DEDICATION

Professor Luciano Martini, 1927–2017

The other Editor in Chief of the Encyclopedia, Professor Luciano Martini, passed away on July 13th, 2017. He was an internationally acclaimed authority in the field of endocrinology, in particular neuroendocrinology, a brilliant and imaginative scientist, and an impressive and erudite scholar.

Luciano achieved the venerable age of 90, and his long career was full of outstanding scientific achievements, leadership positions in academia and in scientific societies, academies, and committees.

Luciano received his MD degree from the University of Milan in 1950. He then rapidly progressed through junior academic ranks up to the position of Professor and Chairman of the Department of Pharmacology at the University of Perugia in 1968, and subsequently, in 1972, he returned to his *alma mater*, the University of Milan, as full Professor and Chairman of the Department of Endocrinology, a post he held until 2001. He served in Milan as director of the training and research program entitled Physiology of Reproduction for nearly 20 years and attracted to his team top-class Italian and foreign scientists to address his main research interests of neuroendocrine regulation of reproductive functions.

Scientific severity, ethical integrity, fine perception, and deep farsightedness describe best Luciano's character as a scientist. He created in his institute a scientific research group devoted to experimental endocrinology, which grew over the years in size and visibility and became widely recognized internationally. Luciano published more than 400 peer-reviewed and highly cited papers mainly in the fields of neuroendocrinology, endocrine oncology, physiology of reproduction, and steroid and energy metabolisms.

Luciano was a prolific editor of scientific books and journals, which include the two volumes of *Neuroendocrinology* and the nine biennial volumes of *Frontiers in Neuroendocrinology*. He was Editor in Chief of *Comprehensive Endocrinology* published in 12 volumes and the first Edition of *Encyclopedia of Endocrine Diseases*. He served as President in many national and international scientific societies including the International Society of Neuroendocrinology, the Italian Society of Endocrinology, the International Society of Endocrinology, and the European Federation of Endocrine Societies. For his scientific achievements Luciano received honorary doctorates in the universities of Liège, Santiago de Compostela, Pécs, and Milan, and he was the recipient of numerous scientific awards and invited academy memberships.

Luciano's portrait could not be complete if one forgets to mention his life-time passion for music. He was a well-trained and accomplished pianist, a passionate music listener, and an enthusiastic connoisseur of all types of music. He also was an amateur in visual arts and deeply interested in history.

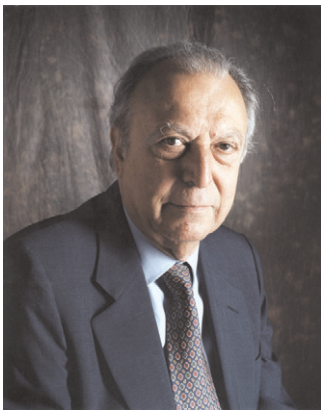
All of us who knew Professor Luciano Martini deeply mourn the loss of a great scientist and friend, the real "Il Maestro", teacher, colleague, and pioneer of modern neuroendocrinology. I trust Luciano would have been proud of this new edition of the Encyclopedia of Endocrine Diseases, and all of us having worked on its production would like to dedicate it to his memory.

Ilpo Huhtaniemi

Editor in Chief
Encyclopedia of Endocrine Diseases, 2nd edition

EDITORS IN CHIEF

Ilpo Huhtaniemi received his MD and PhD at University of Helsinki, Finland, did postdoctoral training in United States (UC San Francisco and NIH, Bethesda), and has been on sabbatical leave in Germany, United States and Scotland. In 1986–2002 he held the post of Professor and Chairman of Physiology at University of Turku, Finland. He moved in 2002 to UK to a Chair in Reproductive Endocrinology at Imperial College London, from which position he retired in 2015. He has received several national and international honors, amongst them a fellowship of The Academy of Medical Sciences, United Kingdom, and a Doctor Honoris Causa at the Medical University Łódź, Poland, and University of Szeged, Hungary. He was the Chief Managing Editor of *Molecular and Cellular Endocrinology* 1999-2017, has served in the Editorial Board of *Endocrinology and Endocrine Reviews* and is/has been the Editor or Editorial Board Member of several other scientific journals (e.g., *European Journal of Endocrinology*, *Clinical Endocrinology*, *Human Reproduction Update*, *Journal of Endocrinology*, *Molecular Human Reproduction*, *Reproduction*, *Asian Journal of Andrology*). He has extensive experience as Official of international scientific organizations (e.g., Past President of International Society of Andrology). His research interests include clinical and basic reproductive endocrinology, in particular the function of gonadotrophins and male reproductive endocrinology. He also has long-term interests in development of male contraception, hormone-dependent cancer, and the endocrinology of aging. He has authored about 700 peer-reviewed research articles and reviews, and his H-factor is 78.



Luciano Martini was born on May 14, 1927, in Milan, Italy. He obtained the degree of Medical Doctor "summa cum laude" on November 24, 1950, from the Faculty of Medicine of the University of Milan, Italy. He was Emeritus Professor of Pharmacology of the University of Perugia, Italy, and Emeritus Professor of Endocrinology of the University of Milan, Italy. He was Doctor Honoris Causa in Medicine of the Universities of Liège, Belgium, Santiago de Compostela, Spain, and Pécs, Hungary, and Doctor Honoris Causa in Biotechnological Sciences of the University of Milan, Italy. He was an author of more than 400 peer-reviewed scientific publications in the fields of endocrinology, neuroendocrinology, pharmacology, physiology of reproduction, steroid biochemistry, and basic oncology. He was elected member of the Accademia Nazionale dei Lincei (Italian National Academy) and of the American Academy of Arts and Sciences (Honorary Foreign Member).

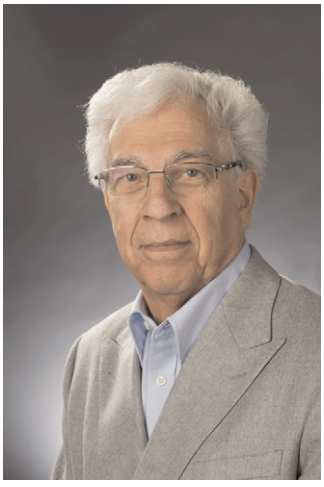
Luciano Martini acted as Editor in Chief of the journal *Frontiers in Neuroendocrinology* from 1990 to 2001, and was a Member of the Editorial Board of *Endocrinology* (Foreign Consulting Editor, 1961–65), as well as of several other speciality journals, such as *Experimental and Clinical Endocrinology*, *Biochemistry*, and *Steroids*. He has acted as Editor of several textbooks (e.g., *Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1966–67, and *Clinical Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1977–82) as well of a series of books under the name *Comprehensive Endocrinology* (13 volumes), Raven Press, New York, 1979–84. He acted as Editor in Chief for the first edition of *Encyclopedia of Endocrine Diseases* (4 volumes), Academic Press-Elsevier, San Diego, 2004.

EDITORIAL BOARD

SECTION EDITORS

Professor **Jean-Jacques Body** has been trained as an endocrinologist and a medical oncologist. He was Head of the Department of Medicine at University Hospital Brugmann in Brussels and Full Professor of Medicine (Internal Medicine) at the Free University of Brussels, (ULB), Brussels, Belgium. He was previously Head of the Internal Medicine Clinic at Institute J. Bordet (Cancer Center of ULB). He has also developed the "Supportive Care Dept" at the same Institute. His particular research interests are osteoporosis and bone metastases. He has a long-standing interest for bone metabolism and turnover in osteoporosis and tumor bone diseases. He has authored or co-authored more than 250 international peer-reviewed papers and he counts more than 200 invited lectures for international meetings.

