or markedly degenerated.

Differential Diagnosis

Differential diagnosis includes congenital glaucoma, mucopolysaccharidosis, intrauterine infections (e.g., congenital rubella), birth trauma from forceps, and other corneal dystrophies (posterior polymorphous corneal dystrophy and macular stromal dystrophy).

Harboyan syndrome is an entity defined as CHED 2 and sensorineural hearing loss (perceptive deafness). This autosomal recessive disease is linked to the SLC4A11 gene mutation.

Prophylaxis

None. Genetic counseling might be helpful.

Therapy

Due to the involvement of the endothelium, full-thickness or endothelial keratoplasty is the mainstay of treatment.

Penetrating keratoplasty (PKP) in children is a complex surgery with multiple challenges like more risk of rejection and glaucoma than adult. One of the major limitations for vision improvement in this group of age is amblyopia. One study of PKP for CHED showed that around two thirds of eyes of patients who underwent PKP had clear graft at 2 years; however, the visual acuity improvement was limited with approximately two thirds of patients who had 20/400 visual acuity or, worse, poor vision in clear graft cases which was thought to be attributed to the development of amblyopia. Adding to the relatively poor results, penetrating keratoplasty in young children has risk of vision-threatening complication such as suprachoroidal hemorrhage.

Descemet stripping automated endothelial keratoplasty (DSAEK) is thought to be safer and has less risk of vision-threatening complications like suprachoroidal hemorrhage. However, DSAEK graft survival is still unclear in this group.

Prognosis

The prognosis is highly dependent on the age of onset. The success rate of corneal transplant

surgery at young age is less compared to older patients because of more risk of rejection and complication. Congenital-onset CHED has less graft survivability and success rate compared to "delayed-onset" CHED.

Epidemiology

It is a rare corneal dystrophy except in specific areas, like Saudi Arabia and South India.

Synonyms

Congenital stromal dystrophy of the cornea

Definition

A congenital stromal corneal dystrophy characterized by central clouding of the cornea without edema and a clear peripheral cornea.

Etiology

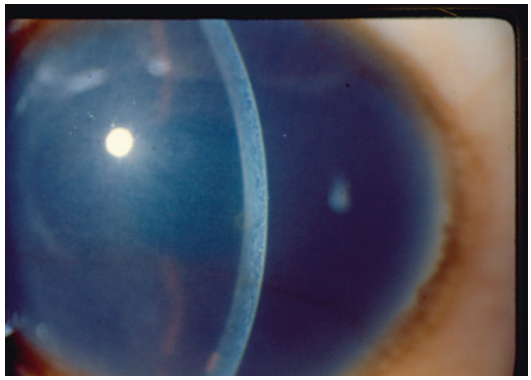
An autosomal dominant disease with a genetic mutation on chromosome 12 involving the Decorin-*DCN* gene (Krachmer et al. 2011).

Clinical Presentation

Patients present at birth with a bilateral clouding of the central cornea involving only the stroma (Rødahl et al. 1993–2013). The epithelium and endothelium are normal, and no erosions, vascularization, or edema are found. Closer examination reveals flake-like lesions in the anterior and posterior stroma and less prominent in the periphery (Weiss et al. 2008). Patients experience a moderate to severe loss of vision that progresses slowly or not at all. Dense amblyopia with a searching nystagmus may be seen in some patients (Fig. 1) (Krachmer et al. 2011).

Diagnostics

Diagnosis is made with clinical presentation and family history. Adjuncts are histology with transmission electron microscopy (TEM) and confocal



Congenital Hereditary Stromal Dystrophy, Fig. 1 Clouding of the central cornea without edema

microscopy. Histology demonstrates smaller than normal collagen fibrils with alternating layers of normal and randomly arranged fibrils. Some areas of the stromal lamellae have amorphous deposits. On TEM, the lamellar layers consist of randomly arranged filaments in an electron-lucent ground substance. Confocal microscopy demonstrates increased reflectivity in the anterior stroma (Weiss et al. 2008).

Differential Diagnosis

Differential diagnosis includes congenital glaucoma, corneal ulcer, interstitial keratitis, Peter's anomaly, congenital hereditary endothelial dystrophy, or metabolic abnormalities such as mucopolysaccharidoses and mucolipidoses.

Therapy

Depending on the degree of corneal cloudy and potential of dense amblyopia, penetrating keratoplasty may be performed at a young age. The corneal pathology does not recur in the donor graft (Krachmer et al. 2011).

Prognosis

Patients usually have moderate to severe vision loss. Even with intervention, visual acuity rarely improves beyond 20/200 (Krachmer et al. 2011).

Epidemiology

The prevalence of the disease is unknown other than it is rare.

Synonyms

Cogan's apraxia; Cogan type; COMA; Congenital gaze palsy; Congenital saccadic palsy; Ocular motor apraxia

Definition

Congenital ocular motor apraxia (COMA) is a rare congenital disorder of conjugate gaze characterized by a defect or absence in voluntary horizontal gaze, compensatory head thrusting, and often retention of both slow pursuit and reflexive eye movements (Olitsky et al. 2011).

Epidemiology

COMA is a very rare disorder and is more common in boys than in girls. It is estimated to occur in less than one in 1,000,000 members of the population (Lavin 2012).

History

COMA was first described in a case report published by Cogan in 1952 (Cogan 1952).

Clinical Features

By 4–8 months of age, the infant typically develops a thrusting head movement strategy, with prominent blinking, to overcome the eye movement deficit. Since the vestibulo-ocular reflex (VOR) prevents a change in direction of gaze on head rotating, the infant closes the eyes to reduce the degree of reflex eye movement while thrusting the head beyond the range of the VOR arc to bring the eyes in line with the target. Then, with the eyes open, the infant slowly straightens the head, while the contralateral VOR maintains fixation. Some patients may use the dynamic head thrust to facilitate saccadic eye movements or reflexively to induce fast phases of vestibular nystagmus (Lavin 2012). Because children with COMA cannot easily pursue new targets before they develop the head thrusting strategy, especially in early infancy, they are sometimes misdiagnosed as being blind (Lavin 2012). Most affected children have delayed motor and speech development including delayed sitting, clumsiness, and gait disturbances (Olitsky et al. 2011).

Tests

Magnetic resonance imaging (MRI) of the brain to rule out cerebral or cerebellar malformations. Test for ataxia-telangiectasia and lysosomal storage diseases, which are often associated with COMA.

Differential Diagnosis

Consider the possibility of ocular motor apraxia in any infant referred for evaluation of visual impairment. If the infant is at least 4 months of age, he or she may display the thrusting head movement strategy outlined in the clinical features section. Additionally, with the head held immobile, the child may not make an effort to initiate horizontal eye movements (Piña-Garza 2013). Studies have indicated a variety of anatomic abnormalities that can be seen on an MRI in children with congenital ocular motor apraxia, including inferior vermian hypoplasia, dysgenesis of the corpus callosum, cerebellar hypoplasia, and posterior fossa tumor (Sargent et al. 1997).

Etiology

COMA has been associated with multiple genetic deletions or mutations; however, more research needs to be done to identify specific genetic causes and hereditary patterns (Lavin 2012).

Treatment

There is no known cure or treatment for COMA. Patients typically benefit from supportive therapies like speech and language therapy, physiotherapy, and occupational therapy. Special education support has been reported to help children adapt to learning at school. As children reach school age, their symptoms variably improve. However, the condition typically does not completely resolve and can be detected in adulthood (Lavin 2012).

Conjunctiva

Allen Pusateri[1] and Ilya Leyngold[2]
[1]USF Eye Institute, University of South Florida College of Medicine, Tampa, FL, USA
[2]Department of Ophthalmology, University of South Florida College of Medicine, Tampa, FL, USA

Basic Characteristics

The conjunctiva is a transparent mucous membrane that lines the posterior surface of the eyelids and covers the globe and orbit. Its primary functions are to act as a physical anatomic barrier to

the environment, to allow for smooth movement of the eye, to help to maintain a suitable environment for the ocular surface and cornea, and also to play a role in immune protective mechanisms of the external eye. Abnormalities of the conjunctiva may lead to restriction of ocular motility, tear film deficiency, and decreased host resistance to infection.

The conjunctiva is embryologically derived from the surface ectoderm. The conjunctiva is divided into the palpebral, forniceal, and bulbar portions. The palpebral portion begins at the mucocutaneous junction of the eyelid and covers the inner surface of the eyelid; it is firmly adherent to the tarsal plate. The forniceal conjunctiva becomes redundant and freely movable. It continues as the bulbar conjunctiva where it fuses with the Tenon capsule and inserts into the corneoscleral limbus

The anterior ciliary arteries supply blood to the bulbar conjunctiva, and branches of the marginal arcades of the lids supply the palpebral and forniceal portions. The innervation is derived from the ophthalmic division of cranial nerve V.

The conjunctiva is the main site for the production of the aqueous and mucous components of the tears. It consists of nonkeratinized stratified squamous epithelium with mucin-secreting goblet cells overlying a loose layer of abundantly vascularised lamina propria. The goblet cells are concentrated in the inferior and medial portions and are sparsely distributed throughout the remainder of the conjunctiva.

Additionally, there is a lymphoid layer with specialized aggregations of conjunctiva-associated lymphoid tissue (CALT) which comprise collections of T and B lymphocytes that function in antigen processing.

Definition

Conjunctival graft should be considered in comparison to conjunctival flap. In the graft technique, the tissue is harvested and transplanted to different

sites without any blood supply. On the other hand, a conjunctival flap has a remaining attachment to the origin site and carries its own blood vessels.

Indication

Common indications for conjunctival graft are:

- Pterygium (the most common indication)
- Cicatricial ocular surface disease (symblepharon)
- Conjunctival tumor lesions

Amniotic membrane is used as alternative of conjunctival graft in these indications.

Contraindication

Conjunctival autograft should not be prepared from a site with history of trauma or surgery. Eyes with uncontrolled inflammation and dry eye disease are not good candidates for conjunctival graft harvest. Amniotic membrane grafts should be considered in glaucoma patients to increase the chance of future successful trabeculectomy if needed. However, inferotemporal conjunctiva could be considered as a potential harvest site in these patients. Furthermore, combined nasal and temporal pterygium or large defects are difficult to be managed by conjunctival graft. The graft should not be transplanted to sites with ischemia, and instead, conjunctival flap should be considered.

Techniques and Principles

These factors are important for successful conjunctival autograft:

1. Obtain adequate size of graft (usually 1 mm oversize).
2. Harvest the graft without the Tenon's tissue and avoid buttonhole.
3. Securely fix the graft in the recipient site.

As superotemporal conjunctiva is mostly selected for graft harvest, tractional suture with Vicryl 6-0 or Silk 6-0 can be used for better exposure of the field. The defect site should be measured. It is recommended that the conjunctiva is outlined 1 mm larger than the defect size with gentian violet and pay attention not to connect harvest and recipient site with each other. Lidocaine with diluted adrenalin is subconjunctivally injected. It makes dissection easier between the conjunctiva and Tenon's layer. Dissection is started in lateral borders with blunt Westcott scissors. Anterior and posterior borders are cut later in order to maintain the conjunctiva in flat position, and conjunctiva dissection form Tenon's capsule can be done more easily in this condition. The surgeon should attempt not to leave the Tenon under the conjunctiva and avoid perforation of the graft. The conjunctiva should be gently grasped with fine instrument. The harvest site is left bare or covered with amniotic membrane. Caution should be taken about the orientation of the graft. If the graft is transplanted upside down, it will cause graft necrosis (Brightbill 2009; Krachmer et al. 2010; Copeland et al. 2013).

Conjunctival autograft can be fixed with sutures or fibrin glue. It is recommended that using nylon 10-0 instead of Vicryl 8-0 or 9-0- because nylon cause less inflammation and pterygium recurrence may be less than using Vicryl suture. The graft usually is sutured at the limbus and conjunctiva border with separated or running sutures. Although fibrin glue is more costly than suture, it will reduce surgical time and patients' discomfort. It is shown that fibrin glue reduces the recurrence of pterygium in comparison with sutures (Pan et al. 2011).

Outcome

Conjunctival autograft is the preferred procedure for pterygium surgery. The procedure is simple and can be done everywhere. The reported recurrences rates are usually under 10%. In comparison with amniotic membrane use in pterygium surgery, conjunctival graft surgery has less recurrence rate and better cosmetic result and is more affordable (Kaufman et al. 2013).

Complications

Possible complications that may occur include:

- Graft edema
- Graft hemorrhage
- Graft dislocation or loss
- Graft retraction
- Graft necrosis
- Corneoscleral dellen
- Infection
- Pyogenic granuloma in the recipient or harvest site
- Epithelial inclusion cysts

Conjunctival Degenerations

Elliott Brodbaker and Nathan Nataneli
Department of Ophthalmology, Bronx Lebanon Hospital, Albert Einstein College of Medicine, Yeshiva University, Bronx, NY, USA

Synonyms

Concretions; Conjunctivochalasis; Pinguecula; Pterygium

Pinguecula

Pingueculae are nodules of bulbar conjunctival thickening that are typically paralimbal at 3 and 9 o'clock positions. Pingueculae may be unilateral or bilateral and are more commonly found nasally. The nodules consist of hyaline and collagen elastic tissue.

Etiology

Pingueculae are thought to be caused by actinic damage via ultraviolet radiation, which results in elastotic degeneration of the conjunctival substantia propria. It is unclear why nasal lesions are more common than temporal ones, although some have theorized that it may be due to the reflection of the sun off of the nose (Perkins 1985; Brodbaker et al. 2008). Other potential causes of pingueculae include trauma, foreign body agitation (e.g., dust), and drying.

Clinical Presentation

Pingueculae are elevated yellowish-white lesions that are located in the interpalpebral conjunctiva. They do not invade the cornea and have few, if any vessels. The lesion may become red and inflamed and the diagnosis of pingueculitis is then assigned Fig. 1.

Diagnosis

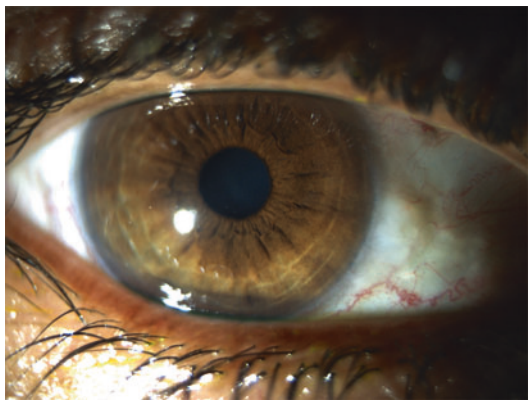
The diagnosis is based on clinical examination. In atypical cases, a tissue diagnosis may be obtained.

Differential Diagnosis

Pterygium
Bitot spot (vitamin A deficiency)
Phlyctenule
Episcleritis
Nodular scleritis
Conjunctival intraepithelial neoplasia
Squamous cell carcinoma
Conjunctival granuloma

Prophylaxis

UV protection with the use of wide brimmed hats and UV-protecting sunglasses can be helpful in preventing the occurrence of pingueculae. Protection from chronic wind and dust exposure minimizes the potential ocular surface irritation that can lead to pingueculae formation.



Conjunctival Degenerations, Fig. 1 Pinguecula (Note the yellowish-white mound located nasal to the limbus)

Therapy

Treatment is often not indicated. Artificial tears can be used for lubrication. A short-term course of a topical vasoconstrictor and/or topical steroid may be indicated for pingueculitis. Surgical excision may be indicated for inflamed lesions unresponsive to conservative management.

Prognosis

Pingueculae are benign lesions with no immediate sight-threatening implications, although they can sometimes cause contact lens intolerance. Pingueculae are associated with a two- to threefold increased incidence of age-related macular degeneration, possibly through a common light exposure effect (Pham et al. 2005). Pingueculae that are tan in color may be associated with Gaucher's disease type I (Chu et al. 1984).

Epidemiology

The prevalence varies among populations, but pingueculae are more prominent in more heavily pigmented populations and in people over 40 years of age.

Pterygium

A pterygium is a slowly progressive, degenerative, fibrovascular, and fleshy winglike growth extending from the conjunctiva unto the cornea.

Etiology

Pterygia are associated with ultraviolet light exposure, dust, drying, and windy environments.

Clinical Presentation

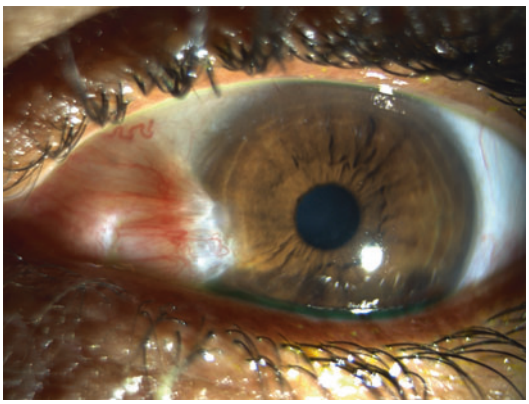
Pterygia are often nasal and bilateral but they can also occur temporally. They can induce astigmatism and, if central enough, can obstruct the visual axis. Patients with pterygia may present with a redness, irritation, foreign body sensation, photophobia, contact lens intolerance, and/or cosmetic concerns regarding the lesion(s) (Kaufman et al. 2013; Young et al. 2013). Whitish opacities, named Islets of Vogt, can be found on the surface of many pterygia, and a linear deposit of iron may be seen on the cornea at the leading edge of the pterygium, called a Stocker line. Pterygia may be exacerbated by keratoconjunctivitis sicca or via trauma (Fig. 2).

Diagnosis

The diagnosis is based on clinical examination. Confirmatory evidence can be obtained via tissue diagnosis following a biopsy or a surgical removal procedure.

Differential Diagnosis

- Cyst
- Phlyctenule
- Episcleritis, scleritis
- Ocular cicatricial pemphigoid



Conjunctival Degenerations, Fig 2 Pterygium (Note the fleshy, fibrovascular, and winglike growth extending from the conjunctiva past the limbus onto the cornea)

- Resolved marginal keratitis
- Squamous cell carcinoma
- Conjunctival intraepithelial neoplasia
- Focal limbal stem cell deficiency
- Hereditary benign intraepithelial neoplasia
- Mucoepidermoid carcinoma
- Pseudoepitheliomatous hyperplasia

Prophylaxis

UV protection with the use of wide brimmed hats and UV-protecting sunglasses can be helpful in preventing the occurrence of pterygia (Mackenzie et al. 1992). Also, protection from chronic wind and dust exposure minimizes the potential ocular surface irritation that can lead to pterygium formation (Mackenzie et al. 1992).

Therapy

Treatment is often not indicated. Artificial tears can be used for lubrication. A short-term course of a topical vasoconstrictor and/or topical steroid may be indicated for an inflamed pterygium. Surgical excision is warranted for recurrent or chronically inflamed lesions, astigmatism, direct involvement of the visual axis, contact lens intolerance, and in cases of significant cosmetic concern (Kaufman et al. 2013). Surgical technique varies from simple excision to procedures associated with lower recurrence rates such as conjunctival and amniotic membrane grafts. Fibrin glue can be used as an aid to tack down the conjunctival grafts. Mitomycin C, β-irradiation, and thiotepa have also been used to lower the rate of recurrence, each with its own set of risks (Young et al. 2013).

Prognosis

Most pterygia are asymptomatic or mild symptomatic and symptom relief can often be obtained using artificial tears. Pterygia have a high recurrence rate after simple excision alone. Recurrences are reduced by the use of conjunctival autograft, β-irradiation, thiotepa, or mitomycin C in the treatment process. Surgical excision of

recurrent pterygia is significantly more complex, owing to copious scar tissue. There is a very small malignant potential, and pterygia specimens are usually submitted for review.

Epidemiology

Pterygia are more common in males than females, particularly among those who live closer to the equator and who work outdoors. The lesions tend to be more prominent in more heavily pigmented populations and in people between 20 and 40 years of age (Perkins 1985).

Concretions

Concretions are chalky-white-to-yellow keratin and epithelial debris-containing cysts located in the fornix or inferior or superior palpebral conjunctiva.

Etiology

Concretions are associated with increasing age and chronic inflammation which causes invagination of conjunctival epithelial cells. Erosion through the overlying conjunctiva can cause a foreign body sensation. Concretions may be secondary, as in the late stages of trachoma.

Clinical Presentation

Concretions are often incidental findings but can occasionally cause a foreign body sensation.

Diagnosis

The diagnosis is based on clinical examination.

Differential Diagnosis

Inclusion cyst
Follicles
Foreign body
Granuloma
Conjunctival tumor
Buildup of meibum

Prognosis

Concretions are typically benign, producing no symptoms. If bothersome, they often respond well to simple excision.

Epidemiology

Concretions occur at a higher incidence with increasing age or chronic inflammation. In a sample taken in the United Kingdom, concretions were found in over 40% of patients, the vast majority of whom were asymptomatic (Kulshrestha and Thaller 1995).

Conjunctivochalasis

Conjunctivochalasis refers to a redundancy of the bulbar conjunctiva between the globe and lower eyelid margins.

Etiology

The etiology is poorly understood and still being researched. It is theorized that it may be due to blockage of lymphatic flow causing lymphatic dilation and eventual conjunctival elastosis and redundancy.

Clinical Presentation

Patients vary in the degree of their symptomatology ranging from being asymptomatic to experiencing ocular irritation, pain, subconjunctival hemorrhage, epiphora, dry eye, and/or ulceration. The symptoms are often exacerbated by blinking.

Diagnosis

Slit lamp examination shows a redundant fold of conjunctiva over the sclera that is usually more pronounced with downgaze and improved with upgaze.

Differential Diagnosis

Chemosis
Acute or chronic conjunctivitis
Dry eye
Conjunctival tumors

Prognosis

Mildly symptomatic patients are often treated with artificial tears, lubricating gels, corticosteroid or antihistamine drops, and/or nocturnal patching as a first line of treatment. Surgery can be performed to remove the redundant conjunctiva with employment of amniotic membrane grafting with sutures and/or and fibrin glue.

Epidemiology

Conjunctivochalasis occurs at an increased rate in the elderly.

Conjunctival Flaps

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Definition

A surgical procedure that entails advancing or rotating a conjunctival pedicle into an adjacent defect.

Indication

Conjunctival flaps have a broad variety of applications. Gunderson flaps have long been used for eyes with poor visual potential and exposure, neurotrophic ulcers, band keratopathy, advanced bullous keratopathy, or the need to comfortably fit a cosmetic scleral shell. More recently, rotational flaps have been proposed as an alternative to

conjunctival autografts in pterygium surgery. They are also used to treat tube erosion with glaucoma drainage devices (Godfrey et al. 2003).

Contraindication

Gunderson flaps in particular are difficult to perform in eyes with multiple prior surgeries and/or scarring due to absence of mobile conjunctiva. Conjunctival flaps to cover glaucoma drainage tubes should not be used if the flap design would incorporate tissue directly adjacent to the lacrimal gland ductules.

Techniques and Principles

Gunderson flaps are created by making liberal conjunctival incisions in the superior and inferior fornices. The conjunctiva is then separated from underlying Tenon's capsule and a 360° peritomy is performed. This creates two flaps that can be advanced over the cornea and sutured together. The corneal epithelium must be thoroughly debrided prior to flap closure (Maguire and Shearer 1991).

Conjunctival flaps for pterygium surgery are designed similarly to autographs, but a limbal anchoring point approximately 1 mm wide is preserved to act as a vascularized pedicle (Kim et al. 2013). The flap is then rotated into the bare scleral defect and sutured.

Flaps to cover eroded glaucoma drainage implants are created such that the length to width ratio is approximately 3:1 (Grover et al. 2013). Tissue is generally recruited from the conjunctival fornix, and the base of the pedicle is created adjacent to, but not on, the drainage plate. Lid splitting can be performed for better visualization and access if needed. The eroded tube is first covered with a new corneal or preserved scleral patch graft and then the rotational flap.

Outcome

The Gunderson flap is generally very successful in reducing ocular surface discomfort (Ma'luf and Awwad 2005). Several authors have reported that rotational flaps for pterygium surgery offer equivalent success rates to autografts with decreased edema and reduced operating time. Pedicle flaps for tube erosion are effective compared to other techniques, but up to half of complex cases still may require additional repairs.

Complications

Complications include dehiscence, retraction, pterygium recurrence, and recurrent corneal or tube exposure.

Conjunctival Inclusion Cysts

Steven Agemy
Department of Ophthalmology, SUNY Downstate Medical Center, Brooklyn, NY, USA

Synonyms

Conjunctival epithelial inclusion cyst; Inclusion cyst of conjunctival epithelium

Definition

Benign, cystic lesion of conjunctiva derived from an inclusion of conjunctival epithelium into the substantia propria (American Academy of Ophthalmology (nd); Shields and Shields 2008).

Etiology

Congenital or more commonly acquired due to chronic inflammation, trauma, or surgery. Inclusion of epithelium into the substantia propria leads to epithelial cell proliferation with resultant formation of a central cavity lined by nonkeratinized conjunctival epithelium (American Academy of Ophthalmology (nd); Shields and Shields 2008).

Occurrence

Uncertain but acquired lesions are commonly seen (American Academy of Ophthalmology (nd); Shields and Shields 2008).

Classification

Congenital or acquired.

Conjunctival Tumors

Saeed Alwadani
Department of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Definition

Conjunctival tumors are a large and varied spectrum of disorders ranging from benign to malignant lesions.

Basic Characteristics

The majority of conjunctiva tumors are benign and malignant tumors and are relatively rare. Conjunctival epithelial tumor is more common than stromal tumor. The former one can be classified according to the type of cells. In general, there are three basic categories of conjunctival tumors including the ones arising from the squamous epithelium, associated with melanocytes, or lymphoid cells.

1. Squamous epithelial lesions:
   - Squamous papillomas
   - Ocular surface squamous neoplasia
2. Melanocytic tumors:
   - Nevus
   - Primary acquired melanosis
   - Melanoma
3. Glandular tumor:
   - Oncocytoma
4. Lymphocytic lesions:
   - Benign lymphoid hyperplasia
   - Lymphoma
5. Other neoplasms: Tumor may occasionally arise in the conjunctiva, including neural, muscular, vascular, and fibrous tumors and metastatic lesions.

Definition

Conjunctivitis refers to inflammation of the conjunctiva, the outer lining of the ocular surface and posterior eyelids, and is generally characterized by vascular dilation causing a hyperemic appearance. Additional features or involvement of additional ocular layers vary based on etiology.

Etiology

The etiology of conjunctivitis is broadly categorized into acute and chronic causes.

Acute conjunctivitis	
Categories	Common agents
Infectious: Bacterial	*Neisseria gonorrhoeae*, *Neisseria meningitidis, Staphylococcus aureus*, *Streptococcus pneumoniae*
Infectious: Viral	Adenoviruses types 3 and 7 causing pharyngoconjunctival fever, Adenoviruses types 8 and 19 causing epidemic keratoconjunctivitis, Herpes simplex virus, Varicella-zoster virus, Epstein-Barr virus, Cytomegalovirus
Infectious: Fungal	*Candida albicans*
Chemical	Preservatives in eye drops and contact lens solutions, idoxuridine, brimonidine, apraclonidine, dipivefrin
Traumatic	
Chronic conjunctivitis	
Infectious: Bacterial	*Chlamydia, S. aureus*, *Moraxella lacunata*, *Actinomyces israelii*
Infectious: Viral	Adenoviruses types 2, 3, 4, and 5. Molluscum contagiosum virus
Infectious: Other	*Sporothrix schenckii, Rhinosporidium seeberi, Coccidioides immitis, Thelazia californiensis, Loa loa, Ascaris lumbricoides, Trichinella spiralis, Schistosoma haematobium, Taenia solium, Pthirus pubis*
Unknown etiology	Chronic follicular conjunctivitis, psoriasis, folliculosis

Conjunctivitis can also be categorized as bacterial or viral in origin. There are many other causes of conjunctivitis that include, chlamydial, fungal, parasitic, rickettsial, allergic, chemical (irritative), associated with systemic diseases like tuberculosis or syphilis, secondary to dacryocystitis or canaliculitis, or unknown in etiology.

Bacterial conjunctivitis		
Type	Duration of illness	Common agents
Hyperacute	Few hours to 3 days	*Neisseria gonorrhoeae*, *Neisseria meningitidis*
Acute	21 days	*Staphylococcus aureus*, *Streptococcus pneumoniae.* Less common*: C. diphtheria*, *S. epidermidis*, *Pseudomonal* species, *Escherichia coli*, *Shigella* species, *Borrelia vincentii*, *Fusobacterium bacilli*
Chronic	Long term (more than 3 weeks)	*Chlamydia, S. aureus*, *Moraxella lacunata*, *Actinomyces israelii* (most common canalicular pathogen)

Bacterial conjunctivitis can be classified into hyperacute, acute, and chronic based on the duration of illness. Hyperacute conjunctivitis is most commonly caused by *Neisseria gonorrhoeae* and *Neisseria meningitides. N. gonorrhoeae* is the most common pathogen causing hyperacute bacterial conjunctivitis (Krachmer et al. 2011).

Staphylococcus aureus and *Streptococcus pneumoniae* are common causes of acute bacterial

conjunctivitis. *H. influenza* (nonencapsulated) is the most common cause of bacterial conjunctivitis in children. *C. diphtheriae* and *S. epidermidis* are infrequent causes of acute bacterial conjunctivitis. Other bacteria are *Pseudomonal* species, *Escherichia coli*, *Shigella* species, *Borrelia vincentii*, and *Fusobacterium bacilli* among others.

Chronic bacterial conjunctivitis is most commonly caused by *S. aureus*. *Moraxella lacunata* is also a common cause. *Actinomyces israelii* is the most common canalicular pathogen. *Chlamydia* can cause chronic inclusion conjunctivitis and also trachoma.

Viral conjunctivitis is most commonly caused by adenoviruses, accounting from 65% to 90% of all viral etiologies. Other causes of viral conjunctivitis are Herpes simplex virus, Varicella-zoster virus, Epstein-Barr virus, Cytomegalovirus, Variola (smallpox) virus, Vaccinia (cowpox) virus, Molluscum contagiosum virus, Picornaviruses (enterovirus and coxsackievirus), Paramyxoviruses (measles, mumps, and Newcastle disease), Rubella (German measles), and Flaviviruses (yellow fever and dengue).

Clinical Presentation

Bacterial Conjunctivitis

Bacterial conjunctivitis is usually bilateral and is characterized by a purulent or mucopurulent discharge. In **hyperacute bacterial conjunctivitis** there is marked conjunctival hyperemia, lid edema, chemosis, and copious amounts of purulent discharge (Krachmer et al. 2011). There may be membranes or pseudomembranes which are associated with preauricular adenopathy. It usually starts unilaterally and often becomes bilateral and the incubation period is anywhere from a few hours to 3 days. In ophthalmia neonatorum caused by *N. gonorrhoeae*, there is chemosis 2–4 days after transit through an infected birth canal along with a hyperacute purulent conjunctivitis.

Acute bacterial conjunctivitis is arbitrarily defined as having a duration of less than 3 weeks. It is also less severe than hyperacute bacterial conjunctivitis. The discharge is mucopurulent but may be mucoid (catarrhal) or purulent. There is frequently a velvety papillary reaction seen on the palpebral conjunctivae. *S. aureus* is associated with a characteristic blepharitis and the mucopurulent discharge may lead to stickiness of the eyelids in the morning. The incubation period for *S. pneumoniae* is about 2 days and maximum severity is reached in 2–3 days after onset. Subjunctival hemorrhages are frequently seen and usually involve the upper tarsal conjunctiva or fornix (Krachmer et al. 2011).

Chronic bacterial conjunctivitis is characterized by symptoms that last longer than 3 weeks and has a more indolent course. Symptoms can be variable but include minimal discharge, foreign body sensation, and stickiness and matting of the eyelashes. Clinical signs include diffuse conjunctival hyperemia, papillae formation, and a mild mucopurulent discharge (Krachmer et al. 2011). *S. aureus* can cause blepharoconjunctivitis with concurrent lid margin involvement with loss of lashes, trichiasis, hordeola, telangiectasis, and erythema (Krachmer et al. 2011). *M. lacunata* causes a follicular conjunctivitis. *Actinomyces* can cause unilateral itching, tearing, and irritation. Mucopurulent drainage can be seen from the puncta and milking of the canaliculi can yield yellow granular material from the punctum (sulfur granules).

Chlamydia conjunctivitis is typically found in young adults and is sexually transmitted. There may be a history of urethritis, cervicitis, or vaginitis. It causes a stringy mucous discharge along with follicles on the inferior tarsal and bulbar conjunctiva, peripheral SEIs, and superior corneal pannus. There is also palpable preauricular lymphadenopathy. Trachoma occurs primarily in endemic areas such as India, Southeast Asia, North Africa, and the Middle East, in areas of overcrowding and poor sanitation. According to the WHO classification, the TF phase (trachomatous inflammation: follicular) presents with five or more follicles on the upper tarsus. The TI phase (trachomatous inflammation: intense) includes inflammation with thickening obscuring >50% of the tarsal vessels. The TS phase (trachomatous scarring) is characterized by

cicatrization of tarsal conjunctiva with fibrous white bands. The TT phase (trachomatous trichiasis) includes trichiasis of atleast one eyelash and the CO phase (corneal opacity) involves corneal opacity involving at least part of the papillary margin.

Viral Conjunctivitis

Viral conjunctivitis is characterized by conjunctival hyperemia, tearing, gritty, or foreign body sensation, sticking of the eyelids or crusting (worse in the mornings), and less than 4 weeks of symptoms. The onset is acute after about 5–14 days. The discharge is watery, and the eyelids are red and edematous. There is a follicular reaction of the conjunctiva and pinpoint subconjunctival hemorrhages can be seen. Superficial punctuate keratopathy, membrane/pseudomembrane, and subepithelial infiltrates can develop as well. It typically starts in one eye and involves the fellow eye a few days later. It is spread by personal contact, swimming pools, or through fomites. **Pharyngoconjunctival fever** is characterized by pharyngitis, fever, preauricular and cervical adenitis, and follicular conjunctivitis. It can also be accompanied by diarrhea and rhinitis (Krachmer et al. 2011). **Epidemic keratoconjunctivitis** is more severe than pharyngoconjunctival fever but there is an absence of extraocular manifestations with severe stromal infiltrates. There can be worsening of photophobia, tearing, and discomfort which signifies keratitis. The keratitis can be superficial but can progress to subepithelial infiltrates. Pseudomembranes and membranes signify severe conjunctival involvement. **Acute nonspecific follicular conjunctivitis** is characterized by milder conjunctival involvement and keratitis that is limited to the epithelium if at all. There is a mild follicular reaction, mild conjunctival hyperemia, and discrete lid edema (Krachmer et al. 2011).

Chronic viral conjunctivitis is characterized by symptoms that can last for months or even years. There are intermittent symptoms including irritation with waxing and waning superficial punctate keratitis and subepithelial infiltrates. **Herpes simplex conjunctivitis** usually presents with unilateral disease with a follicular reaction, mucous drainage, conjunctival hyperemia, and preauricular lymphadenopathy. Dendritic keratitis may be present initially or develop later. Superficial punctuate keratitis can be present without dendritic lesions. **Varicella-zoster virus** can rarely cause conjunctivitis. Phlyctenule-like lesions that are small and ulcerative are found at the limbus, and the cornea can also be affected. The reactivation of varicella in the trigeminal ganglion involves the V1 dermatome and is called **herpes zoster ophthalmicus. Epstein-Barr virus (EBV)** presents with fever, sore throat, lymphadenopathy, lymphocytosis, polyarthritis, myositis, and follicular conjunctivitis (Krachmer et al. 2011). **Cytomegalovirus (CMV)** can also present with follicular conjunctivitis. **Variola and Vaccinia conjunctivitis** are rare. They present with pustules on bulbar conjunctivae along with purulent discharge. **Molluscum contagiosum virus (MC)** typically presents with a follicular conjunctivitis, corneal pannus along with lid margin lesions. These lesions are umbilicated, dome shaped, raised, and flesh colored. Enterovirus and coxsackieviruses can cause **acute hemorrhagic conjunctivitis (AHC)**. This syndrome begins with acute onset of pain, lacrimation, FB sensation, conjunctival injection, subconjunctival hemorrhages along with periorbital swelling (Krachmer et al. 2011). AHC may resemble EKC, but AHC has a more rapid disease course and has less corneal involvement than EKC. The **paramyxoviruses (measles, Newcastle disease, and mumps)** are characterized by follicular conjunctivitis. In measles, catarrhal conjunctivitis, superficial keratitis, and photophobia are the most common clinical features (Krachmer et al. 2011). Keratitis can be severe and can cause blindness. In Newcastle disease, mild follicular conjunctivitis along with subepithelial infiltrates might be seen. In mumps, the parotid salivary glands get swollen. If the lacrimal gland is affected, then there can be orbital pain and a mass. Superficial punctuate keratitis or stromal keratitis may be seen. **Rubella** is a mild childhood disease and presents with follicular conjunctivitis and punctuate keratitis located in the central cornea. **Yellow fever and dengue fever** are arthropod-borne illnesses common in the tropics.

They are characterized by conjunctival injection, lid edema, and photophobia. Conjunctival hemorrhages can be seen if coagulopathy develops (Krachmer et al. 2011).

Diagnosis

Bacterial Conjunctivitis

In cases of hyperacute bacterial conjunctivitis, gram staining and confirmatory culture are mandatory for diagnosis because of the possibility of systemic infection and bacterial resistance.

Acute bacterial conjunctivitis is diagnosed by clinical signs and symptoms and without laboratory studies. Lab studies should be obtained in acute conjunctivitis refractory to treatment and severe conjunctivitis in infants and children (Krachmer et al. 2011).

Diagnosis of chronic bacterial conjunctivitis is often made by history and clinical exam findings; however, culturing of the lid margin and conjunctiva is important in refractory cases. In chronic follicular conjunctivitis, Gram and Giemsa staining may reveal *Moraxella* or *Chlamydia*. Direct *chlamydial* immunofluorescence test, DNA probe, *chlamydial* culture of conjunctiva, or PCR is used to diagnose *chlamydial* conjunctivitis.

Viral Conjunctivitis

Viral conjunctivitis is clinically diagnosed based on acute conjunctivitis, follicles on the inferior tarsal conjunctiva, preauricular lymphadenopathy, a recent URI, and contact with a person who had red eye. If symptoms persist or the condition is chronic, then cell culture along with confirmatory immunofluorescence staining can be obtained. HSV conjunctivitis can be diagnosed clinically; however, the gold standard method for diagnosis is cell culture. Varicella-zoster conjunctivitis is diagnosed clinically but cell cultures can be sent. EBV is diagnosed clinically as is CMV conjunctivitis. Variola and vaccinia conjunctivitis are diagnosed clinically but viral studies can be obtained if the diagnosis is in doubt. MC conjunctivitis is diagnosed by history and clinical exam. Diagnosis of AHC is based on clinical findings but cultures and PCR can be used to isolate the offending pathogen. Conjunctivitis from paramyxoviruses is diagnosed clinically. Togavirus and Flavivirus conjunctivitis are also diagnosed clinically.

Differential Diagnosis

Various conditions present with the appearance of an inflamed conjunctiva, not all of which are infectious. In addition to directly infectious etiologies, which may be bacterial, viral, fungal, or parasitic, the differential of an injected conjunctiva includes:

Immune modulated

- Allergic conjunctivitis
- Vernal keratoconjunctivitis
- Atopic keratoconjunctivitis
- Superior limbic keratoconjunctivitis
- Giant papillary conjunctivitis (often secondary to contact lens wear)
- Inflammation from adjacent structures (e.g., dacrocystitis and canaliculitis)
- Blepharoconjunctivitis
- Keratoconjunctivitis sicca

Trauma

- Floppy eyelid syndrome
- Mucous fishing syndrome
- Toxic papillary keratoconjunctivitis
- Chemical conjunctivitis
- Subconjunctival hemorrhage

Vacsular

- Ligneous conjunctivitis (deficiency in fibrinolysis)
- Lymphangioma (focal reddening may be associated with subconjunctival hemorrhage in a "chocolate cyst" formation)

Neoplastic

- Lymphoma (fleshy, salmon colored in appearance)

Prophylaxis

Prophylaxis is mandatory for contacts of patients with *N. meningitidis* conjunctivitis because of the risk of contracting or carrying the disease. This is accomplished by Rifampin 600 mg PO twice daily for 2 days for adults and a dose of 10 mg/kg for children.

Patients with acute viral conjunctivitis thought to be adenoviral in origin should be instructed in proper hygiene in order to avoid transmission to close contacts, as well as to avoid cross-contamination to the contralateral eye in unilateral cases.

Therapy

Hyperacute Conjunctivitis

N. meningitidis conjunctivitis is treated with 300,000 IU/Kg per day of penicillin administered IV or IM. Topical penicillin G 100,000 IU/mL per hour can also be prescribed. Gonococcal conjunctivitis is treated with a single IM dose of 1 g ceftriaxone followed by a one-time saline lavage of the conjunctiva. A single dose of 1 g of oral azithromycin or 100 mg of oral doxycycline twice a day for 7 days should also be given to treat concomitant chlamydial infection and reduce the risk of post-gonococcal urethritis and salpingitis (Krachmer et al. 2011). *N. gonorrhoeae* conjunctivitis in the newborn is treated with 25–50 mg/kg of IV or IM ceftriaxone administered in a single dose (not to exceed 125 mg) along with concurrent saline irrigation of the conjunctiva.

Acute Bacterial Conjunctivitis

Topical antibiotic therapy with broad spectrum antibiotic ointments or eye drops like trimethoprim/polymyxin B or fluoroquinolone drops q.i.d. for 5–7 days is given for acute bacterial conjunctivitis. *H. influenza* conjunctivitis is treated with oral amoxicillin/clavulanate (20–40 mg/kg/day in three divided doses) since it can be complicated by otitis media, meningitis, and pneumonia.

Chronic Bacterial Conjunctivitis

Chronic *staphylococcal* conjunctivitis often involves the lids, requiring long-term therapy. This includes lid hygiene, lid margin cleansing with mild baby shampoo diluted 50% with water, and the nightly application of bacitracin to the lid margins (good Gram+ coverage). For *chlamydial* conjunctivitis, azithromycin 1 g PO as a single dose, doxycycline 100 mg PO b.i.d., or erythromycin 500 mg PO, q.i.d., for 7 days is given to the patient and sexual partners. Topical erythromycin or tetracycline ointment b.i.d to t.i.d. for 2–3 weeks can also be prescribed. For trachoma, azithromycin 20 mg/kg PO single dose, doxycycline 100 mg PO b.i.d., erythromycin 500 mg PO q.i.d., or tetracycline 250 mg PO q.i.d. for 2 weeks is adequate (Gerstenblith and Rabinowitz 2012).

Viral Conjunctivitis

Viral conjunctivitis treatment and prevention involve avoiding touching the eyes, shaking hands, or sharing towels or pillows. Patients should frequently wash their hands. Single tip vials of preservative-free artificial tears four to eight times per day for 1–3 weeks can be used along with cool compresses several times a day. If there is itching, then epinastine 0.05% b.i.d. can be used as well. If membranes/pseudomembranes are present, then loteprednol 0.5% q.i.d. can be used, although for subepithelial infiltrates, a lower concentration of loteprednol 0.2% b.i.d. is often sufficient.

HSV conjunctivitis must be treated in neonates with both topical and intravenous acyclovir. In adults, treatment is mandatory when dendritic corneal lesions are present. 3% vidarabine or 3% acyclovir ointment for 10–14 days is prescribed. Oral acyclovir may also be given. VZV can be treated with ganciclovir 0.15% or vidarabine 3% ointment t.i.d. or q.i.d. EBV and CMV conjunctivitis are treated symptomatically. Vaccinia conjunctivitis is treated with ganciclovir 0.15% ophthalmic gel five times a day for 2 weeks. Vaccinia immune globulin 100 mg/kg IM or 6,000 units/kg IV is also given.

Molluscum contagiosum conjunctivitis lesions may be treated by unroofing and curettage,

although alternative therapies such as excision and cryotherapy have been utilized. Acute hemorrhagic conjunctivitis is treated symptomatically with cold compresses and artificial tears. For measles, Newcastle disease, and mumps conjunctivitis, no specific treatment is available. Rubella is treated with topical lubricants, while flavivirus conjunctivitis is treated symptomatically.

Prognosis

Hyperacute and acute bacterial conjunctivitis is almost always self limited. If properly treated, it lasts 1–3 days and if untreated it may last 10–14 days (Riordan-Eva and Cunningham 2011). *Staphylococcal* conjunctivitis is an exception as it may progress to blepharoconjunctivitis and enter a chronic phase. *Neisseria* infections can cause serious corneal damage. There can be rapid development of corneal haze and peripheral infiltrates followed by ulcerations of the cornea leading to corneal perforation. Patients with *N. meningitides* conjunctivitis are also at risk of developing meningitis and other systemic manifestations like septicemia.

Phlyctenular keratoconjunctvitis, corneal opacities, and marginal corneal ulceration may develop after *H. influenzae*, biogroup *aegyptius* conjunctivitis. URI, fever, malaise, otitis media, and meningitis may also be caused by *H. influenzae*.

S. aureus can cause a number of corneal complications including corneal epithelial punctate erosions and punctate keratitis. Marginal corneal infiltrates and ulcerations can frequently be seen near the limbus at the 4 and 8' o clock positions. Phlyctenules may also be seen (Krachmer et al. 2011).

Trachoma can lead to trichiasis and subsequent corneal scarring and opacity if untreated.

Viral conjunctivitis is a self-limited conjunctivitis and is worse in the first 4–7 days and usually resolves in 4 weeks. HSV conjunctivitis usually resolved within 2 weeks even without treatment. Ocular vaccinia is usually self limiting. MC conjunctivitis often resolves in 4–6 weeks. AHC is self limiting. In measles conjunctivitis, resolution of symptoms is seen in 3–5 days. Newcastle disease conjunctivitis resolves without sequelae in 7–10 days. Togavirus and flavivirus conjunctivitis are self limiting.

Epidemiology

The global burden of conjunctivitis is seen most strongly with trachoma, from which 8 million people are visually impaired and an estimated 84 million people with active disease require treatment to prevent blindness.

Conjunctivochalasis

Maria J. Suarez
Ocular Pathology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Conjunctival chalasis

Definition

Conjunctivochalasis (CCh) is a Greek term for "relaxation of conjunctiva" and was first described by Braunschweig on 1921 (Hughes 1942). It is an isolated condition that tends to be bilateral, and it is characterized by redundancy and laxity of the conjunctiva which typically affects the inferior bulbar conjunctiva, located between the globe and the lower eyelid (Liu 1986; Meller and Tseng 1998).

Etiology

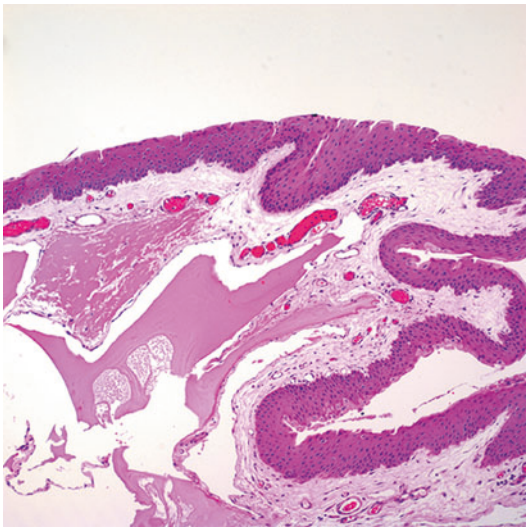
While the pathophysiology has not been entirely established, it has been often considered as a variation of normal aging and as a result of mechanical forces between the lower eyelid and the conjunctiva due to increased pressure of the lower lid margin. This continuous stimulus interferes with the lymphatic flow which, when chronic, may result in lymphatic dilatation and eventually, conjunctivochalasis (American Academy of Ophthalmology 2012) (Fig. 1).