Felipe F. Casanueva is Professor of Medicine at University of Santiago de Compostela and Head of Department of Endocrinology and Nutrition at University Hospital Santiago. He has been President of the scientific societes, such as: European Federation of Endocrine Societies (EFES), The Pituitary Society, International Society of Endocrinology (ISE) and, Sociedad Española para el Estudio de la Obesidad (SEEDO). Has written more than 50 chapters in international books and published more than 700 papers in international journals. He has received several awards for research at national and international level, such as: Rey Jaime I to the Medical Research, Geoffrey Harris Prize in Neuroendocrinology, Fundación Lilly of Bio-medical Research Clinic, Fundacion Danone – Professional Career – Dr Carlos Martí Hennberg, European Hormone Medal by the European Society for Endocrinology (ESE); he has been named Honorary Doctorate in Medicine of the University of Łódź, Erciyes, and Belgrade, and Honorary Member of the European Society of Endocrinology.



Dr. **Jean-Louis Chiasson** is currently Full Professor of Medicine at the University of Montreal. He is Head of the Research Group on Diabetes and Metabolic Regulation at the Research Center of the Centre hospitalier de l'Université de Montréal (CRCHUM).

Dr. Chiasson obtained his MD at Laval University in Quebec City in 1967. He did his specialty training in Internal Medicine at Laval Univesity and in Endocrinology at McGill University. He then did a research Fellowship in Diabetes at Vanderbilt University in Nashville, Tennessee. In 1974–76 and 1978–80, he was appointed Assistant Professor in the Department of Medicine and Physiology respectively at Vanderbilt University. In 1980, he returned to Montreal as Assistant Professor in the Department of Medicine at the University of Montreal and as Endocrinologist at Hotel-Dieu Hospital, now merged into the Centre hospitalier de l'Université de Montréal.

Dr. Chiasson's research interests include the regulation of carbohydrate metabolism in health and diabetes, as well as the development and evaluation of new strategies for the treatment and prevention of diabetes and its vascular complications. He has contributed over 250 scientific publications and lectures nationally and internationally on various topics on diabetes mellitus, its pathogenesis, its treatment, and its prevention. His scientific contribution puts him in the prestigious club of the 100 most cited publications in the world in the field of diabetes.

Sophie Christin-Maitre received her MD at University of Paris XI and her PhD at University Paris VI, Pierre and Marie Curie, France. She did a postdoctoral training in United States (Massachusetts General Hospital, Harvard University, Boston); she specialized in reproductive medicine. She holds the post of Professor of Endocrinology at University of Sorbonne, Paris, France. She has been the head of the Adult Endocrine Unit, in Hôpital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, since 2011. She is a member of the INSERM research unit UMR S_933, specialized in identifying new genes in reproductive disorders. Her interests include clinical and basic reproductive endocrinology, in particular the management of patients with Turner syndrome, patients with primary ovarian insufficiency, patients with hypogonadisms, and patients with abnormalities of sex development. She has authored approximately 150 peer-reviewed research articles and reviews.

Ulla Feldt-Rasmussen is Professor at Copenhagen University and Chief of Medical Endocrinology, National University Hospital. Her research interests involve the thyroid gland and autoimmunity, as well as pituitary and adrenal dysfunction.

She has published more than 410 papers in peer-reviewed journals on e.g., thyroid hormones and body composition, thyroid autoimmunity and cancer, cytokines as regulators of endocrine cells, influence of thyroid disrupting chemicals on thyroid cells, growth hormone deficiency related to body composition, bone metabolism and other pituitary axes, and transition from adolescent to adult care, as well as several aspects of Fabry disease. In recent years her group has embarked on studies on pituitary function after traumatic brain injury in a nationwide setting, and focusing on diagnostic accuracy of pituitary testing procedures. She has further authored numerous proceedings, textbook chapters, and other publications; as well as organized numerous international meetings and postgraduate courses, and has led several European projects and other collaborations within many areas of endocrinology.

Professor Feldt-Rasmussen reviews for international journals, and is an editorial board member of several endocrine journals. She belongs to many international professional organizations, including the Endocrine Society, ETA, ATA, ENEA, and GRS; she has served as Secretary-Treasurer of ETA and as President of the ETA Cancer Research Network.

Professor Feldt-Rasmussen serves on the advisory boards of several ad hoc endocrine committees, and has received many prestigious prizes including the Mayo Clinic's Haynes Lecturer's Award and ETA's Pinchera Research Prize.

Wouter W. de Herder M.D. Ph.D. (1960) is Professor of Endocrine Oncology at the Erasmus MC in Rotterdam, the Netherlands. In this University Hospital he is chairman of a multidisciplinary group for endocrine oncology (tumorwerkgroep endocriene tumoren) and he is head of the ENETS centre of excellence for neuroendocrine tumors. His major research interests are neuroendocrine and endocrine tumors.

Professor de Herder received his M.D. in 1985 and his Ph.D. in 1990 from the Erasmus University in Rotterdam, the Netherlands.

He is a member of several international and Dutch national societies, such as the Dutch Society for Endocrinology (NVE), the Endocrine Society (USA), the European Society of Endocrinology (ESE), European Neuroendocrine Tumor Society (ENETS) and the North American Neuroendocrine Tumor Society (NANETS). He served as a board member of the Dutch Society for Endocrinology (NVE) (2009–14). He served as chairman (2006–08) and vice-chairman of ENETS (2008–10) (European Neuroendocrine Tumour Society). He is member of the advisory boards of ENETS and NANETS.

Professor de Herder has (co-)published over 400 peer-reviewed papers and book chapters and is a reviewer for many international journals.

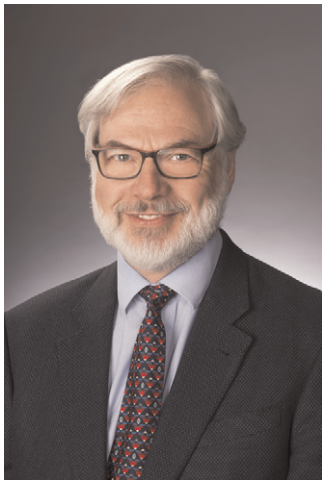
He is a member of the editorial boards of *Neuroendocrinology; Endocrinology, Diabetes & Metabolism Case Reports; Clinical Endocrinology*, and *Endocrine-Related Cancer*.

Professor de Herder has given over 200 invited presentations at Dutch national and international meetings.

Ieuan Hughes is currently Emeritus Professor of Pediatrics at the University of Cambridge and Honorary Consultant Pediatrician at Cambridge University Hospitals NHS Foundation Trust and Cambridge Biomedical Campus. He is the author of more than 300 papers and chapters across the whole range of paediatric endocrinology. His particular expertise is in disorders of sex development for which he coordinated the International Consensus on the approach to the investigation and management of this broad topic. Research interests focus on steroid enzyme deficiencies and molecular mechanisms of androgen action.
Professor Hughes has served on the editorial boards of several journals, including *Clinical Endocrinology*, *Journal of Clinical Endocrinology*, and *Metabolism* and *Archives of Disease in Childhood* where he was also the Associate Editor. He is Past-Secretary and President of the European Society for Pediatric Endocrinology and a recipient of the highest award of the Society, the Andrea Prader Prize. Professor Hughes is a James Spence Medallist of the Royal College of Pediatrics and Child Health for outstanding contributions to paediatric knowledge. He is a Fellow of the Academy of Medical Sciences, a Council Member of the Learned Society of Wales and a Trustee of two charities. The chapter on Disorders of Sex Development in *Williams Textbook of Endocrinology* (now in its 14e) by Hughes and co-authors is considered to be a definitive and up to date regular review of this topic, specific and key to pediatric endocrinology.