Clinical Presentation

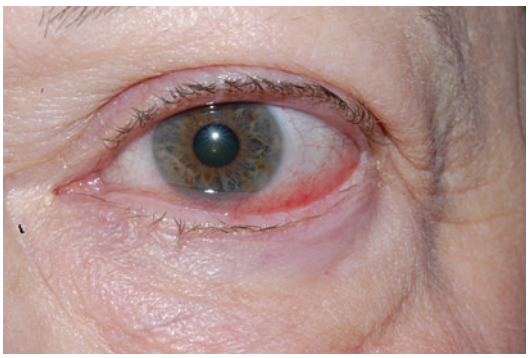
In general, this condition is asymptomatic. However, various clinical problems may present ranging from exacerbation of dry eye at mild stage due to impaired moisture of the extra conjunctival tissue, to tearing secondary to normal tear outflow disruption at the moderate stage, to interference with the inferior tear meniscus, and, less frequently, to occlusion of the lower punctum when this redundant conjunctiva is prominent medially. Subconjunctival hemorrhage might be present in patients with chronic inflamed fragile tissue or secondary to mechanical rubbing. Foreign body sensation and irritation can also be present.

Diagnosis

CCh diagnosis is based on clinical findings during slit-lamp examination and does not require



Conjunctivochalasis, Fig. 1 Conjunctivochalasis, left eye (should be the clinical photo)



Conjunctivochalasis, Fig. 2 Histologic findings in conjunctivochalasis; subepithelial lymphoplasmocytic infiltrate, Hematoxylin & Eosin, 40X

expensive equipment for further testing. In general, CCh lacks inflammatory signs, and fluorescein or rose Bengal staining tends to be negative. Nevertheless, chronic exposure of this loose conjunctiva may result in discrete or punctate staining in addition to localized mild chronic inflammatory changes seen on the redundant tissue, particularly, in the bulbar and tarsal conjunctiva (Fig. 2). Previous authors (Höh et al.) (Table 1) have suggested an objective and reliable system for grading CCh according to the number of folds and height of redundant conjunctiva in relation to the tear meniscus. However, these parameters may vary with age and downgaze. As a result, Meller and Tseng proposed a new grading system which includes the extension of CCh and gaze-dependent changes (Table 2). In this modified system, digital pressure is also considered as a factor in estimating the extent of severity since some patients due to previous surgeries may develop increased pressure and worsen CCh. However, no consensus in the diagnostic criteria has been established and remains subject of debate.

Conjunctivochalasis, Table 1 Grading of conjunctivochalasis by LIPCOF[a]

Grade	Number of folds and relationship to the tear meniscus height
0	No persistent fold
1	Single, small fold
2	More than two folds and not higher than the tear meniscus
3	Multiple folds and higher than the tear meniscus

[a]Modified from Höh et al.[7] with permission of the authors and ophthalmologe

Differential Diagnosis

CCh can be easily mistaken with other ophthalmological entities that also present with tearing and foreign body sensation such as allergy, keratoconjunctivitis sicca (KCS), trichiasis, ectropion, punctum stenosis, or any nasolacrimal obstruction. Systemic conditions including thyroid eye

Conjunctivochalasis, Table 2 Proposed new grading system for conjunctivochalasis[a]

Location	Folds versus tear meniscus height	Punctal occlusion	Changes in downgaze	Changes by gigital pressure
0	A	O+	G⇑	P⇑
1	B	O−	G⇔	P⇔
2	C		G⇓	P⇓
3				
0: none	A: < tear meniscus	O+ = nasal location with punctal occlusion	G⇑ = height/extent of chalasis increases in downgaze	P⇑ = height/extent of chalasis increases on digital pressure
1: one location	B: = tear meniscus			
2: two locations	C: > tear meniscus			
3: whole lid		O− = nasal location without punctal occlusion	G⇔ = no difference G⇓ = height/extent of chalasis decreases in downgaze	P⇔ = no difference P⇓ = height/extent of chalasis decreases on digital pressure

[a]The new grading system defines the extension of redundant conjunctiva as grade 1 = one location, 2 = 2 locations, 3 = whole lid. For 1 and 2, it is further specified as T, M, and N if conjunctivochalasis is found in the temporal, the middle (or inferior to the limbus), and the nasal aspect of the lower lid, respectively. For each location (T, M, and N), further notation is given to indicate if the height of folds is less than (A), equal to (B), or greater than (C) the tear meniscus height. If it is found in the nasal (N) location, the extent of chalasis is further determined as to whether it occludes the inferior puncta. For each location, it is further graded as G⇑ if its height is greater than, as G⇔ if equal to, and as G⇓ if less than the tear meniscus height. Likewise it is further graded as P⇑, P⇓, and P⇑ if it is worse, no difference, or better with digital pressure (P), respectively

disease, allergy, and dry eye including aqueous tear deficiency (ATD) can also present with similar symptoms.

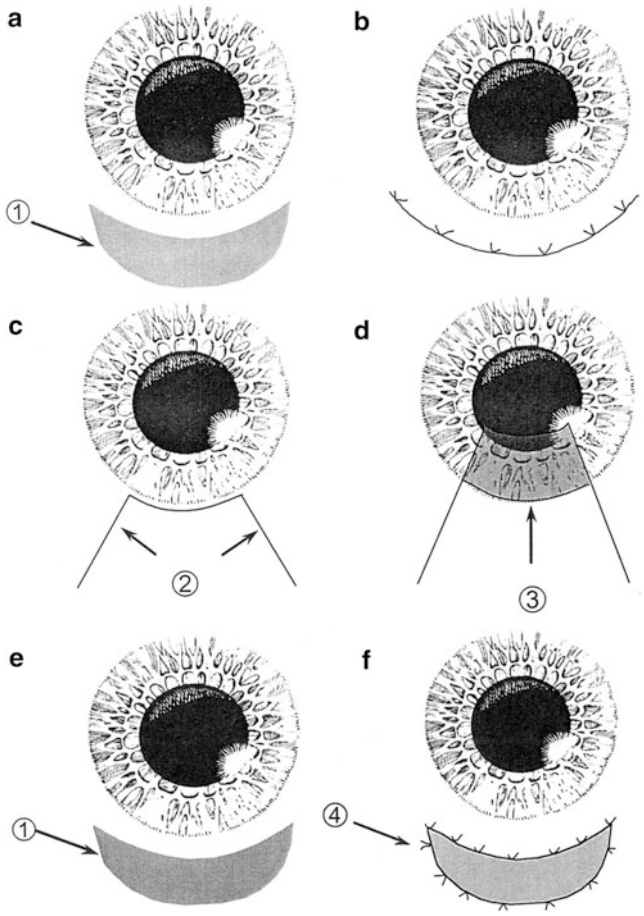
Prophylaxis

Since this condition is often related to aging and block of lymphatic flow, no specific alternatives to prevent it have been described.

Therapy

Asymptomatic CCh does not require treatment. Medical therapy with topical lubricants, anti-inflammatory, and antihistamines may be offered as treatment options for symptom relief. Night patching may be used when symptoms are more severe. When none of the above is effective regardless of patient compliance, surgical treatment becomes a definitive therapy. Surgical excisions of that loose conjunctiva or having it fixed to the sclera are current available approaches. Furthermore, cauterizations of the redundant tissue folds and amniotic membrane grafts have also been offered as treatment.

A variety of surgical techniques to excise the redundant conjunctiva have been described; the most commonly used is a simple crescent excision of the inferior redundant bulbar conjunctiva 5 mm away from the limbus (marked as 1 in Fig. 3a, e) and subsequent closure with absorbable sutures (Fig. 3b). Other authors have proposed a modified technique which includes a peritomy made close to the limbus (marked as 2 in Fig. 3c) as well as



Conjunctivochalasis, Fig. 3 Surgical excision techniques of redundant conjunctiva

two radial relaxing incisions to excise the redundant conjunctiva (marked as 3 in Fig. 3d). A recent modification to the above techniques to reduce the frequency of complications after surgery has been proposed. The use of amniotic membrane graft to replace the affected surface after conjunctival excision has been described (marked as 4 in Fig. 3f) (Meller and Tseng 1998).

Surgeons must be aware to perform careful excision and avoid aggressive resection regarding the technique to reduce rate of complications such as visible scarring, cicatricial entropion, and retraction of the lower fornix that may result in motility restriction and/or corneal problems. Other postsurgical findings including scar formation, suture-induced granulomas, and inflammation surrounding the amniotic graft have also been associated.

Prognosis

CCh is a benign condition that has an excellent prognosis.

Epidemiology

CCh is equally seen in men and women; it is well known to be a degenerative age-related condition and is most commonly seen in the elderly population.

Connective Tissue Disease

► Connective Tissue Disorder of the Cornea

Connective Tissue Disorder of the Cornea

Maanasa Indaram
Department of Ophthalmology, University of California San Francisco, San Francisco, CA, USA

Synonyms

Connective tissue disease

Definition

Connective tissue disorders refer to a family of more than 200 disorders that affect the biologic tissue that connects, binds, supports, or separates different types of tissues and organs in the body. These disorders can either be heritable, which is due to mutations in the genes responsible for the structure and development of these tissues, or they can be autoimmune, which is due to overactivity of the immune system resulting in the production of antibodies that attack the body's own tissues. Both hereditary and autoimmune connective tissue disorders can affect virtually every site in the body, including the skin, bones, blood vessels, heart, lungs, gastrointestinal tract, kidneys, and eyes (Long et al. 2013). More specifically within the eyes, connective tissue disorders have marked effects on the structure and function of the cornea. Ehlers-Danlos syndrome (EDS) type VI and Marfan syndrome are two common hereditary connective tissue disorders affecting the cornea, while numerous autoimmune connective tissue disorders do so as well, including rheumatoid arthritis, systemic lupus erythematosus (SLE), Behçet's disease, Sjogren's disease, scleroderma, granulomatosis with polyangitis, polyarteritis nodosa, and relapsing polychondritis (Wisenthal et al. 2013).

Etiology

Connective tissues contain three principle components: (1) fibroblasts or their counterpart in the cornea, the keratinocyte, (2) ground substance, and (3) fibrous elements comprised of the protein molecules elastin and collagen. Elastin is encoded by the ELN gene, is formed by cross-linked amino acids, and allows many tissues in the body to return to their original shape after stretching. Collagen, on the other hand, is encoded by 34 genes and consists of a triple helix of three amino acid chains. There are four types of collagen found in the body, and each differs from the other by their molecular composition. Type I is present in the corneal stroma, skin, bone, and tendon, type II in the cartilage, type III in the fetal skin and blood vessels, and type IV in basement membranes (Maumenee 1978).

Hereditary connective tissue disorders are transmitted in a simple Mendelian manner and have generalized defects in either collagen or elastin. Ehlers-Danlos syndrome is composed of more than 20 different types of disease, though EDS type VI, known as the ocular-scoliotic type, is the primary one affecting the cornea. It is inherited in an autosomal recessive manner and is secondary to a mutation in locus 1p36 (PLOD1), the gene-encoding lysyl hydroxylase, the enzyme necessary for the formation and stabilization of collagen. Marfan syndrome is inherited in an autosomal dominant manner and is caused by a mutation in locus 15q21.1 (FBN1), the gene-encoding fibrillin-1, a protein essential for the proper formation and maintenance of elastic fibers, including elastin (Kanski and Bowling 2011; Wisenthal et al. 2013).

Autoimmune connective tissue disorders may have both environmentally induced and genetically predisposing causes. As a group, they are characterized by an overactive immune system, one that produces antibodies directed against one's own tissues. These autoantibodies may directly target sites in the corneal epithelium, and they may also result in immune complex deposition in the peripheral cornea, which then recruits further inflammatory cells that release matrix metalloproteinases that degrade collagen and the extracellular matrix (Kanski and Bowling 2011).

Clinical Presentation

Ehlers-Danlos syndrome type VI is associated with many systemic changes, including the thin and hyperelastic skin that bruises easily, hypermobile joints, scoliosis, dissecting aneurysms, and diverticula of the gastrointestinal and respiratory tract in addition to ocular pathology including thinned blue sclera that may rupture easily and epicanthal folds. There are also several abnormalities specific to the cornea, such as microcornea, keratoconus, keratoglobus, and a brittle structure that may easily rupture with trauma (Kanski and Bowling 2011; Wisenthal et al. 2013). Marfan syndrome is also associated with many specific systemic features, including thin, tall stature with disproportionately long limbs, pectus carinatum or excavatum, arachnodactyly, kyphoscoliosis, high-arched palate, dilation of the aortic root, aortic aneurysm, and mitral valve prolapse, in addition to ocular features such as ectopia lens with superotemporal subluxation, cataracts, retinal detachment associated with lattice degeneration, hypoplasia of the dilator pupillae, strabismus, and glaucoma secondary to angle dysgenesis. Marfan syndrome too has many cornea-specific changes, including megalocornea, keratoconus, and cornea plana with excessive flattening in the 35 diopter range of the corneal curvature (Kanski and Bowling 2011; Wisenthal et al. 2013), or more than three standard deviations below normal values of the US population (Maumenee 1978).

Autoimmune connective tissue disorders manifest in the cornea as peripheral ulcerative keratitis (PUK). This occurs most commonly with rheumatoid arthritis but also systemic lupus erythematosus (SLE,) Behçet's disease, Sjogren's disease, scleroderma, granulomatosis with polyangitis, polyarteritis nodosa, relapsing polychondritis, and several more. While these conditions have many varied systemic presentations, PUK may be the first sign of an underlying systemic disease or may indicate exacerbations of systemic disease activity (Wisenthal et al. 2013). PUK usually presents unilaterally and limited to one area of the peripheral cornea; however, it may also be bilateral and extensive. The lesions, which

are characterized by a crescenteric area of absent epithelium and thinned underling stroma, appear within two millimeters of the limbus and are associated with vaso-occlusion of the adjacent limbal vasculature. They may also have significant cellular infiltrate into the corneal stroma as well as adjacent limbitis, episcleritis, or scleritis. In advanced cases, corneal perforation may occur (Kanski and Bowling 2011).

Diagnosis

Ehlers-Danlos syndrome can be diagnosed by the Beighton criteria, which use physical exam to assess the degree of joint hypermobility. Additionally, genetic testing for mutations in collagen genes, skin biopsies to evaluate hydroxylysine levels, and urine studies to detect an abnormal ratio of lysyl pyridinoline to hydroxylysyl pyridinoline may be used to confirm the diagnosis (Long et al. 2013; Wisenthal et al. 2013). The diagnosis of Marfan syndrome is made using the Ghent criteria, which require the detection of major and minor criteria in three body systems by physical exam and imaging or the detection of fibrillin-1 mutation by genetic testing (Long et al. 2013). Corneal manifestations of the ectasias seen in both Ehlers-Danlos type VI and Marfan syndrome may be found with slit lamp microscopy, keratometry, anterior segment ultrasound, and B-scan ocular ultrasound (Kanski and Bowling 2011; Wisenthal et al. 2013). The peripheral ulcerative keratitis seen in autoimmune connective tissue disorders may be diagnosed with slit lamp microscopy. Additionally, though not a standard diagnostic procedure, biopsy of conjunctival tissue adjacent to the corneal disease would show immune-mediated vaso-occlusive changes (Wisenthal et al. 2013).

Prophylaxis

There is no known prevention of the corneal dysgeneses seen in the heritable forms of connective tissue disorders, namely, Ehlers-Danlos and Marfan syndrome. However, control of underlying systemic disease with immunosuppression may play a role in preventing the peripheral ulcerative keratitis associated with autoimmune connective tissue diseases (Kanski and Bowling 2011; Wisenthal et al. 2013).

Therapy

Errors of refraction commonly arise from the abnormal corneal curvature seen in Ehlers-Danlos and Marfan syndrome. Thus, careful refraction and correction are necessary to prevent amblyopia in childhood and improve visual acuity throughout life. Because of the progressive nature of these diseases, refraction may need to be repeated biannually. Additionally, the significant astigmatism seen with these corneal ectasias can be addressed with frequent corneal topography and the use of rigid contact lenses (Maumenee 1978; Wisenthal et al. 2013). Specifically for the management of the brittle cornea seen in Ehlers-Danlos syndrome type VI, early diagnosis is key in order to prevent corneoscleral rupture. However, if this were to occur, patch grafts may be used for repair (Wisenthal et al. 2013). For Marfan syndrome, lens subluxation may be treated with cataract extraction and may require the use of advanced surgical techniques, such as capsular tension rings, scleral fixation, or pars plana lensectomy (Wisenthal et al. 2013).

The goal of therapy for peripheral ulcerative keratitis seen in autoimmune connective tissue disorders is to decrease corneal melting, and this may be achieved with topical lubricants or bandage contact lenses to improve wetting and promote epithelialization, topical antibiotics as prophylaxis against infection, and topical or oral anti-collagenase drugs such as oral doxycycline to slow corneal thinning (Kanski and Bowling 2011). Topical corticosteroids, however, have variable effects and should be used with caution with significant corneal thinning (Wisenthal et al. 2013). Additionally, systemic high-dose

steroids can be used to control acute disease, while cytotoxic or immunomodulatory immunosuppressive agents, such as cyclophosphamide, azathioprine, mycophenolate mofetil, and methotrexate, may be required for longer-term disease management (Kanski and Bowling 2011). Biologic medications, such as infliximab, have also been shown to have some benefit in more severe cases (Wisenthal et al. 2013). In cases that are refractory to the above medical management, PUK may be surgically managed with conjunctival excision, corneal gluing or amniotic membrane patching for perforations, or keratoplasty for more diffuse corneal involvement (Kanski and Bowling 2011).

Prognosis

The corneal manifestation of both Ehlers-Danlos and Marfan syndrome are lifelong conditions that may continue to progress with time. If refraction is at an early age and at frequent intervals to keep up with this progression, patients with the corneal ectasias seen in these diseases may have visual acuities that are correctable with simple spectacle or contact lens wear. EDS type VI patients with the severe brittle cornea, however, are at risk for corneal perforation, and as such, care must be taken when performing intraocular surgery on them (Kanski and Bowling 2011; Wisenthal et al. 2013).

Unlike the above chronic conditions, peripheral ulcerative keratitis seen in autoimmune connective tissue disease has a more waxing and waning course, often only manifesting when there is decreased control of the systemic disease process. Thus, if systemic autoimmune disease is controlled, patients often have less PUK flares and good visual outcomes. When active, if PUK is treated appropriately, visual prognosis is related to the severity of the involved cornea with more extensive involvement leading to possible scar formation. If treated inadequately, however, a high proportion suffers from keratolysis or significant and rapid stromal melting with perforation, a severe disease-related morbidity (Wisenthal et al. 2013).

Epidemiology

Ehlers-Danlos syndrome affects approximately 0.02% of the population, and EDS type VI or the ocular-scliotic type is exceedingly rare, with fewer than 60 cases reported (Jacobson et al. 1997; Long et al. 2013). Marfan syndrome also affects approximately 0.02–0.03% of the population, though ophthalmic manifestations, notably subluxation of the lens, are very common in these patients, occurring in 80% of them. All autoimmune connective tissue diseases affect approximately 8% of the population, 78% of whom are women (Jacobson et al. 1997).

Contact Dermatoblepharitis

Michael Greenwood and Atif Collins
Department of Ophthalmology and Visual Sciences, University Hospitals Case Medical Center, Case Western Reserve University, Cleveland, OH, USA

Synonyms

Allergic dermatitis; Contact dermatitis

Definition

Acute or chronic inflammatory reactions that occur after coming into contact with topical ophthalmic medications, cosmetics, systemic medications, or environmental substances.

Etiology

Systemic contact with a sensitizing agent or medicaments such as topical ophthalmic medications and cosmetics is very common (Peralejo et al. 2008). Any agent via a topical, cutaneous, oral, inhaled, intravenous, or environmental exposure can trigger a local allergic reaction. Industrial chemicals such as nickel, cobalt, and balsam of blue have also been implicated in systemic contact dermatitis. These agents cause an acute anaphylactic reaction or can be delayed 24–72 h. The acute reaction is from a type I IgE-mediated hypersensitivity reaction. The delayed reaction is due to a type IV T-cell-mediated hypersensitivity.

Clinical Presentation

The type I immediate hypersensitivity reactions typically occur within minutes after the first time being exposed to an allergen. This exposure results in itching, eyelid erythema and swelling, and conjunctival injection and chemosis. Instillation of topical anesthetics and antibiotics such as bacitracin, cephalosporins, penicillin, sulfacetamide, and tetracycline are common offenders. This often resolves spontaneously. Rarely, patients may have systemic anaphylaxis.

The delayed type IV hypersensitivity reactions usually occur 24–72 h following contact with the offending agent. These patients have often been sensitized to the offending agent from prior exposure. They experience an acute eczema with erythema, leathery thickening, and scaling of the eyelids. Other sequelae of chronic irritation include hyperpigmentation, dermal scarring, and lower eyelid ectropion. Papillary conjunctivitis and a mucoid or mucopurulent discharge may occur, in addition to punctate epithelial erosions (Suurmond 2009). Common medications include:

1. Cycloplegics (atropine, homatropine)
2. Aminoglycosides (neomycin, gentamicin, tobramycin)
3. Antivirals (idoxuridine, trifluridine)
4. Preservatives (thimerosal, ethylenediaminetetraacetic acid [EDTA], BAK)

Cosmetics deserve a special mention. Mascara and other products applied around the eyes have been reported for cases of allergic dermatitis. Mascara contains emulsifiers such as sodium borate and ammonium stearate, which can irritate the conjunctiva. Eye shadow makeup contains ditertiarybutyl hydroquinone, yellow D & C No. 11 dye, and diisopropanolamine. Nail polish can also cause contact dermatitis when the nails come into contact with the eyelids.

Diagnostics

Clinical exam
Patch testing to help identify the offending agent
Skin culture
Skin biopsy

Differential Diagnosis

Differential diagnosis includes vernal conjunctivitis, bacterial and viral conjunctivitis, cutaneous pemphigoid, and atopic disease.

Prophylaxis

Avoidance of offending agents.

Therapy

Identification and discontinuation of the offending agent are usually required. Most cases resolve with cool compresses and artificial tears. Adjunctive therapy includes topical antihistamines, mast-cell stabilizers, and nonsteroidal anti-inflammatory agents (NSAIDs). A short course of mild topical corticosteroids and topical tacrolimus can be applied to the eyelids and periocular skin as well. The use of topical vasoconstrictors can provide acute symptomatic relief, but should not be used long term (Sutphin et al. 2012–2013). An avoidance diet has also been shown to be effective in both adults and children (Matiz and Jacob 2011).

Prognosis

This is typically a self-limited condition and should resolve with discontinuation of the offending agents.

Epidemiology

Type I hypersensitivity reaction, occurs acutely.

Type IV hypersensitivity reaction, occurs 24–72 h after exposure.

Slight female predominance.

Contracted Socket

Robert J. Peralta[1], Gary Joseph Lelli[2] and Christopher Zoumalan[3]
[1]Department of Ophthalmology and Visual Sciences, University of Wisconsin Hospital and Clinics, Madison, WI, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[3]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA

Definition

Fibrosis of the anophthalmic socket with subsequent volume loss, mucosal lining deficit, and eyelid malposition resulting in varying degrees of disfigurement and the inability to maintain an ocular prosthesis.

Etiology

Socket contracture typically occurs following evisceration or enucleation, especially in the absence of an orbital implant, but can also occur in congenital anophthalmos. It may be more severe in cases of severe traumatic injury, previous reconstructive surgery, chemical burns (particularly alkali), radiotherapy, active cicatrizing conditions (Stevens-Johnson, ocular cicatricial pemphigoid), or chronic inflammation from an ill-fitting implant/prosthesis.

Clinical Presentation

Several classification schemes have been developed but none have gained wide acceptance. Recently a review by Tawfik et al. (2009) proposed the following:

Grade 1

Minimal or no contraction of the inferior and/or superior fornices with an inability to maintain an ocular prosthesis over time. Usually presents with horizontal lid laxity, associated entropion/ectropion, and shortened or prolapsed inferior fornix. Also includes patients with an oversized or displaced orbital implant.

Grade 2

Mild contracture of the inferior and/or superior fornices with an inability to maintain a prosthesis over time. May have associated eyelid malposition as in *group 1*.

Grade 3

More advanced scarring than *grade* 2 with near-complete contracture of the inferior and/or superior fornices. Inability to place a prosthesis.

Grade 4

Severe vertical and horizontal contracture of the palpebral fissure. Also includes cases of recurrence after reconstructive surgery and irradiated sockets.

Differential Diagnosis

Microphthalmos
Anophthalmos

Therapy

The basic goals of reconstruction are excision of fibrotic tissue and replacement of the lost conjunctiva with grafts or flaps. Vascularization of the orbit may be compromised due to scarring. Contraindications to socket rehabilitation include multiple failed attempts at reconstruction, extensive fibrosis, massive injury, and chronic infection. The presence of severe eyelid malposition may be a relative contraindication as an aesthetically acceptable result may not be attainable even after successful socket reconstruction.

Grade 1

A lower lid tightening procedure, i.e., lateral tarsal strip, may be sufficient to correct lower lid laxity. If inferior fornix prolapse persists, fornix-forming sutures may be required. In more advanced cases, posterior lamellar augmentation via spacer grafts may be beneficial. If shallowing of the fornix is due to an oversized or migrated implant, explanting and resizing of the implant are usually adequate.

Grade 2–3

Amniotic membrane or mucous membrane grafts may be used in mild to moderate cases of socket contracture. Amniotic membrane acts as a "substrate" in that it requires healthy adjacent conjunctival epithelium to migrate, differentiate, and multiply over the graft to repair the mucosal lining deficit. Advantages include wide availability, anti-fibroblastic properties, and the avoidance of donor site morbidity. Furthermore, recent studies show comparable efficacy to mucous membrane grafts. Mucous membrane is still a viable option and acts as a "substitute graft," obviating the need for healthy adjoining conjunctiva. Should a concomitant volume deficit be present, implantation of a

dermis fat graft may be more appropriate. Please refer to the chapter on *Dermis Fat Graft* for more information on this topic. After prosthesis fitting, associated eyelid malposition may then be corrected as described above.

Grade 4

The repair of the severely contracted socket is complex and often requires a multidisciplinary approach. Current options include radial forearm free flaps, thoracodorsal artery trilobed adiposal flaps, retroauricular fasciocutaneous flaps, and temporalis fascia flaps. Acquired orbital bony deformities should be concurrently repaired. C- or U-shaped osteotomies and bone grafts may be used to expand the orbit. Interestingly, one recent case report used a high-density polymethylene methylacrylate orbital expander, typically an approach used in the treatment of congenital anophthalmos, in an irradiated socket that had been deemed inoperable. After six seeks, the socket was completely epithelialized, and the fornices were sufficiently deep to accommodate a prosthesis.

Contrast Sensitivity

Oliver K. Klaproth
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Photometric contrast sensitivity

Definition

The contrast sensitivity represents the visual system's ability to detect differences in photometric brightness in the visual field (Bach et al. 2008).

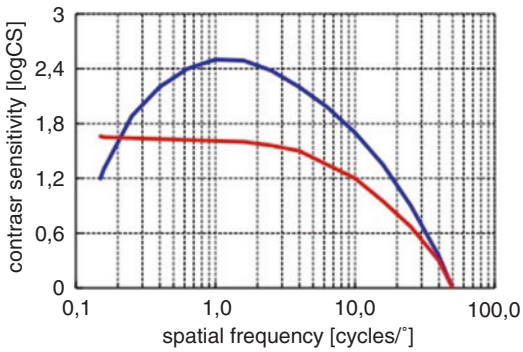
Basic Characteristics

Contrast is defined as a defined ratio of photometric brightnesses.

For the evaluation of CS, optotypes of the same size but with decreasing contrast are used. This contrast, used to characterize small objects in monochromatic surrounding area, is called Weber contrast. Formula 1 defines the respective ratio:

$$CSW = \frac{L_i - L_u}{L_u}$$

L_i is the optotypes photometric brightness [cd/m^2], whereas L_u is the photometric brightness of the surrounding area. Another option is to characterize contrast which changes progressively within the visual field. Respective optotypes can be Gabor patches, which display sinusoidal brightness distributions. This contrast is called Michelson contrast:



Contrast Sensitivity, Fig. 1 Contrast sensitivity function (CSF)

$$CSW = \frac{L_{max} - L_{min}}{L_{max} + L_{min}}$$

L_{max} is the maximum brightness and L_{min} is the minimum brightness. This concept has been derived from the fact that the visual system uses different channels for the detection of optotypes of different sizes. L of course depends on luminous intensity [cd] and thus on surrounding light conditions, which is why contrast sensitivity testing has to be performed separately for photopic and different mesopic conditions.

Contrast sensitivity is the reciprocal value of the smallest detectable photometric contrast (contrast threshold). If a contrast of 1 percent is noticeable, the CS is 100 or 2 log CS (10^2). Plotting CS as a function of object size/spatial frequency for sinusoidal patterns results in the contrast sensitivity function (CSF). The CSF shows that CS depends on object size and is rapidly decreasing for decreasing object size (Fig. 1). In reverse, for detection of small optotypes, a maximum contrast is needed. The smallest value of the CSF on the right end of the function represents visual acuity.

Contrast Sensitivity Function, General

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

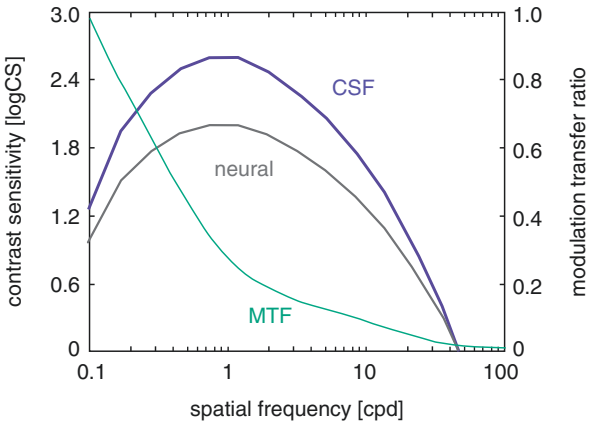
CSF

Definition

The function that characterizes contrast sensitivity as a function of spatial frequency (object size).

Basic Characteristics

The visual system's ability of recognizing objects of different contrasts is dependent from the size of the object. This ability – known as contrast sensitivity – is characterized by the contrast sensitivity function (CSF) (Richman et al. 2013). The CSF is a result of the modulation transfer function (MTF) that depicts the loss of contrast as a function of spatial frequency through a given optical system and the neural contrast sensitivity function (nCSF) that describes the contrast sensitivity of the neural component of the visual system (Fig. 1). The result of both functions is a bell-shaped curve for sinusoidal gratings and a flat-shaped curve for optotypes (Fig. 2). The CSF can be determined psychophysically either by measuring contrast thresholds at different spatial frequencies (optotype sizes) or by measuring visual acuity



Contrast Sensitivity Function, General, Fig. 1 Schematic drawing showing the relations between the contrast sensitivity function (*CSF*), the neural contrast sensitivity function (*nCSF*), and the modulation transfer function (*MTF*)

with optotypes of different contrast. While the CSF has typical values in normal subjects, there is a high interindividual variability.

Pathological conditions can affect the CSF and reduce contrast sensitivity. Aberrations, scatter, and diffraction decrease the MTF. Typical diseases in this group are cataract, corneal scars, keratoconus, and status post-refractive surgery. Other diseases such as optic neuropathies or neural diseases affect the nCSF.

Traditionally, the CSF is measured using sinusoidal gratings of different spatial frequencies. Nowadays, in clinical practice and for scientific purposes, often only parts of the CSF such as the (presumed) peak value are measured (Pelli et al. 1988; Rabin and Wicks 1996), although grating-based tests are still popular. The cutoff spatial frequency at maximum contrast equals visual acuity.

Cornea

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The cornea is the transparent front part of the eye that covers the iris, pupil, and anterior chamber consisting of highly specialized tissue. The difference of refractive indices between air and tear film/cornea renders the cornea the part with the highest dioptric power in the optical system of the eye (ca. 43 D). The average cornea is ca. 0.5 mm thick and consists of five layers (corneal epithelium, Bowman's layer, corneal stroma, Descemet's layer, corneal endothelium). The corneal epithelium is of ectodermal origin; the other layers are of mesodermal origin.

Cornea Farinata

Patricia Kalout and Roberto Pineda
Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Boston, MA, USA

Synonyms

Floury Cornea

Definition

This condition is characterized by fine, multiple, usually bilateral, punctate, and tan-to-white- or gray-white-colored dots localized in the deep central posterior stroma just anterior to Descemet's layer. The deposits can be visualized at the slit lamp and are visually asymptomatic. Ocular treatment is not necessary. The opacities are best visualized with retroillumination of the iris (Rapuano and Heng 2012).

Etiology

The cause is unknown, but the histophatology suggests that they are composed of a lipofuscin-like substance in stromal keratocytes (Yanoff and Duker 2014; Tratller et al. 2010). It was first described by Vogt in 1923 (Yanoff and Duker 2014; Durand et al. 1990). Cornea farinata may result from mutations (at least six) in the steroid sulfatase gene (STS), but they have not been correlated with the presence or absence of corneal abnormalities (Klintworth 2003).

Occurrence

Cornea farinata is a relatively common degenerative condition presenting in the cornea of elderly patients (Yanoff and Duker 2014; Rapuano and Heng 2012).

Classification

Corneal confocal microscopy can be used to help with classification of the disease differing it from deep filiform dystrophy, posterior punctiform dystrophy, punctuate dystrophy, pre-Descemet's dystrophy, and fleck dystrophy. These corneal dystrophies are all characterized by the presence of fine opacities at the posterior corneal stroma. In patients with cornea farinata, the superficial and mid-stroma layers are normal on confocal microscopy, and in the deep stroma can be found highly reflective small particles in the cytoplasm of

keratocytes. The endothelial cells and the Descemet's membrane are normal (Kobayashi et al. 2003).

Cornea Plana

Michael Coleman
Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

Cornea plana is a bilateral inherited disorder of the cornea which typically presents with a small flat cornea, hyperopia, and a shallow anterior chamber (Nischal and Sowden 2003; Gupta and Kim 2011).

Etiology

Cornea plana is an inherited disease which can be autosomal dominant (AD) or autosomal recessive (AR) (Gupta and Kim 2011). The genes localize to the long arm of chromosome 12 with mutations in the KERA genes being implicated (Gupta and Kim 2011). Many consider cornea plana and sclerocornea to be part of the same spectrum (Nischal and Sowden 2003).

It has been postulated that there is an absence of the limbal anlage (Nischal and Sowden 2003). The limbal anlage is the structure responsible for both limbal differentiation and corneal curvature. The formation of the limbal anlage occurs during the seventh to tenth gestational weeks and aids the differentiation of neural crest cells into either sclera or cornea (Nischal and Sowden 2003). This differentiation is critical because it allows the corneal curvature to exceed the scleral curvature. In the absence of the normal differentiation of the sclera and cornea, the corneal curvature is flattened.

Clinical Presentation

Two types of cornea plana exist: CNA1 is the less severe form which is usually inherited in an AD fashion and CNA2 is the more severe form which is usually AR (Nischal and Sowden 2003; Sugar and Wadia 2009; Gupta and Kim 2011). Patients classically present with flat corneas which have keratometry readings of less than 43 diopters, but some may have corneas as flat as 20 diopters. The recessive and dominant forms share clinical signs such as reduced corneal curvature, indistinct limbus, and arcus lipoides at an early age. In the autosomal dominant cornea plana, the corneal refractive power is reduced to 38–42 D, whereas in autosomal recessive cornea plana, corneal refractive power is reduced to 23–35 D. The anterior chamber is usually shallow, which can predispose patients to acute angle-closure glaucoma.

On clinical exam, patients can be both highly hyperopic or myopic, depending on the presence of other ocular abnormalities. Obscuration of limbal landmarks and peripheral scleralization of the cornea is usually present, which can make it difficult to distinguish from peripheral sclerocornea.

Cornea plana can be associated with other concurrent anterior segment abnormalities, including iris colobomas, congenital cataract, and occasional posterior segment colobomas (Nischal and Sowden 2003).

Diagnosis

Clinical evidence of corneal flattening without significant corneal opacification.

Differential Diagnosis

1. Sclerocornea
2. Microcornea
3. Posterior embryotoxin
4. Glaucoma
5. Peter's anomaly

Therapy

Management consists of cycloplegic refraction and correction of refractive error, as well as close follow-up for glaucoma surveillance (Nischal and Sowden 2003; Gupta and Kim 2011).

Prognosis

The prognosis is variable. Vision may be limited by amblyopia, glaucoma progression, or other congenial ocular malformations.

Epidemiology

Rare, it was first described by Rubel in 1912 as congenital familial flatness of the cornea. Many of the first families were from Finland, but since then families of Chinese, Saudi Arabian, and British origin have been described.

Cornea Verticillata

Xiaolin Zhang[1] and Rony R. Sayegh[2]
[1]University Hospitals, Case Medical Center, Cleveland, OH, USA
[2]Department of Ophthalmology, University Hospitals, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Synonyms

Cornea verticillata of Fleischer; Hurricane keratopathy; Vortex keratopathy

Definition

Corneal epithelial pigmented deposits in a linear whorl-like pattern.

Etiology

Cornea verticillata can be drug induced or a manifestation of Fabry disease. In drug-induced cornea verticillata, the underlying pathology is attributable to the diffusion of amphiphilic medication into cell lysosomes. Once within lysosomes, the drug binds phospholipids preventing their enzymatic degradation and leading to an accumulation of lysosomal inclusions within corneal epithelial cells. Similarly, in Fabry disease, an X-linked disorder of reduced alpha-

galactosidase A activity, trihexosylceramide accumulates and forms lysosomal inclusions within corneal epithelial cells (Hollander and Aldave 2004). Shearing forces from the upper lid result in preferential loss of corneal epithelial cells at the apex, thus stimulating the centripetal migration of lysosomal deposit-laden limbal epithelial cells to the central cornea. This forms a whorl of lines extending from the limbus to the center in a curving, clockwise pattern. The lines have a clockwise predisposition due to the ocular electromagnetic field's influence on migrating epithelial cells (Dua et al. 1996). These lines concentrate in the inferior cornea just below the limit of excursion of the upper lid.

Clinical Presentation

Cornea verticillata is typically an incidental finding and is asymptomatic. Rarely, patients may notice haloes. Findings are usually bilateral and located inferiorly. The epithelial deposits appear as grayish or golden-brown opacities that branch out from a central whorl. In patients with drug-induced corneal verticillata, a history of taking an amphiphilic drug such as amiodarone, chloroquine, indomethacin, and phenothiazines is usually present (D'Amico et al. 1981). In patients with Fabry disease, other systemic manifestations such as pain (acroparesthesia), kidney failure, cardiomyopathy, and skin angiokeratomas are usually present. Females can show a wide range of clinical manifestations, although symptoms are typically less severe and of later onset than hemizygous males (Deegan et al. 2006).

Diagnosis

Patients have a history of amphiphilic medication use or signs of symptoms of Fabry disease, which can be diagnosed by an enzyme assay to measure level of alpha-galactosidase activity. Slit-lamp examination shows characteristic corneal epithelial deposits in a vortex-like pattern. Recently, confocal laser scanning microscopy has been used to characterize and differentiate the deposits in Fabry and drug-induced corneal verticillata (Falke et al. 2009). It was also helpful in detecting corneal changes in Fabry disease prior to their appearance on slit-lamp biomicroscopy and in monitoring the response to treatment.

Differential Diagnosis

- Striate melanokeratosis (seen in black individuals with heavy limbal pigmentation after corneal epithelial injury)
- Epithelial iron lines
- Stromal deposits (gold, silver, retinoid depositions)
- Adrenochrome deposits in the cornea

Prophylaxis

None.

Therapy

There is no recommended treatment for drug-induced corneal verticillata, and the offending medication is typically not stopped based on the presence of these deposits. However, in rare cases, if patients are symptomatic, the medication can be stopped. Keratopathy can take months to resolve after cession of medication. Fabry disease is treated with enzyme replacement therapy.

Prognosis

Excellent with no visual involvement in most cases. When the inciting drug is stopped, most cases of corneal verticillata eventually fade away.

Epidemiology

Corneal verticillata is present in 69–100% of patients taking amiodarone (Hollander and Aldave 2004). The duration and dosage of drug ingestion correlate with the degree of cornea

involvement (D'Amico et al. 1981). The prevalence of cornea verticillata in Fabry disease varies between 44% and 94.5% in men and 88% in women (Falke et al. 2009). It is found in 70–80% of heterozygous female carriers.

Corneal Ablation

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Keratectomy; Keratomileusis

Definition

Corneal ablation is the removal of tissue over a defined region using a laser, typically an excimer laser.

History

In the 1980s Steven Trokel investigated the use of the excimer laser to remove fine layers of corneal tissue for the correction of ametropia. Excimer lasers emit light in the UV range. In contrast to many lasers in the visible range such as the argon laser, the excimer laser does not induce thermal effects on the tissue but disrupts the molecular bonds leading to a disintegration ("vaporization") of surface tissue with minimal collateral damage. This characteristic allowed a novel type of extremely precise (µm range) and highly reproducible tissue engineering, the excimer laser ablation. The classical domain of the excimer laser is corneal refractive surgery; however it has been used in keratoplasty in the pre-femtosecond laser era (Seitz et al. 1999). Excimer ablations have also been performed for trabecular meshwork surgery (Wilmsmeyer et al. 2006). Besides living tissue also materials (e.g., poly(methyl-methacrylate) (PMMA)) can be treated with excimer lasers. The use of solid-state lasers instead of (gas-based) excimer lasers is still experimental.

Clinical Features

The surgical-technical performance of a laser ablation requires a specially adapted laser

(excimer laser). The laser beam is delivered using a system of mirrors and apertures for correctly shaping the ablation. An eye tracker system guarantees the ablation taking place exactly at the planned location. The procedure itself is short. The ablation time varies from a few seconds to more than a minute and depends from the number of pulses and from the repetition rate of the laser. Modern excimer lasers have a frequency of up to 750 Hz. The ablation causes only negligible thermal effects but fumes that need to be removed from the operation area. After first-generation photorefractive keratectomy (PRK) procedures, the ablated area could be identified by diffuse whitish scar tissue (haze). In modern corneal excimer refractive surgery, the ablation zone can only be identified using corneal topography.

Tests

The effects of corneal ablation can be checked with pachymetry and, more precisely, with corneal topography and aberrometry. Particularly corneal topography allows visualization over magnitude and centration of the ablation zone on the cornea. There are different concepts of a closed-loop excimer corneal ablation. Real-time interferometry allows monitoring the change of corneal shape during the ablation procedure (Schruender et al. 2002). Optical coherence pachymetry (OCP) continuously measures central corneal thickness (Wirbelauer and Pham 2004). While the interferometric approach did not emerge from an experimental stage, some laser platforms are offered with an OCP unit. For the investigation of wound healing effects after excimer laser ablation, confocal in vivo microscopy is the method of choice.

Corneal Arcus

Aazim A. Siddiqui[1] and Allen O. Eghrari[2,3]
[1]Imperial College London School of Medicine, South Kensington Campus, London, UK
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[3]Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Anterior embryotoxon; Arcus juvenilis; Arcus senilis; Gerontoxon

Definition

Corneal arcus represents a degenerative process of lipid deposition in the peripheral cornea. It is characterized by a circumferential gray-white or yellow band within the corneal stroma, Bowman's

membrane, and Descemet's membrane, with the sparing of corneal epithelium.

Arcus often begins in the inferior, then superior perilimbal cornea, and eventually coalesces to form a complete ring 1 mm in width. A 300 μm wide clear zone separates its peripheral border and the limbus, a space known as the "lucid interval of Vogt." This interval may be due to lipid reabsorption by limbal vasculature; rarely, it may undergo mild thinning and develop into senile furrow. The arcus has a sharp peripheral border ending at the edge of Bowman's membrane and a diffuse central border which may show crossing dark lines of reduced lipid deposition. The arcus is densest and widest superiorly. It is almost always bilateral but may be asymmetric with decreased arcus secondary to ipsilateral carotid vascular disease or increased arcus in association with chronic hypotony.

Histology reveals lipid concentration within anterior and posterior stroma organized in an "hourglass" pattern. This arrangement extends into the corneal stroma from Bowman's and Descemet's membranes. Deposits initially occur in the deep stroma and later superficially, with least density in the mid stroma (Agarwal et al. 2002; Cavallotti and Cerulli 2008; Kanski and Bowling 2011; Krachmer et al. 2011; Yanoff and Duker 2013).

Etiology

In corneal arcus, deposits are made up of cholesterol, cholesterol esters, phospholipids, and neutral glycerides. The predominant lipid consists of extracellular cholesteryl ester-rich particles. Initial deposition forms as a double lamina in the anterior layers of Descemet's membrane. It then deposits and remains within Bowman's membrane without further progression. In advanced stages, deposition may occur between the stromal lamellae, with sparing of the limbus.

Formation of the corneal arcus is related to increasing age, proximity of blood vessels to the peripheral cornea, increased vessel permeability, and hypercholesterolemia, particularly in association with low-density lipoprotein (LDL). The permeability of limbal vessels increases with age. This allows LDL to pass into the corneal stroma from limbal capillaries. In the presence of elevated circulating LDL, the tight junctions formed by the endothelium of limbal vasculature may become dysfunctional. This may also contribute to the passage of vascular LDL into the cornea. The accumulating LDL may transform into a modified LDL and apolipoprotein B. Corneal arcus and atherosclerosis are both related to the level of LDL in the plasma.

Corneal deposits may also occur as a result of rare genetic disorders of high-density lipoprotein (HDL) metabolism. These include lecithin cholesterol acyltransferase (LCAT) deficiency (Norum disease), fish-eye disease, and Tangier disease. These diseases may manifest at an early age and cause corneal clouding which may affect visual acuity. Corneal arcus is also associated with osteogenesis imperfecta type I, Schnyder crystalline corneal dystrophy, myxedema, and Bassen–Kornzweig syndrome (abetalipoproteinemia) (Kanski and Bowling 2011; Krachmer et al. 2011; Yanoff and Duker 2013).

Occurrence

Corneal arcus is the most common of the corneal degenerations. In men, it occurs with increasing frequency between 40 and 80 years of age, affecting 90% of men between 70 and 80 years of age, and nearly 100% of men older than 80 years of age. A similar pattern is seen in women, with a delay of approximately 10 years. Occurrence is also associated with ethnicity; persons of African descent develop arcus most frequently and at a younger age than individuals of other racial origins.

Although arcus senilis generally has no visual significance, premature formation (arcus juvenilis) can be associated with hypercholesterolemia,

particularly in men under 50 years of age. Young patients with arcus have an increased risk for type IIa and less commonly for type IIb hyperlipoproteinemia, but a decreased risk for type IV hyperlipoproteinemia. In addition to corneal arcus, these patients may have systemic signs such as xanthelasma. Men with arcus juvenilis also have a fourfold increased relative risk of mortality from coronary heart disease and cardiovascular disease. Patients with corneal arcus under 50 years of age should undergo lipid profile and cardiovascular evaluation. Corneal arcus in older patients does not correlate with mortality, including those with diabetes.

Arcus juvenilis may also occur in children with familial hyperlipoproteinemia, megalocornea, keratoconus, atopic or vernal keratoconjunctivitis, osteogenesis imperfecta, or blue sclera (Cavallotti and Cerulli 2008).

Classification

Corneal arcus is given different designations based on the age of presentation. Arcus senilis or gerontoxon refers to corneal arcus in the aging population of older than 50 years of age. Arcus juvenilis or anterior embryotoxan occurs in individuals younger than 50 years of age and is primarily due to hyperlipidemia.

Similar lipid deposition may occur in the perilimbal sclera overlying the ciliary body; this may be considered to be a lipid keratopathy rather than corneal arcus (Krachmer et al. 2011).

Corneal Astigmatism

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

General: astigmatism

Definition

The term corneal astigmatism describes different corneal curvatures along two orthogonal meridians. It is a result from anterior and posterior surface astigmatism. In most cases, a small amount of corneal astigmatism (ca. 1 D) is present with the steep axis at 90° (astigmatism with the rule). This corneal astigmatism is compensated for by lenticular (internal) astigmatism with the steep axis at 0°. Corneal astigmatism can be visually significant if its magnitude exceeds the magnitude of compensating internal astigmatism. Corneal astigmatism can be very high in cases of keratoconus and after penetrating keratoplasty.

Corneal Collagen

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Corneal protein fibrils

Definition

Fibrous protein of the cornea.

Structure

Collagen molecules in the corneal stroma form triple-helix collagen fibers; arranged in bundles, these collagen fibers form collagen lamellae. There are at least 12 types of collagen present in the cornea, the most commonly found being type I (Gipson et al. 2005).

Function

Corneal transparency and biomechanical properties depend on and are maintained by the ordered alignment of its collagen fibrils, which are arranged in parallel, thus forming the scaffolding of the cornea (Maurice 1957). In the posterior two thirds of the human cornea, collagen lamellae are found in the plane of the cornea stretching from limbus to limbus with some degree of anteroposterior interweave. At the limbus, the collagen fibrils follow a circular course, while in the anterior stroma, a considerable anteroposterior interweave is found (Morishige et al. 2011).

Collagen makes up 71% of the dry weight of the cornea (Gipson et al. 2005).

Clinical Relevance

In the cornea, collagen is present in the epithelial and endothelial basement membranes, the Bowman's layer, and the stroma. The organization of corneal collagen is key to the maintenance of corneal curvature. Keratoconus, in which the corneal shape is compromised, is known to be associated with the displacement of the axes of the collagen fibrils (Meek et al. 2005).

Corneal Degenerations

Saeed Alwadani
Departmeny of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Definition

Corneal degenerations are a group of sporadic and age-related corneal conditions that are present in previously normal corneal tissue and occur most often near the limbus.

Basic Characteristics

Degenerative corneal processes are characterized by secondary changes in previously normal corneal tissue. Compared to corneal dystrophies, degenerative processes are not inherited, usually affect more than one corneal layer, and are asymmetric, unilateral, and usually peripheral. Often corneal degeneration is associated to neovascularization and inflammation.

There are many corneal degenerative conditions including Salzmann's nodular degeneration, calcific band keratopathy, lipid keratopathy, actinic keratopathy, pannus, and bullous keratopathy.

Corneal Diameter

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

White-to-white distance

Definition

Horizontal measurement across the cornea.

Structure

At birth, a normal human cornea measures 10 mm in horizontal diameter, whereas the size of a normal adult cornea measures approximately 12 mm horizontally, practically always exceeding the vertical diameter. Adult corneal diameter is reached at 2 years of age (Velazquez 2005; Friedman 2007).

Function

To rule out disorders associated with anomalies of the size and shape of the cornea such as buphthalmos in children and to assess biometrical parameters of the anterior chamber prior to intraocular surgery.

Measurements can be performed with a variety of devices such as partial coherence laser interferometry or optical coherence tomography.

Clinical Relevance

Corneal diameter measurements are of importance in disorders such as microcornea,

megalocornea, buphthalmos, and other corneal dystrophies.

Preoperative WTW distance is required in choosing an intraocular lens (IOL), as the calculation of an optimally sized angle-fixated anterior chamber IOL or sulcus-supported posterior chamber IOL depends on horizontal WTW (Velazquez 2005).

Iridocorneal endothelial syndrome (ICE)
Fuchs endothelial corneal dystrophy (FECD)
Posterior polymorphous dystrophy (PPMD)

Definition

Inherited corneal diseases with a spectrum of findings and symptoms secondary to the location of the pathology.

Basic Characteristics

With rare exception, corneal dystrophies are bilateral, relatively symmetric, genetic conditions in which the pathology appears to be localized to ocular tissue. Dystrophies may be classified according to genetic pattern, severity of disease, histopathology, biochemical characteristics, or anatomical location. One of the most commonly employed classification systems is stratification according to the involved levels of the cornea:

anterior or superficial, stromal, and endothelial. A new classification system, IC3D classification of corneal dystrophies, was published in 2009 and combines traditional nomenclature with evolving genetic and clinicopathologic data. Specific symptoms, findings, and management of corneal dystrophies are dictated by the location and the progression of the pathologic findings.

Corneal Ectasia

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Keratectasia; keratoectasia

Definition

A progressive thinning of the corneal stroma with subsequent increase of corneal curvature and induction of higher-order aberrations (HOA) due to irregular astigmatism. The origin of corneal ectasia can be a degenerative disease (keratoconus, pellucid marginal degeneration (Rabinowitz 1998)), a congenital anomaly (keratoglobus), or a mechanical trauma such as surgery (iatrogenic keratectasia (Seiler et al. 1998)). Ectasia due to other reasons (infection) is rare.

Histology

In all ectatic diseases, a stromal thinning can be observed. A recent histological study showed that

ruptures in Bowman's layer that are typical for keratoconus (KC) were absent in eyes with iatrogenic keratectasia (IK) (Meghpara et al. 2008). Immunohistochemical examinations revealed different expression patterns of α_1-proteinase inhibitor and matrix metalloproteinases (MMP) in KC and IK eyes. KC showed lower levels of α_1-proteinase inhibitor and higher levels of MMP-1 compared to normal eyes. Expression patterns in IK eyes were similar to those in normal eyes. These discrepancies suggest that KC and IK are two different entities.

Newer studies applying second harmonic imaging showed that in KC corneas the collagen lamellae in the anterior stroma were less interweaved, and there were less lamellae inserting into Bowman's membrane (Morishige et al. 2007).

Molecular Diagnostics

There are no valid molecular diagnostics available at the moment.

Electron Microscopy

In KC eyes, epithelial cells showed signs of degeneration and accumulation of ferritin (Fleischer's Ring). In the stroma, a reduction of collagen lamellae and deposits beneath the keratocytes can be detected. Also in Descemet's layer, ruptures were found (Vogt's Striae). In IK eyes, collagen fibril thinning and decreased interfibril distance were observed in the stromal bed.

Differential Diagnosis

The most important criterion for an ectatic disease is – by definition – a progressive thinning. In the early stage, all ectatic diseases are difficult to detect without corneal topography and optical pachymetry. Secondly, the differential diagnosis between different corneal ectatic diseases has to be made (e.g., KC vs. pellucid marginal degeneration).

Corneal Guttata

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Definition

Corneal guttae are extracellular matrix excrescences in Descemet's membrane. The name gutta comes from Latin meaning "drop," and guttata is the adjective used to describe "drop-like." They resemble dewdrops on slit lamp examination and appear either as mushroom or as flat anvil profiles on histology preparations.

Etiology

It is believed that corneal guttae are the result of stressed or abnormal endothelial cells. These cells produce focal collagen accumulations that appear on the posterior surface of Descemet's membrane. The Descemet's membrane of the cornea is made of type IV collagen and has anterior banded and posterior nonbanded portions. This nonbanded portion may not be present in diseases like Fuchs dystrophy as the abnormal endothelial cells produce 110° banded portions (Vanmeter et al. 2013). This production of banded collagen is focal and is thought to be the cause of corneal guttae and Hassel-Henle warts (Vanmeter et al. 2013). Initially, guttae begin very small and are first seen on specular microscopy. Eventually, they grow and fuse together thus forming larger guttae and give the cornea a characteristic "beaten metal" appearance on slit lamp exam. These guttae disrupt the normal, orderly hexagonal mosaic of endothelial cells, which leads to increased size and irregularly shaped endothelium with a greater proportion of tetragonal and octagonal cells (Giasson et al. 2007; Weisenthal and Streeten 2011). This formation in the Descemet's membrane leads to endothelial cell dysfunction. This dysfunction can increase to cause edema and eventually clouding of vision (Giasson et al. 2007).

Occurrence

The finding of cornea guttae can be relatively common. They can be characteristic of a normal aging cornea and are found in the 6th, 7th, and 8th decades of life at rates of 6%, 12%, and 29%, respectively (Hillenaar et al. 2012). While the genetic basis and environmental factors have not been fully understood, there is geographic variation in guttae prevalence and differences among sexes (Giasson et al. 2007). Females have a frequency of guttae 2.5 times that of males in the setting of Fuchs dystrophy (Weisenthal and Streeten 2011). Smokers with a >20 pack-year smoking history also have over double the risk of corneal guttata (Zoega et al. 2006). Interestingly, higher body weight is associated with a lower risk of guttae (Giasson et al. 2007).

Cornea guttae are most known for their association with Fuchs dystrophy, but are not specific to the disease. However, guttae can also be seen in posterior polymorphous corneal dystrophy (PPCD), macular corneal dystrophy, and interstitial keratitis (Giasson et al. 2007; Weisenthal and Streeten 2011). There also are corneal pseudoguttae, which appear transiently during underlying trauma, infection, or inflammation (Weisenthal and Streeten 2011).

Guttae occur centrally. In this central region, the median surface area and number of guttae are the largest (Giasson et al. 2007). As the disease progresses, the guttae will appear centrally, but also spread to the periphery. Guttae of diseases like Fuchs dystrophy can often be confused with

Hassal-Henle warts. Hassal-Henle warts are degenerative changes seen in the periphery of normal adult corneas. That is in contrast to corneal guttata, which appears more centrally. Like corneal guttae seen in Fuchs dystrophy, Hassal-Henle warts are also found in the Descemet's membrane. Hassal-Henle warts do not have an association with endothelial cell function or corneal edema (Zoega et al. 2006).

Classification

Guttae are not classified, but the presence of guttae is important to the classification of the pathology they appear with. Cornea guttae are first seen in stage 1 of Fuchs dystrophy and are one of the earliest signs detectable on slit lamp examination. They often appear before symptoms occur. This early sign is important as corneal guttae represent corneal pathology and lowered endothelial cell function.

It is the presence of corneal guttae that is important in the evaluation of surgery. Ten years post cataract surgery, there is a rate of endothelial cell loss that is nearly 3 times greater for those with guttae preoperatively (Giasson et al. 2007). This lowered endothelial cell count can lead to cornea decompensation after cataract or other procedures that may damage the cornea. The risk for postoperative degeneration is greatest in those patients with thickened corneal stroma greater than 640 640 µm mu;m and with the presence of guttae (Vanmeter et al. 2013). Guttae are also important not only in the patient's eye but also in donor corneas. Interestingly, there is no difference in survival time of donor corneas with isolated guttae, but donor corneas with grouped guttae have a decreased survival time (Giasson et al. 2007).

Corneal Intraepithelial Neoplasia

Tin Yan Alvin Liu
Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD, USA

Definition

An abnormal cellular growth process within the epithelial layer of the cornea, characterized by changes that range from localized neoplastic proliferation to carcinoma in situ. Within the lesion, various histopathological abnormalities including but not limited to cellular pleomorphism, increase in mitotic figures, decrease in desmosomal attachments, loss of hemidesmosomes, and suprabasal mitoses can be seen (Waring et al. 1984).

Corneal Patching

Shahram Bamdad[1], Ali Azimi[2] and Siamak Zarei-Ghanavati[3]
[1]Poostchi Ophthalmology Research Centre, Shiraz University of Medical Sciences, Shiraz, Iran
[2]Department of Ophthalmology, Shiraz University of Medical Sciences, Shiraz, Iran
[3]Mashhad University of Medical Sciences, Mashhad, Khora san-Razavi, Iran

Synonym

Eye patch; Ocular pressure patch

Definition

Corneal patching refers to closing the eyelids and putting a pressure patch on the eye. It can be done unilaterally or bilaterally according to the rational for corneal patching. Before corneal patching, it is imperative that there not be any intracorneal foreign bodies.

Overview

Corneal patching is one of the methods used to treat corneal abrasions, either after trauma or in spontaneous cases due to dry eye, recurrent erosion, or neurotrophic conditions. Patching can be used in patients with seven nerve palsy or other causes of corneal exposure, both as prophylaxis and treatment of corneal epithelial injury.

Generally, after 24 h of corneal patching, healthy corneal epithelium will be renewed and the signs and symptoms of the patient related to the abrasion will improve (Fraser 2010).

Advantages and Disadvantages

Patching an eye following a corneal abrasion improves healing and also provides pain relief. Reepithelialization is associated with decreased risk of superimposed infection. Corneal patching may be more effective for large abrasions as smaller abrasions may promptly resolve with less occlusive treatment. Some abrasions may benefit from patching beyond 24 h; however, close follow-up must be maintained, and repatching should only occur after a slit-lamp examination to ensure improvement of the abrasion and the absence of infection.

Caution must be exercised in cases of trauma and contact lens wear, since patching may promote infection. If there is any question of exposure to vegetative material, corneal patching should be avoided. A further consideration is that patching abolished binocular vision, although in the context of a painful abrasion, is likely less of an issue.

Some ophthalmic surgeons prefer to patch the eye for 1 day before using topical medications after intraocular surgeries (Turner and Rabiu 2006; Flynn et al. 1998).

Outcome

The most important outcome of corneal patching is acceleration of epithelial healing, which is associated with decreased pain, increased vision, and decreased rates of injection (Flynn et al. 1998; Wilson and Last 2004).

Indications (Skuta et al. 2010–2011)

The most common indications of corneal patching are:

1. Large corneal abrasions especially due to trauma
2. Persistent epithelial defects
3. Early postoperative treatment after intraocular surgeries
4. Dellen
5. Neurotrophic lesions
6. UV keratitis

Contraindications

Whenever we are suspicious to the presence of infection or the cause of abrasion increases the risk for infectious keratitis, corneal patching should not be done. The contraindications are:

1. The presence of any sign of globe rupture
2. The presence of infiltration in the cornea
3. The presence of corneal foreign body (the corneal foreign body should be removed before patching to diminish the risk of infection)
4. Corneal abrasions that are made by contact lens (before doing corneal patching take the history of contact lens wear)
5. Corneal abrasions due to vegetative injuries (high risk for fungal infection)

Technique

1. Apply topical medications, such as cycloplegic agent and antibiotics.
2. Apply with moderate pressure one to two eyepads on the eye and affix with tape.

Caution the patient on limiting activities, including driving, and stress the importance of prompt follow-up within 24 h.

[1]Dalhousie Medical School, Dalhousie University, Halifax, Nova Scotia, NS, Canada
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[3]Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Definition

Corneal pigmentation refers to discoloration of the cornea at any of its layers.

Etiology

Pigmentations of the cornea may occur with or without ocular or systemic disease (Biswell 2011). Multiple different forms of corneal pigmentation may be encountered; the most common etiologies include local or systemic exposure to metals and medications. Deposition may occur anteriorly from the tear film, peripherally through vasculature (in arcus), or posteriorly (through the aqueous) (Naumann and Apple 1986; Khurana 2007; Biswell 2011).

Occurrence

Iron deposition: iron deposition in the cornea may occur in significant quantity to become clinically visible. This generally involves epithelial uptake of iron from the tear film and therefore correlates with lid position and tear film stasis on the ocular surface (Khurana 2007; Biswell 2011).

The *Hudson-Stahli line* is a horizontal line of deposited iron in the corneal epithelium at the junction of the upper two-thirds and the lower one-third of the cornea. This location corresponds to the line of lid closure. The Hudson-Stahli lines are a normal variant with age (Naumann and Apple 1986; Biswell 2011).

Ferry's line is iron deposition in the corneal epithelium adjacent to a filtering bleb (Khurana 2007; Biswell 2011).

Fleischer's ring is iron deposition in the corneal epithelium surrounding the base of the cone in keratoconus (Khurana 2007; Biswell 2011).

Stocker's line is iron deposition in the corneal epithelium sometimes seen anterior to the advancing head of a pterygium (Naumann and Apple 1986; Biswell 2011).

Siderosis occurs from a foreign body iron deposition in the cornea, mostly in the stroma. Siderosis bulbi refers to degenerative changes produced by an iron foreign body. Siderosis bulbi usually occurs after 2 months to 2 years of foreign body deposition (Khurana 2007).

Coat's white ring is an iron deposit in Bowman's layer associated with a previous corneal foreign body (Khurana 2007).

Copper deposition: Copper ions can become deposited under membranous structures of the eye. Unlike iron ions, copper ions do not enter into chemical combination with the proteins of the cells and therefore do not produce degenerative changes. *Chalcosis* refers to the changes produced by copper in the eye (Khurana 2007).

The *Kayser-Fleischer ring* is a golden brown ring of copper deposition under peripheral parts of the Descemet membrane in the cornea. They are usually 1–3 mm in diameter and located just inside the limbus. In exceptional cases, there is a second ring. The Kayser-Fleischer rings are almost always caused by Wilson's disease (hepatolenticular degeneration); however, they have been described in patients with chronic liver disease not due to Wilson's disease. These rings do not cause any visual problems. The intensity of pigmentation caused by the Kayser-Fleischer rings can be reduced by treatment of the abnormal copper metabolism hallmarking Wilson's disease (Khurana 2007; Biswell 2011).

Blood staining of the cornea: Blood staining occurs occasionally as a complication of hyphema or secondary to raised intraocular pressure. The cornea becomes reddish brown or greenish in color. The corneal staining is due to hemosiderin within the corneal stroma. Vision is decreased, and the cornea clears very slowly from the periphery toward the center. In most cases the cornea gradually clears in 1–2 years (Khurana 2007; Biswell 2011).

Melanin deposition: Changes in the iris can lead to melanin from the iris pigment epithelium to be released into the anterior chamber and aqueous fluid. The melanin can deposit on the posterior surface of the cornea, anterior surface of the iris, the trabecular meshwork and the lens capsule (Khurana 2007).

Krukenberg's spindle is a vertical ellipse of melanin deposited on the corneal endothelium. It is seen in patients with pigment dispersion syndrome. This syndrome is characterized by fine particles of brown uveal pigment which have dispersed from the iris and associated structures into the aqueous humor. The spindle can be seen grossly in severe cases but is best observed with a slit lamp. Pigmentary glaucoma, a type of secondary open-angle glaucoma, can occur from the pigment particles clogging the trabecular meshwork and increasing intraocular pressure. Therefore, patients presenting with Krukenberg's spindle should receive an investigative examination for glaucoma. Visual acuity is only slightly affected, and progression is very slow. This condition typically appears in young myopic males. The exact mechanism of pigment shedding is unknown (Naumann and Apple 1986; Khurana 2007; Biswell 2011).

Ochronosis is a melanin-like pigmentation of the peripheral cornea caused by alkaptonuria (Khurana 2007).

Lipid deposition: Lipids can leak out of limbal capillaries and deposit in the cornea. The deposits are composed of extracellular cholesterol, cholesterol esters, phospholipids and triglycerides (Naumann and Apple 1986).

Arcus senilis are annular gray-white opacities consisting of lipid deposits within the corneal stroma located near the cornea periphery. The arcus, approximately 1–1.5 mm in width, is separated from the limbic edge by the lucid interval of Vogt. This is an age-related change occurring bilaterally in 60% of patients between 40 and 60 years of age and in nearly all patients over the age of 80. Arcus senilis does not require treatment and does not affect vision. When found in individuals under the age of 50, the term used is arcus juvenilis and is possibly a sign of abnormal lipid metabolism and increased LDL production. The lipid deposits will initially form as arcs at the superior and inferior peripheries of the cornea. The arcs may progress with accumulation of lipid deposits to form a complete ring (Naumann and Apple 1986; Khurana 2007; Biswell 2011).

Silver deposition: Discoloration due to inappropriate exposure to chemical compounds containing silver is termed *argyrosis* and can appear throughout the body including the cornea. Discoloration of the cornea is caused by deposition of silver in the Descemet membrane. Peripheral and diffuse corneal depositions have been

documented. Central corneal involvement occurs with longer exposure. Silver deposits cause a blue-gray discoloration (Khurana 2007).

Gold deposition: Gold treatment for arthritis may lead to corneal gold deposition, termed *chrysiasis*. These are gold to violet in color and generally do not affect vision. Deposits are found in the anterior portion of the cornea (epithelium and anterior stroma) with lower cumulative doses of gold (1–2 g), but higher doses result in depositions in the posterior cornea (the Descemet membrane and the posterior stroma) (Khurana 2007).

Adrenochrome deposition: Oxidized epinephrine can be deposited on the conjunctiva or in Bowman's layer of the cornea in patients using topical epinephrine compounds. Depositions cause a dark discoloration (Khurana 2007).

Classification

Location	Substance	Location	Appearance
Anterior cornea	Iron	Epithelium	Brown discoloration, often distributed inferiorly and associated with tear film
	Cornea verticillata (amiodarone, chloroquine, hydroxychloroquine, indomethacin, phenothiazines)	Basal layer of epithelium (substances bind to cellular lipids)	Whorl-like pattern of golden brown or gray deposits, often seen inferiorly
	Adrenochrome deposits (epinephrine, tetracycline, or minocycline)	Bowman's layer	Dark discoloration
	Fluoroquinolone deposits (often ciprofloxacin)	Subepithelial	White crystals in an epithelial defect
Central cornea	Lipid (arcus)	Stroma	Peripheral whitening
	Iron	Stroma	Iron foreign body deposition directly in the stroma may result in a rust ring
Posterior cornea	Hemosiderin	Posterior stroma	Golden brown discoloration
	Silver	Descemet membrane	Blue-gray discoloration
	Copper	Descemet membrane	Kayser-Fleischer ring
	Gold	Descemet membrane or posterior stroma in high doses (lower doses deposit in the epithelium and anterior stroma)	Gold to violet discoloration
	Melanin (Krukenberg's spindle)	Endothelium	Scattered brown pigment on corneal endothelium may be confused for guttae

Corneal Stromal Haze

Martin Baumeister
Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany

Definition

The term "haze" commonly describes a condition of mild anterior corneal stromal opacification which occurs as part of the normal wound healing response after keratorefractive procedures, especially excimer laser surface ablation.

Histology

Haze occurs as a wound healing response to the corneal epithelial and stromal injury caused by excimer laser ablation. The disruption of the epithelial basement membrane leads to apoptosis and necrosis of the stromal corneal cells. This causes activation and centripetal migration of keratocytes which transform into activated fibroblasts which then further transform into myofibroblasts.

Immunohistochemistry

In the development of haze, the distribution of collagens in the cornea changes with an increase of fibrillar type IV collagen. An increased expression of the extracellular matrix by the activated keratocytes is observed. By blocking of TGF-b, the formation of haze has been inhibited in animal experiments.

Confocal Microscopy

Confocal microscopic findings in corneas after corneal surface ablation include an increased light backscattering which is caused predominantly by a higher density of activated keratocytes. (Moller-Pedersen et al. 2000)

Molecular Diagnostics

No publications found.

Differential Diagnosis

Differential diagnoses include corneal scarring after inflammation or trauma and corneal dystrophies.

Corneal Tattoo

Farhan I. Merali
Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Definition

Corneal tattooing refers to the delivery of pigment into the corneal stroma to improve the cosmetic appearance of disfiguring scars or reduce the glare and visual distortion in patients with large iridectomies, traumatic loss of iris, or congenital

iris colobomas. Tattooing can be especially helpful for patients in whom reconstructive surgical procedures will not result in functional improvement or for those who are unable to tolerate a printed contact lens or bulbar shell.

Impregnation techniques have been used for nearly 2000 years, in which the dye is delivered with the use of multiple punctures perpendicular to the corneal surface. Newer techniques include (a) the application of a platinum ion solution to the cornea, which when reacted with a second agent forms a dark black precipitate in the cornea and (b) a dermatography-like manner of tattooing, which employs punctures parallel to the corneal surface with a conventional spatula needle. Most recently, the success of femtosecond-assisted corneal tattooing has been reported. With this technique, an anterior lamellar corneal free flap created using a femtosecond laser is removed and incubated in a commercially available black tattoo pigment and then repositioned on the residual corneal bed and covered with a bandage contact lens. Alternatively, a hinged flap may be used instead, with the direct injection of dye into the lamellar stromal bed before replacement of the flap. Determination of the long-term safety and success of these newer techniques is ongoing.

► Central Corneal Thickness

Corneal Tomography

► Computerized Corneal Topography

C

Corneal Topography

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Computerized videokeratography

Definition

Method for measurement, visualization, and analysis of corneal curvature across the entire cornea.

Purpose

Corneal topography is used to quantify and visualize the curvature of the corneal first surface (Scheimpflug-based devices also image the posterior surface) and to reveal astigmatism and corneal irregularities. It ranges between anatomical imaging and functional exam.

Principle

The use of powerful personal computers, high-resolution video cameras, and modern image analysis software allowed a merge of qualitative keratoscopy and quantitative keratometry: The reflection of a pattern of concentric circles (Placido disk) on the cornea is captured by a digital camera. A computer calculates corneal curvature at each corneal point based on the distance of the mires in the corneal reflection image. On a color contour map, curvature is plotted as a function of location, hence the term "corneal topography."

Placido-based corneal topographers were those first constructed and are still the most widespread

used topography devices. Scheimpflug-based topographers produce optical sections of the cornea, enabling the measurement of both anterior and posterior corneal surface. From raw images, corneal height, curvature, refractive power as well maps of corneal thickness can be calculated. Some manufacturers have equipped their Scheimpflug topographers with a Placido disk for anterior surface imaging, while others rely on the improved resolution of new generation CCD cameras and offer a Scheimpflug-only solution.

Indication

Diagnostics of corneal diseases (e.g., keratoconus, scars), contact lens fitting, preparation, and follow-up of refractive surgical procedures.

Contraindication

Corneal topography is noninvasive. There are no contraindications.

Advantage/Disadvantage

Corneal topographic exams are captured easily without pupil dilation and without discomfort for the patient. Apart from corneal back surface imaging, rotating Scheimpflug cameras have the advantage of high-density imaging of the central cornea, because this region is imaged in each frame. Correspondingly, the disadvantage of Placido topographers is the sparing of the corneal center because of the location of the camera front lens. For measurement of the whole optical properties of the eye, a wavefront sensor (aberrometer) is needed.

Corneoretinal Dystrophy, Bietti's Crystalline

Matthew S. J. Katz[1] and Gowtham Jonna[2]
[1]Albert Einstein College of Medicine Department of Ophthalmology and Visual Sciences, Montefiore Medical Center, Bronx, NY, USA
[2]Department of Ophthalmology and Visual Sciences, Albert Einstein College of Medicine – Montefiore Medical Center, Bronx, NY, USA

Synonyms

Bietti's corneoretinal crystalline dystrophy; Bietti's crystalline dystrophy; Bietti's tapetoretinal degeneration with marginal corneal dystrophy

Definition

A rare hereditary condition marked by concurrent crystalline retinopathy, progressive pigmentary retinopathy, and marginal corneal dystrophy.

Etiology

Bietti's crystalline dystrophy (BCD) is inherited in an autosomal recessive fashion; 39 mutations in the cytochrome P450 4V2 gene have been identified. CYP450V2 codes for a fatty acid omega hydroxylase thought to be active in fatty acid metabolism (Rossi et al. 2013); studies suggest that dyslipidemia may occur in concert with BCD in nearly half of affected patients. Thus, BCD may be caused by a global abnormality of lipid metabolism.

Clinical Presentation

Patients present most commonly in the second or third decades of life with decreased central acuity, progressive nyctalopia, and paracentral scotoma.

Anterior segment involvement may manifest as refractile corneal crystals in the superficial corneal stroma at and about the limbus as well as the conjunctiva. Posterior segment involvement is characterized by yellow or white intraretinal refractile crystals superimposed on diffuse retinal pigment epithelium (RPE) atrophy, pigmentary clumping, and atrophy of the choriocapillaris. Vascular attenuation and optic disc pallor too may be present in advanced disease. These findings are progressive (Mataftsi et al. 2004; Sahu and Rawoof 2002).

Diagnosis

Electroretinogram (ERG) may reveal subnormal photopic and scotopic responses. Electrooculogram (EOG) too may reveal a subnormal response. Perimetry may unmask scotomata corresponding to areas of chorioretinal atrophy.

Pathology

Pathology finds crystalline deposits and lipid inclusions in choroidal fibroblasts, corneal keratocytes, conjunctival and cutaneous fibroblasts, as well as in lymphocytes in the peripheral circulation (Yanoff and Fine 1996).

Differential Diagnosis

Clinical presentation is similar to but must be differentiated from fundus albipunctatus, retinitis pigmentosa albescens, oxalosis, cystinosis,

canthaxantin or tamoxifen retinopathy, talc retinopathy, Sjogren-Larsson syndrome, idiopathic juxtafoveal retinal telangiectasia, and gyrate atrophy.

Prophylaxis

No effective prophylaxis is recognized as yet.

Therapy

No effective treatment is recognized as yet.

Prognosis

Affected patients typically progress to legal blindness by fifth or sixth decades of life.

Epidemiology

Patients are most commonly of East Asian descent, particularly of Japanese or Chinese ancestry. BCD has been estimated to comprise 3% of nonsyndromic retinitis pigmentosa cases.

Corneoscleral Laceration

Nicholas Farber
Department of Ophthalmology, SUNY Downstate, Brooklyn, NY, USA

Synonyms

Corneal laceration; Open globe; Ruptured globe; Scleral laceration

Definition

A partial- or full-thickness injury to the cornea and sclera, extending through the limbus. A - partial-thickness injury does not penetrate the globe, whereas a full-thickness injury results in a ruptured globe.

Etiology

Corneoscleral laceration refers to a penetrating injury by a sharp object and/or projectile. This is not to be confused with a corneoscleral rupture which is caused by blunt trauma inducing defects at the areas of weakness of the globe (the equator and behind the rectus muscles). Lacerations are further described as penetrating vs. perforating:

Penetrating: entry wound without an exit wound
Perforating: entry and exit wound

Clinical Presentation

Any ocular trauma should raise a concern for a corneoscleral laceration. Injuries that include

high-speed projectiles such as metal grinding or wood chipping should be thoroughly investigated before ruling out a ruptured globe. The patient may exhibit a foreign body sensation, tearing, and pain, though the lack of these findings does not rule out a corneoscleral laceration. An intraocular foreign body should always be considered in conjunction.

The following signs are indicative of a ruptured globe:

1. Prolapsed uveal tissue
2. Seidel positive (application of fluorescein shows clear aqueous flowing out of the wound)
3. Vitreal prolapse
4. Visualized intraocular foreign body or intraocular foreign body on radiography

Signs suggestive of a ruptured globe include:

1. Decrease in vision following trauma
2. New afferent papillary defect following trauma
3. Peaked pupil toward the site of injury, often called a teardrop pupil
4. Low intraocular pressure
5. Shallow anterior chamber
6. 360 hemorrhagic chemosis
7. Focal lens defect
8. Full-thickness eyelid laceration

Diagnosis

Patients with corneoscleral lacerations often have other injuries. First and foremost any life-threatening condition should be appropriately treated. Once the patient is stable, the evaluation of a corneoscleral injury can begin. The importance of a careful history cannot be overstated. Among other questions, details regarding the mechanism of injury are vital. These include but are not limited to:

1. High-speed projectile
2. Material of object (i.e., metal, plant matter, soil contamination, wood, etc.)
3. Previous treatment including those undertaken prior to arrival in a situation requiring transfer of a patient
4. Use of eye protection during event

Changes in vision and visual acuity prior to the trauma are vital details affecting management and prognostication. Presurgical questioning such as the time of last meal, allergies, and past ocular, medical, and surgical history is important to elicit early should the patient require emergent repair in the operating room. Past ocular history includes previous surgeries, the presence of refractive errors, the use of ocular medications, and other ocular diseases. Medical history includes diagnoses, medications, vaccination history including tetanus, and further questions by the anesthesia/medical clearance team in the setting of a presurgical anesthesia evaluation. Determining the capacity for medical decision-making and identifying the correct person to consent (especially in the case of a minor or those unable to consent for themselves) should not be overlooked.

A physical and ocular exam follows the history. Document vital signs early at presentation, especially cases with multiple bodily injuries and continue to observe should lifesaving interventions become necessary.

Evidence of extrusion of any intraocular material including uvea, lens, vitreous, or aqueous fluid is diagnostic for a full-thickness laceration.

After instillation of topical anesthetic, a gentle examination of wounds suspicious for laceration is undertaken. During this exam care is taken to avoid pressure on the globe should extrusion of intraocular occur. Pain control and anti-emesis medication is often given prior to exam in an effort to prevent clenching and Valsalva, respectively, which also carry risk of extrusion.

Fluorescein is used for Seidel testing by applying directly to the concerned area. During blue light examination, any flow of clear fluid out of the wound is indicative of a positive test and globe rupture. Gentle digital pressure may be applied to the globe if a self-sealing wound is suspected.

Hemorrhagic chemosis, particularly 360°, may hide a laceration. This should be explored, usually with topical anesthetic and cotton tip applicators, though exploration in the OR is also warranted when a rupture cannot be ruled out.

A CT scan should be obtained to rule out intraocular foreign bodies. MRI is contraindicated unless the physician is sure no metallic objects are involved.

Differential Diagnosis

Corneal abrasion
Scleromalacia perforans

Prophylaxis

A shield should be placed over the eye after diagnosing a laceration. The patient should be kept NPO in the case of surgical management. All procedure that involves pressure on the globe should be avoided.

Broad-spectrum intravenous antibiotics with coverage for *Bacillus* species should be given. These include fluoroquinolones, clindamycin, and vancomycin. Pain control and anti-emetics should be administered to prevent an increase in intraocular pressure and possible extrusion of intraocular contents.

Tetanus vaccine should be given when the patient's tetanus status is not current or unknown.

Therapy

If a partial-thickness laceration is found, then topical antibiotic prophylaxis and optional cycloplegia for comfort can be utilized. In severe cases a bandage contact lens may be placed to avoid further disruption.

If the wound is small with no tissue compromise, then nonsurgical management can be considered. The anterior chamber should be carefully inspected and remain well formed. Management includes antibiotics and frequent follow-up with anterior chamber and wound assessment. A bandage contact lens is also considered when a slow leak is present along with aqueous suppressants. Unresolving leaks and/or lacerations should be surgically closed after 48–72 h of observation.

The primary goal of surgical intervention is to restore the globe integrity with watertight closure and is usually performed within 24 h of presentation when the above conditions are not met. The secondary goal is to restore as much vision as possible. Globe repair is accomplished first followed by adnexal repair of injuries without the usage of muscle retraction sutures. The basic clinical and science course outlines 11 basic steps for closure:

- General anesthesia
- Excision of anteriorly prolapsed vitreous, lens fragments, and corneal foreign bodes
- Repositioning of anteriorly prolapsed uvea, retina
- Closure of corneal component of laceration at limbus, landmarks
- Completion of watertight corneal closure [with] 10-0 nylon
- Peritomy as necessary for exposure of scleral component
- Stepwise excision of posteriorly prolapsed vitreous
- Stepwise repositioning of posteriorly prolapsed uvea, retina
- Stepwise closure of scleral component [with] 9-0 nylon or 8-0 silk
- Conjunctival closure
- Subconjunctival antibiotics and corticosteroids

The patient is assessed for the risk of sympathetic ophthalmia when an NLP eye presents. In these situations enucleation should be considered. Primary enucleation should only occur when tissue injury is completely devastating without a chance of restoration of anatomy and the patient is mentally prepared for this outcome. Twelve to 14 days is generally accepted as the window period prior to the onset of sympathetic ophthalmia though cases have been presented with earlier manifestation. Therefore enucleation can wait to be performed outside the directly emergent setting in order for further assessment.

Postoperative treatments to prevent endophthalmitis and decrease inflammation are also indicated.

Prognosis

Prognosis varies greatly based on the extent of injury and the presence of other factors such as tissue loss, traumatic cataract formation, and stromal scarring. Initial visual acuity, the presence of afferent papillary defect, posterior wound location, and associated lid lacerations are predictive of worse outcomes in the repair of ruptured globes. Visual acuity at presentation is the most reliable predictor of final visual outcome.

Epidemiology

Young males have shown a higher incidence of corneoscleral lacerations.

Coronal Scalp Flap, for Anterior Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

C

Definition

A surgical procedure elevating a coronal flap to obtain broad access and exposure to the anterior and lateral orbit and surrounding areas.

Indications

This technique is most often used for lateral bony or intraconal lesions to allow broad exposure. It also provides direct and broad exposures for patients who have multiple orbital fractures, including the superior orbital rim or bone, as well as multiple other facial fractures (Nerad 2001; Levine 2003; Paolini et al. 2006).

Contraindication

Contraindication for patients unable to medically tolerate surgery or anesthesia or for those with more localized lesions that may be accessed with a more limited technique.

Techniques and Principles

Under general anesthesia, a coronal flap is elevated beveling the incision to maintain hair follicles. It is then carried inferiorly either in a subperiosteal or subfascial plane taking care to avoid damage to the frontal branch of the facial nerve. The area of interest is exposed as necessary for facial fracture repair or lateral orbitotomy (Nerad 2001; Levine 2003; Paolini et al. 2006).

Outcome

Broad exposure for lesion removal or fracture repair of the anterior orbit. Excellent aesthetic closure with incision hidden in hair, avoiding any external skin incisions and risk of scarring.

Complications

Risks of a coronal scalp flap anterior orbitotomy include risks associated with anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, parasthesia diplopia, alopecia, and need for additional procedures (Nerad 2001; Levine 2003; Paolini et al. 2006).

Adrenal cortical steroid; Corticoid; Corticosteroid; Steroid hormone

Definition

Corticosteroids, endogenous hormones produced by the adrenal cortex, are divided into glucocorticoids (GCs) and mineralocorticoids (MCs). Synthetic or semisynthetic GCs have been produced to enhance the anti-inflammatory properties of GCs while reducing their mineralocorticoid activity for therapeutic purposes.

Cortisol is the more abundant circulating GC in human. The synthesis of GCs is regulated by the hypothalamic–pituitary–adrenal axis. The corticotrophin-releasing hormone (CRH) is produced by the hypothalamus and leads to adrenocorticotropic hormone (ACTH) secretion by the anterior pituitary gland, which in turn regulates the GC secretion by the adrenal cortex. Cortisol has a negative feedback on ACTH and CRH production.

Aldosterone is the most potent MC in humans. The secretion of MCs is regulated by the

renin–angiotensin system and blood potassium levels to control body fluid volume and blood pressure.

Among synthetic corticosteroids, the most commonly used for their therapeutic action are cortisone, prednisolone, prednisone, methylprednisolone, dexamethasone, triamcinolone, betamethasone, and fludrocortisone. One of the pharmacological features distinguishing corticosteroids from one another is their relative GC versus MC potency (Table 1). Potency of GCs has been evaluated on the basis of their vasoconstrictor effects (McKenzie test) and on their ability to reduce in vitro inflammatory cell activation. Their mineralocorticoid potency was mostly based on their ability to slow ACTH production or to raise the systemic blood pressure. No classification system has ever been designed for the specific ocular use of GCs.

GCs have pleiotropic effects on development, metabolism, cognitive function, and homeostasis. As potent anti-inflammatory, immunosuppressive, and anti-allergic agents, synthetic GCs have been widely employed for decades in the clinical setting.

In contrast, MCs are a key regulator of the balance of fluids and electrolytes. Pharmacologically, inhibition of the MC pathway at different levels aims at lowering blood pressure and controlling heart and vascular remodeling processes.

Mechanisms of Action

Corticosteroids, being transcription factors, act mainly through classical genomic regulation mechanisms, which are also largely responsible for their side effects. In addition to these genomic effects, corticosteroids also act via rapid non-genomic mechanisms either through binding to their receptors or independently. Most of the genomic effects are indeed mediated by the GC receptor (GR) and MC receptor (MR) (Fig. 1).

Corticosteroids, Table 1 Relative gluco- and mineralocorticoid potency to hydrocortisone of commonly used corticosteroids

Preparation	Glucocorticoid[a]	Mineralocorticoid
Hydrocortisone (cortisol)	1	1
Cortisone	0.8	0.8
Prednisolone	4	0.8
Prednisone	4	0.8
Methylprednisolone	5	0.5
Triamcinolone	5	0
Dexamethasone	25	0
Betamethasone	25	0
Fludrocortisone	10	125

[a]Anti-inflammatory potency

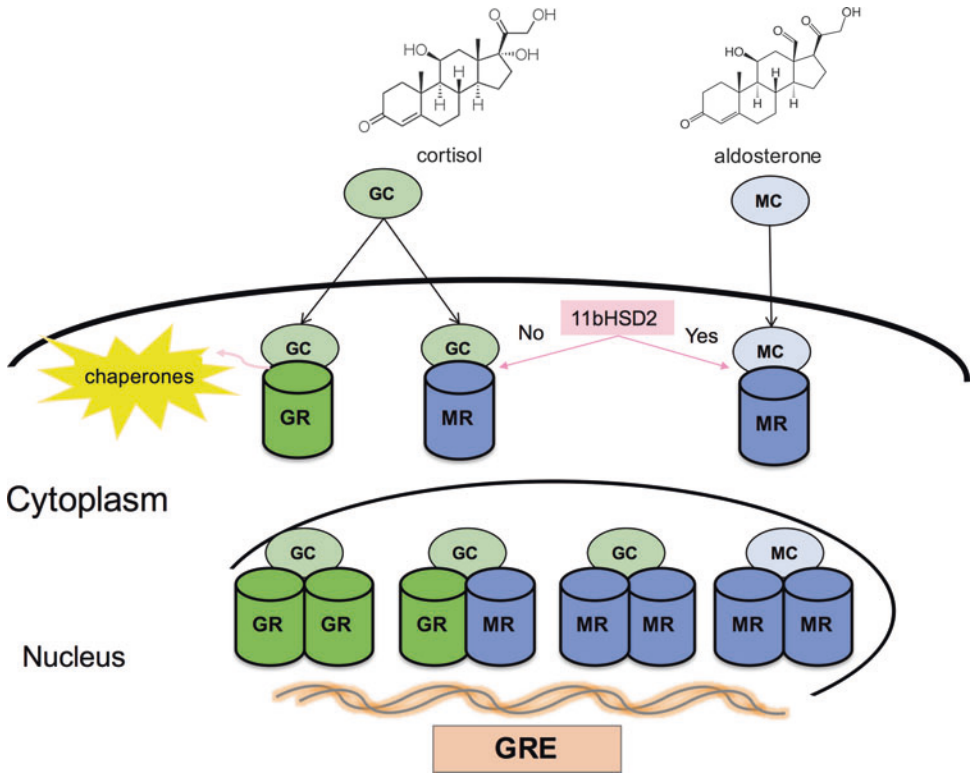
Mineralocorticoid Receptor (MR)

The MR has two ligands, aldosterone and cortisol, which bind to the MR with the same affinity. Since cortisol levels largely prevail over aldosterone levels in the plasma (cortisol is around 1000 times more concentrated than aldosterone), MR is occupied by cortisol unless the 11-ß-hydroxysteroid dehydrogenase type II (11bHSD2), protecting the MR from being occupied by cortisol, is expressed. The 11bHSD2 pre-receptoral enzyme metabolizes cortisol to cortisone which cannot bind to the MR with similar affinity. On the other hand, the 11BHSD type I enzyme exerts the reverse conversion from cortisone to cortisol. There is a balance between both enzymes that control the availability of cortisol to bind to its receptor. Thus, only in tissues where the 11bHSD2 is present, aldosterone can activate the MR, such as the kidney which is the classical mineralo-sensitive organ. Several non-epithelial MR-expressing tissues, including the heart, adipocytes, and macrophages, do not express 11bHSD2, and therefore, the MR is activated by cortisol in these tissues.

Glucocorticoid Receptor (GR)

Cortisol binds with high affinity to the GR, which leads to the dissociation of molecular chaperones from the GR. The cortisol–GR complex moves to the nucleus, where it binds as a homodimer to specific sequences of DNA called glucocorticoid-responsive elements (GREs). The resulting complex recruits either coactivator or corepressor proteins that modify the access to chromatin, thereby facilitating or inhibiting the transcription of target genes.

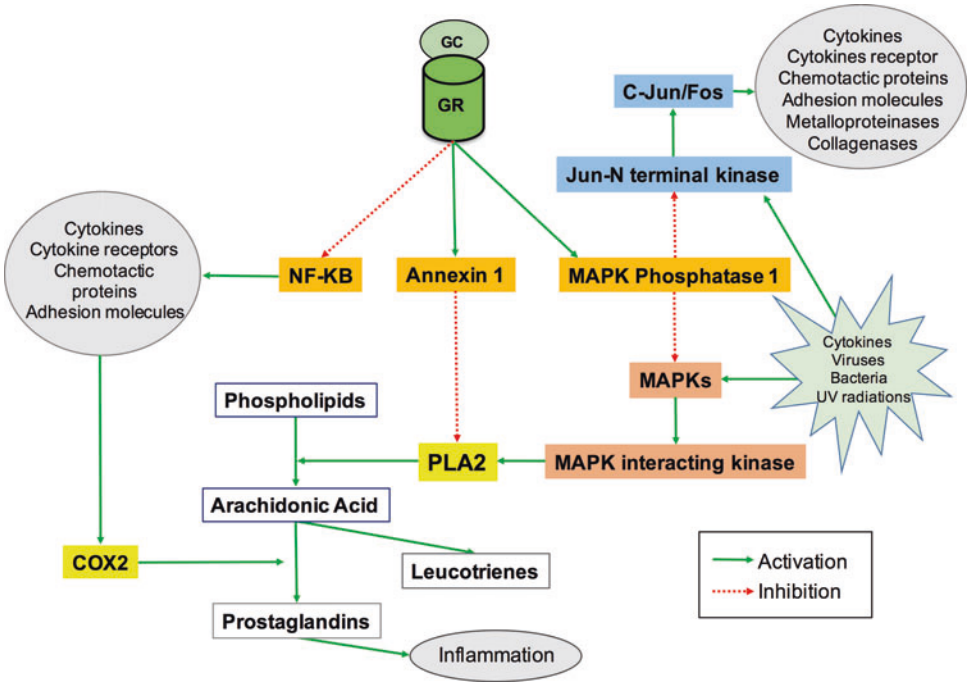
The anti-inflammatory effect of GCs relies on negative regulation of pro-inflammatory mediators and the positive regulation of anti-inflammatory



Corticosteroids, Fig. 1 Genomic mechanisms of action of corticosteroids. Glucocorticoids (*GC*s) bind glucocorticoid receptor (*GR*) or mineralocorticoid receptor (*MR*), which leads to the dissociation of molecular chaperones from the receptor. In cells where the enzyme 11ß-hydroxysteroid dehydrogenase type II (*11bHSD2*) is present, aldosterone can bind the MR. The cortisol–GR complex is displaced to the nucleus, where it binds as a homodimer to DNA sequences called glucocorticoid-responsive elements (*GRE*s)

factors. GCs inhibit prostaglandin and cytokines via three main mechanisms: activation of the transcription of annexin I and mitogen-activated protein kinase phosphatase 1 (MAPK phosphatase 1) and inhibition of nuclear factor-kB (NF-kB) (Fig. 2). First, GCs induce the transcription of annexin I (also called lipocortin-1), which by inhibiting cytosolic phospholipase A2-alpha (PLA2) blocks the release of arachidonic acid and its conversion to eicosanoid as prostaglandins, thromboxanes, prostacyclins, and leukotrienes. GCs induce the transcription of MAPK phosphatase 1 which inactivates Jun N-terminal kinase (JNK pathway), inhibiting c-Jun-mediated transcription that upregulates cytokines as tumor necrosis factor-alpha (TNF-alpha) and enzymes as inducible nitric oxide synthase (iNOS), metalloproteinases, and collagenases, among others. MAPK phosphatase 1 also inactivates all members of the MAPK proteins and thereby PLA2 activity. Third, the cortisol–glucocorticoid receptor complex exerts a strong negative regulation of cytokine expression through its interaction with other transcription factors, such as NF-kB. Indeed, GC inhibits the NF-kB pathway, which is responsible for the transcription of cytokines, chemokines, cell adhesion molecules, complement factors, and cyclooxygenase-2 (COX-2), an essential enzyme for prostaglandin production.

There are two isoforms of the GR: alpha and beta. The alpha isoform is the classical active isoform that binds cortisol, DNA, and other transcription factors and modifies the transcriptional activity of genes. GR-beta acts as a dominant



Corticosteroids, Fig. 2 Molecular events triggered by the genomic action of glucocorticoids. Glucocorticoids (*GCs*) binding to the glucocorticoid receptor (*GR*) induces the transcription of annexin I and MAPK phosphatase 1 and the repression of transcription of nuclear factor-kB (*NF-kB*). Thereby, GCs inhibit the expression of a wide range of cytokines, chemokines, cell adhesion molecules, as well as cyclooxygenase-2 (*COX-2*) and cytosolic phospholipase A2-alpha (*PLA2*), which inhibits the release of prostaglandins and leukotrienes

negative regulator of GR-alpha transcriptional activity. Higher levels of GR-beta in a cell lead to glucocorticoid resistance.