Dr. **Gregory Kaltsas** MD FRCP (Lon) is Professor in General Medicine and Endocrinology at the National and Kapodistrian University of Athens, Greece. He was trained in General Medicine in Athens, Greece and London, UK, and in Endocrinology at the Middlesex and St Bartholomew's Hospital, London, UK. He developed a particular interest in neuroendocrinology (pituitary and neuroendocrine tumors) and adrenal physiology and diseases. Upon returning to Greece he established a neuroendocrine network and he is currently running the European Neuroendocrine Tumor Society (ENETS) Center of Excellence at Laiko Hospital in Athens, Greece. He has served as a member of the advisory board of ENETS and of the Executive Committee of the European Neuroendocrine Association (ENEA) and he has been elected in the Executive Committee of the International Society of Endocrinology. He has recently been elected as a representative of the European Society of Endocrinology in the ExCo of the International Society of Endocrinology. He has published more than 300 original papers, reviews, and chapters and serves on editorial boards and as associate editor in several endocrine journals.

Jean-Marc Kaufman obtained his MD and PhD degrees at the Ghent University, Belgium. He was a Senior Postdoctoral Research Fellow (1982–84) in reproductive physiology at the University of Texas Medical School at Houston. He is board certified in Endocrinology and in Nuclear Medicine. In 1985 he joined the staff of the Ghent University Hospital; he headed the department of Endocrinology from 2003 to 2014 and the Laboratory for Hormonology from 1995 to 2014. He was appointed in 1993 Professor of Medicine at the Ghent University (1993) and is past Chair of the Department of Internal Medicine at the Ghent University (2010–14). From October 1st 2014 he is Professor Emeritus at the Ghent University where he is pursuing clinical and research activities. Main research interests are in the assessment, regulation, and action of sex steroids with focus on their role in health, disease, and aging in men, and in osteoporosis in men. He is (co)author of over 300 publications in international peer-reviewed journals.



André Lacroix, MD FCAHS is Professor of Medicine, Division of Endocrinology at Centre hospitalier de l'Université de Montréal (CHUM). His areas of interest include the mechanisms of adrenal Cushing syndrome, primary aldosteronism, adrenal tumorigenesis, the role of aberrant adrenal hormone receptors in adrenal overfunction, as well as new drugs in the therapy of Cushing disease, primary aldosteronism and adrenocortical cancer.
He was trained at the University of Montreal followed by fellowships in Endocrinology and research at Vanderebilt University and National Institutes of Health, USA. He was Chairman of Medicine and Director of Academic Affairs at CHUM. Former President of the Canadian Society of Endocrinology and Metabolism, he is currently chairperson of the International Society of Endocrinology (2016–20), Editor, Adrenal Section of UpToDate and *Encyclopedia of Endocrinology*, Senior Editor of the *European Journal of Endocrinology*. Fellow of the Canadian Academy of Health Sciences since 2008 and Foreign member of the National Academy of Medicine of France since 2016.

Franco Mantero received his MD at the University of Padua, Italy, did postdoctoral training in Switzerland (Clinique Medicale Therapeutique, Hopital Cantonal, University of Geneva) and in United States (University of California, San Francisco), and has been on sabbatical leave in United Kingdom, United States, and France. He held a post of Associate Professor in Medicine at the Institute of Semeiotica Medica, University of Padua (1981–86). In 1986 he moved to the University of Catania to the Chair of Andrology and Endocrinology, in 1992 to the University of Ancona, and in 2000 to the University of Padua to the Chair of Endocrinology and Chief of the Endocrinology Unit of the Department of Medicine. He has received national and international honors, including a Doctor Honoris Causa at the Semmelweis University, Budapest, Hungary.
He has been Editorial Board Member of several scientific journals (e.g., *Clinical Endocrinology*, *Endocrinology*, *Journal of Hypertension*, *Journal of Endocrinology Investigation Steroids*)
He has served as Member of the Council of several international scientific societies (including International Society of Endocrinology, International Aldosterone Conference, Journee Klotz d'Endocrinologie Clinique, ENS@T) and one of the founders of the European Network for the Study of Adrenal Tumors. His research interests include clinical and basic endocrinology of the adrenal gland and endocrinology of hypertension, in particular pathophysiology of mineralocorticoids and primary aldosteronism. He has authored approximately 500 peer–reviewed articles and edited several books and proceedings.

Jorma Toppari, MD, PhD, is Professor of Physiology at the University of Turku and Chief Physician of Pediatric Endocrinology at Turku University Hospital, Turku, Finland. He is also Adjunct Professor in the Department of Growth and Reproduction at the University of Copenhagen, Denmark. He has served as chief editor of International Journal of Andrology (2001–09), and has been on editorial boards of several endocrinological journals, including currently *Endocrinology* and *Journal of Clinical Endocrinology and Metabolism*. He is the past President of the European Academy of Andrology. He has made numerous contributions to the studies on endocrine disruption in the past 20 years. He has published approximately 400 articles on endocrinology.

Jacquetta Trasler is a James McGill Professor in the Departments of Pediatrics, Human Genetics, and Pharmacology and Therapeutics at McGill University and a Senior Scientist at the Research Institute of the McGill University Health Centre (RI-MUHC). She received her MD and PhD degrees from McGill University followed by postdoctoral training in reproductive molecular biology at Tufts University in Boston. She has served as Director of the McGill University MD-PhD Program, Scientific Director of the Montreal Children's Hospital Research Institute (and simultaneously as Deputy Director/CSO of the RI-MUHC), President of the Canadian Fertility and Andrology Society, Member of the Institute Advisory Board for the Canadian Institutes of Health Research (CIHR) Institute of Genetics and currently serves on the CIHR Stem Cell Oversight Committee and College of Reviewers. Her research focuses on epigenetics and epigenomics to better understand the molecular and cellular targets for drug effects on germ cells with implications for the resulting offspring. She has been involved in scientific program organization for numerous meetings in the field of reproductive biology and medicine and is collaborating with national and international colleagues in clinical studies to examine how assisted reproductive technologies, infertility, drug treatment, and folate deficiency and supplementation impact the human epigenome including that of future generations.

Christina Wang, MD is Professor of Medicine, Assistant Dean at the David Geffen School of Medicine at UCLA, and Associate Director for Clinical and Translational Science Institute and a faculty member of the Division of Endocrinology, Department of Medicine, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, California.

Dr. Wang has been involved in many funded basic and clinical research studies. Her current clinical research studies include androgen replacement therapy, hormonal male contraceptive development, late onset hypogonadism, accurate assessment of serum androgens, and diet and androgen metabolism. Her basic research studies focus on the regulation of spermatogenesis and mitochondrial derived peptides in spermatogenesis.

She has authored over 300 peer-reviewed publications, 67 chapters and reviews mainly on male reproductive biology including characterization of the pharmacokinetics and efficacy of androgens in men, trials of hormonal male contraceptive, regulation of germ cell apoptosis, and reproductive aging. Dr. Wang served on the Executive Council, several committees and was the President of the American Society of Andrology (2006–07). She also served the International Society of Andrology as Secretary (2001–05) and Chair of the Program Organizing Committee (2005–09). She was President of the International Society of Andrology (2009–13). She is a member of the Research Group on Methods for the Regulation of Male Fertility of the World Health Organization since 1984 and Chairperson (1991–2002).

She has mentored many physician and scientist and is an advocate of young investigators. Dr. Wang has been invited speaker and distinguished lecturer at many national and international endocrinology, reproductive endocrinology, and andrology conferences.

LIST OF CONTRIBUTORS

Bo Abrahamsen
University of Southern Denmark, Odense, Denmark; and Holbæk Hospital, Holbæk, Denmark

Catarina Abreu
Hospital of Santa Maria, Lisbon, Portugal

O. Addison
University of Maryland School of Medicine, Baltimore, MD, United States

Laboratory of Clinical and Experimental Endocrinology, KU Leuven, Leuven, Belgium; and University Hospitals, Leuven, Belgium

Isabelle Bourdeau
Centre hospitalier de l'Université de Montréal (CHUM), Montréal, QC, Canada

Jean-Pierre Bourguignon
University of Liège, Liège, Belgium; and CHU de Liège, Chênée, Belgium

Mary L. Bouxsein
Beth Israel Deaconess Medical Center, Boston, MA, United States; Harvard Medical School, Boston, MA, United States; and Massachusetts General Hospital, Boston, MA, United States

Elvira V. Bräuner
University of Copenhagen, Copenhagen, Denmark

S.D. Brain
King's College London, London, United Kingdom

Glenn D. Braunstein
Cedars-Sinai Medical Center, Los Angeles, CA, United States; and University of California Los Angeles, Los Angeles, CA, United States

Ralph Brecheisen
Maastricht University, Maastricht, The Netherlands

Claire Briet
University Hospital of Angers, Angers, France; and University of Angers, Angers, France

Janet Brown
University of Sheffield, Sheffield, United Kingdom

Thierry Brue
Reference Center for Rare Pituitary Diseases, Assistance Publique Hopitaux de Marseille, La Conception Hospital, Marseille Cedex 05, France; and INSERM UMR-U910, Aix Marseille University, Marseille Cedex 05, France

Antonio Bruni
University of Alberta, Edmonton, AB, Canada

Rosa Maria Bruno
University of Pisa, Pisa, Italy

Aude Bruyneel
Free University of Brussels, Brussels, Belgium

Michael Buchfelder
University Hospital Erlangen, Erlangen, Germany

Krupali Bulsari
Princess Alexandra Hospital, Brisbane, QLD, Australia; and University of Queensland, Brisbane, QLD, Australia

Peter Burckhardt
Hirslanden Clinic, Lausanne, Switzerland

Albert G. Burger
University of Bern, Bern, Switzerland; and University of Geneva, Geneva, Switzerland

Alexander S. Busch
University of Copenhagen, Copenhagen, Denmark

Luca Busetto
University of Padua, Padua, Italy

Gary Butler
University College London Hospital NHS Trust, London, United Kingdom; and UCL Great Ormond Street Institute of Child Health, London, United Kingdom

Véronique Cadoret
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France; and CHRU Bretonneau, Medicine and Biology of Reproduction, CECOS, Tours, France

Lorenzo A. Calò
University of Padua, Padua, Italy

Irene Campi
University of Milan, Milan, Italy

Biagio Cangiano
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Letizia Canu
University of Florence, Florence, Italy

Perrine Capmas
Bicetre Hospital, Le Kremlin Bicetre, France

Carlo Cappelli
University of Brescia, Brescia, Italy; and Endocrine and Metabolic Medicine Unit, ASST Spedali Civili di Brescia, Brescia, Italy

Marta Caretto
University of Pisa, Pisa, Italy

Robert M. Carey
University of Virginia Health System, Charlottesville, VA, United States

Rafael Carmena
University of Valencia, Valencia, Spain

Nancy Carrasco
Yale School of Medicine, New Haven, CT, United States

Olivera Casar-Borota
Uppsala University, Uppsala, Sweden

Livio Casarini
University of Modena and Reggio Emilia, Modena, Italy

James Casella-Mariolo
Sapienza University of Rome, Rome, Italy

C. Casellini
Eastern Virginia Medical School, Norfolk, VA, United States

Lidia Castagneto-Gissey
Sapienza University of Rome, Rome, Italy

Maurizio Castellano
University of Brescia, Brescia, Italy; and Endocrine and Metabolic Medicine Unit, ASST Spedali Civili di Brescia, Brescia, Italy

Frederic Castinetti
Reference Center for Rare Pituitary Diseases, Assistance Publique Hopitaux de Marseille, La Conception Hospital, Marseille Cedex 05, France; and INSERM UMR-U910, Aix Marseille University, Marseille Cedex 05, France

Frederic Castinetti
Aix Marseille University, Marseille, France

Victoria Catalán
University of Navarra, Pamplona, Spain; CIBEROBN, ISCIII, Pamplona, Spain; and IdiSNA, Pamplona, Spain

Victoria Catalán
Metabolic Research Laboratory, University of Navarra, Pamplona, Spain; CIBEROBN, Carlos III Health Institute, Pamplona, Spain; and Instituto de Investigación Sanitaria de Navarra (IdiSNA) Pamplona, Spain

Richard L. Cate
Boston University, Boston, MA, United States

Sophie Catteau-Jonard
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Anne Caufriez
Free University of Brussels, Brussels, Belgium

Isadora Pontes Cavalcante
University of São Paulo, São Paulo, Brazil

Etienne Cavalier
University of Liège, Liège, Belgium

Jonas Čeponis
Lithuanian University of Health Sciences, Kaunas, Lithuania

Filomena Cetani
University of Pisa, Pisa, Italy; and University Hospital of Pisa, Pisa, Italy

Nathalie Chabbert-Buffet
Sorbonne University, Paris, France

Alan Chait
University of Washington, Seattle, WA, United States

Peter T. Chan
McGill University Health Center, Royal Victoria Hospital, Montreal, QC, Canada

Philippe Chanson
Assistance Publique-Hôpitaux de Paris, Service d'Endocrinologie et des Maladies de la Reproduction and Centre de Référence des Maladies Hypophysaires Rares, Bicêtre Hospital, Le Kremlin-Bicêtre, France; Université Paris-Sud, Le Kremlin-Bicêtre, France; and Institut National de la Santé et de la Recherche Médicale (INSERM) U1185, Le Kremlin-Bicêtre, France

Karen E. Chapman
University of Edinburgh, Edinburgh, United Kingdom

Helaine Laiz Silva Charchar
University of São Paulo, São Paulo, Brazil

F. Charles Brunicardi
University of California Los Angeles, Los Angeles, CA, United States

Evangelia Charmandari
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Sumana Chatterjee
Barts and the London School of Medicine and Dentistry, London, United Kingdom

Eleftherios Chatzellis
251 Hellenic Air Force and VA Hospital, Athens, Greece

Tim Cheetham
Newcastle University, Newcastle-upon-Tyne, United Kingdom

Wassim Chemaitilly
St. Jude Children's Research Hospital, Memphis, TN, United States

H. Chen
University of Alabama at Birmingham, Birmingham, AL, United States

Sabrina Chiloiro
Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

Luca Chiovato
University of Pavia, Pavia, Italy

E.R. Christ
University of Bern, Bern, Switzerland; and University of Geneva, Geneva, Switzerland