Finally, corticosteroids also exert non-genomic effects through signaling via potential membrane-associated receptors and second messengers, regulating the translation to proteins. One of these non-genomic mechanisms include the decreased stability of messenger RNAs coding for inflammatory proteins such as vascular endothelial growth factor (VEGF) and COX-2.[9] Recent evidence suggests that GCs could influence the methylation of their own genes causing epigenetic regulation of their activity.[10]

Indication

GCs are widely employed in ophthalmology because of their anti-inflammatory, anti-edematous, immunosuppressive, and anti-allergic properties. Systemic or local GCs are essential agents and may be used for the treatment of numerous ocular disorders involving all parts of the eye: conjunctivitis, episcleritis, scleritis, keratitis, anterior and posterior uveitis, retinal edema of many etiologies (uveitis, diabetes, retinal vein occlusion, postoperative), and optic neuropathies.

GCs inhibit PLA2, COX-2, NF-kB, NO synthase, and cytokines: interleukin-1 (IL-1), interleukin-6 (IL-6), TNF-alpha, and prostaglandin E2 (PGE2). GCs attenuate leukocyte recruitment, intercellular adhesion molecule 1 (ICAM-1), mRNA expression, and VEGF. In endothelial cells, GCs induce the expression of junction proteins, such as occludin and claudin-5, contributing to the blood retinal barrier restoration, and directly reduce the formation of new vessels (anti-angiostatic effect). In retinal glial Müller cells, GCs regulate the expression and

distribution of ion channels and water channels. Interestingly, dexamethasone and triamcinolone exert a specific and differential regulation of Kir4.1 (K^+ inwardly rectifying channel 4.1) and AQP4 (aquaporin 4) suggesting that the dose and type of corticosteroid may influence their anti-edematous properties. Finally, GCs protect against oxidative-stress-induced disruption of tight-junction proteins in retinal pigment epithelial cells.

Contraindications

Ocular corticosteroids are contraindicated in patients with hypersensitivity to any components of the product. Special care is recommended in patients presenting with ocular or periocular infection, glaucoma, and history of central serous chorioretinopathy.

Topical corticoids should be avoided when corneal epithelial defects, fungal keratitis, herpes keratitis, or any other uncontrolled infectious diseases of the cornea or conjunctiva are present.

When indicated to treat an ocular disorder, systemic corticosteroids should be used with caution and more so in patients with the following conditions:

- Osteoporosis or any skeletal disease
- Current or past tuberculosis
- Infections of any type (virus, bacteria, fungus, amoeba)
- Underactive or overactive thyroid
- Liver disease
- Digestive disorders
- Diabetes
- Heart disease
- Elevated blood pressure
- Elevated cholesterol
- Kidney disease or kidney stones
- Myasthenia gravis
- Systemic lupus erythematosus
- Emotional or psychiatric problems
- Skin conditions causing the skin to be thinner and bruise more easily

Use and Dosage

For each route of administration, the most frequently used GCs in ophthalmology are:

- Systemic: prednisone and methylprednisolone
- Topical: dexamethasone, prednisolone, betamethasone, fluorometholone, and loteprednol
- Periocular: dexamethasone, betamethasone, and triamcinolone acetonide
- Intravitreal: triamcinolone acetonide (1–4 mg), dexamethasone, and fluocinolone acetonide

Recently, two drug delivery systems have been developed for the sustained intravitreal release of glucocorticoids: the dexamethasone implant (0.7 mg over 4 months) and the fluocinolone acetonide insert (0.2 μg/day over 36 months). These new treatments have expanded the toolbox available for the management of macular edema secondary to a range of retinal conditions.

Adverse Reactions

Ocular Side Effects

Side effects vary with the type of corticosteroid, the route of administration, and the dose and duration of treatment.

Cataract

The mechanisms of steroid-induced cataract are not fully understood. It can develop after either ocular or systemic steroid treatment. Higher doses of GCs are more likely to provoke lens opacification. The intravitreal administration of more hydrophobic GCs seems to be more frequently implicated.

Steroid-induced posterior subcapsular cataracts exhibit three main distinctive characteristics: exclusive association with GC-activity steroids, involvement of aberrant migrating lens epithelial cells, and central posterior location. Transcriptional changes may occur in lens epithelial cells, which express the nuclear GR-alpha, affecting many cellular processes such as proliferation, differentiation, apoptosis, transmembrane transport, protein aggregation, and reactive oxygen species

activity. An imbalance in intraocular cytokines and growth factors affecting the lens homeostasis has also been suggested.

Ocular Hypertension and Glaucoma

Corticosteroid-induced ocular hypertension results from an elevated resistance to aqueous outflow and/or an increased aqueous humor production. Postulated mechanisms include microstructural changes in the trabecular meshwork, deposition of precipitated substances in the trabecular meshwork, and inhibition of trabecular phagocytosis by endothelial cells contributing to this accumulation of substances, as well as changes in gene expression and cell function. A decreased amount of GR-beta in trabecular meshwork cells has been observed in glaucomatous patients. This differential distribution of the beta-isoform of the GR may be responsible for the enhanced GC responsiveness and ocular hypertension in glaucomatous patients compared to the normal population.

Retinal Toxicity

A direct in vitro toxicity of GCs on retinal vascular endothelial cells has been observed via autophagy, caspase-dependent and caspase-independent cell death, and direct DNA damage.

Central Serous Chorioretinopathy (CSCR)

The systemic or local administration of corticosteroids (via inhalation, epidural injections, intra-articular injections, topical dermal, or periocular injections) has been associated with the triggering, prolongation, aggravation, and recurrence of CSCR.

Others

The topical administration of GCs is known to delay corneal wound healing, induce scleromalacia in at-risk eyes, favor the appearance of ptosis, and increase the risk of corneal infections.

Systemic Side Effects of Glucocorticoids

The main systemic side effects of GCs are:

- Endocrine functions: Cushing's syndrome, impaired glucose metabolism
- Cardiovascular system: dyslipidemia, hypertension (fluid retention), thrombosis, and vasculitis
- Kidney: increased sodium retention and potassium excretion
- Central nervous system: changes in behavior, cognition, memory, and mood
- Gastrointestinal tract: gastrointestinal bleeding, pancreatitis, and peptic ulcer
- Immune system: broad immunosuppression and activation of latent viruses
- Skin: delayed wound healing, erythema, hypertrichosis, perioral dermatitis, petechiae, acne, and striae
- Musculoskeletal system: muscle atrophy, osteoporosis, and retardation of longitudinal bone growth
- Reproductive system: delayed puberty, fetal growth retardation, and hypogonadism

Interactions

Several classes of drug present known interactions with systemic corticoids: anticoagulants, anticonvulsants, diabetes medication, HIV medication, certain vaccinations, and nonsteroidal anti-inflammatory drugs, among others.

These interactions are very rare with local corticosteroids, especially with topical or periocular administration, but caution should be taken since severe ocular disorders requiring corticosteroid treatment often occur in fragile patients with multiple treatments.

Corticosteroids, Use in Ophthalmology

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Synonyms

Glucocorticoids; Mineralocorticoids; Steroids

Definition

Corticosteroids are one of two types of steroids produced by the adrenal cortex. Adrenocorticotropic hormone controls the conversion of cholesterol to steroids using cAMP as the mediator. It consists of twenty one carbon atoms and is divided into glucocorticoids and mineralocorticoids.

The natural corticosteroids are cortisol, cortisone, corticosterone, and aldosterone. Some examples of the synthetic forms include prednisone, dexamethasone, triamcinalone, bethamethasone, medrysone, and fluorometholone.

The actions of corticosteroids are both immunosuppressive and anti-inflammatory by reducing lymphocyte availability and interfering with production or function of lymphokines.

Indication

Corticosteroids are the most commonly used anti-inflammatory and immunosuppressant drugs in medicine. Treatment of postoperative inflammation is the most common use in ophthalmology.

They are also used to treat conditions of immune hyperactivity including uveitis, corneal infiltrates, allergic disorders, graft rejection, and others. Corticosteroids help prevent damage from the body's own immune response.

In addition, steroids can be used to treat infectious processes at certain points in the disease. Extreme caution must be used in these cases due to potential worsening of the infection.

Contraindications

Steroids should be used with caution in the presence of bacterial, viral, fungal, and protozoal infections. Patients with diabetes mellitus, hypertension, gastric ulcer disease, history of elevated intraocular pressure in glaucoma or associated with steroid use should be monitored closely for worsening of disease. These individuals may require adjustments in their medications to minimize or avoid permanent damage from corticosteroid treatment.

Use and Dosage

Method of drug delivery includes intramuscular, intravenous, oral, inhaled, and topical. The pharmacological characteristics of these preparations vary by absorption, metabolism, and solubility. Therefore the dosage will depend on the preparation and treatment goals. Initially it may be administered in medium or large doses to suppress inflammation. A gradual taper is necessary to avoid rebound inflammation.

Potential for toxicity can also determine the method of treatment. For example, treatment with oral prednisolone may be necessary if hepatic disease is limiting the conversion of oral prednisone to prednisolone.

Adverse Reactions

Side effects from corticosteroid use can be ocular or systemic. Ocular side effects include cataracts, ocular hypertension, glaucoma, delayed wound healing, corneal melting which could lead to corneal perforation, and secondary bacterial, viral, or fungal infections.

Systemic absorption of ocular steroids can be significant and lead to fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased

susceptibility to infection, osteoporosis, myopathy, and behavioral changes.

Interactions

Individuals taking steroids should not be immunized with live vaccines. Steroids may interfere with vaccines ability to protect against the disease process. Examples of live vaccines include measles, mumps, rubella, oral polio, rotavirus, smallpox, typhoid fever, yellow fever, varicella, H1N1, and nasal flu.

Corticosteroids can also interfere with aspirin, diuretics, Coumadin, insulin, rifampin, phenytoin, and phenobarbitol.

Synonyms

CNIII; Cranial nerve III; Oculomotor nerve

Definition

The *oculomotor nerve* (cranial nerve III) begins in the midbrain, provides motor innervation to many of the extraocular muscles, and provides parasympathetic innervation to the eye. The third nerve begins in the third cranial nerve nucleus located at the level of the superior colliculus in the dorsal midbrain. The fascicular part of cranial nerve III then projects from the nucleus and travels ventrally, passing by the red nucleus, the corticospinal tracts, and other important brainstem structures. The fascicle exits the midbrain into the interpeduncular fossa and travels in the subarachnoid space medial to the cerebral peduncle.

In the subarachnoid space, the oculomotor nerve travels in close association to arteries of the circle of Willis. Specifically, CNIII travels in-between the posterior cerebral artery (PCA) and superior cerebellar artery (SCA). Aneurysms in the PCA or SCA can rarely compress CNII at this point and cause a pupil-involved third nerve palsy. However, because the posterior communicating artery (PCOM) runs parallel to CN III in this location, it is often an aneurysm of the internal carotid artery-PCOMM artery that produces the clinical finding of ipsilateral acute and often painful and pupil-involved CNIII palsy.

As the CNIII continues anteriorly, it enters the lateral wall of the cavernous sinus. Thus, pathology of the cavernous sinus may lead to third nerve palsies in isolation or in combination with other cranial nerves (e.g., IV, V1, V2, and VI) or Horner syndrome. Superior and inferior divisions of CNIII arise after CNIII exits the cavernous sinus. Both divisions of CN III enter the orbit through the superior orbital fissure.

In the orbit, the superior branch innervates the levator palpebrae and superior rectus muscle. The inferior division innervates the inferior rectus, inferior oblique, medical rectus, and ciliary ganglion. Parasympathetic fibers synapse in the ciliary ganglion and supply the pupillary constrictor and ciliary muscle for accommodation.

Synonyms

CN IV; Cranial nerve IV; Trochlear nerve

Definition

CN IV begins in the trochlear nerve nucleus located in the caudal mesencephalon, both ventral to the cerebral aqueduct and caudal to the oculomotor nucleus complex. CN IV fascicles derive from both nuclei, travel dorsally around the cerebral aqueduct, and decussate in the

anterior medullary velum just caudal to the inferior colliculi. Thus, the trochlear nerve emerges contralaterally between the inferior colliculi and superior cerebellar peduncles on the dorsal brainstem. The *trochlear nerve* is unique in that it is the only cranial nerve exiting from the dorsal brainstem as well as providing contralateral innervation to its target. Further, as will be detailed below, the fourth nerve has the longest intracranial pathway and thus is more vulnerable to trauma.

Once in the subarachnoid space, the CN IV travels ventrally around the cerebral peduncles to project toward the cavernous sinus and orbit. CN IV is positioned lateral to the oculomotor nerve (cranial nerve III) and passes between the posterior cerebral and superior cerebellar arteries. Aneurysms of these arteries may rarely lead to a fourth nerve palsy. Associated symptoms include vertical and torsional diplopia and an ipsilateral hypertropia and excyclotorsion on exam.

The fourth nerve then pierces the dura mater between the attached and free margin of the tentorium cerebelli and runs anteriorly along the lateral wall of the cavernous sinus. Therefore, pathologies of the cavernous sinus may also lead to fourth nerve palsy.

Upon passage through the superior orbital fissure, the *trochlear nerve* remains outside of the annulus of Zinn and lateral to the tendinous ring. The cranial nerve then travels medially to innervate the superior oblique muscle.

Synonyms

Trigeminal nerve

Definition

Cranial Nerve V provides sensation to the face as well as motor functions for the muscles of mastication. It is the largest of the cranial nerves and has three major branches, the ophthalmic (V_1), maxillary (V_2), and mandibular (V_3). The mandibular nerve is responsible for cutaneous and motor functions and develops from the embryonic pons basal plate, while the maxillary and ophthalmic are purely sensory and derive from the cranial neural crest. All three branches convene at the trigeminal ganglion within Meckel's cave, which is analogous to the dorsal root ganglia of the spinal cord in that it contains the cell bodies of sensory nerves. From this ganglion stems a single sensory root that enters the brainstem at the pons level. Dermatomes of the

branches are sharply delineated such that local anesthetic injection can anesthetize precise areas of the face and mouth.

Synonyms

Abducens nerve; CNVI; Sixth cranial nerve

Definition

The sixth cranial nerve (CNVI), or abducens nerve, is an efferent motor nerve that controls the ipsilateral lateral rectus muscle of the eye, which abducts the eye away from the midline (Binder et al. 2010). CN VI originates from the abducens nucleus, which is located on the lower portion of the dorsal pons in the brain stem. CN VI exits the pons at the pontomedullary junction, and it courses superiorly over the clivus, encased within a fibrous sheath (Dorello canal), and enters the dura just inferior to the posterior clinoid process. The sixth cranial nerve's long, oblique course over the clivus and its enclosure in the Dorello canal make it susceptible to injury due to compression or stretching of the nerve by increased intracranial pressure (ICP), trauma, aneurysm, or space-occupying lesions like tumor (Binder et al. 2010).

After piercing the dura, CN VI then courses over the medial petrous apex and into the cavernous sinus, where it then runs inferolateral and parallel to the internal carotid artery. CN VI then passes through the superior orbital fissure and into the orbit, where it innervates the ipsilateral lateral rectus muscle (Binder et al. 2010).

Sixth nerve palsy is a common neurological ocular motor palsy because of its long intracranial course and potential for stretching – especially over the clivus – which results in horizontal binocular diplopia (Spalton 2005). It may be congenital or acquired and unilateral or bilateral. Sixth nerve palsy may be caused by any lesions in the pons, subarachnoid space, cavernous sinus, or

orbit (e.g., inflammation, infection, trauma, neoplasm) or as a non-localizing finding of increased ICP (Friedman and Kaiser 2007).

Synonyms

Facial nerve

Definition

Cranial nerve VII (CN VII) has regular and special sensory, regular and special motor, and autonomic (i.e., parasympathetic) functions. The CN VII is derived from the second pharyngeal branchial (hyoid) arch, with the motor division developing from the basal plate of the pons and the sensory from the embryonic cranial neural crest. The special sensory function of CN VII includes taste information from the anterior two-thirds of the tongue and oral cavity. There is also parasympathetic supply on CN VII to the submandibular and sublingual glands via the chorda tympani nerve for saliva flow. CN VII exits the brainstem between the pons and medulla to provide parasympathetic innervation to head and neck ganglia, while supplying the nasal mucosa and lacrimal glands. The main regular motor function of the CN VII is voluntary control of the muscles of facial expression as well as innervation of middle ear musculature (e.g., the nerve to the stapedius muscle). CN VII also serves as the efferent limb of the corneal reflex. The motor segment originates from the facial nerve nucleus in the pons with the parasympathetic and sensory portions rising from the nervus intermedius. After reaching the temporal bone, the CN VII divides into the internal auditory canal, labyrinthine segment, intratympanic segment, and descending or vertical segment. The nerve exits the stylomastoid foramen and enters the parotid to branch into its terminal segments. The facial nerve also forms the geniculate ganglion at the genu of the facial canal.

Etiology

Cranial nerve VII is responsible for idiopathic acute facial nerve paralysis such as Bell palsy and can result from viral infection or multiple cranial nerve ganglionitis. Paralysis can also result from other etiologies including Lyme disease or misplaced local anesthesia in inferior alveolar nerve block, inflammatory disease, and neoplasm.

Clinical Presentation

Since CN VII performs many functions, damage may lead to complex symptoms within a range of

severity, commonly leading to facial distortion. Most symptoms arise quickly and peak within 48 h. Presentation includes ipsilateral weakness of the face, saliva and tear production may be affected with increased drooling or drying of the eyes and loss of taste, and increased sensitivity to sound is possible (i.e., hyperacusis).

Diagnostics

Magnetic resonance imaging (MRI) or computed tomography (CT) may show an etiologic cause of CN VII palsy.

Therapy

The treatment of CN VII palsy should be directed at the underlying etiology. Corticosteroid and/or antiviral therapy has been recommended for some idiopathic or presumed postviral cases.

Prognosis

Although recovery is dependent upon treatment of the underlying etiology, most idiopathic cases recover normal function within 6 months.

Definition

A craniopharyngioma is a rare, benign tumor of the sellar region that may present with disturbances in the hypothalamic-pituitary axis, the visual system, and the flow of craniospinal fluid (CSF).

Etiology

Craniopharyngiomas are generally considered to be embryonic vestigial epithelial remnants of the Rathke pouch located between the anterior and posterior lobes of the pituitary (Yanoff and Duker 2008).

Clinical Presentation

All of the clinical features are caused by the tumor encroaching upon the nearby structures of the brain. Compression of the optic chiasm causes a bitemporal often inferior quadrantanopia or an incomplete or complete bitemporal hemianopsia (Yanoff and Duker 2008). Whereas compression of the pituitary stalk or the gland itself can produce a wide variety of symptoms such as diabetes insipidus, eating disorders, and growth retardation or delayed puberty in children. In addition, patients often present with headaches due to the obstruction of CSF flow (Lumenta et al. 2010).

Diagnostics

The most important diagnostic tool is the magnetic resonance imaging (MRI) of the head and, in some instances, a computed tomography (CT) scan of the head as well. The MRI will typically show a cystic and solid tumor located in the sella often displacing and compressing the pituitary gland. The tumor itself usually contains one or multiple heterogeneous cysts often with calcification (Lumenta et al. 2010). Two distinct variants of the craniopharyngioma are seen upon histological examination. The adamantinomatous craniopharyngioma demonstrates cords of squamous epithelium with peripheral palisading and compact lamellar keratin formation known as "wet keratin." This subtype often contains cholesterol rich, thick brownish fluid that looks like "machine oil." Papillary craniopharyngiomas, the second subtype, contain both solid sheets and papillae lined by well-differentiated squamous epithelium (Kumar et al. 2010).

Differential Diagnosis

The two more common causes of the neuro-ophthalmologic manifestations found in patients with a craniopharyngioma are pituitary adenoma and meningioma, but other sellar lesions including aneurysm, inflammation, demyelination, infection, or metastases can mimic the clinical presentation (Lumenta et al. 2010).

Therapy

There are no medical treatments for craniopharyngiomas, so these tumors must be removed surgically. Residual or recurrent tumor may be treated with radiation therapy (Lumenta et al. 2010).

Prognosis

Craniopharyngiomas have a 10-year survival rate of over 90%, but there are often recurrences due to the locally invasive nature of the capsule. The combination of surgery and radiation limits the likelihood of recurrence (Lumenta et al. 2010; Prayson 2008).

Epidemiology

The occurrence of this tumor is bimodal with one peak in the first two decades of life and another peak in the sixth and seventh decades of life (Lumenta et al. 2010; Prayson 2008). These tumors represents 2–4% of intracranial neoplasms, 8–13% of pediatric intracranial neoplasms, 20% of suprasellar masses in adults, and 54% of suprasellar masses in children (Yanoff and Duker 2008).

Cryptophthalmos

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Definition

A congenital lid malformation where the lids are continuous with the underlying globe

Etiology

During development, the lids either completely or partially fail to separate from the underlying globe (Keefe et al. 2008; Gupta and Kim 2011). This leaves the conjunctiva and cutaneous epithelium as a continuous structure (Kersten et al. 2013).

Clinical Presentation

This is a congenital malformation. The complete form of cryptophthalmos has skin replacing normal eyelids and this skin connects to the underlying globe (Keefe et al. 2008). Usually this presents bilaterally, but there are reports of asymmetric unilateral cases (Gupta and Kim 2011; Sachdeva and Traboulsi 2013). There are no lashes or eyebrows and the individual may or may not have lacrimal glands and canaliculi (Gupta and Kim 2011; Dollfus and Verloes 2013). The globes may also be microphthalmic. On examination, there will be a small or absent anterior chamber due to severe dysgenesis with many of the anatomic structures replaced by connective tissue (Gupta and Kim 2011). There are multiple forms of cryptophthalmos:

- The complete form has lids replaced by layer of skin and do not have a conjunctival sac (Sachdeva and Traboulsi 2013). Cornea and conjunctiva are still present but dermoid transformation changes them into skin (Gupta and Kim 2011).
- The incomplete form has colobomatous lids with a conjunctival sac and an exposed opaque cornea (Dollfus and Verloes 2013; Sachdeva and Traboulsi 2013).
- A related disease is pseudocryptophthalmos. The normal cornea and conjunctiva are covered by skin of eyelids that failed to separate (Gupta and Kim 2011).

Diagnosis

Diagnosis is by clinical observation

Differential Diagnosis

Anophthalmos
Pseudocryptophthalmos
Microblepharon
Mesodermal corneal metaplasia

Prophylaxis

Unclear.

Therapy

Surgical repair is the only therapy and is only recommended in a few cases. Surgery for cryptophthalmos involves pedicle rotation flaps, skin grafts, and mucous membrane grafts to reconstruct the conjunctival surfaces (Kersten et al. 2013). Pseudocryptophthalmos can be surgically treated by simply creating a palpebral fissure (Gupta and Kim 2011).

Prognosis

Prognosis depends on the form of cryptophthalmos

- Complete: No chance of gaining vision due to the dermoid transformation of corneal and conjunctiva (Kersten et al. 2013)
- Incomplete: Vision may be improved and cosmesis improved, but this is unlikely (Kersten et al. 2013)
- Pseudocryptophthalmos: Excellent visual acuity but may have problems maintaining a functional eyelid (Gupta and Kim 2011)

Epidemiology

Very rare with only case reports available. Can be found as an isolated disease, but more than half have cryptophthalmos as part of Fraser syndrome (Keefe et al. 2008; Dollfus and Verloes 2013). The syndrome is inherited and is autosomal recessive (Gupta and Kim 2011).

Cryptophthalmos-Syndactyly (Fraser) Syndrome

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Fraser-François syndrome; Meyer-Schwickerath syndrome; Ullrich-Feichtiger syndrome

Definition

Fraser syndrome is a sex-linked recessive genetic condition that causes developmental defects. Ocular manifestations include cryptophthalmos, where the eyelids are fused together and failed to separate during development. Other developmental defects include fused fingers or toes (syndactyly), genital malformations, renal

maldevelopment, laryngeal stenosis, ear malformation, and mental retardation.

► Crystalline Dystrophy

Crystalline Corneoretinal Dystrophy (Bietti)

► Corneal Dystrophies

Crystalline Dystrophy

Ophelia Yin
Department of Ophthalmology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Crystalline corneal dystrophy

Definition

A group of hereditary, often progressive disorders characterized by symmetric bilateral crystalline deposits of varying depths of the cornea. Crystalline deposits are usually clear on indirect illumination, but may be white or gray with direct illumination.

The most common crystalline dystrophies broken down by corneal depth include:

1. Superficial cornea – Meesmann's dystrophy and gelatinous droplike dystrophy
2. Stromal cornea – lattice dystrophy, Schnyder's dystrophy, and Bietti's dystrophy (Holland et al. 2011)

Etiology

There is a high variability in terms of age of onset, genetic abnormality, and composition of crystalline substances observable in the cornea for crystalline dystrophies.

Clinical Presentation

1. Superficial Cornea
   - Meesmann's dystrophy – as early as infancy, photophobia, recurrent punctiform epithelial erosions, and lacrimation may present (Munier and Schorderet 2008). Bilateral, well-delineated intraepithelial cysts of 10–50 μm affect the entire cornea. These appear gray on direct illumination (Holland et al. 2011).
   - Gelatinous droplike dystrophy – irritation, redness, tearing, and decreased vision (Munier and Schorderet 2008) due to bilateral gelatinous amyloid deposits limited to the central cornea appear refractile on indirect illumination and take the shape of a mulberry (Holland et al. 2011).
2. Stroma
   - Lattice dystrophy – superficial amyloid dots in the central cornea radiate out (Munier and Schorderet 2008) to produce refractile lines with nodular dilations that are white in direct light and translucent or crystalline in indirect light (Holland et al. 2011). Recurrent epithelial erosions are common and a diffuse ground-glass haze develops (Munier and Schorderet 2008).

- Schnyder's dystrophy – progresses from a central cornea haze/subepithelial cholesterol crystal deposition to an arcus lipoides complicated by a midperipheral panstromal haze. Systemic findings include genu valgum and hypercholesterolemia (Jensvold and Tindall 2008).
- Bietti's dystrophy – nyctalopia, peripheral visual field loss, or central visual acuity loss. Glistening crystalline-like changes in the retina and crystals in the stromal cornea composed of cholesterol that can also be found in fibroblasts and circulating lymphocytes (Hinton et al. 2013). Associated retinal pigment epithelial atrophy and choroidal sclerosis can also present (Holland et al. 2011).

Diagnostics

Routine eye exam using slit lamp with special attention to depth and color of crystalline deposits, histopathologic examination of deposits, lab findings, and molecular genetic testing may all aid in the diagnosis of crystalline dystrophies (Munier and Schorderet 2008).

Differential Diagnosis

The differential diagnosis for a specific crystalline dystrophy includes the other diseases included under this general category.

Prophylaxis

None

Therapy

Patching, hypertonic agents, artificial tears, or therapeutic contact lenses for erosion. Surgically, anterior stromal micropuncture, superficial keratectomy, excimer laser ablation (phototherapeutic keratectomy), and lamellar or penetrating keratoplasty can be considered (Goldstein et al. 2014).

Prognosis

Dependent on specific dystrophy.

Epidemiology

Crystalline dystrophies, a subset of corneal dystrophies, are generally considered ubiquitous but rare conditions (<0.10% in the USA) with small pockets of high prevalence throughout the world (Musch et al. 2011).

Crystalline Keratopathy, Infectious

Daniel Nelson
Department of Ophthalmology, Wake Forest Baptist Medical Center, Winston-Salem, NC, USA

Synonyms

ICK

Definition

A spectrum of corneal infectious processes which share a branching, needlelike pattern of opacities within the corneal stroma (Keenan and McLeod 2013).

Etiology

Infectious crystalline keratopathy (ICK) is a less common form of bacterial corneal infection that is typically seen in corneal grafts. It has also been described in other conditions including chronic corticosteroid therapy, herpetic keratitis, and others. Current theory suggests that a colony of slow-growing organisms is implanted at the mid-stroma level in an immunocompromised cornea. Most cases have been attributed to the *Streptococcus viridians* group; however, many organisms, including some fungal species, have been associated with ICK (Reidy et al. 2011; Keenan and McLeod 2013).

Clinical Presentation

The most common presentation occurs several months status post penetrating keratoplasty. Symptoms are similar to those seen in other forms of infectious keratitis and include redness, photophobia, and conjunctival swelling. Discomfort can range from mild to severe. Examination of the patient shows conjunctival injection and chemosis. Slit lamp examination will reveal nonsuppurative stromal infiltrates. In the eyes with corneal grafts, the infiltrates will typically extend to the graft margin. The infiltrates can vary from fine and feathery to thick and arborizing. There may or may not be associated with epitheliopathy. The anterior chamber is usually quiet but hypopyon has been reported in the literature (Kinota et al. 1993; Reidy et al. 2011; Keenan and McLeod 2013).

Diagnosis

As with all corneal infectious processes, diagnosis is based on clinical and microbiological examination. Conjunctival swabs, as with many corneal infections, are low yield; therefore, deep corneal scrapings or corneal biopsy are the preferred method for species identification. Histopathological examination generally reveals pockets of gram-positive cocci between intact collagen lamellae without significant inflammatory cell infiltrate. Bacterial cultures and sensitivities should be obtained. The most commonly isolated organism is *Streptococcus viridians* (Kinota et al. 1993; Fillmore et al. 2007).

Differential Diagnosis

Central crystalline dystrophy of Schnyder, Bietti crystalline corneoretinal dystrophy, cystinosis, lymphoproliferative disorders, herpetic keratitis, and other forms of infectious and noninfectious keratitis (Ehlers and Shah 2008).

Prophylaxis

Due to the rare appearance of ICK, there are currently no guidelines for prophylaxis other than standard precautions used for penetrating keratoplasty.

Therapy

No specific guidelines have been identified specifically for ICK. Like all corneal infectious processes, therapy is initially focused on the most common causative organisms. Regarding ICK, the culprit is usually *Streptococcal viridians*. Fourth-generation fluoroquinolones, such as moxifloxacin, have relatively good activity against gram-positive organisms; however, some authors advocate fortified vancomycin as the primary treatment. Historically, aminoglycosides have also been used. The treating provider should consider susceptibility patterns found in the area and target therapy accordingly once a species has been identified. In some cases, systemic antibiotic therapy has been added (Kinota et al. 1993; Fillmore et al. 2007; Keenan and McLeod 2013).

Prognosis

Prognosis depends on the severity of the initial infection and the successful eradication of the bacteria. Stromal scars usually develop. Repeat penetrating keratoplasty is sometimes needed to optimize visual potential (Kinota et al. 1993).

Epidemiology

Exact prevalence is unknown. It is typically seen in patients who have undergone penetrating keratoplasty. It has also been reported with incisional keratotomy, contact lens use, chemical burns, chronic corticosteroid use, topical anesthetic abuse, and others (Keenan and McLeod 2013).

Crystalline Lens

Martin Baumeister[1] and Thomas Kohnen[2]
[1]Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The lens is a transparent biconvex structure inside the eye with the primary function of focusing light on the retina and changing the focus of the eye.

Anatomy

The lens consists of the lens capsule, the epithelium, cortex, and nucleus. It is held in its position between the iris and the vitreous cavity by the zonular fibers and has the ability to refract light because its refractive index (about 1.4 in the center and 1.36 in the periphery) is different from that of the aqueous humor and the vitreous (1.336) (Atchison and Smith 2002).

The lens capsule is a membrane enveloping the lens with a thickness between 5 and 25 μm consisting of collagen type IV. The anterior capsule is thickest in the midperiphery and thinnest at the anterior pole of the lens. The capsule on the posterior surface is likewise thinnest in the area of the posterior pole and thickens towards the periphery. Under the anterior capsule of the lens and at the lens equator the monolayered lens epithelium is found. The lens grows throughout life because the lens epithelium continues to generate new clear lens fibers with a hexagonal diameter which form several layers and thus constitute the lens cortex. The oldest fibers form the lens nucleus. At birth the equatorial diameter of the lens is about 6.4 mm, the central anteroposterior thickness, 3.5 mm, and the weight 90 mg. The adult lens measures about 9 mm in its equatorial diameter and 5 mm anteroposteriorly and weighs about 255 mg. In its distance-accommodated state the lens contributes 15–20 D to the total dioptric power of the human eye of about 60 D. With advancing age, the ratio of cortex to nucleus increases because the size of the nucleus remains stable. Also, the curvature of the lens increases with age. Therefore, older lenses should theoretically have a higher dioptric power than younger lenses. This effect is, however, balanced by an age-related shift in the refractive index, presumably due to accumulation of insoluble protein particles.

Development

The lens is of ectodermal origin. The development begins with thickened ectodermal cells overlying the optic vesicle and forming the lens placode which invaginates into the optic cup and finally becomes the lens vesicle with the cells turned inwards. With further differentiation these cells elongate into lens fibers and finally fill the lens vesicle entirely.

Physiology

The crystalline lens is the only transparent cellular structure in humans. Its transparency follows from several factors such as the lack of vascularization (the lens receives nutrients from the vitreous and aqueous humor), the lack of nuclei and organelles in the lens fibers, the regular and tight organization of the hexagonal fibers, and the production of transparent proteins.

The young human lens is able to change its shape due to the elasticity of the capsule and the lens material thereby changing the focus of the eye. This is achieved by the action of the ciliary muscle via slackening or tightening of the zonular fibers, a process called accommodation.

Cutaneous Horn+B2658

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Cutaneous horn; Hyperkeratosis

Definition

A lesion with extensive hyperkeratosis projecting in a protruding, sometimes conoid, manner.

Etiology

Thickening of the keratin layer from the base of a proliferative lesion, results in a cutaneous horn. The base lesion may be a benign, premalignant, or malignant lesion.

Clinical Presentation

Present as hyperkeratotic papules that protrude from the skin, usually several millimeters in height. They are more common in sun exposed areas.

Diagnostics

Biopsy of the base of the lesion is required to determine if malignancy is present. The majority of lesions are benign, but 20% of lesions may be premalignant or malignant (Albert and Jakobiec 2008).

Differential Diagnosis

Actinic keratosis
Squamous cell carcinoma
Seborrheic keratosis
Verruca vulgaris
Basal cell carcinoma

Prophylaxis

Sun exposure and UV protection may be recommended, based on the type of lesion at the base of the cutaneous horn.

Therapy

Biopsy of the base of the lesion is required to determine if malignancy is present. Benign lesions do not require further therapy; however, malignant lesions will require surgical excision with appropriate margins.

Prognosis

Prognosis is dependent on the lesion present at the base. Follow-up examinations are necessary for new or recurrent lesions.

Epidemiology

Cutaneous horns tend to be more common later in age in those with a history of sun exposure and of fairer complexions.

Cutler-Beard Procedure

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Bridge flap technique; Lid sharing procedure

Definition

A lower eyelid sharing technique in which a full-thickness flap of skin muscle and conjunctiva are developed from beneath the lower eyelid margin and advanced into an extensive upper eyelid defect for reconstruction.

Indication

The Cutler-Beard procedure is used to reconstruct extensive (usually 50% or more) full-thickness upper eyelid defects involving the eyelid margin.

Contraindications

An intact healthy lower eyelid is required for the reconstruction. The flap will remain closed for usually a minimum of 6 weeks completely obstructing vision out of the ipsilateral eye; therefore, a seeing eye on the contralateral side is required for vision. The Hughes flap should be avoided in monocular patients or in children at risk of amblyopia development.

Techniques and Principles

Extensive upper eyelid defects require reconstruction for viability and protection of the eye. On occasion, these extensive upper eyelid defects mandate utilization of an otherwise normal lower eyelid for reconstruction in the form of a Cutler-Beard procedure.

Surgery begins with an assessment of the defect size. The proximal and distal cut ends of the eyelid are grasped with forceps, and any slack is gently removed so the defect size can be accurately measured. After marking the lower eyelid for an appropriately sized flap to reconstruct the upper eyelid, a full-thickness incision is made 5 mm below the lower eyelid margin. The incision is facilitated by placing an eyelid plate or malleable retractor into the inferior fornix as a backstop for globe protection. An incision in this location is designed to preserve the marginal arcade blood supply to prevent ischemia of the lower eyelid margin bridge. Back cuts are made perpendicular to the infraciliary incision extending into the inferior fornix to allow superior mobilization of this flap which consists of lower eyelid skin, orbicularis oculi muscle, and conjunctiva/lower eyelid retractors. The flap is then separated into layers: conjunctiva, orbicularis oculi muscle, and skin with scissors. The conjunctiva of the

inferiorly based flap is sutured to residual upper eyelid conjunctiva with absorbing sutures. The inferiorly based orbicularis oculi muscle is then sutured to residual levator muscle if present, and inferiorly based skin is sutured to residual upper eyelid skin to complete three-layer closure. A modified procedure exists in which a tarsal substitute, such as ear cartilage, is sandwiched between the skin and muscle as a tarsal substitute.

Separation of the flap is carried out usually 6–8 weeks later. The tissue bridge is divided with a scalpel or scissors. The opening should be beveled such that the conjunctival side is approximately 2 mm longer than the skin side. This encourages healing with mucosal tissue at the new eyelid margin as opposed to keratinized tissue which can abrade the cornea.

The lower eyelid is then reformed by freshening the inferior border of the lower eyelid margin bridge and suturing this border to the divided full-thickness tissue bridge. Postoperative edema of the eyelid can persist for 4–6 weeks after which the newly reconstructed upper eyelid usually begins to assume a more normal appearance and function.

Outcome

This is a two-stage procedure, which can often achieve a functional upper eyelid capable of providing adequate protection of the globe when extensive tissue loss is present. The reconstructed eyelid however is often thickened with limited mobility and devoid of lashes.

Complications

Upper eyelid entropion can occur with subsequent corneal irritation and decompensation. Some authorities feel that modification of the procedure with placement of a tarsal substitute may decrease the probability of this outcome. Lower eyelid scarring and malposition, usually ectropion, may result. Loss of the lower eyelid margin bridge secondary to ischemia will result in significant lower eyelid deformity.

Cyanoacrylate Adhesive

Irina Livshitz and Rony R. Sayegh
Department of Ophthalmology, University Hospitals, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Synonyms

Dermabond; Histoacryl; Histoacryl Blue; Indermil; Nexacryl

Definition

Cyanoacrylates are esters of cyanoacrylic acid. These are monomers that harden by polymerization through contact with fluids such as water or blood. Hydroxylation occurs and results in varying tensile strengths depending on the type of cyanoacrylate derivative. The application of this rapidly polymerizing glue can restore structural integrity to any surface with which it comes in contact.

Indication

The most extensively documented uses of cyanoacrylate tissue adhesive are in treatment of impending or frank corneal perforations, as well

as descemetoceles. In these cases the glue acts as a barrier between the cornea and inflammatory cells and other collagenase-secreting cells in the tear film. The best outcomes occur in perforations less than 1–2 mm in diameter, although successful treatment of perforations up to 3 mm has been reported with the use of cyanoacrylate glue. Frequently, cyanoacrylate tissue adhesives are used as a temporizing measure until a definitive procedure such as a penetrating keratoplasty can be performed. Given evidence that in both infectious and traumatic perforations corneal transplantation has better outcomes if it can be delayed until the eye is less inflamed, tissue adhesives have come to play a vital role.

Furthermore, glue can be used for wound leaks, filtering bleb leaks, punctual occlusion, skin closure in oculoplastics, securing of hard/rigid contact lenses in severe ocular surface disease, treatment of amblyopia, and temporary tarsorrhaphy in corneal exposure.

Contraindication

There are no reported contraindications to the use of cyanoacrylate glue in the literature. Perforations larger than 2–3 mm or with significant surrounding necrotic tissue may not be amenable to adhesive repair. Of note is that the Food and Drug Administration (FDA) has not yet approved the use of tissue adhesives in the human eye, so such use is considered "off label."

Techniques and Principles

Principle: In addition to restoring structural integrity and providing a mechanical barrier to the outside world, application of cyanoacrylate glue to the ulcer bed interrupts progressive corneal stromal melting. The proposed mechanism is via the inhibition of polymorphonuclear leukocytes (PMNs). PMNs have been shown to produce collagenolytic enzymes that are key players in corneal melt. Furthermore, PMNs themselves have collagenolytic and proteolytic activity. For best results, it is best to apply cyanoacrylate early on, before overwhelming PMN infiltration has occurred.

Furthermore, cyanoacrylate glue has been found to have significant antibacterial effect. Specifically, glue has significant bacteriostatic activity against Gram-positive organisms (*Staphylococcus aureus*, *Streptococcus pneumonia*, and group A streptococci) but virtually no effect on Gram-negative microbes. The proposed theory underlying this difference has to do with the lipopolysaccharide capsule surrounding the cell wall in Gram-negative organisms which serves as barrier to the glue.

Techniques: Many techniques for application have been described, many of which are based on the same principles and differ only with regard to instruments and applicators used to apply the adhesive. All techniques have one common goal in mind: to use the minimum amount of glue to plug the perforation. If possible, the application of glue should be performed in a minor surgery room with an operating microscope and with the patient supine; however this can also be done in the office at a slit lamp if necessary. On a side table, the tissue adhesive is drawn up in a TB syringe with a 30-gauge needle or dental micropipette. Several drops of topical anesthetic are placed in both eyes and an eyelid speculum is gently inserted into affected eye. The 1–2-mm area of epithelium surrounding the ulcer is then debrided with cellulose spear because the glue does not adhere to epithelium. The perforation site is then carefully dried with a cellulose sponge in one hand, while the other hand uses the 30-gauge needle or micropipette to place one drop of tissue adhesive on the surface. The glue should solidify completely within a few minutes. Too much glue may cause the patient significant discomfort since its polymerized surface is rough, even with the bandage contact lens. Additional applications may be necessary. Alternatively, a flat sheet or drape can be used to apply the glue to the ocular surface and can be left in place resulting in a smoother surface. The area should then be inspected for aqueous leak before the application of bandage contact lens (BCL), which is preferably a low-water-content, high-Dk extended-wear silicone-hydrogel soft contact lens with a flat base curve.

Postoperative management includes placing the patient on topical and/or systemic aqueous suppressants as well as prophylactic broad spectrum topical antibiotics three to four times per day. For surface lubrication and to protect BCL, preservative-free artificial tears should be used at least four times a day. Lastly, a protective shield should be placed on the eye. Ideally, the glue should remain in place for weeks to months to allow for stromal healing and vascularization to occur. It typically loosens enough with time to provide for easy removal or spontaneously dislodges. The BCL should be replaced every 2–3 months.

Outcome

The literature focuses mostly on the use of cyanoacrylate glue in the management of corneal perforations. Outcomes in this subset of people have been largely good, and there is a clear benefit to the management of corneal perforations and descemetoceles with this technique. Studies have shown improved visual outcomes with reduced enucleation rates. While corneal patching with cyanoacrylate glue has traditionally been thought of as a temporizing procedure until more definitive surgical treatment can be performed, a significant subset of patients needed no further intervention.

Complications

The main concern with corneal application of cyanoacrylate glue is tissue histotoxicity, which occurs through the accumulation of breakdown products and increases with tissue vascularity. For this reason, there is more concern for toxicity with glue application to conjunctiva, sclera, or skin than to the corneal epithelium and stroma. However, most problems occur with inadvertent instillation of glue into structures such as the anterior chamber; this can result in polymerization over the corneal endothelium and iridocorneal and iridolenticular adhesions.

There is also increased risk for superimposed microbial keratitis the longer the glue remains in place. This is likely not because of the glue itself, but rather a consequence of the prolonged use of a therapeutic BCL. The risk has been shown to be increased especially once glue has been present for more than 6 weeks. Additional reported complications include glaucoma, giant papillary conjunctivitis, and retinal toxicity.

Cyclocephaly

▶ Cyclopia

Cyclopia

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Synonyms

Cyclocephaly

Definition

Cyclopia is the most severe ocular abnormality and the most extreme form of holoprosencephaly, a cephalic developmental disorder in which the forebrain of the embryo fails to develop into two hemispheres, allowing structures that are normally paired on the left and right to merge. In cyclopia, two separate orbital cavities fail to develop during embryogenesis. This congenital condition is very rare.

Etiology

A number of teratogenic risk factors have been noted in association with the development of holoprosencephaly. Among these are gestational diabetes, exposure to transplacental infections, hypercholesterolemia, consanguinity, and female sex. Other possible teratogenic factors include exposure to ionic radiation, contraceptives, rubella vaccine, nicotine, anticonvulsants, antibiotics, amidopyrine, and alcohol.

Sporadic and inherited disruptions of the sonic hedgehog pathway have been reported to cause holoprosencephaly with cyclopia. The sporadic form occurs more frequently than the familial. The sonic hedgehog pathway gives cells information needed for proper embryonic development. There are at least four genetic regions that are implicated in the pathogenesis of holoprosencephaly. Sonic hedgehog is the only one of three homologous vertebrate genes to be expressed early in the midline of the developing central nervous system. It is expressed in the ventral forebrain and eye.

Clinical Presentation

The clinical presentation of holoprosencephaly can vary from true cyclopia, which is incompatible with life, to midfacial clefting. It is divided into three subtypes: alobar, semilobar, and lobar holoprosencephaly. The degree of CNS involvement dictates the clinical presentation of holoprosencephaly. In alobar holoprosencephaly, the brain consists of a single spherical forebrain structure with a single ventricle. Infants with the severe alobar form die after birth. The brain is missing the midsagittal fissure, corpus callosum, and olfactory bulbs and tracts are almost always absent. This form is most commonly associated with true cyclopia.

In true cyclopia, the fetus or infant presents with one central eye. The anterior brain and the midline structures do not develop normally. The result is a central cavity or pseudo-orbit with a proboscis but without a nasal cavity. In synophthalmia, the two globes are partially fused in the center. The head can be small for the age or of normal size with a proboscis over a central opening for the single or fused eye.

Differential Diagnosis

Synophthalmia

Prophylaxis

Avoidance of ingested or environmental teratogenic factors.

Prognosis

Cyclopia is not compatible with life due to the accompanying CNS abnormalities.

Epidemiology

Cyclopia can occur in all races and has been reported more frequently in females than in males. One case series reported an incidence of 1/40,000 births while the frequency of cyclopic fetuses was estimated between 1/250 and 1/500. Holoprosencephaly has a prevalence of 1:16000 live births and 1:250 during embryogenesis.

The estimated median maternal age is 35 years.

Cylindroma

► Cylindroma of Eyelid

Cylindroma of Eyelid

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Adenoid cystic carcinoma; Cylindroma

Definition

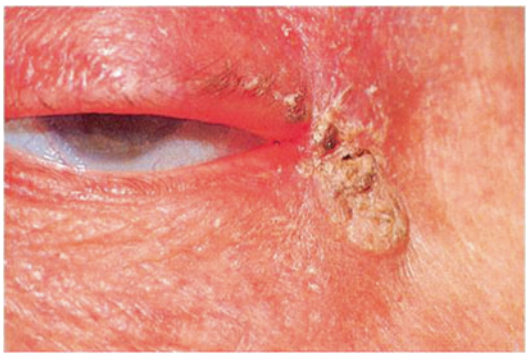
Benign sweat gland tumors involving the head, neck, and scalp. They are rare on the eyelids and brow.

Basic Characteristics

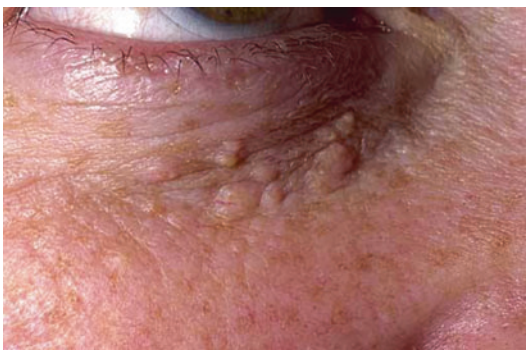
The tumor was previously thought to be of apocrine gland origin; however, more recent immunohistologic studies suggest the tumor exhibits apocrine, eccrine, secretory, and ductal features. It may be seen in combination with spiradenomas and trichoepitheliomas. There have been rare reports of malignant transformation.