Mirjam Christ-Crain
University Hospital Basel, Basel, Switzerland

Sophie Christin-Maitre
Hospital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, Paris, France; and Sorbonne University, Paris, France

George P. Chrousos
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Janet S. Chuang
Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States

Maria Verena Cicala
South Tyrolian Academy of General Practice, Bolzano, Italy

Francesca Cioppi
University of Florence, Florence, Italy

Frédérique Clément
Project-team Mycenae, Inria Center of Paris, Paris, France

Philippe Clézardin
INSERM, Faculty of Medicine Lyon East, Lyon, France

Hedi L. Claahsen van de Grinten
Radboud University Medical Center, Nijmegen, the Netherlands

Mélanie Claps
University of Brescia, Brescia, Italy

Bart L. Clarke
Mayo Clinic, Rochester, MN, United States

Laurie E. Cohen
Harvard Medical School, Boston, MA, United States; and Dana-Farber/Boston Children's Hospital Cancer and Blood Disorders Center, Boston, MA, United States

Annamaria Colao
University of Naples Federico II, Naples, Italy

Annamaria Colao
Federico II University of Naples, Naples, Italy

Robert Coleman
University of Sheffield, Sheffield, United Kingdom

James J. Colt
Weill Cornell Medicine, New York, NY, United States

Oscar Coltell
Carlos III Health Institute, Madrid, Spain; and University Jaume I, Castellón, Spain

Robert V. Considine
Indiana University School of Medicine, Indianapolis, IN, United States

Lindsay S. Cooley
University of Bordeaux, Pessac, France

Martine Cools
Ghent University Hospital, Ghent, Belgium

Cyrus Cooper
MRC Lifecourse Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom

Cyrus Cooper
University of Southampton, Southampton, United Kingdom; University of Southampton and University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; WHO Collaborating Centre for Public Health Aspects of Musculoskeletal Health and Aging, Liège, Belgium; and University of Oxford, Oxford, United Kingdom

Georges Copinschi
Free University of Brussels, Brussels, Belgium

F. Coppedè
University of Pisa, Pisa, Italy

Claire Cordroch
University Hospital of Bordeaux, Bordeaux, France

Dolores Corella
University of Valencia, València, Spain; and Carlos III Institute of Health, Madrid, Spain

Isabel M. Cornejo-Pareja
Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Giovanni Corona
University of Florence, Florence, Italy; and Bologna Maggiore-Bellaria Hospital, Bologna, Italy

Dalila B. Corry
David Geffen UCLA School of Medicine, Los Angeles, CA, United States

Karen E. Cosgrove
University of Manchester, Manchester, United Kingdom

Maria Manuel Costa
Centro Hospitalar São João, Porto, Portugal; and Queen Mary University of London, London, United Kingdom

Luís Costa
Hospital of Santa Maria, Institute of Molecular Medicine, Faculty of Medicine, University of Lisbon, Lisbon, Portugal

Mariana Costanzo
Hospital de Pediatría Garrahan, Buenos Aires, Argentina

Carine Courtillot
Sorbonne University, Paris, France

Rafael Coveñas
University of Salamanca, Salamanca, Spain

Danila Covelli
University of Milan, Milan, Italy

Laura E. Cowen
Georgetown University Medical Center, Washington, DC, United States

Brittany Croft
Murdoch Children's Research Institute, Melbourne, VIC, Australia

William C. Cushman
University of Tennessee Health Science Center, Memphis, TN, United States

Daniele Cusi
Bio4Dreams, Milan, Italy

Lanfranco D'Elia
Federico II University of Naples, Naples, Italy

Stella D'Oronzo
University of Sheffield, Sheffield, United Kingdom

Catherine Dacou-Voutetakis
University of Athens, Athens, Greece

Rozenn Dalbies-Tran
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Adrian F. Daly
University Hospital Center of Liège, Liège, Belgium

A.H. Jan Danser
Erasmus MC, Rotterdam, The Netherlands

Jessica Daolio
Arcispedale Santa Maria Nuova of Reggio Emilia, Reggio Emilia, Italy

Emile Daraï
Sorbonne University, Paris, France

Mehul T. Dattani
Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom; and UCL Institute of Child Health, London, United Kingdom

Justin H. Davies
Southampton Children's Hospital, Southampton, United Kingdom

Stephen N. Davis
University of Maryland School of Medicine, Baltimore, MD, United States

Shanlee M. Davis
University of Colorado, Boulder, CO, United States

Adolfo J. de Bold
University of Ottawa, Ottawa, ON, Canada

Giuseppina De Filpo
University of Florence, Florence, Italy

K. De Gendt
Catholic University of Leuven, Leuven, Belgium

Wouter W. de Herder
Department of Internal Medicine—Sector of Endocrinology, Erasmus MC - University Hospital Rotterdam, Rotterdam, The Netherlands

Frank H. de Jong
Erasmus University Medical Center, Rotterdam, The Netherlands

Frank H. de Jong
Erasmus University Medical Centre, Rotterdam, The Netherlands

Peter W. de Leeuw
Maastricht University Medical Center, Maastricht, The Netherlands

Laura De Marinis
Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

Maria Cristina De Martino
University of Naples Federico II, Naples, Italy

Sabine M.P.F. de Muinck Keizer-Schrama
Erasmus Medical Center – Sophia Children's Hospital, Rotterdam, The Netherlands

Beatriz Marinho de Paula Mariani
University of São Paulo, São Paulo, Brazil

Jean De Schepper
Free University of Brussels, Brussels, Belgium

Miguel Debono
The University of Sheffield, Sheffield, United Kingdom

Peter A. Deddish
University of Illinois College of Medicine, Chicago, IL, United States

Asma Deeb
Mafraq Hospital, Abu Dhabi, United Arab Emirates

Olaf M. Dekkers
Leiden University Medical Centre, Leiden, The Netherlands

Rita Del Pinto
University of L'Aquila, L'Aquila, Italy

Anne Delbaere
Free University of Brussels, Brussels, Belgium

Elaine M Dennison
MRC Lifecourse Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom

Didier Dewailly
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Nathalie di Clemente
Pierre and Marie Curie University, Paris, France

Guido Di Dalmazi
Alma Mater Studiorum University of Bologna, Bologna, Italy

N. Di Iorgi
University of Genoa, Genoa, Italy

Paola Di Mauro
INSERM, Faculty of Medicine Lyon East, Lyon, France

Chantal Diaz-Latoud
INSERM, Faculty of Medicine Lyon East, Lyon, France

Michael DiMattina
Dominion Fertility, Arlington, VA, United States

Georgios K. Dimitriadis
University of Warwick Medical School, Coventry, United Kingdom; and Imperial College London, London, United Kingdom

Na Ding
Anhui Medical University, Hefei, China

Maria R. Dionísio
Hospital of Santa Maria, Lisbon, Portugal

S. Dizon
Queen's University, Kingston, ON, Canada

Graham J. Dockray
University of Liverpool, Liverpool, United Kingdom

Marie-Madeleine Dolmans
Pôle de Recherche en Gynécologie, Institut de Recherche Expérimentale et Clinique (IREC), Catholic University of Leuven, Brussels, Belgium; and Cliniques Universitaires Saint Luc, Brussels, Belgium

G.A. Donnan
University of Melbourne, Melbourne, VIC, Australia

Jacques Donnez
Society for Research into Infertility (SRI, Société de Recherche pour l'Infertilité), Brussels, Belgium; and Catholic University of Leuven, Leuven, Belgium

Olivier Donnez
Institut du Sein et de Chirurgie Gynécologique d'Avignon (ICA), Polyclinique Urbain V, Avignon, France

Robert M. Dores
University of Denver, Denver, CO, United States

Maria Dracopoulou
University of Athens, Athens, Greece

A. Drexler
UCLA School of Medicine, Los Angeles, CA, United States

ENETS NET Center of Excellence (CoE), Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Christian A. Koch
Technical University of Dresden, Dresden, Germany; and Medicover MVZ Oldenburg, Oldenburg, Germany

X. Kodji
King's College London, London, United Kingdom

Kamila Kolanska
Sorbonne University, Paris, France

Efstratios M. Kolibianakis
Aristotle University of Thessaloniki, Thessaloniki, Greece

Anne-Sophie C.A.M. Koning
Leiden University Medical Center, Leiden, The Netherlands

George Kontogeorgos
``George Gennimatas'' General Hospital of Athens, Athens, Greece; National and Kapodistrian University of Athens, Athens, Greece; and University of Toronto, Toronto, ON, Canada

John J. Kopchick
Ohio University, Athens, OH, United States

Márta Korbonits
Queen Mary University of London, London, United Kingdom

Olympia Koulouri
University of Cambridge, Cambridge, United Kingdom; and National Institute for Health Research Cambridge Biomedical Research Centre, Cambridge, United Kingdom

Stavroula Kousteni
Columbia University, New York, NY, United States

Jolanta Krajewska
Maria Sklodowska-Curie Memorial Institute-Cancer Center, Gliwice, Poland

Csilla Krausz
University of Florence, Florence, Italy

Berit Kriström
Umeå University, Umeå, Sweden

Helen Kroening
University of Sheffield, Sheffield, United Kingdom

Abraham A Kroon
Maastricht University Medical Center, Maastricht, The Netherlands

Heiko Krude
Charité–Medicine University, Berlin, Germany; and Institute of Experimental Pediatric Endocrinology, Berlin, Germany

George A. Kuchel
University of Connecticut Health Center, Farmington, CT, United States

Alexandra Kulle
Christian-Albrechts University of Kiel (CAU), Kiel, Germany; and University Hospital of Schleswig-Holstein (UKSH), Kiel, Germany

Ioannis Kyrou
Harokopio University, Athens, Greece; Aston University, Birmingham, United Kingdom; University of Warwick, Coventry, United Kingdom; and University Hospitals Coventry and Warwickshire NHS Trust, Coventry, United Kingdom

André Lacroix
Endocrine Division and Research Center, Centre hospitalier de l'Université de Montréal (CHUM), Montreal, QC, Canada

Svetlana Lajic
Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

Elizabeth M. Lamos
University of Maryland School of Medicine, Baltimore, MD, United States

Fabio Lanfranco
University of Turin, Turin, Italy

Bente L. Langdahl
Aarhus University Hospital, Aarhus, Denmark

Seppo W. Langer
ENETS NET CoE, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

A. Lania
University of Milan, Milan, Italy

E. Laspa
University Hospital of Ioannina, Ioannina, Greece

Guido Lastra
University of Missouri, Columbia, MO, United States

Ana Claudia Latronico
University of São Paulo, São Paulo, Brazil

Vincent Laudet
Sorbonne University, Banyuls-sur-Mer, France

S. Lauhon
University of Michigan, Ann Arbor, MI, United States

Michaël R. Laurent
University Hospitals Leuven, Leuven, Belgium

Fabio Lauria
National Research Council of Italy, Avellino, Italy

John H. Lazarus
Institute of Molecular and Experimental Medicine, Cardiff University, Cardiff, United Kingdom; and University Hospital of Wales, Cardiff, United Kingdom

Albert Lecube
University Hospital Arnau de Vilanova, Lleida, Spain; Obesity, Diabetes and Metabolism Research Group (ODIM), Lleida Biomedical Research Institute (IRBLleida), Lleida, Spain; and University of Lleida, Lleida, Spain

Benjamin Z. Leder
Harvard Medical School, Boston, MA, United States

E.C.-H. Lee
University of Connecticut, Storrs, CT, United States

Peter Lee
Penn State Hershey Medical Center, Hershey, PA, United States

Christoph Lees
Queen Charlotte's and Chelsea Hospital, London, United Kingdom; and Imperial College London, London, United Kingdom

Pierre J. Lefèbvre
University of Liège, Liège, Belgium

Lisa-Marie Legault
University of Montreal, Montreal, QC, Canada

Jacques W.M. Lenders
Radboud University Medical Center, Nijmegen, The Netherlands; and Technical University Dresden, Dresden, Germany

Livia Lenzini
University of Padua, Padua, Italy

A.M. Leung
Division of Endocrinology, UCLA David Geffen School of Medicine, Los Angeles, CA United States

Stafford Lightman
University of Bristol, Bristol, United Kingdom

Padiporn Limumpornpetch
University of Leeds, Leeds, United Kingdom; and Prince of Songkla University, Songkhla, Thailand

M. Link
University of Utah, Salt Lake City, UT

Benjamin A. Lipsky
University of Washington, Seattle, WA, United States; and Veterans Affairs Puget Sound Health Care System, Seattle, WA, United States

Saúl Lira-Albarran
National Institute of Medical Sciences and Nutrition SZ (INCMNSZ), Mexico City, Mexico

Kirstie Lithgow
University of Calgary, Calgary, AB, Canada

Peter Y. Liu
Clinical and Translation Science Institute, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Sarantis Livadas
University of Athens, Athens, Greece

Clare H. Llewellyn
University College London, London, United Kingdom

V. Llorente-Cortés
Cardiovascular Research Center, CSIC-ICCC Hospital Santa Creu I Sant Pau, Barcelona, Spain

Jay S. Loeffler
Massachusetts General and Harvard Medical School, Boston, MA, United States

Marc Lombès
University Paris-Sud, University of Paris-Saclay, Le Kremlin-Bicêtre, France; and Bicêtre Hospital, Le Kremlin Bicêtre, France

Lindsey A. Loomba-Albrecht
University of California Davis, Davis, CA, United States

Miguel López
CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain; and University of Santiago de Compostela (USC), Santiago de Compostela, Spain

Carolina López-Cano
University Hospital Arnau de Vilanova, Lleida, Spain; Obesity, Diabetes and Metabolism Research Group (ODIM), Lleida Biomedical Research Institute (IRBLleida), Lleida, Spain; and University of Lleida, Lleida, Spain

Isabel Losano
University of Turin, Turin, Italy

David A. Lovejoy
University of Toronto, Toronto, ON, Canada

María Lozano-Madrid
Carlos III Health Institute, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Gertrud Lund
CINVESTAV Irapuato Unit, Irapuato, Gto, Mexico

Elena Lundberg
Umeå University, Umeå, Sweden

Aldons J. Lusis
University of California Los Angeles, Los Angeles, CA, United States

Lorenza Macrina
IRCCS San Raffaele Scientific Institute, Milan, Italy

Filippo Maffezzoni
University of Brescia, Brescia, Italy

Mario Maggi
University of Florence, Florence, Italy; and Istituto Nazionale Biostrutture e Biosistemi, Rome, Italy

M. Maghnie
University of Genova, Genova, Italy

Amita Mahajan
University of Calgary, Calgary, AB, Canada

Erasmus MC, Rotterdam, The Netherlands; and Monash University, Melbourne, VIC, Australia