Cylindromas present sporadically as slowly growing, singular, dome-shaped, pink rubbery nodules, varying in size from a few millimeters to several centimeters, usually on the scalp and face. Cylindromas are asymptomatic, presenting in middle age or later (Figs. 1 and 2).

In familial cylindromatosis or Brooke-Spiegler syndrome, an autosomal dominantly inherited disease, multiple cylindromas and other dermal appendage tumors may be present. Multiple larger lesions develop shortly after puberty. They may occur profusely on the scalp, in which they may be referred to as turban tumors. The proposed gene responsible in this condition is the CYLD gene on chromosome 16q12-q13. It is thought



Cylindroma of Eyelid, Fig. 1 Cylindroma of eyelid and canthus



Cylindroma of Eyelid, Fig. 2 Cylindroma of eyelid and canthus

to be a tumor suppressor; however, the exact function of this gene is not fully understood (Kim et al. 2007; Albert and Jakobiec 2008).

Solitary or multiple, small, discreet, round or oval, elevated, white vitreoretinal lesion at the peripheral retina, composed primarily of glial tissue and represent visible sites of vitreoretinal adhesions. Vitreous condensations are attached to its surface, and its base may have pigmentary changes. It is congenital and is a potential cause of retinal tears and detachments following partial or complete posterior vitreous detachment.

Cysticercosis, Orbital Involvement and

Pete Setabutr
Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA

Definition

Parasitic infection by *Cysticercus cellulosae* (larval form of *Taenia solium*).

Etiology

Human infection caused by ingestion of contaminated water or uncooked vegetables infested with eggs of the worm and autoinfection.

Clinical Presentation

May present in many periocular and ocular locations including subconjunctival, intraocular, extraocular, eyelid, and intraorbital muscles or elsewhere causing related symptoms such as motility restriction, mass lesion, orbital cellulitis, and dacryoadenitis.

Diagnostics

Clinical examination, orbital imaging, B-mode ultrasonography.

Differential Diagnosis

Orbital cellulitis, orbital inflammatory diseases, orbital and ocular infectious disease.

Prophylaxis

Avoidance of eating and drinking uncooked vegetables or food and water in endemic areas.

Therapy

Systemic antiparasitic agents such as albendazole. Prednisone as an adjunctive measure has been used. Primary surgical excision is also possible.

Prognosis

Local sequelae such as proptosis, ptosis, motility defects, diplopia, or strabismus may be seen.

Epidemiology

Endemic in regions with poor sanitation. Ocular and orbital infection seen in 13–46% of systemic disease. Most common form of systemic disease is neurocysticercosis.

Cystinosis, Ocular Findings in, Retinal Degeneration

Mordechai Rosner
Goldschleger Eye Research Institute, Sheba Medical Center, Tel Hashomer, Israel
Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel

Definition

Cystinosis is a rare autosomal recessive metabolic disorder characterized by the intracellular accumulation of cystine, the disulfide of the amino acid cysteine (Tsilou et al. 2007).

A pigmentary retinopathy has also been seen in cystinosis patients. This finding precedes the appearance of the crystals in the cornea and has been seen as early as 5 weeks of age or even in fetal life. However, pigmentary retinopathy does not appear to be a constant finding in cystinosis (Wong et al. 1967; Tsilou et al. 2007).

Clinical Presentation

The most commonly described ophthalmoscopic findings are pigmentary changes consisting of patches of depigmentation with pigmentary mottling at the periphery of the fundus and the macula. In the early stages the pigmentary abnormality is confined to the periphery, and the changes are more marked in the temporal than the nasal segments and appear bilateral and symmetric. In older patients the changes are seen more posteriorly. However, the macular abnormalities have been described as early as 6 years of age (Wong et al. 1967).

Usually there is no abnormality in visual function that accompanies the early findings (Wong et al. 1967). Because of successful renal transplantation and cystine depleting therapy, cystinosis patients are living longer and manifest the long-term complications of the disease, including the retinal degeneration. At the advanced stage, decreased visual acuity can result from both anterior and posterior segment complications (Dufier et al. 1987a). Decreased color, peripheral and night vision are often encountered by older cystinosis patients (Tsilou et al. 2007).

Fluorescein angiography reveals window defects corresponding to the patches of depigmentation, and indocyanine green videoangiography reveals a submacular choroidal neovascular membrane with feeder vessel. Intraretinal crystals are also detected (Tsilou et al. 2007).

Humphrey visual fields and electroretinography can confirm the presence of the retinopathy.

The histopathologic findings are poor as due to their water solubility, most cystine crystals are lost in aqueous fixatives. When processed in absolute alcohol, however, the crystals are identified within intracellular, single membrane-bound lysosomes. Rare crystals have been reported in the retina.

Focal degeneration has been frequently noted in the retinal pigment epithelium, and pigment migration into the inner retina has been seen on occasion. Focal destruction of the outer segments of the photoreceptors has also been reported (Francois et al. 1972; Dufier et al. 1987b). Ultrastructural examination showed numerous electron transparent polygonal spaces bounded by a single membrane in or adjacent to the lysosomes of the retinal pigment epithelial cells and in some choroidal resident cells (Tsilou et al. 2007).

CMV retinitis

Definition

A slowly progressive, necrotizing retinitis that may appear as granular or hemorrhagic lesions associated with cytomegalovirus virus infection.

Etiology

Cytomegalovirus (CMV) is a double-strand DNA virus and the largest member of the herpesvirus family (230 kb). The prevalence of CMV infection among individuals aged >6 years old was found to be around 60%, and it seems that most people are exposed to CMV throughout their life. Like many other herpesviruses, CMV remains latent in the host and may reactivate if host immunity is compromised, especially in cases with a compromised cell-mediated immune system (AIDS, transplant recipients or patients with malignancy, or autoimmune disease with iatrogenic immunosuppression). Although majority of CMV retinitis cases affect immunosuppressed patients, there are few reports on CMV retinitis among immunocompetent individuals previously exposed to CMV with comorbid diabetes mellitus, hypertension, or hypercoagulable states. Congenital CMV is the most common perinatal systemic viral infection and is found in nearly 1% of all live births in the United States. Most of infected neonates will be asymptomatic. The incidence of CMV retinitis has been reported as high as 25% of infants with severely symptomatic congenital CMV, but some cases were also reported among asymptomatic infants (Whitcup 2010; Radwan et al. 2013).

Clinical Presentation

Patients may appear asymptomatic as lesions' location infrequently begins in the macular area, therefore usually vision can be nearly normal. Symptomatic patients may complain of blurred vision:

- There are two types of clinical appearances:
  - Indolent type: mild granular appearance with a few punctate hemorrhages,

sometimes with atrophic retina, and no vasculitis. It starts in the periphery and progresses slowly.
  - Fulminating type: yellow-white lesions that may become confluent, associated with retinal hemorrhages and perivenous vasculitis ("cottage cheese with catsup" or "pizza pie"). As compared to the indolent type, it progresses much faster (Figs. 1 and 2).
- Both types may be associated with a mild vitritis and sometimes fine anterior chamber reaction with pigmentary cells and keratic precipitates.
- The disease progresses slowly at approximately 250 μm/week. The disease may progress in two distinct ways: first and most common, new lesions spread from old lesions' borders. The active border generally advances posteriorly. Therefore new lesions may appear along with old atrophic lesions and mottled pigmentation of the RPE. Second is via hematogenous spread, in which new lesions will be found away from an old lesion.
- Lesions may be distributed along major retinal vessels.
- Among HIV patients CMV retinitis may present with frosted branch angiitis (Whitcup 2010).

Complications

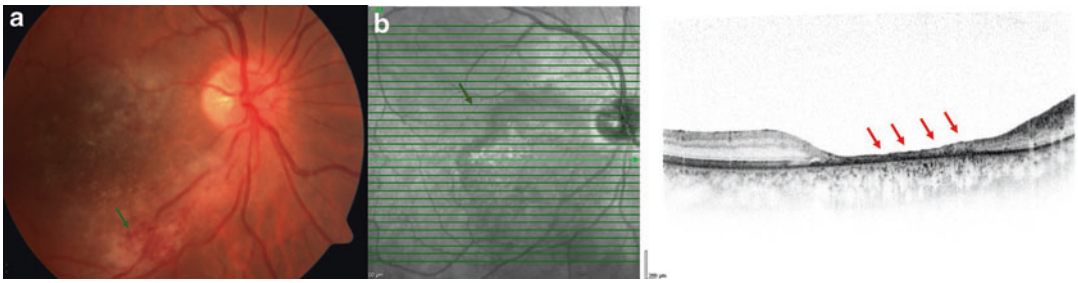
- Macular complications include retinal necrosis, cystoid edema, and epiretinal membrane; all can cause a severe permanent visual loss.
- Optic disk involvement may cause severe vision loss even with a mild retinitis.
- Retinal detachment may develop in approximately 20% of the patients. It can appear even after months to years post-initial diagnosis. Risk for developing retinal detachment is greater in the eyes with significant amount of peripheral retinal involvement. Mechanism proposed for this complication is probably a vitreous traction of the thinned, atrophic retina and the presence of retinal breaks (Fig. 3) (Whitcup 2010).

Diagnostics

- Diagnosis is usually based upon clinical appearance and history.
- The disease can be confirmed by the demonstration of CMV DNA in aqueous, vitreous, and serum samples by polymerase chain reaction (PCR).
- Serial serum PCR results may aid in disease monitoring (Whitcup 2010).

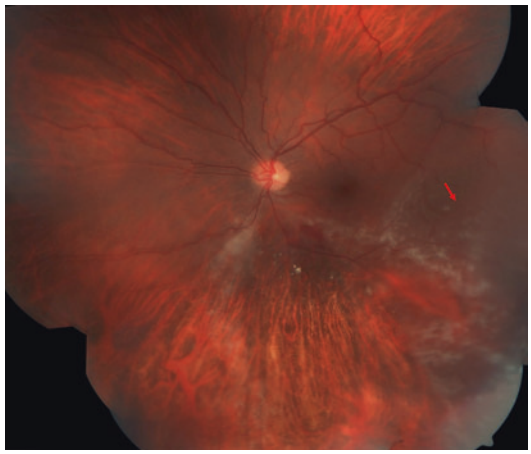
Ocular Imaging

- Serial fundus photographs help the clinician assess retinitis progression and treatment course.
- Autofluorescence imaging is valuable in detecting and localizing active CMV retinitis. A hyperautofluorescent signal is correlated with the border of advancing CMV retinitis. Stippled areas of alternating hyperautofluorescence and



Cytomegaloviruses, Retinitis, Fig. 1 (**a**) Fundus color picture (right eye): acute phase of CMV retinitis, fulminating type, involving the posterior pole showing confluent white lesions with hemorrhages (*green arrow*); (**b**) spectral domain OCT demonstrating atrophic neurosensory retina 3 months later (*red arrows*)

Cytomegaloviruses, Retinitis, Fig. 2 Fundus color picture of the left eye with fulminant-type CMV retinitis demonstrating peripheral confluenting white lesions with hemorrhages (*green arrow*), atrophic area posterior to the lesions (*blue arrow*), and recent newer lesions (*red arrow*)



Cytomegaloviruses, Retinitis, Fig. 3 Fundus color picture of the left eye with fulminant CMV retinitis complicated by temporal retinal detachment (*red arrow*)

hypoautofluorescence are observed in regions of retinal pigment epithelium atrophy from prior CMV retinitis.

– Fluorescein angiogram used to assess areas of ischemia. Findings may include blocking defects from hemorrhages and leaking or non-perfusion of vessels in involved areas of retina.
– Spectral Domain Optical Coherence Tomography (SD-OCT) imaging demonstrates loss of architecture and significant atrophy. In some eyes vitreoretinal gliotic bands on top of the retina and connected to the cortical vitreous may be found at the border of normal and affected retinas. These bands may be a source of vitreoretinal traction leading to potential complications such as retinal breaks or retinal detachment (Fig. 1b).

Differential Diagnosis

Acute retinal necrosis syndrome (ARN) – usually appears in immunocompetent patients, in the periphery with an occlusive arteritis, significant vitritis, and a rapid disease progress. The disease may be caused by VZV, HSV1, and HSV2 and rarely by CMV and Epstein-Barr virus.

Progressive outer retinal necrosis (PORN) – herpetic retinitis that occurs in patients with AIDS and CD4 T-cells counts $\leq$ 200 cells/µl. It is characterized by extensive, rapidly progressing full-thickness necrosis of the retina involving initially the posterior pole, with little or no inflammatory component, and spares the retinal vasculature.

Toxoplasmosis – usually has a typical scar appearance adjacent to an active lesion. However, among immunocompromised patients toxoplasmosis may mimic a CMV retinitis.

Syphilis and *Behcet's disease* may also resemble CMV retinitis (Whitcup 2010).

Therapy

The goal of treatment is to preserve vision and prevent further disease progression. As CMV retinitis is a systemic infection that may affect also the fellow eye and other organs, patients should receive systemic therapy, with or without concurrent local treatment. Management consists of drugs with selective inhibition of viral DNA polymerase (virostatic) and includes induction and

maintenance phases. During the induction phase, the drug is given for 2–3 weeks or until clinical response is seen, and thereafter the drug dosage is reduced and is given for a long period of time, usually months. The CDC (Center of Disease Control) recommends continuing treatment to immunocompromised patients until CD4 T-cell values rise above 100 cells/μL for at least 3–6 months. During the entire treatment period, patients should be monitored closely for active cytomegalovirus retinitis lesions, and treatment should not be stopped until all lesions have become inactive (Whitcup 2010).

Intravenous Therapy

- Ganciclovir (Roche Pharmaceuticals, NJ) is the first FDA-approved drug (1989) for CMV retinitis. It is given twice daily at a dose of 5 mg/kg for 2–3 weeks (induction phase) and then the same dose daily as maintenance for weeks to months. Adverse effects include bone marrow suppression including neutropenia, anemia, and thrombocytopenia; therefore, complete blood count test should be done frequently.
- *Foscarnet* (Foscavir, AstraZeneca, Wilmington, DE), the second drug approved by the FDA (1991). It is also administrated intravenously with 2–3-week induction dosage (60 mg/kg three times a day or 90 mg/kg twice daily). Foscarnet was found to be less toxic to the bone marrow than ganciclovir; however, it is nephrotoxic and leads to electrolyte abnormalities. Therefore kidney function test should be done regularly and patient should be told to require adequate hydration.

  At the SOCA trial (Studies of Ocular Complications of AIDS) published at 1992, newly diagnosed CMV retinitis patients were randomized to either ganciclovir or foscarnet. Both drugs were found to be equally effective.
- Cidofovir (Vistide, Gilead, Foster City, CA), the third drug approved by FDA (1996). Induction consists of 5 mg/kg once weekly for 2 weeks and then the same dose every other week. It may cause dose-dependent nephrotoxicity and therefore intravenous hydration should be used with each treatment. It has been proved as replacement therapy for failure of ganciclovir and/or foscarnet (Whitcup 2010).

Oral Treatments

- Valganciclovir (Valcyte, Roche). An L-valyl ester prodrug of ganciclovir, approved by the FDA (2001). Unlike oral ganciclovir it has good bioavailability properties, ten times higher than oral ganciclovir, and can be used to both induction and maintenance phases. Nowadays it is considered to be the standard of care for CMV disease. Dosing should begin with a 900 mg twice a day for 3 weeks and then reducing to 900 mg per day for the maintenance phase. Main adverse effect includes pancytopenia, in addition to nausea, vomiting, seizures, confusion, and peripheral neuropathy. It is category C drug with reproductive toxicity and therefore should not be given to pregnant women. Complete blood count test should be done frequently (Whitcup 2010; Heiden et al. 2014).

Intraocular Injections

Intravitreal injections may be given as an adjunctive to systemic treatment in cases of sight-threatening retinitis (zone 1 disease) or as replacement therapy when systemic treatment is contraindicated or intolerated:

- Ganciclovir – Dosage is 2 mg/0.1 ml per injection twice a week in the induction phase and then once a week for maintenance. The low cost of the drug enables wide use in developing countries as replacement to systemic treatment. However, using only intravitreous treatment may endanger the fellow eye and other organs.
- Foscarnet – Dosage is 2.4 mg/0.1 ml per injection twice a week in the induction phase and then once a week for maintenance (Whitcup 2010).

Antiviral Resistance

Mutations in the CMV UL97 gene, a viral phosphotransferase necessary for ganciclovir activation, confer low-level resistance to ganciclovir,

while mutations in both the CMV UL97 and CMV UL54 genes lead to high-level ganciclovir resistance. In such cases treatment with either foscarnet or cidofovir is recommended (Whitcup 2010).

CMV Retinitis Among Human Immunodeficiency Virus (HIV) Patients

Before the availability of highly active antiretroviral therapy (HAART), CMV retinitis affected 25% of patients infected with HIV, having CD4 T-cell values below 100 cells/μL. As HAART treatment suppresses HIV replication, HIV load declines and CD4 T-cell values rise with an immune recovery. As a result, the incidence rates of CMV retinitis have declined. The LSOCA (Longitudinal Studies of the Ocular Complications of AIDS) study reported that the 4-year cumulative incidence of CMV retinitis among HIV patients treated with HAART, with CD4 T-cell values below 100, was 7%, a 72% reduction as compared to the pre-HAART area. In fact, only 12% of patients who had severe immunodeficiency (i.e., a CD4 T-cell count below 50 cells/μL) developed CMV retinitis during the first 4 years following the diagnosis of AIDS, a 52% reduction as compared to the pre-HAART area. However, HIV patients remain at risk for developing CMV retinitis either because of delayed diagnosis of HIV infection or because they are noncompliant with, intolerant of, or unresponsive to HAART treatment, as was recently reported by the WHO. Nevertheless, CMV retinitis remains the most common ocular opportunistic infection in patients with AIDS; hence, frequent screening is mandatory to detect the disease before it becomes sight threatening (Sugar et al. 2012).

Immune Recovery

Recovering of the immune system can control CMV retinitis without the need for ongoing prophylactic therapy. However, HAART has also been associated with the development of immune recovery uveitis (IRU) in nearly 20% of patients with CMV retinitis. IRU may induce vision loss, mainly from vitritis, macular edema, epiretinal membrane, and cataract. Corticosteroids are the mainstay of therapy for IRU patients (Whitcup 2010).

Dacryoadenitis

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Definition

Acute or chronic inflammation of the lacrimal gland.

Etiology

Dacryoadenitis is classified as acute or chronic based on speed of onset and duration of symptoms. Acute dacryoadenitis is typically viral, bacterial, or inflammatory (a subset of idiopathic orbital inflammation, IOI) in origin. Chronic dacryocystitis is more likely to be associated with systemic conditions such as sarcoid, Wegener's granulomatosis, Sjögren's syndrome, or Graves' disease (Karesh et al. 2006). Rare infectious causes of chronic dacryocystitis include tuberculosis, leprosy, syphilis, Lyme disease, and trachoma.

Clinical Presentation

Symptoms often develop rapidly over hours to days, although chronic and atypical cases may have an insidious onset. The lacrimal gland is enlarged and easily palpated in the superotemporal orbit. This classically produces an "S-shaped" deformity of the upper eyelid, with swelling and mechanical ptosis more prominent laterally. With significant gland enlargement, the globe may be displaced inferomedially. The upper eyelid is typically painful and tender with prominent inflammatory signs. Chemosis, conjunctival injection, and discharge also may be present. Dacryocystitis is usually unilateral. Bilateral enlargement can be seen in up to half of lacrimal gland-involving pediatric IOI, but the likelihood of systemic disease is increased. Children may have constitutional signs and symptoms, including fever, malaise, loss of appetite, and nausea.

Diagnosis

Most cases are diagnosed clinically and empiric therapy is instituted. If present, discharge can be cultured to guide antibiotic coverage. Biopsy is reserved for atypical presentations and nonresponders (Guo et al. 2012). If bloodwork is done, increased ESR and eosinophilia are frequently present. Imaging is often helpful. On CT scan, dacryoadenitis appears as ill-defined enlargement of the lacrimal gland, often with stranding of the surrounding orbital fat. Bony erosion is absent. Contrast enhancement is seen acutely (Vaidhyanath et al. 2008).

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

Differential Diagnosis

Ruptured dermoid
Hordeolum
Preseptal cellulitis (with or without abscess)
Orbital cellulitis
Lacrimal gland tumor (Hayek and Esmaeli 2006)
Metastatic orbital disease

Therapy

A short course of oral antibiotics is often administered along with warm compresses and NSAIDs. Cephalexin is a popular initial agent. The majority of cases in children are viral and improve with supportive care alone. Oral corticosteroids are the first-line therapy for IOI. Steroid-sparing agents may be used for failures and relapses. Therapy for cases associated with systemic disease is directed toward the underlying condition.

Prognosis

Prognosis for acute dacryoadenitis is generally excellent. For chronic dacryoadenitis, prognosis depends on control of the underlying condition.

Epidemiology

Dacryocystitis is relatively rare and there are no reliable estimates of incidence in the literature. Apart from specific subsets, there is no known predilection based on gender or race. Age of onset is highly variable. IOI-associated dacryoadenitis may be seen in children as young as 3 years of age.

Dacryoadenoma

Michael Greenwood and Atif Collins
Department of Ophthalmology and Visual Sciences, University Hospitals Case Medical Center, Case Western Reserve University, Cleveland, OH, USA

Synonyms

Conjunctival epithelial tumor

Definition

A rare conjunctival tumor that presents as a pink mass in the inferior bulbar or palpebral region.

Etiology

This is a benign tumor that appears to originate from metaplasia of the surface epithelium and proliferates into the stroma (Yanoff and Sassani 2008).

Clinical Presentation

Dacryoadenoma is a rare conjunctival tumor that is found in children or young adults. It is not known if it is congenital or acquired, as there has been very

few case reports ever described. One case was noted in a 33-year-old patient who had the inferior fornix lesion removed when she was 48 (Jakobiec et al. 1989). It was unknown if she had the lesion since birth. In another case, the lesion was on the bulbar conjunctiva of a 14-year-old girl (Shields and Shields 2008). It was noted to be a darker red mass on the bulbar conjunctiva, which slowly enlarged over time. This benign tumor originates from the surface epithelium and proliferates into the stroma where it forms glandular lobules similar to the lacrimal gland.

Diagnostics

Rarely suspected on clinical exam.

Histopathology: Metaplasia of the conjunctiva epithelium with invagination into the underling stroma, forming tubules and glands.

Electron microscopy: Presence of zymogen-type lacrimal secretory granules.

Differential Diagnosis

Differential diagnosis includes lymphoma and other pink- or salmon-colored masses in the conjunctiva.

Prophylaxis

None

Therapy

Careful monitoring
Excisional biopsy

Prognosis

Excellent

Epidemiology

Children and young adults

Dacryocystitis

Ben Janson[1] and Sana Idrees[2]
[1]School of Medicine, Johns Hopkins University, Baltimore, MD, USA
[2]The George Washington University, Washington, DC, USA

Definition

Dacryocystitis is a bacterial or fungal infection of the nasolacrimal sac, which results from an obstruction of the nasolacrimal duct and stasis of tears in the lacrimal drainage system.

Etiology

Dacryocystitis may develop at any age, but it occurs more commonly in infants, young adults, and the elderly. Infantile dacryocystitis may result from incomplete canalization of the nasolacrimal duct, nasolacrimal atresia, facial cleft, and dacryocystocele (Tower 2008). Simple congenital nasolacrimal duct obstruction secondary to incomplete nasolacrimal duct canalization at the level of the valve of Hasner is more common than congenital dacryocystocele. Dacryocystocele is a distended noninfected lacrimal sac, which may be present at birth due to amniotic fluid entering and

obstructing the nasolacrimal sac. Few of the infants affected by dacryocystocele go on to develop acute infections. Acquired causes of obstruction include trauma, gradual narrowing over time, dacryolith, tumor impinging on sac or duct, granuloma, foreign body, or result of previous infections (Tower 2008; Jordan 2011). Young adults commonly develop dacryocystitis secondary obstruction from trauma or a dacryolith (Jordan 2011). A tumor intrinsic to the lacrimal sac or extrinsic and impinging on the sac or duct may cause an obstruction. A retained foreign body, such as from a prior lacrimal intubation, may also be a cause (Tower 2008). Obstruction causes accumulation of microorganisms and cellular debris in the nasolacrimal sac with the potential for development of an infection. Upper respiratory tract organisms such as β-hemolytic Streptococcus or Staphylococcus are common etiologic organisms (Jordan 2011).

Clinical Presentation

Acute dacryocystitis has a rapid onset. There are also chronic and subacute forms of dacryocystitis. There is often redness, tenderness, and swelling that is inferior to the medial palpebral ligament. Pain is often intense and is due to distension of the nasolacrimal sac (Jordan 2011).

The infection can spread and become cellulitis of the eyelid and orbit or become an abscess (Hurwitz 2014; Jordan 2011). This may cause swelling of the eyelids to be prominent at presentation. With massaging of the lacrimal sac, mucopurulent discharge can reflux through the canaliculus (Coats 2008; Tower 2008). Because of the obstruction, there often is overflow tearing and an increased tear lake (Coats 2008).

Epiphora and mattering of the eyelids may be a sign of congenital nasolacrimal obstruction in infants. Symptoms present within the first 6 weeks of life and may also be accompanied by chronic mucopurulent discharge from one or both eyes (Tower 2008). Important to note is the lack of conjunctival erythema.

Chronic dacryocystitis tends to be indolent, presenting with tearing and mild to moderate recurrent unilateral discharge. Applying pressure over the nasolacrimal sac may produce a reflux of mucoid or mucopurulent discharge from the punctum (Jordan 2011). Various bacteria may be involved, the most common of which are *Staphylococcus aureus*, *Streptococcus* species, and *Escherichia coli* (Durand 2010). Other pathogens include other *Staphylococcus* species; Gram-negative bacteria, including *Haemophilus influenzae*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*; and anaerobic bacteria, such as *Arachnia propionica*. Rarely, *Mycobacterium tuberculosis*, *Chlamydia trachomatis*, and fungi, such as *Candida*, *Aspergillus niger*, and *Pityrosporum*, may be involved. Complications of chronic dacryocystitis include acute recurrent dacryocystitis, infectious keratitis, and endophthalmitis following corneal trauma or intraocular surgery (Jordan 2011). Patients may also develop a dacryocutaneous fistula following cases of spontaneous rupture (Tower 2008).

Diagnosis

Typically diagnosis is based on clinical presentation. Infantile dacryocystitis may be diagnosed by classic symptoms of epiphora and discharge in the absence of conjunctival erythema (Tower 2008). Acquired acute dacryocystitis is typically a clinical diagnosis (Jordan 2011). Digital pressure or massage over the lacrimal sac may result in reflux of mucopurulent material. Cultures are sent to determine the organism and appropriate antibiotic therapy. Another test that may be useful is the fluorescein dye retention test to determine if the lacrimal drainage is poor as expected with obstruction (Coats 2008; Tower 2008). While not often needed, dacryocystography can be useful in determining the site of stenosis or obstruction (Hurwitz 2014).

Differential Diagnosis

The differential diagnosis for infantile dacryocystitis includes simple congental obstruction secondary to incomplete canalization of the nasolacrimal duct, punctal or canalicular atresia,

conjunctivitis, conjunctival foreign body, nasal mucosal edema, and orbital cellulitis (Tower 2008). Simple congenital obstruction secondary to incomplete canalization and atresia may manifest as epiphora and mattering of the eyelids. Additionally, they may present with minimal dilation of the lacrimal sac. This condition is benign, but must be distinguished from acute dacryocystitis (Jordan 2011). Conjunctivitis causes the conjunctiva to appear red and typically responds to topical antibiotics. Conjunctival foreign body typically presents as an acute onset red eye. Nasal mucosal edema results in tearing secondary to inferior meatus obstruction, and it typically resolves with decongestants (Tower 2008). Dacryocystitis may be mistaken for orbital cellulitis in newborns and infants. It is preferable to hospitalize these patients and initiate therapy with intravenous antibiotics to prevent orbital abscess or sepsis (Jordan 2011).

Punctal or canalicular stenosis and conditions causing impairment of the lacrimal pump must be ruled out when a diagnosis of acquired and chronic dacryocystitis is considered. In cases of stenosis, patients present with epiphora without mucus. Obstruction of the upper canalicular system may be revealed by probing and irrigation. Epiphora may result from conditions leading to a poor lacrimal pump function, such as cranial nerve VII palsy, eyelid deformity impairing lid movement, senile eyelid laxity, and flaccidity (Tower 2008).

Prophylaxis

With congenital dacryocystocele, there is controversy, but some clinicians start with antibiotics and massage (Jordan 2011). If it fails to resolve, the dacryocystocele may be surgically treated using endoscopically guided marsupialization of the dacryocystocele and stenting the nasolacrimal system (Jordan 2011). Prophylaxis for acquired forms of dacryocystitis is unclear.

Therapy

With infants and younger children, they should be hospitalized for intravenous broad-spectrum antibiotics empirically until culture results indicate a narrow spectrum antibiotic (Jordan 2011; Tower 2008). Treatment is important and can be life threatening in infants and young children.

Congenital obstruction typically resolves spontaneously, but probing by passing a probe into the lower canaliculus and up through the nose is the first intervention (Hurwitz 2014). This is typically successful with a 90% success rate (Tower 2008). If this fails, silastic tubes for 3–6 months are often tried, and then if this too fails, dacryocystorhinostomy is performed, but this is rarely needed (Tower 2008; Hurwitz 2014).

For all forms, warm compress and pain relief can help the symptoms of dacryocystitis. The main goal of therapy is to treat the infection. Topical and systemic antibiotics are used first. If there is no improvement in 48–72 h, intravenous antibiotic therapy should be started (Jordan 2011). If postseptal orbital cellulitis is suspected, a CT scan should be ordered to look for abscesses in which intravenous antibiotics are indicated (Hurwitz 2014). If a superficial fluctuant mass is present, a stab incision to drain is part of therapy (Jordan 2011). A dacryocystotomy is reserved for when infection continues to persist and perforation is impending (Hurwitz 2014). Probing may be used to drain the lacrimal sac by inserting a probe through the canaliculus until the sac contents empty into the conjunctiva (Tower 2008). Chronic forms require treatment with antibiotics and digital decompression until surgical intervention (Tower 2008).

Surgical treatment for adults includes external dacryocystorhinostomy, endonasal endoscopic dacryocystorhinostomy, or balloon catheterization (Tower 2008). Balloon catheterization is less studied but has shown promise in some reports (Tower 2008; Coats 2008). External dacryocystorhinostomy has a 95% success rate when done by experienced surgeons (Tower 2008).

Prognosis

Most infants experience spontaneous resolution of dacryocystitis within the first 6 months of life.

More than 90% outgrow the condition by 1 year. With proper therapy, acute dacryocystitis resolves within 7–14 days (Tower 2008). Acute dacryocystitis may spread to the anterior orbit, resulting in significant swelling of the eyelid, or the posterior to the orbital septum, producing orbital cellulitis with complications of globe displacement, afferent pupillary defect, optic neuropathy, and visual loss. Of patients with an initial attack of acute dacryocystitis, 60% will experience a recurrence (Hurwitz 2014).

In patients requiring incision and drainage for a lacrimal abscess, approximately 8% will require a repeat procedure. One study found that 25% of patients with a lacrimal sac abscess who did not undergo definitive surgical treatment with dacryocystorhinostomy or dacryocystectomy developed a recurrent lacrimal sac abscess (Durand 2010). When dacryocystorhinostomy is required, it is reported to have a success rate of 95% when performed by experienced surgeons (Tower 2008).

A common complication of not treating dacryocystitis is rupture through the skin causing a dacryocutaneous fistula (Tower 2008). Complications can include infectious dermatitis, endophthalmitis, and acute recurrent dacryocystitis (Jordan 2011). Unfortunately, recurrent attacks are not uncommon and can occur in 60% of patients.

Epidemiology

Congenital forms are present in 2–6% of live births (Coats 2008; Tower 2008). Acquired forms are most common in certain age groups including mid-30s and older than 65 (Jordan 2011). Young women are the most likely to have dacryoliths, which is the most common form of acquired dacryocystitis (Tower 2008; Jordan 2011).

Darier Disease (Keratosis Follicularis)

Samantha Dewundara and Nadeem Fatteh
Department of Ophthalmology, Kresge Eye Institute, Wayne State University, Detroit, MI, USA

Synonyms

Darier-White disease; Dyskeratosis follicularis

Definition

Keratosis follicularis is a genodermatosis characterized by abnormal keratinization of the epidermis, nails, and mucous membranes.

Etiology

Keratosis follicularis is an autosomal dominant disorder caused by mutations in the ATP2A2 gene, which encodes the Ca^{2+} ATPase 2 isoform. This defect results in disturbed cell-to-cell adhesion and differentiation of the epidermis (Ringpfeil et al. 2001).

Clinical Presentation

Clinical features consist of disseminated warty papules and plaques with an affinity for the seborrheic areas of the body including the face, scalp, and upper trunk (Sehgal and Srivastava 2005).

Ocular involvement in keratosis follicularis is relatively uncommon. Eyelid manifestations parallel cutaneous findings and are characterized by warty hyperkeratotic plaques with accumulation of seborrhea-like debris at the eyelid margin. Most of the affected patients have dry eye syndrome with and without Sjögren's syndrome (Mielke et al. 2002). Possible corneal manifestations are peripheral arcus lipoides-like opacifications, asymptomatic nebular dot-like opacities of the peripheral corneal epithelium, and central epithelial surface irregularities.

Diagnostics

Histopathologic examination of the peripheral corneal lesions shows corneal edema and separation of the basal epithelium of Bowman's layer by granular material. Electron microscopy has shown this granular material to represent remnants of cell debris and an electron-dense granular substance (Blackman et al. 1980).

Clinical diagnosis can be confirmed by biopsy. Histopathologic findings of cutaneous lesions include dyskeratosis represented by eosinophilic corps rounds and grains and acantholysis with suprabasal intraepidermal cleavage. These cutaneous lesions are histopathologically different from corneal lesions as the cornea is not normally a keratinizing epithelium (Daicker 1995).

Differential Diagnosis

The differential diagnosis for keratosis follicularis includes other genodermatoses with corneal changes including keratosis plantaris, Kyrle disease, and tyrosinemia. Anterior basement membrane dystrophy and Salzmann's nodular degeneration may be included in the differential for the peripheral corneal opacities found in keratosis follicularis (Blackman et al. 1980).

Prophylaxis

Uncertain

Therapy

Keratosis follicularis may result in reduced corneal protection and microbiological colonization which may lead to recurrent corneal ulcerations. Along with long-term dermatological medical care, intensive ocular therapy with lubricants with the consideration of antibiotics is recommended (Mielke et al. 2002).

Prognosis

Uncertain

Epidemiology

The incidence varies from 1:30,000 to 1:100,000, with an average age of onset in the first or second decade.

Synonyms

Dark adaptometry

Definition

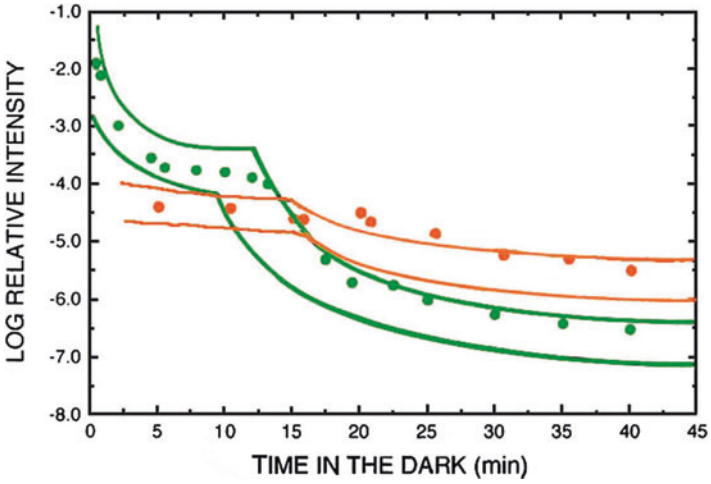
A test for monitoring time-dependent changes in retinal sensitivity to light stimuli when moving from a bright light environment to darkness.

Purpose

To evaluate the rate at which sensitivity to light stimuli of the "cone system" and of the "rod system" recover when ambient illumination is changed from bright light to darkness. *The terms "cone system" and "rod system" refer respectively to the cones and rods, each class of photoreceptors has its own associated neural network in the retina, conveying signals to the brain in order to elicit visual perception.

Principle

Dark adaptation test is a psychophysical test in which patient cooperation is mandatory. The patient is required to fixate the tested eye (the non-tested eye is covered with an eye patch) to a red fixation light, while a flickering (typically 1 Hz) test light field is modulated in intensity. The task of the patient is to signal the detection of the flickering test light. The testing procedure usually starts with a learning phase in which the patient becomes acquainted with the setup and with his/her task. Then, the patient is instructed to fixate at a bright light source for about 3 min in order to bleach at least 80% of rhodopsin, the visual pigment of the rod photoreceptors. Cones' visual pigments are bleached too but to a lesser extent. Following the bleaching exposure, the actual dark adaptation test starts, and threshold for detecting the flickering test light is measured periodically. For threshold determination, the intensity of the flickering test light is lowered to levels that cannot be detected, and the patient is asked to fixate on the red fixation light while the intensity of the flickering light is gradually increased until the patient signals its detection. The intensity at which the flicker was detected is the threshold for that period of time in darkness. In the complete test, thresholds are determined during 2 h in darkness after the bleaching; however it is usually sufficient to follow only the first 40 min since sensitivity recovery is close to 99% complete. In order to determine which visual component, the cone system or the rod system determine visual sensitivity during the dark adaptation process, it is advised to use intermittently green (500 nm) light and orange (600 nm) light for the flickering test light as illustrated in Fig. 1. The cone system is more sensitive to the 600 nm light compared to the 500 nm light, while the rod system is more sensitive to the green light compared to the red light. A clear change from cone-mediated vision to rod-mediated vision is seen at 8–10 min in darkness.



Dark Adaptation Testing, Fig. 1 Normal dark adaptation curve after a substantial bleaching of rhodopsin (at least 75%), using green (500 nm) and orange (600 nm) test lights. The two continuous lines mark the normal spread of 20 volunteers with normal vision. The data points show results of a patient with normal dark adaptation

The size of the flickering test light may vary in dimension but has to stay fixed throughout the test. A field of 2° in diameter is usually used. Another important parameter that needs to be considered is the retina region that is illuminated by the flickering test light. Usually, a region located 15–20° from the fovea is used, since this locus contains the highest density of rod photoreceptors. However, other loci may be considered depending upon the patient complaint and medical history. In order to get reproducible test results, it is important to standardize the test procedure and parameters.

Figure 1 shows the range of dark adaptation for 20 volunteers with normal day- and night-vision (continuous curves) and data from one subject who complained of visual difficulties at night (red and green data points) and was found to have normal dark adaption curve. The first 6–7 min after bleaching reflects sensitivity recovery of the cone system, which stabilizes after about 6–8 min. This is a relatively fast sensitivity recovery phase, and it is beneficial to measure threshold every 30 s. At around 10 min following termination of the bleaching exposure, a second phase of sensitivity increase is detected, the recovery of the rod system. This lasts for another 20–25 min and stabilizes after about 35–40 min in darkness. Separation between dark adaptation of the cone system and that of the rod system can be done by asking the patient if she/he sees color when detecting the flickering light; during the recovery of the cone system, the patient can easily identify the color of the stimulus, while during the rod recovery phase it appears gray. As shown in Fig. 1, when intermittent green (500 nm) light and orange (600 nm) light are used for the flickering test light, two components can easily be identified in the dark adaptation curve, reflecting recovery of the cone system and of the rod system. Since the total range of visual sensitivity recovery from immediately after the bright light exposure to complete dark adaptation is very large, in the order of 100,000-fold, threshold is given in log units in the ordinate of the dark adaptation curve (Fig. 1).

Indication

Evaluation of visual function at night: The dark adaptation test is used to complement the electroretinogram (ERG) test in patients complaining of difficulties in night vision. Regardless of the results of the dark-adapted ERG responses, psychophysical testing of dark adaptation is recommended because it is more quantitative in determining the magnitude of difficulty in night vision compared to the ERG recording and because discrepancies between ERG findings and dark adaptation may be seen in several settings including Duchene Muscular Dystrophy and Dominant Electronegative ERG.

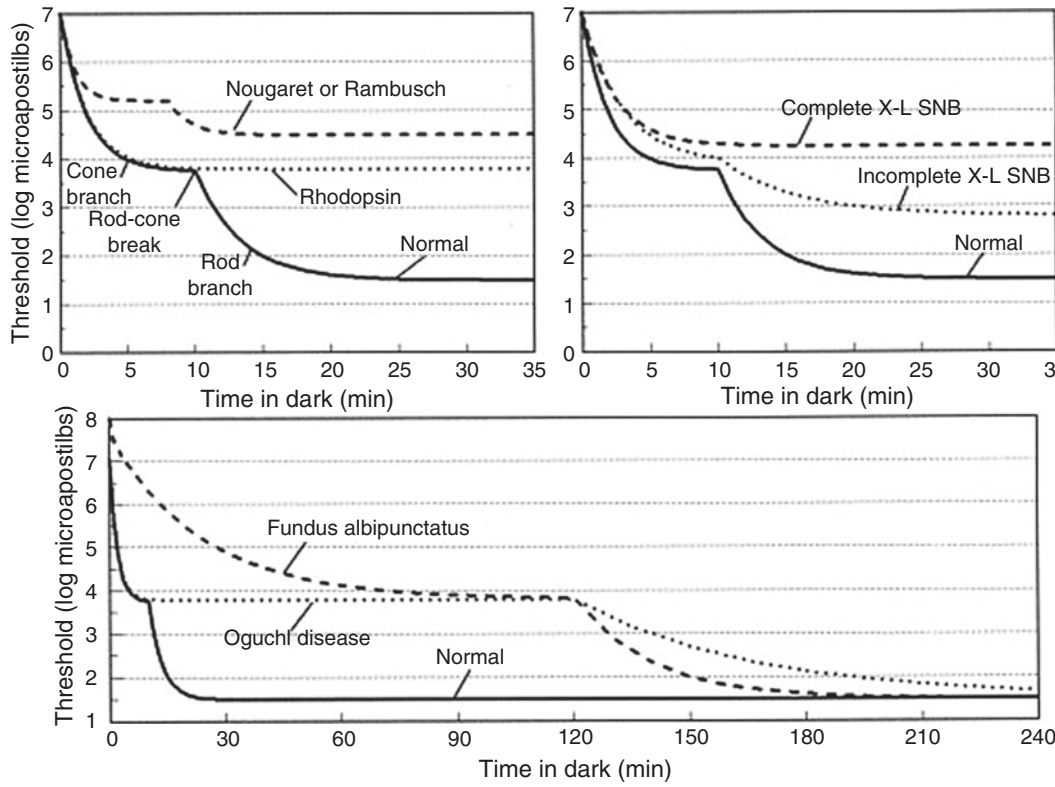
Suspected inherited stationary disorder in night vision: Inherited stationary disorders in night vision

reflect mutation in genes coding for proteins participating in the rhodopsin cycle or proteins associated with the rod system in the retina. These cases are associated with typical changes in the ERG responses, but for quantitative assessment of night vision and for exact determination of the type of disorder, dark adaptation test is recommended, as illustrated for a few typical cases in Fig. 2 (Dryja 2000).

The dark adaptation curve found in incomplete x-linked congenital stationary night blindness (CSNB) demonstrates a slight reduction in the rate of cone system recovery, a normal timing of rod system-cone system break, and a reduction in the rate of rod system recovery with final dark adapted thresholds higher than normal, but the rod system dominates light detection. In contrast, in the complete form of CSNB, the dark adaptation curve shows only a cone system component of elevated threshold compared to the normal, but there is no rod system recovery and vision is controlled by the cone system.

In other two types of congenital difficulties in night vision, shown in Fig. 2, the rate of dark adaptation is delayed, but final threshold is normal. In fundus albipunctatus, sensitivity recovery of the cone system and of the rod system are considerably delayed, but after sufficient time in the dark, the sensitivity to light of the rod system is normal. In contrast, patients with Oguchi disease, show normal recovery of the cone system, but delayed recovery of the rod system. In patients with Oguchi disease, normal sensitivity to light of the rod system is reached if they stay in darkness for sufficiently long period of time.

Vitamin A deficiency: Patients suffering from vitamin A deficiency from any underlying cause



Dark Adaptation Testing, Fig. 2 Representative dark-adaptation curves of patients suffering from different genetic source leading to night vision deficiency. (Dryja 2000)

should be tested for dark adaptation because difficulties in night vision start relatively late after vitamin A deficiency starts. In the western world, cases of vitamin A deficiency due to malnutrition are rare, but other causes for vitamin A deficiency, including liver cirrhosis, bariatric surgery and extreme weight losing diets, increase in number.

Contraindication

Non cooperating patient

Advantage/Disadvantage

Advantage: physiologic, quantitative and functional assessment of night blindness. May be used to follow up on disease progression and response to treatment.

Disadvantage: lengthy process that requires patient cooperation.

Synonyms

Heliophobia; Photophobia

Definition

Day blindness (hemeralopia) is a symptom in which vision is impaired in daytime (photopic conditions), whereas night vision (scotopic conditions) is preserved.

Etiology

The visual system consists of two components that are relatively independent of one another. One component is responsible for vision in daytime, the photopic system, which is based upon the cone photoreceptors. The other component is responsible for vision under dark conditions, the scotopic system, which is based upon the rod photoreceptors. There is a slight overlap between the two systems during dim background illumination (mesopic conditions), but in general, rods cannot replace cones for daytime vision and cones cannot replace rods for night vision.

Difficulties in day vision, ranging from slight photophobia to day blindness, can result from any condition in which cone photoreceptor function is diffusely impaired, or from conditions in which too much light enters the ocular globe.

1. Cone dystrophy, cone-rod dystrophy, and achromatopsia (inherited disorder of complete

absence of functioning cones in the retina) can lead to difficulties in visual function during bright ambient illumination, resulting in day blindness and photoaversion.

In contrast, ocular conditions affecting only macular cone photoreceptors such as inherited macular degeneration (Stargardt's disease, best vitelliform macular dystrophy) and age-related macular degeneration will not typically cause hemeralopia, as functionally preserved peripheral cones can light adapt when ambient illumination increases.

2. Other conditions potentially associated with aversion from bright light include conditions in which intraocular light dispersion occurs, such as ocular albinism, central cataract, corneal abrasion, aniridia, anisocoria, and a tonic pupil (Adie's pupil) in which pupillary constriction in response to light is inadequate.

Occurrence

It cannot be specified because it changes according to the diversity of pathologies causing hemeralopia (photophobia) and the variability of each of these causes in different populations.

Decentration

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Off-center optics

Definition

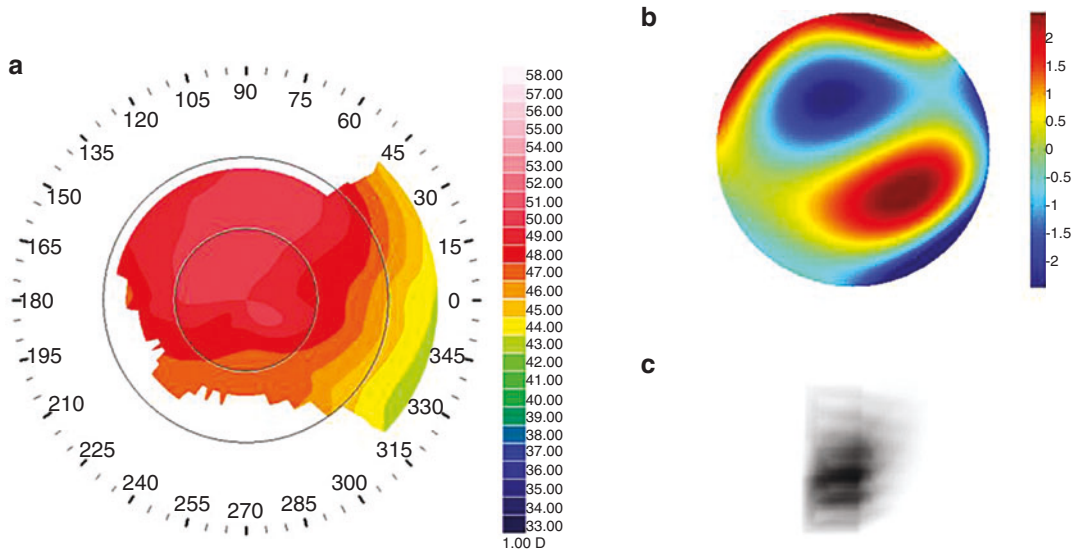
Misalignment of an optical component relative to the reference axis. In geometric optics, the misalignment can be a shift or tilt relatively to the optical axis, or a combination of both. In ophthalmic optics, the term "decentration" refers to the shift of the crystalline lens, an intraocular lens (IOL), a corneal refractive treatment, a contact lens, or the lens in a frame relatively to the visual axis. Decentration of the pupil is called korectopia.

History

From the construction of optical systems and from the introduction of glasses it became evident that for an optimum image quality the components of an optical system need to be aligned along a reference axis. Phoropters were equipped with centration crosses to ensure proper alignment during the process of subjective refraction. The introduction of IOL implantation and excimer laser corneal refractive surgery in ophthalmology brought the problem of tilt and decentration into the focus of ophthalmic surgeons and ophthalmic research.

Clinical Features

A tilted optical system causes a prismatic effect (tilt) while decentration by shift induces astigmatism (of oblique bundles) and higher-order aberrations (HOA), mainly coma. Coma is typically induced if spherical aberration is present. Patients then often complain about a ghost image or "shadow." The clinical symptoms are highly dependent of the amount of decentration and the power of the decentered optical system. A decentration of a spherical IOL of less than 500 µm might be asymptomatic (Baumeister et al. 2009). In contrast, a decentration of a corneal excimer ablation of −12 D with a small optical zone over the same range – as it was common in the early days of excimer laser refractive surgery – can cause significant symptoms due to



Decentration, Fig. 1 Decentered hyperopic LASIK ablation. **A**, corneal topography **B**, wavefront map **C**, simulation

coma induction. Simulation studies showed that the effects of decentration on retinal image quality are more pronounced if spherical aberration is introduced and the pupil diameter is large (Bühren et al. 2007; Bühren et al. 2010b). Consequently, aspheric ablation profiles that introduce less spherical aberration are more tolerant to decentration (Bühren et al. 2010a).

Tests

The diagnostic procedure is dependent from which optical component is assumed to be decentered. A grossly decentered (subluxated) IOL or LASIK flap can be seen at the slit-lamp. Quantification of IOL tilt and decentration can be achieved by Scheimpflug photography, optical coherence tomography, or with a Purkinje meter. In case of decentered corneal excimer ablation (Fig. 1), corneal topography can reveal the decentration. Aberrometry is capable of quantification of coma, spherical aberration, and other HOA of the whole eye. Devices that combine topography and aberrometry are the ideal tools for separating HOA originating from the cornea and the lens or IOL.

Differential Diagnosis

Because the symptoms of decentration-induced HOA are similar regardless of the origin of decentration, the first step involves the differential diagnosis between corneal and lenticular aberrations or even aberrations due to a misaligned lens in a frame of glasses. Other differential diagnoses include corneal scars, keratoconus (which could be considered as a decentered optical system sui generis), and cataract.

Etiology

Decentration of a corneal laser treatment occurs if the treatment is misaligned relative to the visual axis. This can either happen due to a primary misalignment (failure to center the treatment correctly) or as secondary decentration due to shift during the treatment. The introduction of eye trackers that compensate for eye movements during the process of treatment has increased alignment precision. The correct initial alignment relative to the optical axis is achieved by a fixation laser beam that visualizes the patient's visual axis to the surgeon. Decentration of IOLs occurs

typically in case of poor capsular or zonular support, decentered capsulorrhexis, asymmetric shrinkage of the capsular bag, misplacement of the haptics, and misalignment of an iris-supported IOL relatively to the pupil. A recently more prevalent problem is the late (sub-) luxation of IOLs implanted in the capsular bag in eyes with pseudoexfoliation.

Treatment

For a decentered corneal refractive treatment (ablative, incisive, or coagulative), the most efficient treatment is the correction of HOA by a rigid contact lens which is, however, seldom tolerated in refractive patients. Another, yet not always effective, option to reduce HOA is topography-guided excimer surgery. An IOL subluxated with the capsular bag that causes symptoms can be either recentered (e.g., using a Cionni ring) or can be replaced by an iris-fixated IOL.

Very important is the prophylaxis of decentration: a correct centration of the ablation to the visual axis, a centered capsulorrhexis in cataract surgery, and in case of sulcus implantation of IOLs an anterior optic capture.

Prognosis

In case of decentered corneal refractive treatment, there is no progression to be expected. Decentration of IOLs due to zonular weakness in pseudoexfoliation syndrome is likely to increase over time. In terms of vision, prognosis is good, if a rigid contact lens can be fitted or if the IOL can be recentered or replaced.

Deep Anterior Lamellar Keratoplasty (DALK)

Luis Santiago-Caban and Mark Mifflin
Department of Ophthalmology and Visual Sciences, John A. Moran Eye Center, University of Utah School of Medicine, Salt Lake City, UT, USA

Synonyms

Descemet's deep anterior lamellar keratoplasty; Maximum depth deep anterior lamellar keratoplasty; Predescemet deep anterior lamellar keratoplasty

Definition

Deep anterior lamellar keratoplasty (DALK) is a surgical procedure in which diseased corneal stroma is replaced by donor tissue, preserving host Descemet's membrane and endothelium.

Indications

DALK is the corneal transplant procedure of choice for patients harboring diseases of corneal stroma but normal Descemet's membrane and endothelium. Indications include ectatic disorders (keratoconus, keratoglobus, pellucid marginal degeneration, post-refractive ectasia), corneal scars, and anterior corneal dystrophies. DALK may be preferred over penetrating keratoplasty in monocular or noncompliant patients.

Compared to penetrating keratoplasty, DALK may result in better long-term graft survival, less dependency on steroids, earlier suture removal, less stringent follow-up and donor tissue requirements, and decreased graft rejections. Although penetrating keratoplasty may be efficacious, DALK is becoming the procedure of choice for corneal stromal diseases.

Contraindications

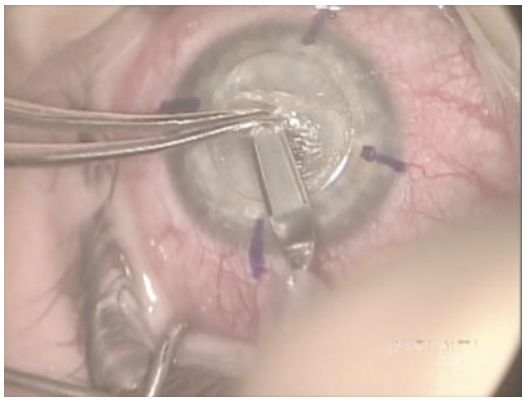
DALK is contraindicated in any condition in which Descemet's membrane or endothelium is unhealthy, including corneal hydrops or Descemet's scarring.

Techniques and Principles

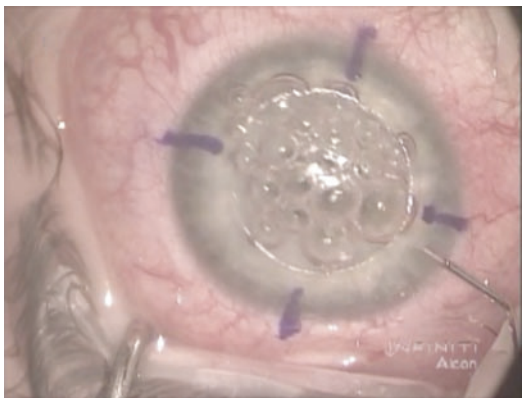
Achieving optimal visual results with DALK depends on the smoothness of the graft-donor interface and deepness of dissection. The big-bubble technique, described by Anwar and Teichman, achieves these two principles, making it the most popular DALK technique among cornea surgeons worldwide.

The big-bubble technique involves the following steps:

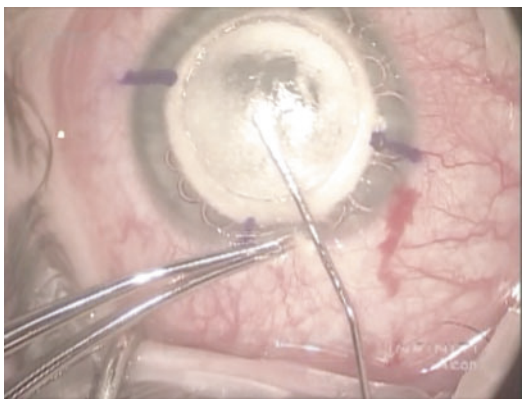
1. Trephination of the central host cornea with or without lamellar dissection, depressurization of the anterior chamber, and injection of small air bubbles in the anterior chamber (see Figs. 1 and 2)
2. Stromal delamination with the big-bubble formation (see Fig. 3)



Deep Anterior Lamellar Keratoplasty (DALK), Fig. 1 Lamellar dissection



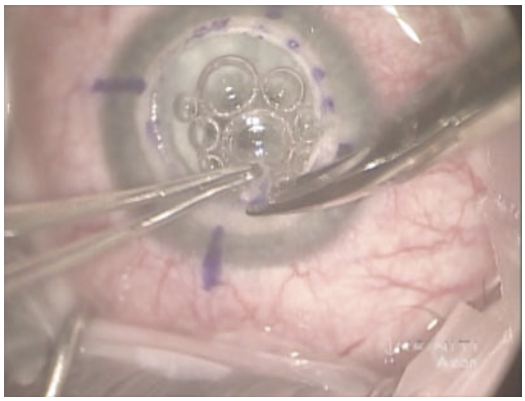
Deep Anterior Lamellar Keratoplasty (DALK), Fig. 2 Depressurization and injection of air bubbles in the anterior chamber



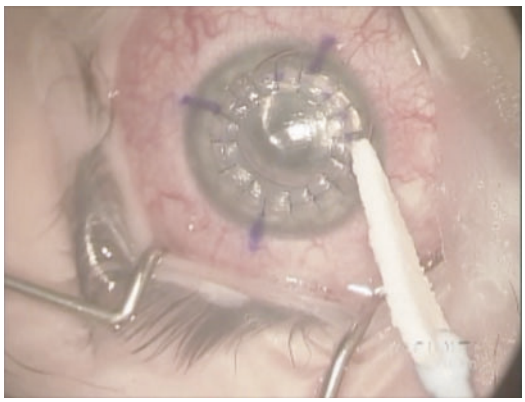
Deep Anterior Lamellar Keratoplasty (DALK), Fig. 3 Stromal delamination with big-bubble formation

(a) Air is injected intrastromally through a small-bore needle or cannula creating a separation between the stroma and Descemet's membrane.

3. Removal of residual stroma and baring of Descemet's membrane (see Fig. 4)
   (a) Small incision is made in the posterior stroma, and the big-bubble plane is entered.
   (b) Gentle dissection is performed if necessary, often with the aid of viscoelastic.
   (c) Dissected stroma is removed using blunt-tipped scissors.
4. Donor tissue preparation and placement into lamellar bed (see Fig. 5)



Deep Anterior Lamellar Keratoplasty (DALK), Fig. 4 Removal of residual stroma



Deep Anterior Lamellar Keratoplasty (DALK), Fig. 5 Donor tissue placement into lamellar bed

Other described DALK techniques include manual lamellar dissection and automated lamellar keratoplasty.

Outcome

Penetrating keratoplasty is the standard against which deep lamellar keratoplasty has been compared in terms of outcomes. The interface between the host and donor tissues has been postulated to be a possible cause of decreased visual acuity in DALK. Due to the increased popularity of lamellar procedures in recent years, several studies have compared DALK and penetrating keratoplasty in terms of visual outcomes, endothelial cell loss, graft survival, and resistance to trauma.

In terms of visual outcomes, DALK is at least equally effective in restoring vision compared with penetrating keratoplasty. Deep dissections baring Descemet's membrane must be achieved in order to obtain visual results comparable to full-thickness corneal transplants.

Uncomplicated DALK cases have less endothelial cell loss than the traditional penetrating keratoplasty. Cases in which Descemet's membrane has been perforated have the same rate of endothelial cell loss as in full-thickness transplants.

Studies have demonstrated graft survival is higher in lamellar procedures, mainly due to decreased endothelial cell loss and decreased rates of rejections.

Theoretically, lamellar corneal transplants have greater resistance to trauma compared to penetrating keratoplasty. There are several reports of traumatic wound dehiscence after DALK in the literature.

Based on the evidence we have, DALK should be the procedure of choice in diseases affecting corneal stroma.

Complications

The most common intraoperative complication in DALK is rupture of Descemet's membrane. It may be violated during trephination, stromal dissection, and passing a suture needle. Care must be

taken during these three steps. In the event of a big rupture, case must be converted into a penetrating keratoplasty.

Postoperative complications unique to DALK include papillary block, pseudoanterior chamber, Urrets-Zavalia syndrome, and post-keratoplasty atopic sclerokeratitis.

Deep Lamellar Endothelial Keratoplasty (DLEK)

Sana Idrees
The George Washington University, Washington, DC, USA

Synonyms

Posterior lamellar keratoplasty

Definition

Deep lamellar endothelial keratoplasty (DLEK) is a procedure that involves the selective transplantation of components of the cornea. DLEK is performed through the limbal scleral incision, leaving the corneal surface of the recipient untouched. In 1998, Gerrit Melles, MD, of the Netherlands laid the foundation of modern endothelial keratoplasty in a procedure he termed posterior lamellar keratoplasty (PLK). He was the first surgeon to perform an endothelial keratoplasty using a scleral limbal approach in a human (Shamie et al. 2009). The technique that Melles utilized in PLK involved dissection of the posterior lamella, Descemet's membrane, and the endothelium through a 9.0 mm sclerocorneal incision, and grafting of a donor disk of these three layers. The graft is held in place by an air bubble while the patient lies supine (Fernandez and Afshari 2010). Melles utilized air for resection of the recipient tissue and stabilization of the donor graft after insertion. Additionally, this technique obviated the need for corneal sutures (Shamie et al. 2009).

Melles named the procedure posterior lamellar keratoplasty, which was the same name utilized by surgeons performing endothelial keratoplasty under a hinged flap in the past (Shamie et al. 2009). Melles later revised the procedure using a 5.0 mm incision and bending the graft tissue to allow for insertion. This revision resulted in rapid improvement in visual acuity with only a small increase in astigmatism at 6 months postoperatively. However, the procedure was technically difficult, and it required the manual dissection of both donor and host stromal beds (Fernandez and Afshari 2010).

In the United States, Mark Terry, MD, adopted the PLK procedure and termed it deep lamellar endothelial keratoplasty. Terry worked to simplify the procedure, using a cohesive viscoelastic agent to stabilize the anterior chamber (Fernandez and Afshari 2010). When Terry adopted the PLK procedure, he worked on simplifying the procedure while maintaining or improving its results. He used Healon, a cohesive viscoelastic agent, to stabilize the anterior chamber. The cohesive characteristics of Healon allowed it to be easily removed in its entirety without residual coating of the tissue and without hindering the donor graft adhesion. He renamed the procedure deep lamellar endothelial keratoplasty to differentiate it from the posterior lamellar keratoplasty procedure used

in the past, which involved the creation of a hinged corneal flap, and to emphasize the endothelial transplantation involved in the procedure (Shamie et al. 2009). This procedure was technically difficult, but its development led to an accelerated movement of advancements in endothelial keratoplasty (Fernandez and Afshari 2010).

In endothelial keratoplasty, only a portion of the recipient's posterior cornea is removed and a small graft is transplanted in its place. By grafting only a portion of cornea, less foreign antigen is introduced to the donor. Additionally, few to no sutures are used in the procedure and minimal astigmatism is introduced. With this method, less foreign antigen is introduced to the donor and the incidence of vascular ingrowth and graft rejection are lowered. A partial thickness corneal transplant provides for faster visual recovery and improved globe stability (Fernandez and Afshari 2010).

Indication

The cornea is composed of the following layers from anterior to posterior: epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium. The cornea is maintained in a state of deturgescence by the Na^+/K^+ ATPase on the endothelial cells and the tight junctions between the cells that limit the movement of fluid into the stroma. By maintaining the cornea at an optimal level of hydration, the endothelial cells preserve the ordered arrangement of collagen, which is essential for corneal transparency. Once damaged or lost, endothelial cells cannot be physiologically replaced (Fernandez and Afshari 2010). Corneal endothelial dysfunction is the major indication for most of the penetrating keratoplasty (PKP) procedures that are performed in the United States annually. However, because endothelial dysfunctions often initially only affect certain layers of the cornea, corneal surgeons have moved toward selective endothelial keratoplasties for surgical replacement with donor tissue.

Deep lamellar endothelial keratoplasty is indicated for procedures that cause irreversible corneal endothelial dysfunctions, including the following:

1. Posterior corneal dystrophies, such as Fuch's dystrophy, nonguttate endothelial dystrophy, and posterior polymorphous dystrophy
2. Aphakic and pseudophakic corneal edema and bullous keratopathy
3. Iridocorneal endothelial syndrome (ICE)
4. Other causes of endothelial dysfunction, including trauma, foreign body, and age (Hannush 2011)

Descemet's stripping endothelial keratoplasty (DSEK) and Descemet's stripping automated endothelial keratoplasty (DSAEK) are modifications of Melles' PLK procedure, which quickly replaced DLEK and PLK given their simplified techniques and better visual outcomes. However, there continue to be indications for DLEK in patients at high risk for complications unique to DSEK and DSAEK, such as graft dislocation. In DLEK, the stromal bed of the recipient is roughened, which allows for better adherence (Shamie et al. 2009).

Prolonged intraocular air in the anterior chamber has been proposed as a method to stabilize the graft. DLEK would be the procedure of choice in any condition in which retention of the intraocular air bubble in the anterior chamber would not be possible. Such conditions would include a stable anterior chamber intraocular lens, aphakia, and irreparable iris defects, which allow for movement of the air bubble to the posterior pole (Shamie et al. 2009).

Contraindication

The following conditions are considered contraindications for the DLEK procedure:

1. Corneal ectasias
2. Stromal dystrophies
3. Any other cause of stromal scarring or opacification, including infection, interstitial keratitis, and lipid keratopathy
4. Anterior corneal dystrophies and degenerations, including Reis-Bücklers, Salzmann's, and Meesmann's (Hannush 2011)

Techniques and Principles

DLEK surgery is usually done under retrobulbar block anesthesia with a seventh cranial nerve block. This allows for both anesthesia and akinesia of the lids. General anesthesia may be used in patients who are uncooperative or in whom posterior pressure must be minimized. The DLEK procedure may be performed in combination with a cataract extraction. In such cases, cataract extraction is done prior to DLEK and after epithelial scraping to improve visualization if significant corneal haze is present. Dispersive viscoelastic agents should be avoided as they may adhere to the stromal interface and prevent adherence or the donor disk to the recipient stromal bed. The cataract surgery should be performed through a separate scleral limbal incision, which should be sutured tightly prior to creation of the stromal pocket of the DLEK procedure (Shamie et al. 2009).

Preparation of the Recipient Cornea

In DLEK, the corneal surface is left untouched in an effort to preserve the natural corneal topography, and the corneal limbus is preserved in order to maintain the globe's structural integrity (Terry 2003). The DLEK procedure is usually performed from the temporal side for ease of entry. A circular corneal marker, ranging in size from 8.0 to 9.0 mm, is used to create a circular imprint on the corneal surface. A sterile marker is then used to accentuate the circular indentation with dotted marks, which will serve as the template for the posterior lamellar resection that is done later in the procedure. Two 1.0 mm diameter corneal limbal stab incisions are placed 5 o'clock hours apart, which will be used as entry points to the anterior chamber. A 1.0 mm diamond knife is preferred as it creates a better paracentesis wound with easier anterior chamber entry compared to a metal blade. These entry ports can be marked with a sterile marker to allow for ease of identification and reentry. The cohesive viscoelastic Healon can be into the anterior chamber through one of the stab incisions, replacing the aqueous to maintain normal pressure during the procedure (Shamie et al. 2009).

A conjunctival peritomy is performed prior to creation of the 5.0 mm temporal scleral tunnel. Cautery is used for hemostasis. A 5.0 mm length incision with a depth of 350 μm is created 1.0 mm posterior and parallel to the superior corneal limbus temporally (Shamie et al. 2009). This incision is made using a trifaceted, guarded diamond knife. A specialized semisharp stromal dissector is then used to dissect a deep lamellar pocket at a depth of 80% into 1.0 mm of clear cornea. Straight and curved stromal dissectors are then used to extend the lamellar pocket beyond the pupillary axis. The lamellar pocket is extended from limbus to limbus (Terry 2003). This step is technically challenging, particularly locating the appropriate plane for dissection and preventing perforation of the cornea. Devers dissectors have sharp tips with blunt sides, which can be used to create this lamellar interface without perforating the cornea. After the stromal pocket has been created, additional Healon should be used to fill the chamber. A 2.8 mm keratome is then used to enter the anterior chamber through the scleral tunnel at the proximal mark of the corneal circular template mark (Shamie et al. 2009).

Microscissors are used to excise a posterior disk of the recipient's cornea using the circular template made on the surface of the cornea, and the wound is extended to measure 5.0 mm. The lamellar disk is removed using Utrata forceps. A 10–0 nylon, interrupted suture is placed in the corneal wound to maintain the anterior chamber while keeping a 3.0 mm opening. The cohesive viscoelastic Healon is then removed through this opening. The chamber is maintained with balanced saline solution (BSS) (Shamie et al. 2009).

Preparation of the Donor Cornea

Next, the donor cornea must be prepared for grafting. The donor tissue may be precut by an automated keratome, or the surgeon may prepare it. If the surgeon chooses to cut the donor tissue, an artificial anterior chamber with a microkeratome can be used to prepare the donor lamellar graft. The anterior chamber must initially be injected with Optisol-GS until a meniscus is formed on the post (Shamie et al. 2009). The corneal-scleral

cap tissue received from an eye bank is coated with Healon on the endothelial side and placed onto the post of the artificial anterior chamber with the endothelial side down (Terry 2003). Another less common practice is to place the donor cornea epithelial side down on the artificial anterior chamber to prevent endothelial cell compromise. The donor cornea is then capped into place and more Optisol-GS is injected into the artificial anterior chamber until the desired pressure is achieved. Then a sterile marker is used to mark the central cornea and the horizontal meridian peripherally (Shamie et al. 2009).

For manual lamellar dissection, random and scattered marks can be made on the corneal surface to help visualize the depth of dissection. A Barron suction recipient trephine with a diameter 0.5 mm larger than the desired donor graft size is placed over the donor tissue, suction is applied, and trephination is done to about 60% depth. The trephine should be removed and the cut should be inspected. The lamellar pocket dissection is then done at 80% depth through the donor tissue with the crescent blade and stromal dissectors. It can also be initiated with the trifaceted diamond knife set at 350 μm (Shamie et al. 2009).

When using an automated microkeratome, the artificial anterior chamber should be pressurized by injecting Optisol. A Barraquer tonometer should be used to verify that the pressure is at least 65 mmHg. The epithelium is then removed with a Merocel surgical sponge, and the microkeratome is set into its gear tract without the stopper. A Merocel sponge soaked in Optisol is used to pain the surface of the cornea, and the microkeratome cut is made smoothly across the cornea. The cut cap is examined for completion of the cut, thickness, and diameter. The diameter of the cut cap should be at least 1.0 mm larger than the planned graft to allow a 0.5 mm margin of error in centration. If the cap size is inadequate, the surgeon can manually extend the lamellar dissection. The outer edge of the exposed stromal bed is demarcated with small dots to allow for improved centration of the trephine in later steps of the procedure. Merocel sponges are used to dry the stromal bed and the free cap replaced in the proper orientation (Shamie et al. 2009).

When manual dissection of the donor graft is done, the dissection should extend to the metal cap of the artificial anterior chamber that ensures a large margin of error in case of accidental decentration. The pedestal of the artificial anterior chamber is slowly lowered. Optisol is injected into the anterior chamber during this step to prevent trauma to the endothelial cells. When adequate separation is established between the pedestal and the metal cap, the ends of the tissue are freed from the artificial anterior chamber's metal cap. This is done by gently nudging with the tip of closed forceps. The tissue is gently removed from the pedestal, allowing the cohesive Healon to fall away in one piece, and residual Healon may be washed away with Optisol (Shamie et al. 2009).

If precut tissue from the eye bank is used, the donor graft is placed with the endothelial side down onto a sterile, lint-free surface. The tissue is then placed endothelial side up onto a standard punch trephine block and a donor button of the same size is punched. A linear ribbon of Healon is injected into the horizontal meridian of the donor graft. The tissue is folded asymmetrically into a taco-like shape with the endothelial surface facing inward (Shamie et al. 2009).

Donor Graft Insertion and Attachment

All previously placed sutures placed in the 5.0 mm tunnel wound should be removed. The folded donor graft is held with specialized forceps and swiftly inserted into the anterior chamber. If the anterior chamber partially collapses as the forceps exit the wound, BSS should be injected through the paracentesis ports to deepen the chamber. The scleral wound may need to be closed with 10–0 nylon sutures to maintain the depth of the chamber. At this point, the donor tissue is already partially adherent to the recipient stromal bed and has begun to unfold perpendicular to the plane of the iris (Shamie et al. 2009). The tissue is thought to initially self-adhere because of the hydrophilic attraction between wet tissues. An

air bubble can be injected into the anterior chamber between the two sides of the donor tissue at this juncture to aid in its unfolding and reinforce adhesion of the donor tissue (Terry 2003).

A reverse Sinskey hook or an equivalent instrument may be necessary for final positioning of the donor disk. The hook is inserted into the anterior chamber from one of the side ports furthest from the direction in which the disk must be shifted, and the hook is used to gently push the graft into position. This is easier done when the anterior chamber is only partially filled with an air bubble. Once the graft is in place, the anterior chamber is completely filled with an air bubble, and any interface fluid is swept out. The wound is then fully closed, knots buried, and conjunctiva is closed. The air bubble is fully removed and replaced with BSS. When the air is replaced, the adherence between the tissues is thought to result from the donor endothelial pump function creating stromal suction adherence (Terry 2003).

Outcome

DLEK preserves the normal corneal surface, and thus it has many benefits over PKP. DLEK does not require penetrating corneal wounds and avoids the need for surface sutures. The lack of surface sutures in DLEK results in lower risk of suture-related complications, such as irregular refractive astigmatism, unpredictable corneal curvature, suture-related graft rejection, and infections. Additionally, because selective suture removal is not a component of the DLEK procedure, rigorous and prolonged follow-up is not required. Because the scleral tunnel wound of endothelial keratoplasty has greater tensile strength than the wound of PKP, DLEK results in more rapid wound healing (Shamie et al. 2009). The procedure also results in marked stability and preservation of the preoperative keratometry readings, making posttransplant corneal power predictability possible and allowing for the DLEK procedure to be combined with cataract extraction and IOL placement. Compared to PKP, the stromal wound of DLEK appears to be quite stable (Terry 2003). Studies of donor endothelial survival after DLEK have revealed cell loss that continues for several years after surgery and stabilizes at 60–72% cell loss by 5 years postoperatively (Terry 2011).

Complications

Despite its many benefits, the DLEK procedure is technically challenging, which limits its utility on a large scale. Additionally, the deep lamellar dissection in both the donor and recipient forms an interface between the deep stroma to stroma. It has been postulated that this interface limits the final visual potential postoperatively (Shamie et al. 2009). There is minimal risk of graft dislocation, which occurs at a rate of less than 3% (Terry 2011). Another potential complication of DLEK is the posterior migration of the air bubble injected into the anterior chamber, which can result in pupillary block or secondary angle closure glaucoma with increased postoperative intraocular pressures (Shamie et al. 2009).

Retinoschisis

Definition

Retinoschisis is characterized by the abnormal splitting of the ▶ retina's layers. Most frequently, it is observed at the inferotemporal peripheral fundus and is often a bilateral condition. Characteristically, it is a well-defined, circumscribed, smooth, dome-shaped elevation of the inner retina extending posteriorly from the ora serrata.

Etiology

Pathogenesis is unknown but chronic vitreous traction in the periphery of retinal areas predisposed to suffer degenerative changes may play a role.

Histologically, there is splitting of the retinal layers, which starts at the external plexiform layer (EPL). This causes cystoid cavities in the EPL that contain a viscous mucopolysaccharide-rich substance. A microscopic degeneration of neuroretinal and glial supporting elements is observed. This entity is known as typical peripheral cystoid degeneration, a condition that is present in almost all adults to some extent. Its coalescence and cavity extension causes typical retinoschisis. This is a slow, gradual process resulting in the complete destruction of the neurons in the area with absolute loss of vision in the corresponding zone.

Posterior and continuous to typical peripheral cystoid degeneration, another entity may appear. This is reticular peripheral cystoid degeneration, which is much less common. The cystoid spaces in this case are located in the nerve fiber layer. Progression of this condition may lead to reticular degenerative retinoschisis ("bullous" retinoschisis).

Retinoschisis Classification

1. **Degenerative**
   - Typical
   - Reticular
2. **Hereditary**
   - X-linked juvenile retinoschisis
3. **Tractional**
4. **Exudative**
   - Secondary to optic disc pit

Clinical Presentation

Most common forms are asymptomatic and non-progressive. In both degenerative forms, possible

symptoms presented include sporadic photopsia, floaters, visual acuity loss (depending on the affected area), and absolute scotoma of the visual field.

Diagnosis

Although described as two different entities, it is often difficult to differentiate clinically between typical and reticular retinoschisis.

Indirect ophthalmoscopy and biomicroscopy help to differentiate retinal detachment because of the individual characteristics. External scleral depression improves visualization when the retinoschisis is located at the periphery and does not extend far from the *ora serrata*. It also detects changes in the outer layers.

Typical Degenerative Retinoschisis

The splitting of the layers occurs at the external plexiform layer level. With ophthalmoscopy, an oval elevation most commonly located at the inferotemporal quadrant of the outer retina is observed. Irregular small white spots ("snowflakes") may be occasionally observed in the posterior zone of the degenerative area; but the origin of these spots is still unclear. It is believed that they may belong to Müller cell remains or to neurons that form bridges within the zone. Sclerotic retinal vessels are found within the zone, as well as cystoid degeneration anterior to schisis.

It is rare to find typical degeneration in the macular area or holes within the zone and therefore retinal detachment is uncommon.

Reticular Degenerative Retinoschisis

This is associated with more complications such as progression to the posterior pole and retinal detachment. In most cases, it appears at the inferotemporal quadrant and is associated with hypermetropia and bilateral affection in 50–80% of cases. There is approximately 23% incidence of holes in the external layer, therefore with a higher risk of retinal detachment. However, it is estimated that retinal detachment risk is around 0.04%.

Large posterior retinoschisis is more likely to develop outer wall holes that may cause shallow retinal detachment even in the absence of inner retinal holes. This shallow retinal detachment may difficult to diagnose before it extends beyond the posterior edge of the retinoschisis.

Other auxiliary tests:

Wide-field retinography: for follow-up, in order to evaluate progressions or new associated lesions.

Visual fields: absolute scotomas are found at the area affected by retinoschisis.

Spectral domain optical coherence tomography (*SD-OCT*): for the visualization and identification of the separated layers.

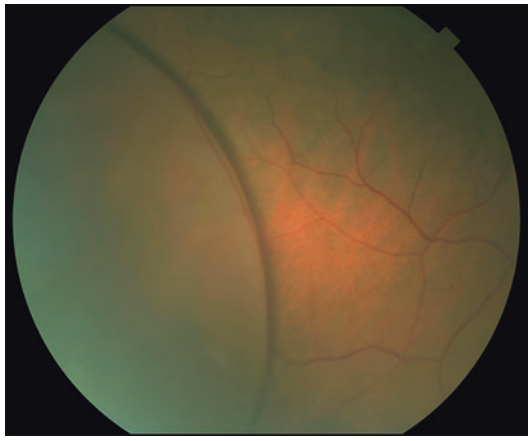
Fluorescein angiography: shows no changes at the underlying retinal pigment epithelium (RPE) unless there are holes or retinal detachment. In some cases, retinal leakage into the inner layers may be observed.

Lab Diagnostics

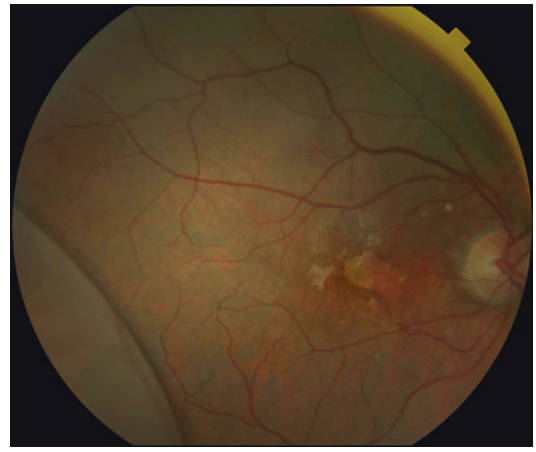
No need for typical or reticular retinoschisis. Only in the rare event of needing to confirm the diagnosis of X-linked juvenile retinoschisis, a genetic DNA may be performed. Systemic studies are not necessary.

Differential Diagnosis

This must be performed in the case of rhegmatogenous retinal detachment. Features may sometimes be similar, especially in chronic retinal detachment. Retinoschisis generates an absolute scotoma in the affected area, whereas rhegmatogenous retinal detachment causes relative scotoma.



Degenerative Retinoschisis, Typical and Reticular, Fig. 1 Large posterior retinoschisis extending to the posterior pole of the right eye in a 85 years-old male. The patient has been followed-up closely due to frequent visits to treat exudative AMD in the same eye. The retinoschisis has not shown further posterior progression for the last 3 years and has not shown outer layer holes. No treatment for the retinoschisis has been required



Degenerative Retinoschisis, Typical and Reticular, Fig. 2 Large posterior retinoschisis extending to the posterior pole of the right eye in a 85 years-old male. The patient has been followed-up closely due to frequent visits to treat exudative AMD in the same eye. The retinoschisis has not shown further posterior progression for the last 3 years and has not shown outer layer holes. No treatment for the retinoschisis has been required

Signs such as tobacco dust and vitreous hemorrhage found frequently in retinal detachment are not present in retinoschisis.

In retinoschisis, the separated surface appears smooth and regular, whereas in retinal detachment, it is irregular and corrugated, not dome shaped. However, old chronic rhegmatogenous retinal detachment may look like retinoschisis due to the thin, smooth detached retina. Long-standing retinal detachments will usually show demarcation lines and atrophy of underlying RPE, which will help to differentiate this from retinoschisis.

There are no specific changes at the foveal area, unlike in patients with X-linked juvenile retinoschisis.

SD-OCT may be useful in differential diagnosis in certain cases when the macula is affected in order to rule out vitreomacular traction or schisis secondary to optic disc pit.

Therapy

Retinoschisis anterior to the equator is followed up. Larger retinoschisis posterior to the equator may be observed in the absence of outer retinal holes. In large posterior retinoschisis that shows progression toward the posterior pole or has outer retinal holes, a prompt photocoagulation treatment is required in order to avoid complications. Laser is applied at the posterior edge of the retinoschisis, around the outer retinal holes or both, in cases of progression and presence of outer retinal holes (Figs. 1 and 2).

When shallow retinal detachment is present, laser therapy may still be effective in some cases, around the outer holes and as a barrier posterior to the retinoschisis.

If retinal detachment is larger, surgical repair with vitrectomy and intravitreal gas is required.

Prognosis

For typical degenerative retinoschisis anterior to the equator or minimally posterior to it, and with the absence of outer retinal holes, the prognosis is favorable and monitoring may be annual. Other situations, as described previously, will be followed up carefully and proactively treated in order to prevent retinal detachment or progression of the retinoschisis into the macular area.

Epidemiology

Related to aging, according to some case series, incidence varies from 4% to 20% in persons of 40 years or older.

Delle (singular)

Definition

First described in 1911, dellen are saucer-like depressions in the corneal surface, typically at the corneal margin, caused by interruptions of the tear film and resultant local dessication of the cornea. Surface elevations such as those produced by dermoids, pterygia, large filtration blebs, significant chemosis, or tissue interruption from a limbal approach to muscle surgery prevent the eyelid from adequately resurfacing the cornea with tear fluid during blinking. Local stromal dehydration and thinning are accompanied by punctate irregularities of the epithelium, mild discomfort, or rarely pain. Treatment with frequent ocular lubrication, with or without a bandage contact lens, restores stromal hydration and provides symptomatic relief. Surgical management (e.g., bleb revision) is reserved for severe cases that are unresponsive to medical therapy. Though rare, untreated dellen can cause descemetocele formation or lead to corneal perforation.

Definition

Demyelination is the hallmark pathologic finding in the disease multiple sclerosis (MS).

Etiology

Although there are several theories regarding the etiology of demyelination in MS, the most widely accepted view is that immune dysregulation leads to demyelination of the central nervous system (CNS). Early on in the disease, oligodendrocytes are shown to help regenerate myelin after attacks from T cells (although some studies implicate B cells and natural killer (NK) cells); however, as the disease progresses, the destructive processes of the immune system overtake the rate of regeneration leading to a neurodegenerative condition. Despite these theories, autopsies have demonstrated that the actual cause of tissue damage is variable. Relatives of patients with MS have a higher risk of developing the disease; however the genetic contributions to this disease are likely multifactorial. Some studies have implicated genes coding for class two major histocompatibility complexes (MHC II), while other studies have implicated non-MHC genes such as genes regulating neurotrophic factors or chemokine receptors (Cohen and Rae-Grant 2010).

Clinical Presentation

The demyelination of various neurological pathways can lead to a wide range of clinical presentations including but not limited to visual problems, gait/motor problems, urinary symptoms, sexual dysfunction, cognitive impairment, and fatigue. 70 to 80% of patients begin with a relapsing-remitting course where new or worsening neurologic symptoms develop over days to weeks and then abate over the course of several weeks resulting in full or partial recovery. After 10–15 years, the accumulation of small deficits from each attack causes increased debilitation, and patients transition to secondary progressive MS. Unfortunately some patients begin with the progressive phase of the illness which is termed primary progressive MS (Cohen and Rae-Grant 2010).

Diagnostics

The most important tools for diagnosis of demyelination in MS are the history, physical, and magnetic resonance imaging (MRI) of the brain. The MRI is able to detect demyelination of current MS lesions, past MS lesions, and MS lesions that are currently asymptomatic. Combined with the history and physical, one can identify MS due to its dissemination over both anatomical space and time. Other diagnostic tools include cerebrospinal fluid (CSF) analysis and evoked potentials. CSF analysis can show increased IgG antibodies and/or myelin basic protein, whereas evoked potentials will demonstrate slowed conduction velocity of brain stem pathways. However, these tests are typically only used as confirmation (Cohen and Rae-Grant 2010).

Differential Diagnosis

The demyelination in MS has a presentation similar to that of other central nervous system (CNS) insults such as monophasic CNS inflammatory demyelinating syndromes, fulminant idiopathic CNS inflammatory syndromes, inflammatory/immune syndromes, infection, vascular complications, genetic/degenerative diseases, metabolic disorders, neoplasms, and spinal disorders (Cohen and Rae-Grant 2010).

Therapy

The mainstay treatment for MS attacks is corticosteroids. They help with the recovery and theoretically might help to delay the next relapse; however, the prophylactic efficacy of this treatment is not strongly supported by research. All other treatments are considered disease-modifying agents since their goal is not to cure MS or reverse any of the damage caused by demyelination but rather to prevent further relapses. One such agent, glatiramer acetate, is a mixture of peptides that is theorized to bind MHC II sites on T cells, inhibiting their inflammatory actions. Interferon beta is another common treatment that modulates B- and T-cell functioning, helping to regenerate the blood-brain barrier and reduce cytokines. The humanized monoclonal antibody natalizumab prevents migration of leukocytes into the CNS by binding and inhibiting integrin. In addition, mitoxantrone can be used as a chemotherapeutic agent to suppress the immune system. The overall goal of these treatments is to suppress the immune system in order to prevent demyelination (Cohen and Rae-Grant 2010).

Prognosis

Prognosis is uncertain given that this disease has a variable presentation. Roughly 5% of patients have a rapidly progressing disease that can lead to early debilitation and mortality; however, another 10–20% have a relatively benign form of the disease that will lead to minimal debilitation. Some factors such as female sex, predominantly sensory symptoms, and few MRI lesions suggest a more favorable prognosis, while the male sex; pyramidal, cerebellar, or cognitive symptoms; and many MRI lesions indicated a less favorable prognosis. Nevertheless, patients with presumed good prognostic factors can have a rapidly progressing disease, while patients with poor prognostic factors can have a more indolent disease (Cohen and Rae-Grant 2010).

Epidemiology

MS affects roughly 400,000 people in the US and 200,000 people around the world with a prevalence of about 1/1,000 worldwide. The onset of the disease typically begins between the second and fourth decade of life with women being affected more than men in a 3:2 ratio. In addition, the disease occurs more in patients living at higher latitudes in both the northern and southern hemispheres. There have been no environmental factors implicated in MS, but there is likely a combination of environmental and genetic factors that predispose one to developing this disease (Cohen and Rae-Grant 2010).

Synonyms

Atopic dermatitis; Contact dermatitis; Eczema

Definition

Dermatitis generally refers to pruritic, erythematous, and inflamed skin that is most commonly caused by allergens or irritants. Ocular complications include eyelid dermatitis, chronic blepharitis, keratoconjunctivitis, vernal conjunctivitis (with cobblestoning of the palpebral mucosa), keratoconus, uveitis, retinal detachment, and cataracts. Chronic scratching of the eyelid may lead to corneal abrasion. Dennie-Morgan lines are single or double folds beneath the lower eyelids that are diagnostic for atopic dermatitis.

Dermis-Fat Grafts

Christopher Zoumalan[1] and Gary Joseph Lelli[2]
[1]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

A graft that provides volume augmentation, eliminates the risk of implant extrusion, and preserves the conjunctiva, advancing it in the fornices, thereby providing deeper forniceal spaces.

Indications

There are several indications for using a dermis-fat graft (DFG). The most common are as follows:

1. Extrusion or migration of orbital implant following enucleation
2. Expand or augment orbital volume
3. Treatment of contracted sockets in order to preserve conjunctiva and advance it in the fornices
4. Augment superior sulcus deformities
5. Primary implant after enucleation or evisceration (2008)

Techniques and Principles

DFG is usually performed under general anesthesia, and the donor site of the graft may be the lower abdomen, thigh, or inferomedial buttocks, depending on the surgeon's preference. Local anesthesia is given to the orbit and the donor site.

In cases of an extruding implant or one which has severe contractures, the conjunctiva is incised and the implant, if present, is removed. Muscle

remnants within the socket should be identified if possible. This allows for greater graft survival (due to the vacularity the muscles provide to the graft) and motility of the socket. An approximate 20–25 mm diameter DFG is harvested from the donor site first by removing the epithelium. A sharp blade is then used to incise subcutaneous tissue and fat to a depth of 15–20 mm in a circular fashion. The graft is then sutured into the socket onto a vascularized source (i.e., extraocular muscles or orbital fat). The dermis is left bare to epithelialize from the surrounding conjunctiva. A temporary conformer is placed. Full epithelialization of the dermis occurs in approximately one month. An ocular prosthesis can be fitted in 2–3 months (Stewart 1995).

Outcomes

Allows for enhanced orbital volume or increased socket surface area in cases of contractures or wound dehiscences.

Complications

Complications can occur intraoperatively and postoperatively. Intraoperative complications include removal of the wrong eye and orbital hemorrhage. Postoperatively, hemorrhage, edema, infection, delayed would healing, central graft necrosis and ulceration, central pitting, and graft failure can complicate the course of recovery. Fat atrophy and resulting loss of volume are variable; the rates increase in cases of compromised orbital vascular supply or the inability to isolate and attach the extraocular muscles to the dermis.

Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Impending perforation

Definition

Descmetocele refers to focal, near-complete thinning of the cornea, with total destruction

of the epithelium and stroma in an area where Descemet membrane and corneal endothelium remain and bulge anteriorly. It is dome-shaped and translucent in appearance, often in contrast to a surrounding melting or necrotic process. If leaking, the lesion has progressed by definition to perforation. Presence of Descemetocele often portends a poor prognosis (Honig and Rapuano 2004).

Synonyms

Desferrioxamine mesylate; Desferal; Desferoxamine B; Desferrioxamine B; DFB; DFOA; DFO-B; Induced retinal toxicity; Retinopathy

Definition

Desferrioxamine is a bacterial siderophore produced by the Actinobacteria *Streptomyces pilosus*. Its main medical use is as a chelating agent, used to remove excess iron from the body. The mesylate salt of desferrioxamine is commercially available.

Desferrioxamine mesylate is frequently used to treat hemochromatosis, a chronic disease of iron accumulation, that can be either genetic or acquired. Acquired hemochromatosis is common in patients with certain types of chronic anemia (e.g., thalassemia and myelodysplastic syndrome), who require regular blood transfusions, which can greatly increase the amount of iron in the body. Desferrioxamine has also been used for the treatment of acute iron intoxication, especially in small children, and as a screening test for increased aluminum body stores in chronic renal failure. It can be used to treat aluminum toxicity in selected patients and to minimize doxorubicin cardiotoxic side effects.

Desferrioxamine has a high affinity for ferric iron (Ka 1031), and it removes iron from hemosiderin and ferritin, and, to a lesser extent, transferrin. It is most commonly administered as a slow subcutaneous infusion (over a period of 8–12 h each day), but can also be given intramuscularly or, less commonly, intravenously.

Adverse reactions of desferrioxamine have been reported for most major organ systems,

including cutaneous, cardiovascular, respiratory, gastrointestinal, and nervous systems. Severe side effects of desferrioxamine include bone dysplasia and auditory toxicity, consisting of high-frequency sensorineural hearing loss. Ocular findings of desferrioxamine toxicity include cataract, optic neuropathy, and pigmentary retinopathy involving the macula, as well as in some cases, the midperiphery or entire retina.

Desferrioxamine ocular toxicity first came to light in 1983 (Davies), when four patients with 13-thalassemia major were treated with a high intravenous dose to counter the effects of transfusion-induced iron overload. Two of them developed night blindness and visual field defects, which were improved on withdrawal of the drug.

Since then, numerous cases of desferrioxamine retinopathy have been described; however, the literature contains conflicting reports regarding the incidence, severity, and reversibility of desferrioxamine retinopathy, as well as the toxic desferrioxamine dosage or safe administration protocol. A retrospective study carried in a large pediatric center concluded that desferrioxamine-related ocular toxicity is a rare and mild finding; of a total of 84 children that received regular desferrioxamine treatment for transfusional hemochromatosis, related ocular toxicity was found only in one patient (1.2%).

Symptoms of desferrioxamine toxicity include decrease in central vision, metamorphopsias, difficulty in night vision, visual field defects, and photopsias. Characteristic fundus lesions of desferrioxamine retinopathy include pigmentary degeneration in the macula, peripapillary region, and periphery, retinal pigment epithelium (RPE) atrophy, pattern dystrophy – like maculopathies and bull's-eye maculopathy. Other ocular findings include cataract (sunflower shaped), optic disc edema, and optic atrophy.

Phenotypic investigation of desferrioxamine retinopathy has been based on ophthalmoscopy and fundus photography used for screening asymptomatic patients. Until recently, fluorescein angiography (FA) was used for detection and monitoring of presumed retinal toxicity. In the early FA stages, there is patchy blocked fluorescence or mottled fluorescence, followed in most patients by late hyperfluorescence. Optic disc hyperfluorescence is evident in some patients as well. However, fundus autofluorescence (FAF) imaging is probably superior to ophthalmoscopy in detection of early characteristic RPE abnormalities in patients at risk of desferrioxamine retinopathy, as well as in monitoring the disease progression over time. Abnormal FAF was classified into four phenotypic patterns: minimal change, focal, patchy, and speckled.