Alexander D. Miras
Imperial College London, London, United Kingdom

Philippe Monget
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Danielle Monniaux
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Silvia Monticone
University of Turin, Turin, Italy

Rebecca J. Moon
Southampton Children's Hospital, Southampton, United Kingdom

Stefano Mora
IRCCS San Raffaele Scientific Institute, Milan, Italy

G. Morana
University of Genoa, Genoa, Italy

Rachel C. Morgan
Indiana University School of Medicine, Indianapolis, IN, United States

Alberto Morganti
Centro Fisiologia Clinica e Ipertensione, Policlinico Hospital, Milan, Italy; and University of Milan, Milan, Italy

Luigi Mori
University of Brescia, Brescia, Italy

A. Ross Morton
Queen's University, Kingston, ON, Canada

Howard A. Morris
University of South Australia, Adelaide, SA, Australia

Giovanna Motta
University of Turin, Turin, Italy

Pierre Mouriquand
Hôpital Mère-Enfant – Claude-Bernard University, Lyon, France

Miguel Muñoz
Virgen del Rocío University Hospital, Sevilla, Spain

Maria Teresa Muñoz
University Hospital Niño Jesús, Institute of Investigation La Princesa, Madrid, Spain; and Center for Biomedical Research in Network on the Pathophysiology of Obesity and Nutrition (CIBEROBN), Carlos III Health Institute, Madrid, Spain

Araceli Muñoz-Garach
Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Maria Lorenza Muiesan
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Dick Mul
Diabeter, Center for Pediatric and Adolescent Diabetes Care and Research, Rotterdam, The Netherlands

Manfred J. Müller
University of Kiel, Kiel, Germany

Beat Müller
Medical University Clinic, Kantonsspital Aarau, Aarau, Switzerland; and University Hospital Basel, Basel, Switzerland

Paolo Mulatero
University of Turin, Turin, Italy

Tayane Muniz Fighera
Federal University of Rio Grande do Sul, Porto Alegre, Brazil

K.S. Murthy
Virginia Commonwealth University, Richmond, VA, United States

Marina Muzza
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Angel Nadal
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Y. Nagayama
Nagasaki University, Nagasaki, Japan

Bimota Nambam
Louisiana State University, Shreveport, LA, United States

Ruta Navardauskaite
Lithuanian University of Health Sciences, Kaunas, Lithuania

M.-L. Névoret
Impeto Medical, San Diego, CA, United States

Markella Nezi
National and Kapodistrian University of Athens, Aretaieion Hospital, Athens, Greece

Brian T. Nguyen
Keck School of Medicine of University of Southern California, Los Angeles, CA, United States; and Los Angeles Biomedical Research Institute and Harbor-UCLA Medical Center, Torrance, CA, United States

Atossas Niakan
University of Tennessee Health Science Center, Memphis, TN, United States

Nicolas C. Nicolaides
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Claus H. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Henriette S. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Lynnette K. Nieman
National Institutes of Health (NIH), Bethesda, MD, United States

Sarah M Nikkel
University of British Columbia, Vancouver, BC, Canada

Charlotte M. Niznik
Northwestern University Feinberg School of Medicine, Chicago, IL, United States

James D. Nobles
Leeds Beckett University, Leeds, United Kingdom

Pavel Nockel
National Cancer Institute, Bethesda, MD, United States

Ruben Nogueiras
CIMUS, USC, IDIS, Santiago de Compostela, Spain; and Carlos III Health Institute, Madrid, Spain

Ruben Nogueiras
CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain; and University of Santiago de Compostela (USC), Santiago de Compostela, Spain

Anna Nordenström
Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

M. Nowak
Medical University of Lublin, Lublin, Poland

Tsuneo Ogawa
University of Ottawa, Ottawa, ON, Canada

Onyebuchi Okosieme
Cardiff University, Cardiff, United Kingdom

Wilma Oostdijk
Leiden University Medical Center, Leiden, The Netherlands

Jacques Orgiazzi
Lyon 1-Claude Bernard University, Lyon, France

Andrés E. Ortiz-Flores
University Hospital Ramón y Cajal, Madrid, Spain; University of Alcalá, Madrid, Spain; Ramón y Cajal Institute for Health Research IRYCIS, Madrid, Spain; and Biomedical Research Network Center in Diabetes and Related Metabolic Diseases CIBERDEM, Madrid, Spain

Nantia Othonos
University of Oxford, Oxford, United Kingdom

Susan M. Ott
University of Washington, Seattle, WA, United States

Karel Pacak
University of Connecticut Health Center, Farmington, CT, United States; and National Institutes of Health, Bethesda, MD, United States

Stephanie T. Page

University Hospital Erlangen, Erlangen, Germany

Stephan Zipfel
Medical University Hospital Tübingen, Tübingen, Germany

PREFACE

The first Edition of the *Encyclopedia of Endocrine Diseases* was published in 2004. Because of the enormous development in the field it was found important to produce a completely revised and updated Second Edition of the Encyclopedia. The new Edition is a must-have one-stop reference covering every aspect of the physiological background, pathogenesis, clinical diagnostics, and therapeutic aspects of the wide array of endocrine and related metabolic diseases.

The functional balance of the body (homeostasis) is maintained by two regulatory circuits, i.e., the nervous and the endocrine systems. Among the most complex constructs in the body, the endocrine system comprises a group of glands that secrete hormones directly into the bloodstream, where they reach their specific receptors in other parts of the body, evoking specific intracellular signaling pathways leading to their biological effect. Many classically non-endocrine organs (e.g., the heart) have also turned out to have endocrine functions. The endocrine system maintains and regulates the body's homeostasis by using hormones to control metabolism, temperature, biological cycles, internal fluid volume, reproduction, growth, body composition, and development. The system is a marvel when functioning optimally, i.e., maintaining the body homeostasis. Unfortunately, there is a myriad of ways these processes, actions, and functions can go awry, resulting in various endocrine and metabolic diseases, which form the over-arching theme of the Encyclopedia.

The Encyclopedia is not meant as a primer on the subject of endocrinology, but instead intended to provide a comprehensive reference work on the extensive spectrum of diseases and disorders that can occur within the endocrine and metabolic system. The updated version of this groundbreaking encyclopedia is especially timely, as it covers the dramatic discoveries in the field of endocrinology and metabolism over the past 10 years, particularly with respect to novel diagnostic techniques and treatment approaches. In particular, there have been tremendous advancements in our understanding of the molecular basis of endocrine and metabolic diseases (mutations, epigenetics, signaling), as well as pathogenesis and therapy of the common forms of these diseases (e.g., diabetes, obesity, and endocrine malignancies).

The Encyclopedia offers a unique source of up-to-date information for the physicians and basic scientists working in the field. It is an essential resource for every clinician diagnosing and treating endocrine patients. The Encyclopedia also offers the prime source of information for students of medicine and science around the world, as well as basic research workers in academia, the pharma industry, and in other areas in need of information on endocrinology and metabolism. It also offers useful information for the lay public about normal and abnormal functions of hormones.

The Encyclopedia is intended to serve as a useful and comprehensive source of information spanning the many and varied aspects of the endocrine and metabolic system. The chapters have been written to be accessible to both clinical and nonclinical readers. The articles have been formatted in similar fashion and each is intended as a stand-alone presentation. Each article begins with a glossary list defining key terms that may be unfamiliar to the reader and are important for understanding the article. The body of the article begins with a brief introduction to the subject under discussion, bold headings lead the reader through the text, and figures and tables explain and illuminate most articles. The main text is followed by referenced citations to provide the reader with access to additional information on the topic, and cross-references lead the reader to related entries in the encyclopedia. The relatively short stand-alone articles have allowed us to recruit the best experts available for each topic.