Recently, Viola et al. retrospectively reviewed charts and multimodal imaging of 20 patients with b-thalassemia diagnosed with desferrioxamine retinopathy after a minimum of 10 years of DFO treatment. Mean age was 45 years, and mean duration of subcutaneous DFO therapy was 32 years (range, 20–52 years). Ten patients (50%) showed different types of pattern dystrophy-like fundus changes, including butterfly-shaped-like, fundus flavimaculatus-like, and fundus pulverulentus-like, and vitelliform-like changes. Ten patients (50%) presented only minimal changes in the macula; these patients were significantly younger than patients presenting other patterns ($P = 0.023$). Abnormal fundus autofluorescence and/or near-infrared reflectance signals corresponded to the accumulation of material located within the outer retina or in the Bruch's membrane – retinal pigment epithelium (RPE) complex on spectral domain optical coherence tomography. Follow-up examinations during a 40-month period revealed progressive development of RPE atrophy in areas of pattern dystrophy-like changes.

Electroretinogram (ERGs) and electrooculogram (EOGs) performed in symptomatic patients with desferrioxamine toxicity were mostly, with few exceptions, abnormal. ERG findings include prolonged rod and cone implicit times and reduced scotopic and photopic a and b wave amplitudes. EOG findings include reduced Arden ratio (light peak to dark trough) and no detectable EOG response. In addition to ERG and EOG, visual field, visual-evoked potential, and pattern electroretinogram testing may also be informative.

The precise pathophysiological mechanism of desferrioxamine retinopathy is still unknown; however, it is likely to be multifactorial. Animal experiments and histology studies in human eyes with desferrioxamine retinopathy have shown that the degenerative process affects primarily the RPE and Bruch's membrane. Rahi et al. documented light and electron microscopy changes in the retinal pigment epithelium (RPE) following treatment with high-dose desferrioxamine for systemic iron overload. The changes included loss of microvilli from the apical surface, patchy depigmentation, vacuolation of the cytoplasm, swelling and calcification of mitochondria, and disorganization of the plasma membrane. In addition, Bruch's membrane overlying degenerate RPE cells appeared abnormally thickened owing to the accumulation of large amounts of mature elastic fibers, pre-elastic oxytalan, and long-spacing collagen. However, whether these RPE changes were in part due to ocular siderosis is difficult to determine.

Definition

Desquamating skin conditions are disorders in which the skin sheds in sheets or scales. Normally, terminally differentiated keratinocytes are shed as individual cells, but under pathological conditions, such as diseases like Stevens-Johnson syndrome or injury to the skin, keratinocytes are shed in clusters forming visible sheets or scales.

Dexamethasone Implant

Barry Kuppermann
Department of Ophthalmology, UC Irvine Medical Center, University of California, Irvine, CA, USA

Introduction

In the past decade, the diseases of the posterior segment of the eye have constituted an area of unmet medical need and as a result became an important therapeutic target. Among the diseases of the posterior segment are the retinal vascular diseases, particularly diabetic retinopathy as well as retinal venous occlusive disease, as well as age-related macular degeneration and uveitis.

Historically, the most common drug delivery method for treating ocular disorders has been topical application, as it is more convenient and safe compared to systemic administration. To treat the above mentioned diseases, intraocular injections are now routinely applied in clinical practice. In order to minimize the number of injections, the therapeutic drug concentration should ideally be maintained for longer time periods. One way of achieving this is to load drugs onto polymeric implants releasing the active in a sustained manner, by diffusion or degradation of the polymer block (Eljarrat-Bienstock et al. 2010).

Pathology and Pathophysiology of Ocular Inflammation and Edema

Inflammatory components within the vascular tissue play a central role in the development of uveitis as well as in macular edema secondary to retinal vein occlusions and diabetic retinopathy. Inflammation is a protective tissue response to injury or destruction of tissues, which serves to destroy, dilute, or wall off both the injurious agent as well as the injured tissues (Kumar and Clark 2009).

Classic generalized systemic signs of acute inflammation are pain, heat, swelling, and loss of function (Marieb and Hoehn 2007).

In the retina there is no pain or redness, however swelling (edema), a variable loss of visual function as well as presence of cells and proteins (Augustin 2010).

Cell monolayer integrity or the vascular barrier can be disrupted by a number of different inflammatory agents. Angiotensin II, VEGF, prostaglandins, cytokines, interleukins, VCAM-1 and ICAM-1, as well as macrophages and neutrophils are part of the local inflammatory process. To date the complex chain of interaction of all these substances is not fully clarified (Pasqualetti et al.2007).

Edema and leakage due to inflammation are biochemically distinct from that induced by VEGF. Vascular permeability and the resulting macular edema is driven by both VEGF-independent and VEGF-dependant inflammatory pathways (Saishin et al. 2003).

In the development of macular edema, early stages of vasculature dysfunction are characterized by a breakdown of the blood retinal barrier, leading to accumulation of fluid and serum macromolecules in the intercellular space and in turn to loss of visual acuity (Girach and Lund-Andersen 2007; Kanski 2008).

In contrast, uveitis is primarily characterized by an inflammation of the uvea (iris, ciliary body, and choroidea), which may also lead to the development of macular edema (Kanski 2008).

Steroids for Intravitreal Use: Comparative Potencies, Mechanism of Action, Efficacy, and Safety

While the most commonly used steroids are dexamethasone, triamcinolone acetonide, and fluocinolone acetonide and all are structurally similar, they can be significantly differentiated by their aqueous and lipid solubility, delivery system requirements, pharmacokinetics, and interactions with functional glucocorticoid receptor (Edelman 2010).

Dexamethasone has the highest relative strength of any steroid used in ophthalmic practice. A single dose of 0.18 mg/ml dexamethasone is equivalent to 1 mg/ml triamcinolone acetonide in terms of corticosteroid efficacy (Kiernan and Mieler 2009).

The mechanism of action is thought to be complex. Corticosteroids act as anti-inflammatory, immunosuppressive, and antimitogenic agents (blocking the arachidonic acid pathway, formation of Il-1). They also have antiapoptotic (protection of signals evoked by cytokines, cAMP, tumor suppressors, and death cells), antiedematous (suppression of leukocyte adhesion to vessel walls), and antiangiogenic effects such as suppression of VEGF gene and the metabolic pathway of VEGF (Golan and Loewenstein 2010).

Data on their use in diseases of the posterior segment of the eye has been limited.

Initially only intravitreally applied triamcinolone acetonide was investigated, mostly in uncontrolled pilot trials and case studies. Only recently a variety of prospective randomized clinical trials as well as data analyses have shown a useful role of these compounds in the treatment of diabetic macular edema and macular edema secondary to retinal vein occlusion (Kiernan and Mieler 2009).

In uveitis, corticosteroid treatment remains the mainstay of management. While topical corticosteroids are effective to control anterior uveitis, systemic application is widely used for management of posterior forms, especially when both eyes are involved. However, in case of unilateral posterior inflammation, local therapy has shown to have considerable advantages. In such mild to moderate ocular uveitis cases, intraocular injections have recently proven to be a useful alternative to systemic medication (Taylor and Hazlita 2010).

Potential complications of intravitreal steroid treatment may be divided into steroid-related and injection-related adverse effects.

Intravitreal steroid treatment commonly causes formation or progression of cataract. In an elderly population, intravitreal triamcinolone treatment led to clinically significant cataract with eventual cataract surgery within 1 year after first injection. The steroid-induced rise of IOP is usually temporary and can normally be controlled with topical IOP-lowering medications in most cases. Only 1% of cases would require surgical intervention (Golan and Loewenstein 2010).

Injection-related side effects may include retinal detachment, vitreous hemorrhage, bacterial or noninfectious endophthalmitis, as well as pseudoendophthalmitis. Data have shown that less than 1% of cases would experience injection-related side effects.

Advanced Intravitreal Drug Delivery Systems: Concepts, Biodegradable and Non- Biodegradable Implants

The delivery of drugs to the posterior eye segment is difficult due to the long diffusion distance, the lens iris barrier, and the acellular nature of the vitreous body. Pharmacokinetics of drug diffusion is influenced by the sclera surface area and its thickness. Advanced delivery systems for posterior segment disorders can be divided into two categories. The first category includes gels, emulsions, viscosity enhancers, penetration enhancers, prodrugs, liposomes, and iontophoresis. The second category consists of nanoparticles, polymeric inserts, and implants (Eljarrat-Bienstock et al. 2010).

A number of nonbiodegradable and biodegradable implants have undergone clinical development to achieve sustained levels of steroids in the vitreous. Nonbiodegradable implants are usually reservoir implants suitable for long-term drug exposures. While the drug is released over the time the reservoir remains at the site of action and would need to be surgically removed.

Biodegradable implants are based on a polymer matrix system, where the active is distributed throughout the matrix and released as the polymer degrades. Degradation may occur by hydrolysis, leading to bulk erosion.

Biodegradable implants are typically constructed from synthetic aliphatic polyesters of the poly-α-hydroxy acid family, which include polyglycolic acid (PGA), polylactic acid (PLA),

and the PGA/PLA copolymer, polylactic-co-glycolic acid (PGLA). The ratio of lactic to glycolide used for the polymerization can be varied and will influence the biodegradation characteristics of the product. PGLA is easy to construct into various shapes such as rods, screws, plates and pins, suture material, as well as vascular grafts and stents. It is widely used in orthopedic and dental surgery. Biocompatibility of PGLA-containing sutures and fracture fixation devices has been confirmed in human clinical trials. PLA and PGLA biocompatibility has also been studied in ocular tissues, and the polymers have been suggested to show an even better tolerability than when placed in nonocular tissues.

These new delivery systems target a variety of retinal diseases, among them uveitis, DME, and ME secondary to RVO. They are meant to maximize efficacy in chronic diseases requiring frequent and repeated administration to the back of the eye over longer time periods. They are capable of a more controlled drug release, keeping a stable and sustained concentration of the drug at site of action and thus minimizing systemic exposure. Additionally, they are striving to improve safety by reducing the risk of complications due to the actual injection, such as injury to the lens, retinal detachment, and – most significantly – endophthalmitis. In cases where implants require one or more surgical procedures for placement or removal, however, patients are potentially at risk to experience associated complications (Kearns and Williams 2009; Kiernan and Mieler 2009; Lee et al. 2010).

Dexamethasone Implant

A Pharmacodynamic and Pharmacokinetic Properties

Within the WHO Anatomical Therapeutical Chemical (ATC) classification system, the Dexamethasone Implant is grouped as an ophthalmological and anti-inflammatory agent (ATC code: S01BA01). Dexamethasone, a potent corticosteroid, has been shown to suppress inflammation by inhibiting edema, fibrin deposition, capillary leakage, and phagocytic migration of the inflammatory response. Vascular Endothelial Growth Factor (VEGF) is a cytokine which is expressed at increased concentrations in the setting of macular edema. It is a potent promoter of vascular permeability. Corticosteroids have been shown to inhibit the expression of VEGF. Additionally, corticosteroids prevent the release of prostaglandins, some of which have been identified as mediators of cystoid macular edema.

The Dexamethasone Implant consists of a polylactic-co-glycolic (PGLA) rod-shaped matrix (Novadur ^{TM}) loaded with 700 μg dexamethasone.

Plasma concentrations were obtained from a subset of 21 patients in two, 6-month efficacy studies prior to dosing and on day 7, 30, 60, and 90 following the intravitreal implant containing 350 μg or 700 μg dexamethasone. Ninety-five percent of the plasma dexamethasone concentration values for the 350 μg dose group and 86% for the 700 μg dose group were below the lower limit of quantitation (0.05 ng/ml). The highest plasma concentration value of 0.094 ng/ml was observed in one subject from the 700 μg group. Plasma dexamethasone concentration did not appear to be related to age, body weight, or sex of patients.

In a 6-month monkey study following a single intravitreal injection of Dexamethasone Implant, the dexamethasone vitreous humour C_{max} was 100 ng/ml at day 42 postinjection and 5.57 ng/ml at day 91. Dexamethasone remained detectable in the vitreous at 6 months post-injection. The rank order of dexamethasone concentration was retina > iris > ciliary body > vitreous humour > aqueous humour > plasma.

In an in vitro metabolism study, following the incubation of [14C]-dexamethasone with human cornea, iris-ciliary body, choroid, retina, vitreous humour, and sclera tissues for 18 h, no metabolites were observed. This is consistent with results from rabbit and monkey ocular metabolism studies.

Dexamethasone is ultimately metabolized to lipid and water soluble metabolites that can be excreted in bile and urine (Ozurdex Summary of Product Characteristics 2013).

The Dexamethasone Implant polylactic-co-glycolic (PGLA) matrix represents a bulk eroding polymer. The biodegradation rate of PGLA is governed by the proportion of lactide and glycolide, i.e., the higher the glycolide content, the faster the degradation rate. The PGLA matrix exhibits a biphasic release of the drug: an initial diffusion of the drug at or near the surface of the matrix with a higher dose over a period of 6 weeks is followed by a lag phase releasing lower but therapeutic doses for up to 6 months. This happens by the polymer achieving bulk erosion, resulting in a significant increase in pores or water channels, thus allowing the remaining drug to diffuse out of the porous implant structure. The initial dose is controlled by the total surface area of the implant, the dexamethasone loading, and its hydrophobicity. The second phase is well regulated by the speed of polymer degradation from the outside and inside. The matrix hydrolyses to lactic and glycolic acids; the lactic acid is further metabolized to H_2O and CO_2.

The Dexamethasone Implant is inserted through a single-use proprietary DDS intravitreal applicator system, using a 22 gauge biplanar injection. The small puncture caused is self-sealing (Kuppermann and Loewenstein 2010).

Clinical Data

Phase II clinical trial results with the Dexamethasone Implant demonstrated statistically significant therapeutic results. The study evaluated 306 patients who were diagnosed with macular edema due to four complicating conditions, among them uveitis, retinal vein occlusions, and diabetes. Participants were randomized to one of the following treatment groups: Dexamethasone 350 μg Implant, Dexamethasone 700 μg Implant, or control group. The trial showed that after 180 days, 21% of patients in the control group, 24.3% of patients receiving the lower concentration, and 32.4% of patients receiving the higher concentration achieved an improvement of at least two lines in their visual acuity ($p = 0.06$). There was also a significant decrease in retinal thickness and FA leakage in both dosing groups at 3 and 6 months. Three months after implantation contrast sensitivity was significantly better in the Dexamethasone 700 μg Implant group versus control. The trial reported relatively few adverse effects, except for mild cases of increased IOP. At the primary endpoint at 90 days 2% of patients treated with either Dexamethasone Implant showed an increase over baseline of $\geq$10 mmHg, compared to 1% in the observation group. All were successfully managed with either observation or IOP-lowering medication. Cataracts were present in 15% of the Dexamethasone 350 μg Implant group, 17.8% of the Dexamethasone 700 μg Implant, and 12.4% of the control group (Kuno and Fujii 2010); Kiernan and Mieler 2009; Kuppermann and Loewenstein 2010).

Efficacy and Safety in Central Retinal Vein Occlusion (CRVO) or Branch Retinal Vein Occlusion (BRVO)

Based on the results above two multicenter, double-masked, randomized, sham-controlled, parallel phase 3 studies of identical design were undertaken. Together they comprised 1,267 patients suffering from macular edema following central or branch retinal vein occlusion (CRVO/BRVO) who were randomized to receive treatment with dexamethasone 350 μg or 700 μg implants or control (sham injections). A total of 427 were randomized to the Dexamethasone 700 μg Implant, 414 to Dexamethasone 350 μg Implant, and 426 patients to control.

Based on the pooled analysis results, treatment with Dexamethasone Implants showed statistically significantly greater incidence of responders, defined as patients achieving a $\geq$ 15 letter improvement from baseline in best corrected visual acuity (BCVA) at 90 days following injection of a single implant, when compared with control ($p < 0.001$).

A treatment effect was seen at the first observation time point of day 30. The maximum treatment effect was observed at day 60, and the difference in the incidence of responders was statistically significant favoring the Dexamethasone

700 μg Implant compared with control at all time points to day 90 following injection. There continued to be a numerically greater proportion of responders for a ≥15 letters improvement from baseline in BCVA in patients treated with Dexamethasone 700 μg Implant compared with control at day 180.

The mean change from baseline BCVA was significantly greater with Dexamethasone 700 μg Implant compared to control at all time points.

In each Phase III study and the pooled analysis, the time to achieve ≥15 letters (3-line) improvement in BCVA cumulative response curves was significantly different ($p < 0.001$), with Dexamethasone Implant treated patients achieving a 3-line improvement in BCVA earlier than control treated patients. Dexamethasone Implant was numerically superior to control in preventing vision loss as shown by a lower of proportion of patients experiencing deterioration of vision of ≥15 letters in the Dexamethasone Implant group throughout the 6-month assessment period. In each of the phase III studies and the pooled analysis, mean retinal thickness was significantly less, and the mean reduction from baseline was significantly greater, with Dexamethasone Implant (−207.9 μm) compared to control (−95.0 μm) at day 90 ($p < 0.001$, pooled data). The treatment effect as assessed by BCVA at day 90 was thus supported by this anatomical finding. By day 180, the mean retinal thickness reduction (−119.3 μm) compared with control was not significant.

Patients who had a BCVA score of <84 OR retinal thickness >250 μm by optical coherence tomography OCT and in the investigator's opinion treatment would not put the patient at risk were eligible to receive a Dexamethasone Implant treatment in an open label extension. Of the patients who were treated in the open label phase, 98% received a Dexamethasone Implant injection between 5 and 7 months after the initial treatment.

As for the initial treatment, peak response was seen at day 60 in the open label phase. The cumulative response rates were higher throughout the open label phase in those patients receiving two consecutive Dexamethasone Implant injections compared with those patients who had not received an injection in the initial phase.

The proportion of responders at each time point was always greater after the second treatment compared with the first treatment. Whereas, delaying treatment for 6 months results in a lower proportion of responders at all time points in the open label phase when compared with those receiving a second injection.

A total of 47.3% of patients experienced at least one adverse reaction. The most frequently reported adverse reactions in patients who received the Dexamethasone Implant were increased intraocular pressure (24.0%) and conjunctival hemorrhage (14.7%). The adverse reaction profile for BRVO patients was similar to that observed for CRVO patients, although the overall incidence of adverse reactions was higher for the subgroup of patients with CRVO. Other common adverse reactions recorded were headache, vitreous detachment, cataract and subcapsular cataract, as well as visual disturbance. Additional common adverse reactions considered to be related to the injection procedure rather than the Dexamethasone Implant were the occurrence of vitreous hemorrhage, vitreous opacities (including vitreous floaters), eye pain, photopsia, conjunctival edema, and conjunctival hyperemia.

Increased intraocular pressure (IOP) with the Dexamethasone Implant peaked at day 60 and returned to baseline levels by day 180. Elevations of IOP either did not require treatment or were managed with the temporary use of topical IOP-lowering medicinal products. During the initial treatment period, 0.7% (3/421) of the patients who received the Dexamethasone Implant required laser or surgical procedures for management of elevated IOP in the study eye compared with 0.2% (1/423) with control.

The adverse reaction profile of 341 patients analyzed following a second injection of the Dexamethasone Implant was similar to that following the first injection. A total of 54% of patients experienced at least one adverse reaction. The incidence of increased IOP (24.9%) was similar to that seen following the first injection and likewise returned to baseline by open label day

180. The overall incidence of cataracts was higher after 1 year compared to the initial 6 months (Ozurdex Summary of Product Characteristics 2013).

Efficacy and Safety in Uveitis

The clinical efficacy of the Dexamethasone Implant has been assessed in a single, multicenter, masked, randomized study for the treatment of noninfectious ocular inflammation of the posterior segment in patients with uveitis. A total of 229 patients were randomized to receive dexamethasone 350 μg or 700 μg implants or sham. Of these, a total of 77 were randomized to receive Dexamethasone 700 μg Implant, 76 to dexamethasone 350 μg, and 76 to control (sham injections). A total of 95% of patients completed the 26-week study.

The proportion of patients with vitreous haze score of 0 in the study eye at week 8 (primary endpoint) was fourfold higher with the Dexamethasone 700 μg Implant (46.8%) compared to control (11.8%), $p < 0.001$. Statistical superiority was maintained up to and including week 26 ($p \leq 0.014$).

The cumulative response rate curves (time to vitreous haze score of 0) were significantly different for the Dexamethasone 700 μg Implant group compared to the control group ($p < 0.001$), with patients receiving dexamethasone showing an earlier onset and greater treatment response.

The reduction in vitreous haze was accompanied by an improvement in visual acuity. The proportion of patients with at least 15 letters improvement from baseline BCVA in the study eye at week 8 was more than sixfold higher with Dexamethasone 700 μg Implant (42.9%) compared to control (6.6%). Statistical superiority was achieved at week 3 and maintained up to and including week 26 ($p < 0.001$).

The percent of patients requiring escape medications from baseline to week 8 was nearly threefold less with the Dexamethasone 700 μg Implant (7.8%) compared to control (22.4%) ($p = 0.012$).

The most frequently reported adverse reactions in the study eye of patients who received Dexamethasone 700 μg Implant were conjunctival hemorrhage (30.3%), increased intraocular pressure (25.0%), and cataract (11.8%). Other commonly observed adverse reactions were retinal detachment, myodesopsia, vitreous opacities, blepharitis, eyelid pruritis, and visual impairment. Adverse reactions considered to be related to the injection procedure were abnormal sensation in the eye as well as sclera hyperemia (Ozurdex Summary of Product Characteristics 2013).

Efficacy and Safety in Diabetic Macular Edema (DME)

The use of the Dexamethasone 700 μg Implant in patients suffering from diabetic macular edema (DME) was initially approved in patients who have an artificial lens as well as patients with a natural lens, but scheduled for cataract surgery. However, the FDA subsequently expanded the label to include all patients with DME with the only restriction being those eyes with a torn or ruptured posterior capsule. Data from the following major trials has so far been published: Haller and colleagues compared the Dexamethasone Implant (in two concentrations: 350 μg or 700 μg) to no treatment. The implants were inserted through a 20 gauge transscleral incision. The study included a total of 171 patients. At day 90, the group with the Dexamethasone 700 μg Implant showed a statistically significantly proportion of patients with a 10 or more letter gain compared to no treatment (33% vs. 12%, $p = 0.007$). Mean central macular thickness (CMT) was reduced by 132.27 μm (SD 160.86) from baseline in the Dexamethasone 700 μg Implant group, which was statistically significant compared to no treatment ($p > 0.001$). An increased IOP was recorded in 9.4% of cases in the Dexamethasone 700 μg Implant group (compared to 14.5% of cases having received the 350 μg implant).

Another trial recorded the efficacy of the Dexamethasone 700 μg Implant in combination with laser compared to laser as monotherapy ($n = 253$). A significantly greater improvement in mean best corrected visual acuity (BCVA) was seen during the first 9 months in the group receiving the implant followed by laser

photocoagulation after 1 month compared to laser only treatment ($p < 0.05$). A mean of 1.6 implants were used over a period of 12 months. At months 1 and 6 the combination group also had significantly greater mean reductions from baseline in CMT ($p < 0.001$). An elevated IOP was found in 20% of patients in the combination group (compared to only 1.6% in the laser group), but only 1% of patients experienced an IOP elevation of more than 10 mmHg (Ford et al. 2013).

Additionally, results from a multicenter, randomized clinical study assessing the efficacy and safety of Dexamethasone Implants (700 or 350 μg) compared with control in 1,048 patients were reported recently. All three treatment groups were followed for a period of 3 years. The mean number of implants received was 4.1, 4.4, and 3.3 with the Dexamethasone 700 μg Implant, the Dexamethasone 350 μg Implant, and the control (sham), respectively. At study end, the percentage of patients with an improvement of 15 or more letters was greatest in the group with the Dexamethasone 700 μg Implant (22.2% vs. 18.4% and vs. 12% with $p \leq 0.018$). The mean reduction of central retinal thickness (CRT) was also greatest in this group (111.6 vs. 107.9 μm and vs. 41.9 μm with $p < 0.001$). Rates of cataract related adverse events in phakic eyes were 67.9%, 64.1%, and 20.4% in the three respective groups. Increases in IOP were usually controlled with medication or no therapy. Only two patients (0.6%) in the Dexamethasone 700 μg Implant group and one patient (0.3%) in the Dexamethasone 350 μg Implant group required trabeculectomy. These results confirmed the efficacy endpoints of the study, while the safety profile was considered acceptable and consistent with previous reports (Boyer et al. 2014).

Furthermore, real world results from a retrospective analysis were also recently published. In this study charts from 74 patients suffering from DME who had received the Dexamethasone 700 μg Implant and had been followed-up for a minimum of 6 months were evaluated. Values from month 2 and 6 after injection of the implant were reported. While the average CRT decrease was 239 μm and 135 μm at month 2 and 6, respectively, a gain greater than 15 letters in BCVA was found in 27% of patients at month 6. The mean rate of injections was 1.2 at month 6, with an average of 5.4 months to reinjection. Ocular hypertension greater than 25 mmHg was observed in 13.4% of patients and managed solely by topical treatment (Guigou et al. 2014).

Summary and Conclusion

The Dexamethasone 700 μg Implant has already successfully passed the regulatory hurdle for treatment of ME secondary to CRVO and BRVO as well as for management of uveitis, and most recently for DME. For all indications the effect of the Dexamethasone 700 μg Implant in terms of improvement of the patient's VA as well as reduction of CRT is significant when compared to control. Until now there are hardly any large and well planned trials directly comparing the Dexamethasone 700 μg Implant with other existing intravitreal treatments. Overall, steroids act broadly against inflammatory molecules, reducing not only VEGF but many other angiogenic and inflammatory cytokines involved in the formation of edema and leakage.

An additional advantage of the Dexamethasone Implant is its slow release mechanism, enabling the treating physician to manage the patient with fewer overall injections compared to alternative existing treatments without sustained release approaches. This implies that injection-related side effects are minimized.

Dexamethasone is a well-know compound that has been used for many years in a plethora of different indications, administration routes, and dosages. Side effects such as cataract formation and elevation of IOP are well documented. However, especially for the latter, it seems that this new intravitreal route does not cause a significant number of unmanageable rises in IOP.

In conclusion, the Dexamethasone Implant appears to be a useful addition to the currently limited existing armamentarium of treatments for ME secondary to RVO and DME as well as uveitis.

Synonyms

Center-involved diabetic macular edema; Clinically significant macular edema (CSME); DME

Definition

Diabetic macular edema (DME) is retinal thickening within the posterior pole that is attributed to diabetes mellitus. It may be recognized on stereoscopic fundus biomicroscopic examination, stereoscopic fundus photography, and/or ocular coherence tomography (OCT).

Epidemiology

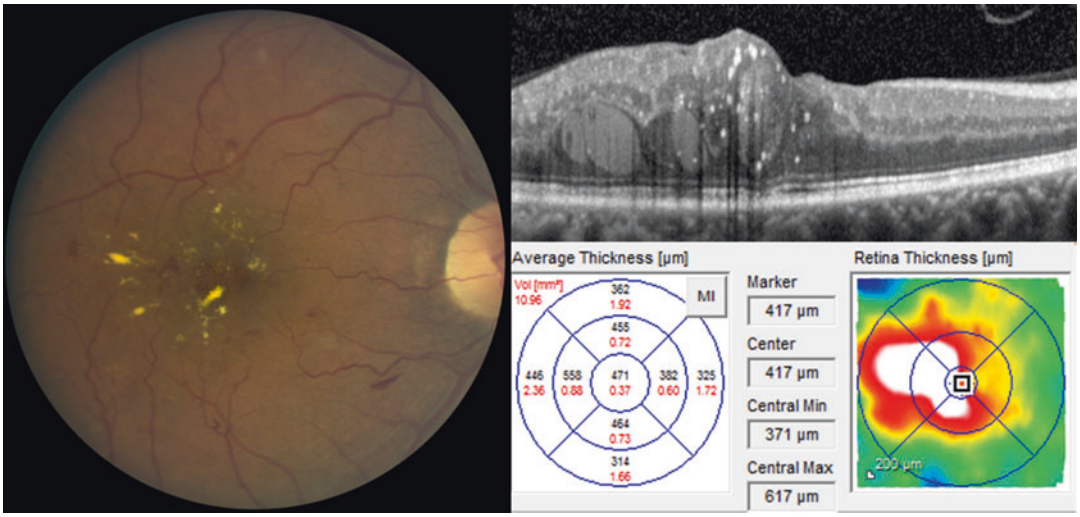
From 1980 through 2014, the number of US adults aged 18 years or older diagnosed with diabetes has risen dramatically, from 5.5 million to 21.9 million (CDC 2015). Despite advances in the treatment of diabetes and in diabetes-related eye disease, diabetic macular edema and complications related to diabetic retinopathy remain the leading causes of vision loss and new-onset visual impairment in working-age adults in the United States (Cheung et al. 2010).

Etiology

DME is a multifactorial condition in which hyperglycemia is associated with vascular hyperpermeability and inflammation. Chronic elevation in blood glucose promotes pericyte dropout and loss of capillary integrity, retinal hypoxia, and upregulation of multiple pro-inflammatory cytokines and chemokines (Das et al. 2015). Vascular endothelial growth factor (VEGF), a potent pro-permeability cytokine and mediator of angiogenesis, is found in elevated concentrations in the diabetic retina and promotes inflammation and retinal vascular leakage. VEGF, in concert with other vasoactive mediators, matrix metalloproteinases, pro-adhesion molecules, reactive oxygen species, and sorbitol, contributes to a positive feedback loop, causing further endothelial compromise, inflammation, and vascular permeability (Augustin et al. 2010). Leakage of plasma into the retina leads to DME.

Clinical Presentation

Patients with center-involving DME (CI-DME) have retinal thickening that involves the foveal center. These individuals may present with blurred central vision and metamorphopsia, or they may not recognize any symptoms. As a generality, the degree of vision impairment associated with CI-DME correlates with the severity of foveal thickening as measured on OCT, but the magnitude of this correlation has varied widely between studies ranging from low to high correlation indices (DRCR et al. 2007). It is possible for patients to present with relative preservation of central visual acuity and the absence of symptoms despite marked central macular thickening (Fig. 1), as well as the converse; there may be



Diabetic Macular Edema, Fig. 1 Best-corrected visual acuity is 20/25 in this eye of a 45-year-old man who denies any vision symptoms, despite center-involved diabetic macular edema. The central subfield thickness on OCT is moderately thickened at 471 um, and there is a moderate amount of juxtafoveal intraretinal lipid and intraretinal hemorrhages

moderate compromise in visual acuity with mild macular thickening. The latter may be due to chronic DME that has led to irreversible loss of neurosensory retinal tissue with or without atrophic retinal pigment epithelial (RPE) changes. Patients may also be aware of color vision compromise, poor night vision, or poor dark–light adaptation (Danis 2008). DME may be present at any point along the spectrum of nonproliferative diabetic retinopathy (NPDR) and proliferative diabetic retinopathy (PDR).

Diagnosis

Stereoscopic fundus biomicroscopy performed with direct contact lens or indirect lens (+78 or +90 diopter) facilitates identification of retinal thickening. OCT is a rapid, noninvasive imaging modality that has become the most commonly utilized imaging tool to confirm the presence of DME or identify subclinical DME (retinal thickening, two standard deviations beyond average normal thickness that is not appreciated on clinical examination). OCT provides both qualitative and quantitative data to characterize DME. Severity (degree of thickening), location (central, inner, and outer subfield involvement within a 6-mm diameter zone centered on the fovea), and accompanying retinal features (intraretinal lipid, cystoid abnormalities, and RPE abnormalities) can be monitored for disease evolution and response to treatment. Although the Early Treatment Diabetic Retinopathy Study (ETDRS) previously offered a definition of clinically significant diabetic macular edema (CSME), this classification predated OCT and is largely being replaced by OCT identification of retinal thickening that is described as center-involving (central DME) or non-center-involving DME. Gender and instrument-specific thresholds to classify the eyes as manifesting center-involved DME have been published. Historically, CSME was defined on clinical exam or stereoscopic color fundus photographs as (1) thickening of the retina at or within 500 μm of the center of the macula; (2) hard exudates at or within 500 μm of the center of the macula, if associated with thickening of the adjacent retina; or (3) a zone of retinal thickening $\geq$1 disk area, any part of which lies within 1-disk diameter of the center of the macula (ETDRS Research Group 1985). Fluorescein angiography (FA) may also be helpful in the evaluation of DME, in that FA frequently identifies the source of leakage responsible for the DME, namely, microaneurysms and dilated capillaries. FA provides a road map of potential targets when and if focal/grid laser photocoagulation is considered in the treatment plan. FA also assists in identification of areas of macular ischemia which may be helpful to determine the mechanism of vision compromise in patients with diabetic retinopathy.

Differential Diagnosis

The differential diagnosis for DME includes other retinal vascular diseases that may also be associated with vascular leakage and macular thickening and/or intraretinal lipid. Some of the more common entities within the differential diagnosis would include branch or central retinal vein occlusion, idiopathic juxtafoveal telangiectasia, hypertensive retinopathy, radiation retinopathy, ruptured retinal macroaneurysm, and pseudophakic cystoid macular edema.

Predictive Factors for Incident DME

The risk of developing DME is similar to the risk of developing diabetic retinopathy (DR) in general. Well-known risk factors for DME and DR among persons with DM include longer duration of diabetes, post-puberty, and pregnancy. No genetic association has been reported for the development of DME (Das et al. 2015). Non-Hispanic black race, longer duration of diabetes, and higher levels of hemoglobin A1C were associated with greater prevalence of DME in cross-sectional multivariate regression analysis within the National Health and Nutrition Examination Survey (NHANES) (Varma et al. 2014).

Hyperglycemia is the most important modifiable risk factor associated with the development

of DME. Both the Diabetes Control and Complications Trial (DCCT, Type 1 DM) and the UK Prospective Diabetes Study (UKPDS, Type 2 DM) showed that tight glycemic control (hemoglobin A1C < 7%) reduces the risk of developing and having progression of DR (DCCT Group 2000; UKPDS 1999). In addition, at the final DCCT visit (mean follow-up of 6.5 years), tight control reduced the prevalence of CSME when compared to conventional control (3.8% vs. 6.8%, $p = 0.02$) (DCCT et al. 2015). The Epidemiology of Diabetes Interventions and Complications (EDIC) study extended the follow-up on the DCCT participants for up to an additional 18 years from closeout of the DCCT. Throughout EDIC, the prevalence of DME continued to increase in each group, and tight control continued to reduce the prevalence of CSME through the EDIC 10-year exam (9.4% vs. 20.4%, $p = 0.004$, tight vs. conventional control, 95% CI). As the level of glycemic control in the two treatment arms became more similar during EDIC, approximately 8% in each group (compared to the treatment group differences during the DCCT, about 7% vs. 9%), the probability of developing new CSME became similar between the two groups during the interval between the 10- and 15–18-year EDIC visits. These findings highlight the long-term benefits of better control early on in the course of these individuals but also emphasize that there is a limit to this favorable metabolic memory.

The Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR) is a large population-based study which reexamined a cohort of persons with diabetes 10 years after their initial examination. Ten-year incidence rates of CSME ranged from 8% to 18% depending on insulin use and age at DM diagnosis. Among the younger and older onset study participants, the higher the glycosylated hemoglobin at the baseline examination, the higher the incidence of macular edema at the 10-year visit (OR = 1.56 for each Hgb A1c%, 95% CI, 1.38, 1.76; OR = 1.65, 95% CI, 1.42–1.92 younger/older onset participants, respectively). Incident DME also was higher among those with a greater increase in their glycosylated hemoglobin between the baseline and the 4-year visit (18–37% increase per % point increase depending on age at DM onset). In all participants incident macular edema increased significantly with increasing severity of baseline retinopathy level ($P < 0.0001$). These findings suggest that a sustained reduction in hyperglycemia may result in a beneficial reduction in incident macular edema (Klein et al. 1995).

Associations between development of DME and dyslipidemia have been inconsistent. There is no current evidence that intensive control of dyslipidemia by statin agents is useful in treating or preventing DR or DME (Lee et al. 2015). Prophylaxis for DME and DME-related vision loss is best accomplished by tight glycemic control and early and regular retinal examination of individuals with diabetes.

Therapy

Focal/Grid Photocoagulation

Prior to 2010, the gold standard therapy for management of DME was focal/grid photocoagulation. Laser photocoagulation may be applied directly to microaneurysms (focal treatment) and in a grid pattern to areas of leaking capillaries, each confined to areas of retinal thickening. The mechanism by which focal/grid laser leads to reduction in anatomic DME is not completely understood. The ETDRS concluded that focal/grid laser was safe and effective in reducing vision loss in eyes with CSME from diabetes (ETDRS 1985, 1991). Patients with CSME and less severe (mild or moderate) NPDR randomly assigned to the immediate focal/grid laser group were less likely to experience moderate vision loss (loss of 15 or more letters) than those assigned to the deferred laser (deferral of focal laser) group (12% immediate focal vs. 24% delayed focal at 3 years). Although laser treatment has been able to limit vision loss in eyes with DME, it seldom is associated with vision improvement. Among the subgroup of eyes in the ETDRS with center-involving DME and vision impairment of 20/40 or worse, at 3 years about 40% of the immediate focal/grid laser group had a six or more letter improvement in ETDRS letter score compared

with approximately 20% of the deferred treatment group (ETDRS 1985). Less than 3% of patients achieved visual improvement of at least 15 letters in each of the subgroups. Focal/grid laser often requires more than one application, but it is generally well tolerated and has a low complication rate which includes potential inadvertent foveal burns, paracentral scotomas, choroidal neovascularization, laser scar expansion over time (so-called laser creep), vitreous hemorrhage, subretinal fibrosis, and migration of intraretinal lipid into the fovea. Focal/grid laser is still in use, but it may no longer be a first-line therapy for CI-DME when access to pharmacologic agents is available. More typically, its present use is reserved for non-central diabetic edema. Among patients with CI-DME, it may be used among those for whom intravitreal injections are contraindicated or for those who will not accept intravitreal medications and the frequent visit schedule needed to deliver this treatment. It also still has a role as an adjuvant therapy in eyes receiving intravitreal medications to manage DME.

Vitrectomy

Vitrectomy with or without the removal of the internal limiting membrane (ILM) has been utilized in the treatment of DME. Vitrectomy may increase oxygen tension within the vitreous cavity, promoting constriction of retinal arterioles, leading to decreased vascular hydrostatic pressure in capillaries and venules, and resultant decreased edema (Stefansson 2001). Increased oxygen tension may also reduce production of VEGF. Further, vitreomacular traction may contribute to or exacerbate DME, and this can be anatomically altered with surgery. A Diabetic Retinopathy Clinical Research (DRCR) network protocol followed a cohort of 87 eyes for 1 year following vitrectomy surgery to manage DME and vitreomacular traction (DRCR 2010). Preoperative visual acuity was a median of 20/100 (range 20/63–20/400). The method of vitrectomy was at the surgeon's discretion and may or may not have incorporated adjunctive intravitreal steroid, focal/grid laser photocoagulation, or ILM peeling. At 6 months, 68% of eyes showed a reduction in the median central subfield thickness by ≥50% on OCT, but only 38% of eyes showed improvement in ETDRS letter score of ten or more letters.

Pharmacotherapy

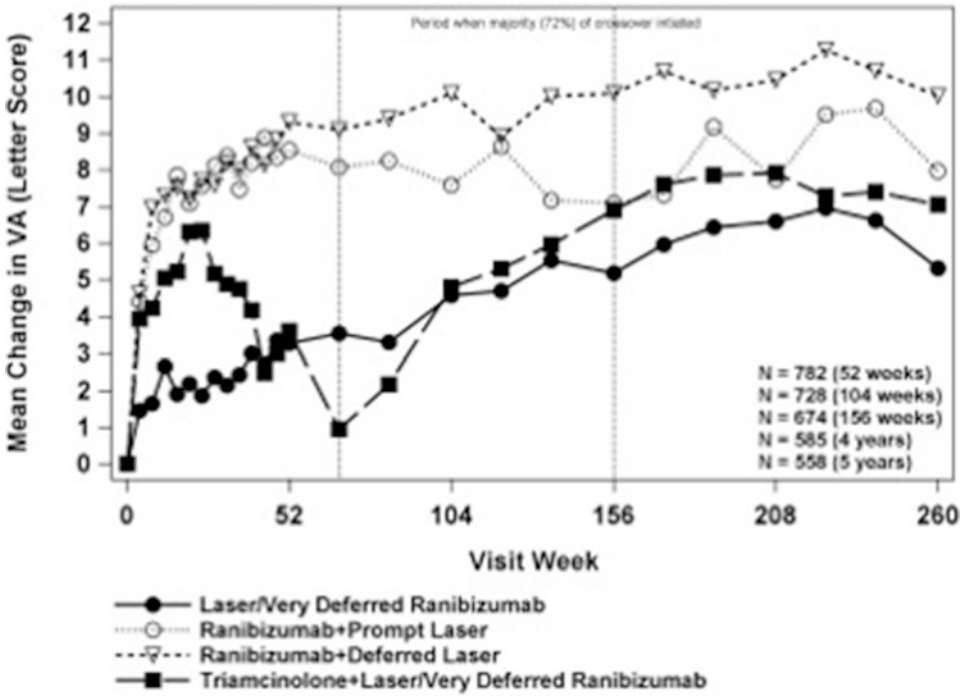
Anti-vascular Endothelial Growth Factor Therapy

Anti-VEGF is the current first-line therapy for CI-DME. Several anti-VEGF-A agents have been evaluated in the treatment of DME. Some of the pivotal clinical trials that have established the efficacy of anti-VEGF agents over previous management strategies are summarized below.

Ranibizumab (Lucentis, Genentech, South San Francisco, CA), a monoclonal antibody that blocks all isoforms of VEGF-A, has been proven effective in the management of DME as it restores DME-related vision loss in many and prevents further vision loss in the majority of eyes receiving this therapy. The DRCR.net protocol I (the Laser–Ranibizumab–Triamcinolone Study) study enrolled 854 eyes with center-involving DME (confirmed with time-domain OCT central subfield thickness >250 μm) and vision impairment of 20/32–20/320 (Elman et al. 2011). Patients were randomly assigned to sham injection plus prompt laser, intravitreal ranibizumab 0.5 mg plus prompt laser, intravitreal ranibizumab 0.5 mg plus deferred (≥24 weeks) laser, or intravitreal triamcinolone 4 mg plus prompt laser. The mean change in visual acuity between baseline and the 1-year visit (the primary outcome of the study) was +3 letters in the sham plus prompt laser group, compared with +9 letters in the ranibizumab plus prompt laser ($P < 0.001$) or ranibizumab plus deferred laser group ($P < 0.001$). Follow-up of the ranibizumab groups through 5 years has shown the stability of this outcome (Bressler et al. 2016). The proportions of eyes experiencing a 10–14-letter improvement and those improving 15 or more letters from baseline were 16% and 32% in the ranibizumab plus prompt laser group and 16% and 37% in the ranibizumab plus deferred laser group. The rates of at least a ten-letter loss were each only 3% in the respective ranibizumab groups. The rapid rise in mean change in visual acuity that

occurred in the initial 6 months of follow-up was accompanied by a simultaneous rapid reduction in central subfield thickness (CST). The mean decrease in CST was 174 μm in the sham plus laser group compared with 225 μm in the ranibizumab plus prompt laser group ($P < 0.001$) and 226 μm in the ranibizumab plus deferred laser group ($P < 0.001$) at 1 year. While applying the structured re-treatment protocol (based on changes in CST and VA), the cumulative injection number was 8 in the ranibizumab plus prompt laser group and 9 in the ranibizumab plus deferred laser groups in the first year of the study. Between the 1- and 2-year visits, the median number of injections fell dramatically to 2 and 3 and remained 0–1 for years 3, 4, and 5. In contrast to managing neovascular age-related macular degeneration with anti-VEGF therapy, when one is managing DME, it is apparent the anti-VEGF treatment burden decreases after the first year of treatment, while visual gains and reductions in central retinal thickness are maintained through 5 years (Fig. 2) (Bressler et al. 2016).

The RISE and RIDE trials, two parallel, randomized, phase 3 studies, also demonstrated superior visual outcomes among eyes treated monthly with 0.3-mg or 0.5-mg intravitreal ranibizumab compared with those in the control arm (sham injections, focal/grid laser permitted but not required beginning at month 3) (Brown et al. 2013). In RISE the mean change in VA letter score between baseline and the 2-year visit in the sham, 0.3-mg ranibizumab and 0.5-mg ranibizumab groups, was +2.6, +12.5, and +11.9 letters, respectively ($P < 0.001$ for each ranibizumab comparison to sham), while in the RIDE trial, the same outcomes were +2.3, +10.9, and +12 letters, respectively ($P < 0.001$ for each ranibizumab comparison to sham). At 2 years in the RISE study, 18% of sham participants gained at least 15 letters vs. 45% of 0.3-mg ($P < 0.0001$)



Diabetic Macular Edema, Fig. 2 Mean change in visual acuity letter score over 5 years from a randomized trial comparing ranibizumab with prompt or deferred laser, laser with deferred ranibizumab, and triamcinolone plus deferred ranibizumab in eyes with vision impairment from center-involving DME (Reprinted with permission, Bressler et al. 2016. American Journal of Ophthalmology, volume 164, 2016, 57–68)

and 39% of 0.5-mg ranibizumab group ($P < 0.001$). Similarly, at 2 years In RIDE, significantly more ranibizumab-treated patients gained 15 letters or more: 12% of sham eyes vs. 34% of 0.3-mg eyes ($P < 0.0001$) and 46% of 0.5-mg eyes ($P < 0.0001$). Reductions in CST paralleled the rise in VA in the ranibizumab eyes, with greater reductions in CST among the ranibizumab groups relative to the control arm (mean decrease in CST ranged from 251 to 271 μm in the ranibizumab groups and 126–133 μm in the control group at 24 months).

In addition to protocol I, RIDE and RISE also provided data demonstrating low rates of both ocular and systemic adverse events in all treatment groups; in particular no increase in thromboembolic events (events described by the Antiplatelet Trialists' Collaboration) occurred in the ranibizumab groups compared to the control arms. In addition, all three studies provided exploratory evidence that eyes managed with ranibizumab were more apt to have improvement in the severity of their retinopathy level (regression of disease) and slower progression or worsening of retinopathy compared with the control groups.

Bevacizumab (Avastin, Genentech, South San Francisco, CA) is a full-length monoclonal antibody that blocks all isoforms of VEGF-A. Bevacizumab is a commonly used "off-label" in the management of DME. The bevacizumab or laser therapy (BOLT) trial compared intravitreal bevacizumab to focal/grid laser (Rajendram et al. 2012). Among the 65 patients enrolled in this study, the 28 eyes randomly assigned to laser had a mean change of −0.5 letters in their ETDRS letter score at month 24, while the 37 eyes assigned to repeated intravitreal bevacizumab every 6 weeks showed a mean change of +8.6 letters at the same time point ($P = 0.005$). At 24 months, more eyes gained ≥10 letters and ≥15 letters in the bevacizumab group than the laser group (49% vs. 7%, $P = 0.001$, and 32% vs. 4%, $P = 0.004$, respectively). While no bevacizumab-treated eyes lost ≥15 letters, 14% did so in the laser group ($P = 0.03$).

Aflibercept (Eylea, VEGF-Trap Eye, Regeneron, Tarrytown, NY), another VEGF-A antagonist, is a soluble protein which contains the extracellular VEGF receptor 1 and 2 sequences fused to the Fc domain of a human immunoglobulin-G1 molecule. Aflibercept has 100-fold greater binding affinity to VEGF than either ranibizumab or bevacizumab (Das et al. 2015). In addition, aflibercept blocks all isoforms of placental growth factor, a substance which may also contribute to vascular permeability and retinal neovascularization. The VIVID and VISTA trials were two parallel phase 3 trials which compared two different aflibercept-dosing regimens to focal/grid laser (Brown et al. 2015). Eyes were randomly assigned to aflibercept 2 mg every 4 weeks (2q4), aflibercept 2 mg every 8 weeks after 5 monthly doses (2q8), or focal/grid laser. Mean change in ETDRS VA letter score from baseline to week 100 in the aflibercept 2q4 and 2q8 groups were +11.5 and +11.1 compared with +0.9 in the laser group in VISTA ($P < 0.0001$ for each aflibercept regimen compared to control) and +11.4, +9.4, and +0.7 letters, respectively, in VIVID ($P < 0.0001$ for each aflibercept regimen compared to control). The proportion of eyes that improved by ≥15 letters at week 100 was 38% (2q4), 33% (2q8), and 13% (focal/grid) in VISTA and 38%, 31%, and 12%, respectively, in VIVID ($P < 0.0001$ for each aflibercept comparison to laser for both studies). The proportion of eyes that lost ≥15 letters at week 100 also statistically favored aflibercept with rates of 3.2% (2q4) ($P = 0.022$), 0.7% (2q8) ($P < 0.001$), and 9.7% (focal/grid) in VISTA and 2.2% (2q4) ($P < 0.001$) and 1.5% (2q8) ($P < 0.001$) compared to 12.9% (focal/grid) in VIVID. Exploratory analyses from these trials also found significantly more eyes in the aflibercept groups vs. those in the laser group who had a ≥2 step improvement in the ETDRS retinopathy level in both VISTA and VIVID.

Given the Level 1 evidence supporting efficacy and safety of each of the presently available anti-VEGF agents to manage DME, the DRCR.net

protocol T performed a comparative efficacy trial of ranibizumab, bevacizumab, and aflibercept in eyes with CI-DME and vision impairment (DRCR et al. 2015, 2016). In eyes with CI-DME and relatively good vision (20/32 or 20/40), all three drugs were effective in achieving a mean improvement of about eight letters in ETDRS letter score at 1 year, which was maintained through the 2-year visit. Aflibercept, however, outperformed ranibizumab 0.3- and 1.25-mg bevacizumab among eyes that presented with vision impairment of 20/50–20/320. In this cohort, from baseline to 1 year, the mean improvement in VA letter score was +13.3 letters with aflibercept, +9.7 letters with bevacizumab (aflibercept–bevacizumab, $P < 0.001$), and +11.2 with ranibizumab 0.3 mg (aflibercept–ranibizumab, $P = 0.03$, ranibizumab–bevacizumab, $P = 0.21$). At 2 years, in the subgroup of eyes with lower baseline VA (20/50–20/320), the mean change in VA was +18.1, +13.3, and +16.1 letters, in the aflibercept, bevacizumab, and ranibizumab groups, respectively. Only the aflibercept–bevacizumab comparison remained significant ($P = 0.02$). At the 2-year visit, OCT CST decreased on average ($\pm SD$) by 171 ± 141 μm with aflibercept, 126 ± 143 μm with bevacizumab, and 149 ± 141 μm with ranibizumab (aflibercept vs. bevacizumab, −48.5 μm, $P < 0.001$; aflibercept vs. ranibizumab, −15.5 μm, $P = 0.08$; and ranibizumab vs. bevacizumab, −33 μm, $P < 0.001$). Focal/grid laser was required if CI-DME persisted and was no longer showing successive improvement following six consecutive injections. Eyes assigned to bevacizumab were most apt to receive laser (64%), followed by ranibizumab (52%), while the aflibercept eyes were less likely to need laser (41%) ($P < 0.001$). In all treatment groups, the number of injections needed in the second year was about half the number required in the first year with a cumulative median number of about 15 injections in all groups. Antiplatelet Trialists' Collaboration (APTC) events occurred in 5% with aflibercept, 8% with bevacizumab, and 12% with ranibizumab ($P = 0.34$ for aflibercept vs. bevacizumab, $P = 0.047$ for aflibercept vs. ranibizumab, and $P = 0.20$ for ranibizumab vs. bevacizumab). The significance of this observation is unclear as it is inconsistent with other studies to date.

Steroids

As many inflammatory mediators have been implicated in the pathogenesis of DME and diabetic retinopathy, it follows that steroids may have a role in the management of DME. Cataract formation and elevation of intraocular pressure are two drug-related adverse events, seen with varying frequency depending on the specific steroid preparation, that limit the use of intraocular steroids in DME management, often relegating these agents to second-line therapy.

The DRCR.net protocol B found that 4-mg intravitreal triamcinolone was no better than focal/grid laser at altering vision outcomes at 2 (DRCR 2008; Elman et al. 2011). Similarly, in the DRCR protocol I, eyes randomly assigned to 4-mg intravitreal triamcinolone plus prompt laser did not experience superior vision outcomes relative to the sham plus prompt laser group at 1 year (Elman et al. 2011). However, in a subgroup analysis of eyes that were pseudophakic at baseline ($n = 273$), the triamcinolone plus prompt laser group had a mean change of +8 letters which appeared comparable to the two ranibizumab groups at 1 year. However, by the year 5 visit, the pseudophakic subgroup assigned to triamcinolone plus prompt laser did not appear to maintain this level of improvement (Bressler et al. 2016).

The MEAD study randomly assigned 1048 eyes with CI-DME and vision of 20/50–20/200 to 0.7-mg or 0.35-mg dexamethasone intravitreal implant (Ozurdex; Allergan, Inc., Irvine, CA) or sham injections (Boyer et al. 2014). Only 58% (607/1048) completed the 3-year trial, limiting the interpretation of the results. Some eyes experienced vision improvement, while others lost vision. Cataract formation and steroid-related elevations in intraocular pressure were observed.

Another intravitreal steroid implant, the fluocinolone acetonide implant, was evaluated in the FAME trial (Campochiaro et al. 2011). Study eyes had persistent DME (CI-DME that persisted despite one or more prior focal/grid laser treatments) and were randomly assigned to 0.2 μg/day or 0.5 μg/day fluocinolone acetonide implants or sham injections. The mean improvement in VA letter score between baseline and the 2-year visit was +4.4 letters in the 0.2-μg implant and +5.4 letters in the 0.5-μg implant group compared with +1.7 letters in the sham group ($P = 0.02$ and $P = 0.016$). One subgroup appeared to benefit more than others, which were eyes with DME duration greater than 3 years at study entry. In this subgroup, 34% of the 0.2-μg ($P < 0.001$) and 29% of the 0.5-μg group ($P = 0.002$) had at least a 15-letter improvement compared with 13% of the sham group.

The FAME study did allow treatments other than the random assignment if CI-DME persisted, and more eyes in the implant group avoided focal/grid laser compared to the sham group (63–65% in the implant groups compared with 41% in the sham group). Similarly more eyes in the sham group (29%) received alternative rescue treatments for DME (which may have included anti-VEGF therapy) than those in the low-dose (13%) or high-dose (14%) implant groups. Elevated intraocular pressure-requiring incisional glaucoma surgery was reported in 8% of patients in the 0.5-μg group and 4% in the 0.2-μg group. Almost all phakic patients in the implant groups developed visually significant cataract. Following cataract surgery, eyes that had been phakic at baseline but assigned to the implant groups demonstrated similar visual benefit compared to eyes that were pseudophakic at study entry.

Future Therapies

Several large clinical trials have established anti-VEGF agents as current first-line therapy for CI-DME treatment. However, some patients may not be able to comply with the frequent visits that are needed in the first few years of therapy in order to realize the benefits of this treatment. Some eyes will manifest persistent CI-DME despite receiving regular anti-VEGF therapy with long-term vision outcomes that may not be as robust as what occurs among eyes that anatomically respond with time (Bressler et al. 2016). Therefore, research continues into alternative treatment strategies.

The use of steroid medications in combination with anti-VEGF therapy is being studied as a strategy to further improve visual outcomes while decreasing treatment burden in DME patients. Longer-acting anti-VEGF agents administered by way of sustained drug delivery systems are also being evaluated as potential DME treatments.

Designed ankyrin repeat proteins (DARPins), proteins with high-affinity binding for VEGF administered by intravitreal injection, are in early phase 3 testing as another potential therapy for DME (Agarwal et al. 2015; Das et al. 2015). Vascular adhesion protein-1 (VAP-1) inhibitors, insulin-like growth factor inhibitors, interleukin inhibitors, chemokine inhibitors, and inhibitors of the angiopoietin/TIE-2 pathway are all in various phases of early investigation as novel therapies in DME, as is sirolimus, an inhibitor of various pro-inflammatory cytokines and inflammatory-associated genes (Das et al. 2015).

Prognosis

The prognosis for maintenance of good vision is more favorable if DM is diagnosed and controlled early in its course. With regular monitoring of glycemic control and regulation of modifiable systemic risk factors by the medical team, coupled with consistent retinal exams, individuals with DM are far less likely to experience significant vision loss from DME. Prognosis for visual acuity among those individuals that do develop DME is very good in the present era of anti-VEGF therapy. Large clinical trials demonstrate that eyes that present with a better level of visual acuity when initiating therapy are most apt to maintain the best level of acuity in follow-up. This emphasizes the need for regular surveillance examinations to detect DME early in its course before greater levels of vision impairment occur.

Definition

Diabetic papillopathy (DP) describes unilateral or more commonly bilateral optic disc edema with variable visual loss seen in diabetic patients. DP can occur in both type 1 and type 2 diabetes mellitus. Some authors believe that DP is a separate nosologic entity, while others believe it is on the spectrum of nonarteritic anterior ischemic optic neuropathy (NAION) in a diabetic patient.

Etiology

The precise pathogenesis of DP is not known and there is no direct relationship between the metabolic control of the diabetes and the presence or stage of diabetic retinopathy. Though diabetic microangiopathy has been proposed by some as a possible etiology, no pathologic studies of DP have been performed. Thus, many authors argue that DP is in fact a milder form of NAION. Both NAION and DP share the following features: diabetes as a risk factor, a small optic cup/crowded optic nerve head (i.e., the "disc at risk"), nerve fiber layer defects, and subsequent sector or diffuse optic disc pallor. On the other hand, there are some differences that have been proposed to differentiate DP from NAION: the disc edema of NAION usually resolves within 3 months, whereas a length of up to 10 months or longer is common in DP; DP also tends to more commonly affects younger age groups and is more often bilateral than NAION, and the disc appearance may have more prominent telangiectasias in DP than NAION.

Clinical Presentation

The presentation of DP can mimic "garden variety" NAION with ipsilateral visual acuity or visual field loss; a relative afferent pupillary defect (if unilateral or bilateral but asymmetric), concomitant vasculopathic risk factors, a fellow eye with the structural "disc at risk"; and optic disc edema that eventually becomes optic atrophy. There may also be concomitant diabetic retinopathy and/or diabetic macular edema but this is quite variable.

Diagnostics

If bilateral disc edema is present, potentially life-threatening causes, such as increased intracranial pressure resulting in papilledema, should be considered (e.g., neuroimaging, typically contrast cranial MRI, and MRV followed by consideration for a lumbar puncture).

The fundoscopic exam of DP may also mirror NAION but sometimes shows a more distinctive disc with prominent telangiectasias and dilated vasculature of the optic disc. The optic disc edema in DP may be unilateral or bilateral, and diabetic macular edema (DME) is frequently a comorbid finding, occurring in up to 70% of patients. The presence of DME may be another differentiating ophthalmoscopic sign of DP compared with NAION. Other diabetic retinopathy (DR) findings, usually nonproliferative DR (NPDR), occur in the involved or unaffected eye in 35–90% of patients. An exam of the fellow eye typically shows a small optic disc cup (the structural disc at risk). The optic disc findings in DP typically resolve spontaneously in follow-up examinations, with a reported mean duration of 4–8 months (longer than typical NAION). Fluorescein angiography often shows disc leakage in patients with DP and also can better illustrate the radial pattern of dilated telangiectatic vessels that may help to differentiate DP from proliferative diabetic neovascularization of the disc (NVD) from NAION.

Differential Diagnosis

DP is considered a diagnosis of exclusion. The differential diagnosis includes papilledema, optic disc neovascularization, malignant hypertension, papillitis, and NAION.

Therapy

Although corticosteroids have been proposed in NAION, this is controversial in patients with DP because of the potential for worsening diabetic glucose control. Additionally, reports of intravitreal injection of vascular endothelial growth factor inhibitors (anti-VEGF), bevacizumab, and ranibizumab have been documented to show improvement of optic disc swelling and improved vision in anecdotal reports. However, several of these patients also had macular edema and larger studies are needed to accurately assess the efficacy of this therapeutic approach.

Prognosis

DP generally has a favorable prognosis with no required treatment beyond treating the diabetes, but it is essential to differentiate it from more malignant or aggressive processes including NAION, papilledema and other infectious and inflammatory papillitis.

Epidemiology

DP is a relatively uncommon condition considering the prevalence of diabetes mellitus. The estimated incidence of DP is 0.5%. Though it was initially described only in younger patients with type 1 diabetes, it has subsequently been documented in older type 2 diabetic patients (up to 79 years old). Though duration of diabetes is not an established risk factor, most cases of DP have been reported in patients with long-standing diabetes.

Proliferative retinopathy due to diabetes

Definition

Introduction and Definition

Proliferative diabetic retinopathy (PDR) is an advanced form of diabetic retinopathy characterized by the growth of new vessels arising from the optic disc, surface of the retina, iris, or anterior chamber angle. It is associated with a significant loss of vision and at least 12% of the new cases of blindness each year in the United States (Albert et al. 2008). Growth of new vessels at the disc is known as neovascularization of the disc (NVD), whereas origin of new vessels from retinal vasculature elsewhere is neovascularization elsewhere (NVE). As the disease progresses, fibrous tissue around the vessels increases, and when this fibrous tissue contracts, it can lead to tractional retinal detachment and vitreous hemorrhage, which are the leading causes of visual loss associated with PDR (Yanoff and Duker 2014).

The prevalence of diabetic eye disease is steadily increasing. More than 150 million people around the world suffer from diabetes, and this number is expected to double by the year 2030. In the background of this diabetes *tsunami*, diabetic retinopathy and its complications remain a major medical and social challenge.

Classification of PDR

Based on the clinical manifestations, diabetic retinopathy has been classified as either nonproliferative diabetic retinopathy (NPDR) or proliferative diabetic retinopathy (PDR). PDR is marked by the presence of retinal neovascularization (Table 1).

Eyes with early PDR have a 75% risk of progression to high-risk PDR in a 5-year period. These eyes require prompt therapy with laser photocoagulation (Albert et al. 2008; Ryan et al. 2013).

Diabetic Retinopathy, Proliferative, Table 1 Classification of proliferative diabetic retinopathy (PDR)

Proliferative diabetic retinopathy (PDR) is characterized by NVD or NVE, preretinal or vitreous hemorrhage or fibrous tissue proliferation	
Early PDR	New vessels, but criteria for high risk not met
High-risk PDR	1. NVD (1/3–1/2 disc area)
	2. NVD and vitreous or preretinal hemorrhage
	3. NVE $\geq$1/2 disc area and vitreous or preretinal hemorrhage

Etiology

Systemic Risk Factors for Progression to PDR

(a) Glycemic control

In the majority of studies, poor glycemic control has been associated with an increase in the severity of diabetic retinopathy. Both the duration and severity of diabetes mellitus are known to affect the outcome in patients with retinopathy. The duration of diabetes has been directly associated with increased prevalence of retinopathy in the population with both type 1 and 2 diabetes. In patients with poor metabolic control, intensive therapy and achievement of good control of blood glucose have been shown to have an initial detrimental effect on the retina. However, after 3 years, intensive therapy has been shown to ultimately reduce the risk of progression of retinopathy in insulin-dependent diabetics (Albert et al. 2008).

(b) Systemic hypertension

The effect of hypertension on diabetic retinopathy is unclear. However, several studies have indicated that increased diastolic and systolic blood pressures may be associated with increased severity of progression of diabetic retinopathy (Albert et al. 2008).

(c) Nephropathy

In diabetic patients, it has been noted that the presence of diabetic nephropathy and increased urinary protein leakage is associated with an increased severity of diabetic retinopathy. Changes in the retina due to uremia include edema of the optic disc and the retina (Albert et al. 2008).

(d) Pregnancy

Pregnancy may result in an increased risk of progression of diabetic retinopathy attributed to physiological changes experienced during gestation. However, this difference may be small (Albert et al. 2008).

Ocular Risk Factors

Ocular risk factors that may result in progression to proliferative retinopathy in diabetes include cataract surgery, especially when complicated by rupture of the posterior capsule or vitreous loss. This may predispose the patient to higher levels of inflammation and the release of pro-inflammatory and angiogenic cytokines. Other various intraocular procedures are known to increase the risk of progression to PDR, including glaucoma surgery (Albert et al. 2008; Ryan et al. 2013).

Pathogenetic Role of Various Pro- and Anti-inflammatory Factors

The hallmark of diabetic retinopathy is microvascular damage due to tissue ischemia. This results in the release of various angiogenic factors that are thought to play a role in the development of PDR. Among these factors, vascular endothelial growth factor (VEGF) is thought to play the most important role, as indicated by the high concentration of VEGF in the vitreous of eyes with PDR. Additionally, the angiogenic properties of the vitreous fluid from eyes with PDR can be blocked with the addition of a VEGF inhibitor in vitro. Along with VEGF, it is thought that angiopoietin, erythropoietin, basic fibroblast growth factor, insulin-like growth factor, protein kinase C, tumor growth factor, interleukins (IL-1, IL-6, and IL-8), and platelet-derived growth factor also play a role in the pathogenesis of PDR (Ryan et al. 2013; Yanoff and Duker 2014).

Neovascularization occurs in response to these factors in the retina and other ocular structures. New vessels start out small, but they typically progress to a caliber that is one eighth to one fourth the size of a major retinal vein found at the optic disc margin (Ryan et al. 2013).

Pathogenesis of Fibrous Proliferation and Retinal Traction

Retinal neovascularization is accompanied by a proliferation of white fibrous tissue adjacent to the vessels. These neovascular networks found on the retina nearly always form adhesions with the vitreous. Over time, the fibrous tissue along the posterior vitreous contracts, and as it does so, it causes a forward force on the posterior vitreous that results in its detachment from the retinal surface. However, the vitreous remains attached to the retina at the points of adhesion formed with the new vessels. Vitreous traction on these vessels results in vitreous hemorrhage, which is one of the main causes of visual loss associated with PDR. Vitreous hemorrhage results in pooling of blood in the posterior fluid vitreous, and it typically requires many months for the blood from a large hemorrhage to be absorbed. When a large sheet of fibrovascular tissue contracts, it may also result in a displacement of the macula, typically nasally and somewhat vertically toward the optic disc as this is a common site of neovascularization. Vitreoretinal adhesions also present the risk of tractional retinal detachment (TRD) following the contraction of the areas of fibrovascular proliferation. TRD may be relatively minor or it may be a more extensive detachment (Ryan et al. 2013).

The development of PDR is illustrated in Fig. 1.

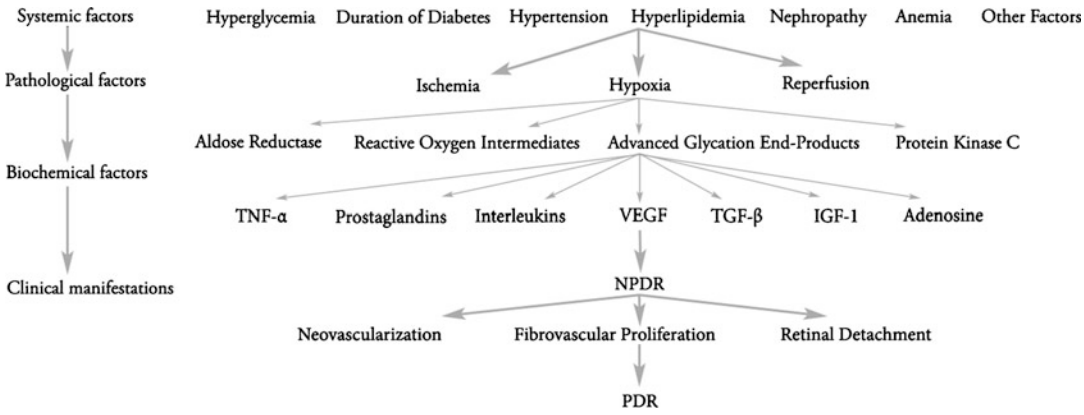
Clinical Presentation

Visual Acuity

Patients with PDR are at an increased risk of blindness due to various complications including vitreous hemorrhage, TRD, and macular edema. Severe visual loss (SVL), defined as 5/200 or worse on two consecutive visits 4 months apart, can be reduced substantially by early treatment in patients with PDR. The 5-year risk of SVL in patients with PDR is as high as 60% if left untreated (Albert et al. 2008).

Symptomatology

Patients with PDR present with decreasing vision due to various causes including macular edema. There may be a sudden drop in vision or floaters in patients secondary to vitreous hemorrhage or retinal detachment. PDR results in blindness in a majority of patients due to unresolved vitreous hemorrhage (Ryan et al. 2013).



Diabetic Retinopathy, Proliferative, Fig. 1 Flowchart showing the risk factors for development of proliferative diabetic retinopathy. The chart summarizes the systemic, biochemical, and local factors responsible for the clinical manifestations of proliferative diabetic retinopathy. *IGF* Insulin-like growth factor, *NPDR* nonproliferative diabetic retinopathy, *PDR* proliferative diabetic retinopathy, *TGF* transforming growth factor, *TNF* tumor necrosis factor, *VEGF* vascular endothelial growth factor

D

Other Measures of Visual Function

PDR may also affect a number of other visual functions including visual fields. Retinal detachment secondary to traction may result in scotomas. Treatment including laser photocoagulation is associated with peripheral field constriction. Electroretinogram (ERG) shows evidence of decreased function of photoreceptors. Vascular manifestations of the retina may be associated with changes in the b-wave of the ERG. ERG may also be used to predict the prognosis after surgery in eyes with dense vitreous hemorrhage (Ryan et al. 2013).

Anterior Segment Features

Slit lamp biomicroscopy in patients with PDR may reveal the presence of floating red blood cells in the anterior chamber in patients with vitreous hemorrhage. There may be increased progression of nuclear sclerosis resulting in media opacity and decreased vision. Iris neovascularization (INV) may result due to the effect of VEGF in the anterior chamber. On gonioscopy, small tufts of anterior chamber angle new vessels (ANV) may be evident in certain patients. Patients with NPDR may progress to PDR after complicated cataract surgery with signs of posterior capsular rupture. Examination of the vitreous may show presence of deep red glow or red blood cells floating in patients with vitreous hemorrhage (Skuta et al. 2011; Ryan et al. 2013).

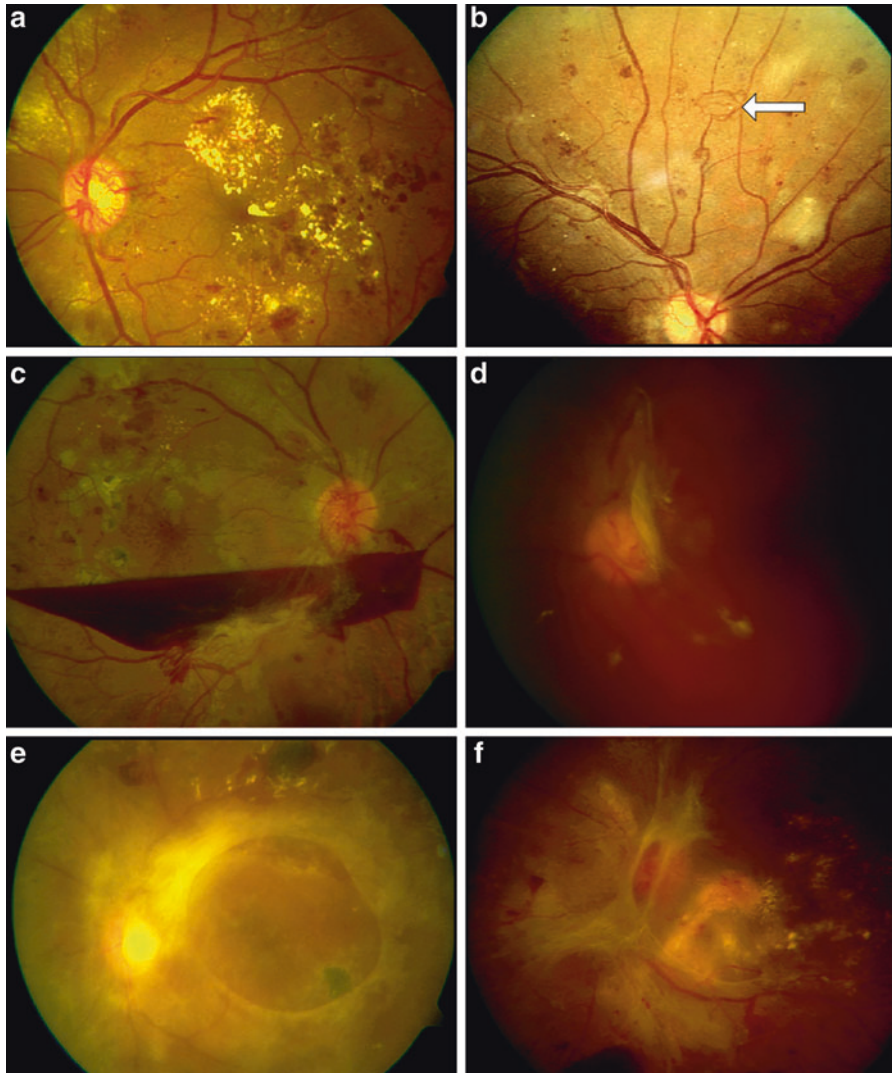
Posterior Segment Features

(a) Diabetic retinopathy

Background diabetic retinopathy consists of changes in the retinal microvasculature including microaneurysms, dilation and beading of the retinal venules, thinning of the retinal arterioles, intraretinal microvascular abnormalities, nerve fiber layer infarcts (cotton wool spots), retinal edema, intraretinal hemorrhages, and hard exudates that appear as discrete, yellow intraretinal deposits composed of lipids (Skuta et al. 2011; Ryan et al. 2013).

(b) Retinal neovascularization

New retinal vessels may be present anywhere on the retina, but they are most frequently seen in the posterior pole. They may present as neovascularization of the disc (NVD; Fig. 2a) or as neovascularization elsewhere (NVE; Fig. 2b). The newly formed vessels often take the form of a wheel, with the vessels radiating outward from a central complex like the spokes of a wheel and joining with a vessel surrounding the circumference of the neovascular network. However,



Diabetic Retinopathy, Proliferative, Fig. 2 Fundoscopic features of proliferative diabetic retinopathy (*PDR*). (**a**) Neovascularization of the optic disc (NVD) appears as a fine, lacy pattern of new vessels on the optic nerve head. (**b**) Neovascularization elsewhere (NVE) (marked with a *white arrow*) more than half the size of optic disc in a patient with high-risk characteristics PDR. (**c**) Subhyaloid hemorrhage appears as a typical boat-shaped, dark-colored collection of blood behind the posterior hyaloid membrane. (**d**) Vitreous hemorrhage resulting in obscuration of media clarity is a major cause of poor vision in patients with PDR. (**e**) Tractional retinal detachment is seen in a patient with advanced PDR forming a tabletop configuration at the macula. (**f**) Combined retinal detachment results due to the development of a large retinal break in a patient with tractional retinal detachment, requiring surgical intervention

they may also assume an irregular shape (Ryan et al. 2013). The irregular vessels can be distinguished from normal vessels because they cross both arterioles and venules (Albert et al. 2008; Yanoff et al. and Duker 2014).

(c) Vitreous/preretinal hemorrhage

Complete detachment of the posterior vitreous occurs naturally with aging in diabetic patients. However, among patients with PDR, neovascular proliferations remain attached to

the posterior vitreous, major retinal vessels, and the optic disc. Traction on these adhesions can result in vitreous or preretinal hemorrhage. When the blood is limited by the posterior hyaloid, it is termed a preretinal hemorrhage or subhyaloid hemorrhage (Fig. 2c). The break in the continuity of the posterior hyaloid phase results in vitreous hemorrhage (Fig. 2d) (Albert et al. 2008).

(d) Fibrous proliferation/tractional retinal detachment (TRD)

Contraction of fibroproliferative tissue may be associated with TRD (Fig. 2e). On indirect ophthalmoscopy, the retina appears pulled and concave in configuration with limited mobility. The traction may progress resulting in the formation of a tabletop configuration of the TRD (Ryan et al. 2013).

(e) Combined retinal detachment

Pulling and traction on the retina may result in the development of subsequent retinal breaks and seepage of fluid underneath the retina, resulting in a combined retinal detachment (Fig. 2f). The detached retina assumes a convex configuration and corrugations with underlying subretinal fluid (Ryan et al. 2013).

Macular Edema in PDR

As the severity of diabetic retinopathy progresses, there is an increased risk for the development of diabetic macular edema (DME). Edema occurs due to the incompetence of the retinal capillaries and subsequent exudation leading to retinal thickening. If the edema occurs in the macula, this poses a significant threat to vision. The presence of hard exudates in the foveal center may have detrimental effects on vision (Albert et al. 2008).

Neovascular Glaucoma

Neovascular glaucoma occurs when proliferation of new vessels occurs in the anterior chamber angle, leading to an obstruction in aqueous outflow and a subsequent rise in intraocular pressure. It is thought to occur due to the diffusion of pro-angiogenic factors from the ischemic retina. Eyes with neovascular glaucoma may have a poor visual outcome (Ryan et al. 2013).

Involutional PDR

In the end stage of the disease, diabetic retinopathy becomes involutional or quiescent. This occurs after vitreous contraction is complete and the vitreous remains attached to the retina only at locations where there are adhesions with new vessels. At this stage, there is a decrease in vitreous hemorrhage, and retinal vessels typically return to their previous size or smaller. The visual outcome in this stage is variable. Loss of vision in this stage is related to macular ischemia, edema, and detachment, as well as opacity within the globe or optic nerve disease (Ryan et al. 2013).

Diagnosis

Schedule for Screening for PDR

Patients diagnosed with both non-high-risk and high-risk PDR should be examined every 2–3 months with careful follow-up to identify progression or potential complications (Skuta et al. 2011).

Clinical Examination

Diagnosis of PDR is established clinically using slit lamp biomicroscopy and indirect ophthalmoscopy. Examination of the periphery may reveal the presence of retinal microvasculature abnormalities including neovascularization (Yanoff and Duker 2014).

Fluorescein Angiography

Fluorescein angiography of the retina is used for both the diagnosis and management of diabetic retinopathy. Standard 7-field photography is performed to identify various changes in microvasculature including telangiectasias, microaneurysms, and leakage from new blood vessels (NVD or NVE). There may be accumulation of dye resulting in hyperfluorescence at the posterior pole due to macular edema. Patients with PDR may present with an irregular foveal avascular zone (FAZ) and extensive areas of retinal capillary non-perfusion (CNP).

Wide-field photography performed using newer technology can provide a wide-field view

of the fundus and can help identify various retinal pathologies that begin in the periphery. Significant microvascular changes in the retina of patients with diabetic retinopathy identified by fluorescein angiogram may predict the risk of progression to PDR (Skuta et al. 2011; Ryan et al. 2013).

Optical Coherence Tomography (OCT)

Optical coherence tomography (OCT) imaging is a very important tool in monitoring status of disease in patients with PDR. There may be diffuse thickening, distortion, and other irregularities within the retina due to contraction of the fibrovascular tissue. If DME is present, fluid will be seen within the macula along with retinal thickening. Abnormalities may be found at the vitreoretinal interface due to vitreoretinal adhesions. These may be associated with TRD, which can be visualized as an accumulation of fluid beneath the retina. OCT is of particular value in cases of TRD because it allows for an assessment of macular and foveal involvement and thus may aid in determining subsequent plans for treatment (Ryan et al. 2013).

Differential Diagnosis

Hypertensive Retinopathy

With a chronic elevation in blood pressure, the blood-retina barrier becomes disrupted, leading to an exudative phase in which microaneurysms, retinal hemorrhages, hard exudates, and cotton wool spots may be found in the retina, leading to similar findings to those of diabetic retinopathy (Ryan et al. 2013; Yanoff and Duker 2014).

Retinal Vasculitis

Retinal vasculitis may present with microvascular abnormalities including exudation, sheathing, and retinal neovascularization. These findings may be similar to changes found in PDR. However, unlike PDR, retinal vasculitis may be associated with signs of ocular inflammation (Albert et al. 2008).

Hemoglobinopathies

The hemoglobinopathies result from a number of mutations in the hemoglobin subunits, with the most common form being sickle cell disease (SCD). Similar to PDR, eyes of patients with SCD may show neovascularization of the retina due to tissue ischemia, which may lead to vitreous hemorrhage and vision loss (Ryan et al. 2013).

Miscellaneous

Various retinal pathologies may mimic PDR, including retinal macroaneurysms, retinal vein occlusions, and ocular ischemic syndrome, to name a few (Ryan et al. 2013).

Therapy

Panretinal Photocoagulation (PRP)

i. Indications

Panretinal photocoagulation (PRP) is an important treatment modality for patients with PDR. High-risk PDR is an indication for PRP, and the disease usually has a poor outcome without treatment.

Additional indications include INV, ANV, moderate to severe NVE without vitreous or preretinal hemorrhage, and the presence of widespread capillary dropout and retinal ischemia as demonstrated by fluorescein angiography. PRP may be performed in patients unlikely to follow-up. Special consideration may also be given to pregnant women with PDR and to the second eye of a juvenile diabetic when the other eye has severe PDR (Albert et al. 2008).

ii. Technique

PRP may be done with multiple wavelengths and instruments, but a 514 nm argon green laser is most commonly used. For adults, a transpupillary slit lamp approach is most common. Topical anesthesia is typically sufficient. The duration of each laser pulse is typically 0.1–0.2 s, and each pulse creates a burn that is about 500 μm in diameter. The laser is typically placed one-half burn width

apart. Treatment is given panretinally, typically over a series of two to three sessions. A total of 800–1,600 burns are created with avoidance of the macula and optic disc. Additional laser therapy may be required if there is persistence of neovascularization. One must avoid areas of fibrous tissue proliferation and vitreoretinal traction during laser (Albert et al. 2008).

iii. Results

The Diabetic Retinopathy Study (DRS) was a large-scale study intended to assess the benefits of laser photocoagulation in patients with diabetes mellitus. According to the DRS, eyes with PDR and high-risk characteristics have a 25% risk of developing severe visual loss within 2 years. However, treatment with PRP is able to reduce this risk by 50% (Albert et al. 2008; Yanoff and Duker 2014).

One of the objectives of the Early Treatment of Diabetic Retinopathy Study (ETDRS) was to determine the optimal timing of laser photocoagulation in eyes with diabetic retinopathy. The data showed that, for patients with type II diabetes, there is a benefit in early treatment with PRP of eyes with severe NPDR or early PDR. These recommendations, however, must be taken into consideration along with other factors such as health of the other eye and other clinical findings (Albert et al. 2008).

iv. Complications

Treatment with PRP has been demonstrated to protect against severe visual loss in eyes with PDR, but complications may still arise. There may be pain during treatment and intraocular pressure may transiently elevate. There may be temporary loss of accommodation, decreased night vision, color vision, glare, and photopsia. More severe complications that may occur include foveal burns, optic disc damage, macular edema, hemorrhages, retinal detachment, corneal abrasions, lens opacities, and loss of visual field (Albert et al. 2008).

Vitrectomy for PDR

i. Indications

There are many indications for pars plana vitrectomy (PPV) in eyes with PDR. PPV may be indicated in the presence of non-clearing dense vitreous hemorrhage or subhyaloid and premacular bleeds. PPV is also indicated in eyes with TRD that involves the macula and combined retinal detachment. PPV may be performed in diffuse macular edema with a taut posterior hyaloid membrane. Additional indications include red blood cell induced glaucoma and anterior hyaloid proliferation. In eyes with iris neovascularization and lens opacities, PPV is indicated so that an endolaser may be used for PRP treatment of the retina. With advancements in surgical techniques, the indications of PPV have expanded to include many clinical scenarios (Albert et al. 2008; Ryan et al. 2013).

ii. Technique

The main goals of vitrectomy are to remove media opacities such as hemorrhage and to relieve vitreous traction on the retina that is resulting in detachment, distortion, or displacement of the fovea (Albert et al. 2008). The most commonly used technique is PPV with three port entry sites. With recent advances in surgical instrumentation, PPV is increasingly being performed using smaller gauge vitrectomy systems including 23- and 25-gauge techniques instead of conventional 20-gauge systems. Higher cut rates and aspiration parameters are now available to ensure better surgeon control. Specialized instrumentation may be required to aid in surgeon manipulation, including intraocular scissors to cut the fibrous tissue, intraocular pick and forceps, chandelier illumination system, and bimanual cautery. PRP with the use of an endolaser is performed during a vitrectomy in eyes with PDR in order to ensure treatment of areas in the retinal periphery and around areas of neovascularization. In complicated cases of retinal detachments, additional agents may be used for surgical ease. These include

the use of intraoperative heavy perfluorocarbon liquid in patients with complex retinal folds. Filtered air may then serve as a short-term tamponade, and gases such as SF_6, C_2F_6, and C_3F_8 may provide longer tamponade for 2–8 weeks. Silicone oil can be used as a tamponade in cases requiring a longer tamponade such as reoperations or severe cases (Ryan et al. 2013).

iii. Results

Results following vitrectomy vary depending upon the indication for the surgery. In eyes with vitreous hemorrhage only, about three quarters of patients will have improvements in vision 6 months after surgery and the similar number will have a visual acuity of 5/200 or better. In eyes with TRD that involves the fovea, about one half to three quarters will have improvements in visual acuity and about half will have a visual acuity of 20/200 or better at 6 months. However, less than a quarter of these patients may experience recurrent macular detachment. About two thirds of eyes with combined detachment attain long-term macular reattachment post vitrectomy and improved visual acuity is seen in about half of the cases (Albert et al. 2008).

iv. Complications

Cataracts may form postoperatively due to inadvertent intraoperative lens touch or due to exposure to the tamponade gas postoperatively. Injury to the cornea may also occur during the time of surgery. Hemorrhage may occur postoperatively but usually clears spontaneously over several weeks. If the hemorrhage is so extensive that the fundus cannot be visualized, ultrasound is recommended to rule out retinal detachment (Ryan et al. 2013). Ghost cell glaucoma and endophthalmitis are rare, but serious, complications of vitrectomy. INV and ANV may also occur postoperatively in cases where retinal ischemia is not adequately treated with endolaser (Albert et al. 2008).

v. Advances: transconjunctival sutureless vitrectomy (TVS)

With recent advances in technology, vitrectomy may now often be performed using 23- or 25-gauge trocars and small gauge vitrectomy instruments. The small incisions necessary for this technique are self-sealing and rarely require sutures and may lead to shorter times in the operating room, faster visual recovery, and improved patient comfort postoperatively. However, they also have disadvantages of increased postoperative retinal tears, endophthalmitis, and hypotony (Skuta et al. 2011).

Pharmacologic Vitreolysis

In diabetic eyes, it has been observed that complete posterior vitreous detachment is associated with a decreased risk of developing PDR. While this may be achieved through vitrectomy, pharmacologic vitreolysis may provide a less invasive means of achieving a posterior vitreous detachment. Various agents including plasmin, tissue plasminogen activator, microplasmin, and hyaluronidase have been investigated as potential vitreolytic agents. Future research may show pharmacologic vitreolysis to be an effective means of achieving posterior vitreous detachment and delaying the onset of PDR (Ryan et al. 2013).

Role of Intravitreal Anti-VEGF Injections

VEGF inhibitors such as bevacizumab and ranibizumab have been demonstrated to counteract the neovascular complications of PDR. The effects of these agents appear to be temporary and require repeated dosing. However, there is some evidence to indicate that, after a period of treatment with these agents, reduction in the frequency of the dosing may be possible without reactivation of the disease (Ryan et al. 2013). Anti-VEGF injections have shown to reduce the chances of development of PDR by various studies including RISE and RIDE. Presently, the use of anti-VEGF therapy for PDR is continuously evolving (Yanoff and Duker 2014).

Other Surgical Modalities

(a) Anterior retinal cryopexy (ARC)

The use of cryotherapy to cause aseptic chorioretinal inflammation in the anterior

retina has been performed in certain patients with PDR and vitreous hemorrhage. Ablation of peripheral retina with ARC is performed with an aim to destroy the ischemic retina. Peripheral cryopexy must be avoided in patients with known TRD. ARC is no longer a preferred modality due to its higher number of complications (Ryan et al. 2013; Yanoff and Duker 2014).

(b) Pituitary ablation

In the past, suppression of the pituitary gland was used as a means to control the vascular changes seen in PDR. Methods included external irradiation, transfrontal hypophysectomy, and transsphenoidal implantation of yttrium. The benefits seen in pituitary ablation are thought to stem from the suppression of growth hormone and its effects on insulin-like growth factor. Pituitary ablation as a means to control PDR is of little significance due to other methods such as photocoagulation being more effective while avoiding the side effects of a hypopituitary state (Ryan et al. 2013).

Prognosis

Eyes with PDR are at a significant risk for visual loss. Among eyes with PDR, those with one or more high-risk characteristics are at a greater risk for visual loss. The most common causes of visual loss in PDR are vitreous hemorrhage and traction retinal detachment. Visual loss may also occur due to distortion or displacement of the macula, macular edema, and neovascular glaucoma (Ryan et al. 2013).

Epidemiology

The Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR) was a population-based study that provided information regarding the epidemiology of diabetic retinopathy. According to the study, 23% of patients with type I diabetes and 6% with type II diabetes had PDR. In addition, the risk of progression to PDR among type I diabetics was 10.5% over a 4-year period. This risk was 7.4% and 2.3% for type II diabetics taking and not taking insulin, respectively (Ryan et al. 2013). It has been reported that after the diagnosis of type 2 diabetes, 67% of patients develop retinopathy and 10% have PDR (Yanoff and Duker 2014).

According to the available data, diabetic retinopathy was more prevalent in type II diabetic African Americans when compared to whites but similar in type I diabetics. Mexican Americans with both type I and type II diabetes have been shown to have higher frequencies of diabetic retinopathy when compared to non-Hispanic whites. Initial data on Native American diabetics indicated higher frequencies of diabetic retinopathy when compared to whites, but more recent data indicates that it likely varies between different Native American groups. Among Chinese Americans, the incidence of retinopathy was similar when compared to whites, but they showed higher rates of progression to more severe forms of the disease (Ryan et al. 2013).

Synonyms

Diffusion-weighted magnetic resonance imaging; DWI

Definition

Diffusion-weighted imaging (DWI) is a well-established magnetic resonance imaging (MRI) sequence that is dependent upon random "Brownian motion" of water molecules. DWI was first introduced to clinical practice in the 1990s and has been applied to the evaluation of various intracranial diseases. DWI has shown the capability in detecting early and subtle changes within the brain prior to any visible abnormality can be detected on the conventional imaging. DWI has shown superb sensitivity in the detection of acute brain ischemia and in the differentiation of acute infarction from other intracranial disease processes. The reported sensitivity ranges from 88% to 100% and specificity from 86% to 100%. Restricted diffusion in ischemic brain tissue can be observed within few minutes after acute brain ischemia, while conventional (T1/T2) MRI

sequences may not demonstrate the infarct until 6 h or more and may be especially hard to appreciate on CT even after several hours to days.

Basic Characteristics

Physics

To obtain DW images, a pair of strong gradient pulses is added to the pulse sequence to dephase and rephase the spins if no net movement occurs. If net movement occurs, this leads to signal attenuation. The degree of signal reduction depends on the extent of molecular translation and diffusion weighting. The extent of diffusion weighting is determined by the strength of the diffusion gradients, the time between the gradient pulses, and the duration of the gradients.

The diffusion data can be presented as signal intensity or an image map of the apparent diffusion coefficient (ADC). ADC calculation requires two or more acquisitions with different diffusion weightings. Low ADC corresponds to high signal intensity (restricted diffusion), and a high ADC corresponds to low signal intensity on DWI. The degree of restriction of water diffusion in biologic tissue is inversely correlated to the tissue cellularity and the integrity of cell membranes.

In acute brain ischemia, if the cerebral blood flow drops to 10 ml/100 g/min, the cell membrane ion pumps will fail, and the excess sodium will enter the cell, this will cause movement of water from the extracellular to intracellular compartment and cytotoxic edema. The diffusion of the intracellular water molecules is restricted by the cell membranes. Thus, the restricted diffusion of water causes a decreased ADC and increased signal intensity on DWI. This restricted diffusion appears as bright on DWI and dark on ADC.

Clinical Application

The clinical applications of DWI are increasingly widespread. The major clinical applications for DWI are as follows:

- To diagnose acute ischemic stroke
- To differentiate stroke from stroke mimics
- To differentiate epidermoid cyst from arachnoid cyst
- To differentiate brain abscess from necrotic tumors
- To assess cortical lesions in Creutzfeldt Jakob disease (CJD)
- To differentiate herpes encephalitis from diffuse temporal gliomas
- To assess the extent of diffuse axonal injury
- To assess active multiple sclerosis plaques

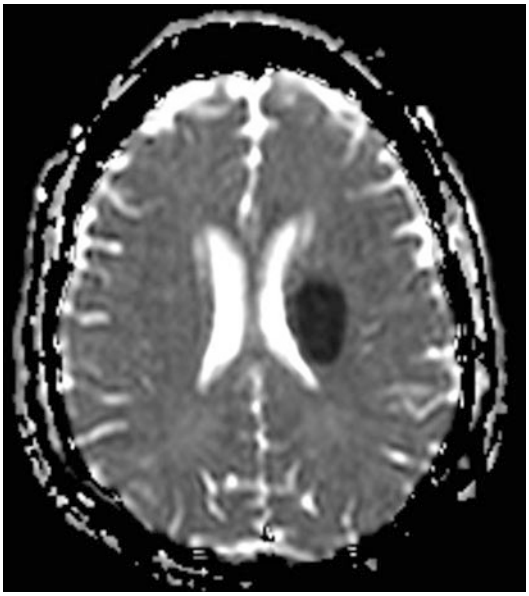
D

Radiographic Features

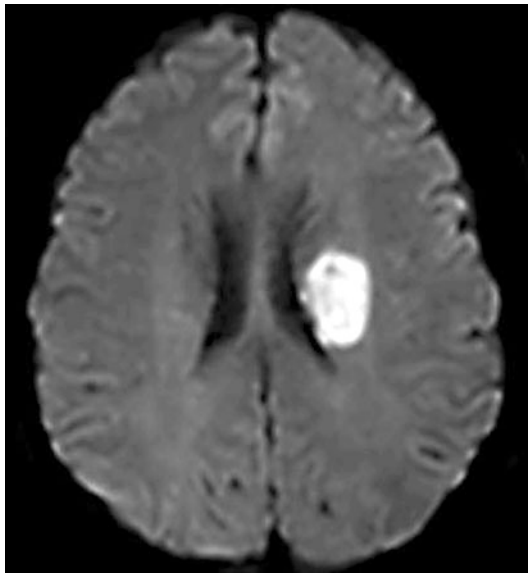
The time line of the radiographic features of DWI/ADC in acute brain ischemia is as follows:

Acute (0–7 days):

- Marked hyperintensity on DWI and hypointensity on ADC images.
- Maximal signal reduction of ADC is 1–4 days.



Diffusion-Weighted MR Image, Fig. 1 Apparent diffusion coefficient (ADC) sequence of MRI shows a hypointense lesion that corresponds to the hyperintense lesion on diffusion weighted imaging (DWI)



Diffusion-Weighted MR Image, Fig. 2 This combination of hypointensity on ADC and hyperintensity on DWI is consistent with restricted diffusion (e.g., acute ischemic stroke)

- Cytotoxic and vasogenic edema and extravasation of water molecules from blood vessels due to the release of inflammatory mediators from ischemic brain tissue.

Subacute (1–3 weeks):

- (7–15 days) ADC pseudonormalization.