Unlike the first Edition, where the articles were arranged in alphabetical order, the 2nd Edition is arranged in organ-based thematic order, where each organ-based group of diseases is presented as cluster of articles in the first four volumes. The fifth volume is a stand-alone compilation of all articles on pediatric endocrinology. The thematic organization gives the reader a better general view of the coverage of articles on a specific endocrine organ or disease type.

The Second Edition of the Encyclopedia builds of the first edition. Nevertheless, to bring a major reference work with such a broad scope from initial conception to final publication involved a great deal of planning and organization, together with the efforts of innumerable individuals. The authors of the first edition were invited to update their earlier texts. If this was not possible, the Section Editors invited another expert in the topic either to update the previous text or to write a de novo text; the latter happened in most of these cases. Hence, the Second Edition contains to a large extent totally new information, or at least the fluency of all texts has been scrutinized. Furthermore, all manuscripts have undergone peer-review arranged by the Section Editors.

Assembling a large volume of articles with the purpose to cover all essential topics of endocrine diseases posed multiple challenges. Coverage was a significant problem: on one hand some redundancy of the topics was almost impossible to avoid in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these gaps in future editions. We also note that as can be expected for a large multi-author compilation the individual articles do differ in detail and approach. We considered it more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines.

Most of the editing work of the Encyclopedia has been carried out by a highly competent board of 16 Section Editors, each of them internationally renowned experts in their respective field within clinical endocrinology. First, the broadest possible list of topics was compiled, aiming at the best possible coverage. Throughout the editorial process, the Section Editors supervised their subject area of expertise, recommended and corresponded with fellow editors and article contributors, reviewed the manuscripts, and continuously helped to refine the final list of topics. This has made the task of the Editor in Chief easy, mainly entailing the supervision of smooth progress of the project.

The Section Editors and their fields deserve being listed here: *Jean-Jacques Body* (Belgium, bone endocrinology), *Felipe F. Casanueva* (Spain, metabolism and obesity), *Richard N. Clayton* (United Kingdom, pituitary gland), *Jean-Louis Chiasson* (Canada, diabetes), *Sophie Christin-Maitre* (France, female reproduction), *Wouter W. de Herder* (The Netherlands, neuroendocrinology), *Ulla Feldt-Rasmussen* (Denmark, thyroid gland), *Ieuan Hughes* (United Kingdom, pediatric endocrinology), *Gregory Kaltsas*, Greece, and *Martin O. Weickert*, United Kingdom, (gastrointestinal hormones), *Jean-Marc Kaufman* (Belgium, endocrinology of aging), *André Lacroix* (Canada, adrenal cortex), *Franco Mantero* (Italy, adrenal medulla and endocrine hypertension), *Jorma Toppari* (Finland, endocrine disruptors), *Jacquetta Trasler* (Canada, endocrine epigenetics) and *Christina Wang* (United Kingdom, male reproduction).

The Elsevier editorial staff, *Will Smaldon*, *Laura Escalante Santos*, and *Kate Miklaszewska-Gorczyca*, have been of enormous help to the editors at every step during this long project. I admire the professionalism of everyone and am deeply indebted to all for their dedication and hard work to make the Encyclopedia the leading reference book of clinical endocrinology.

The authors of the individual chapters, more than 450 in total, were specifically selected by the Section Editors to represent the best available knowledge on the topic available. They all should be thanked for their dedication and the excellent quality of their contributions.

Ilpo T. Huhtaniemi
Editor in Chief

VOLUME 1 – General Principles of Hormone Production and Action, Diabetes, Lipid Metabolism and Atherosclerosis, Obesity, Gastrointestinal Hormones, Multi-Organ Endocrine Diseases, Endocrinology of Aging, and Endocrine toxicology and EDCs

General Principles of Hormone Production and Action

History of Endocrinology *Wouter W de Herder* 1
Statistics in Endocrinology: Meta-Analysis Advantages and Pitfalls *Olaf M Dekkers* 11
Evolution of Hormonal Mechanisms *Vincent Laudet and Gabriel V Markov* 16
General Principles of Endocrine Genetics *Constantin Polychronakos* 23
Endocrine Epigenetics, Epigenetic Profiling and Biomarker Identification *Virginie Bertrand-Lehouillier, Lisa-Marie Legault, and Serge McGraw* 31
Protein and Peptide Hormone Synthesis *Johannes Hofland and Frank H de Jong* 36
Protein and Peptide Hormone Action *Frank H de Jong and Johannes Hofland* 43
Roles of Plasma Binding Proteins in Modulation of Hormone Action and Metabolism *Geoffrey L Hammond, Lesley A Hill, and Phillip W Round* 51
Dynamic Endocrine Rhythms *Thomas J Upton and Stafford Lightman* 61
Growth Factors *Uxía Fernandez, Luisa M Seoane, and Ruben Nogueiras* 69

Diabetes

Normal Glucose Physiology *Mazen Alsahli and John E Gerich* 72
Glucose Metabolism and Hormonal Regulation *Keith Tornheim* 87
Insulin Secretion: Functional Biochemical Aspects *Willy J Malaisse* 95
Insulin Action; Post-Receptor Mechanisms *Ashok K Srivastava, Preeti Bajpai, and Ashish Jain* 100
Diagnosis and Classification of Diabetes Mellitus *Jean-Marie Ekoé* 105
Type 1 Diabetes *Bimota Nambam, William Winter, and Desmond Schatz* 110
Type 2 Diabetes *Susan L Samson and Alan J Garber* 116
Diabetes Mellitus and Pregnancy *Emily D Szmuilowicz, Charlotte M Niznik, and Boyd E Metzger* 122
Diabetes Mellitus; Diagnosis and Treatment in the Elderly *Odilia I Bermudez* 133

Carbohydrate Metabolism: Diabetes Mellitus, Genomic Aberrations *RK Semple* 141
Lifestyle Diabetes Prevention *Ahmad Alkhatib and Jaakko Tuomilehto* 148
Hyperglycemic Hyperosmolar State *J Maletkovic and A Drexler* 160
Hypoglycemia *Darleen A Sandoval, Elizabeth M Lamos, Lisa Younk, Maka S Hedrington, and Stephen N Davis* 163
Glycation- and/or Polyol Pathway-Inducing Complications *Naila Rabbani and Paul J Thornalley* 170
Hypertension and Diabetes *Atossas Niakan and William C Cushman* 180
Dyslipidemia in Diabetes *Savitha Subramanian and Alan Chait* 186
Ocular Manifestations Associated With Diabetes *S Lauhon, MS Stem, and PE Fort* 199
Kidney Disease in Diabetes *Stephanie Toth-Manikowski and Mohamed G Atta* 202
Diabetic Nerve Disease; Neuropathy *Jean-Marie Ekoe* 207
Neurological Disease and Diabetes, Autonomic *Aaron I Vinik, Tomris Erbas, M-L Névoret, and C Casellini* 210
Foot Disease in Diabetes *Jean-Marie Ekoé, Benjamin A Lipsky, and David G Armstrong* 216
Cardiovascular Disease in Diabetes *Marie-Eve Piché and Paul Poirier* 219
Treatment: Alpha Glucosidase Inhibitors *Markolf Hanefeld and Gabriele Mertes* 238
Insulin Pumps and Artificial Pancreas *Nadine Taleb, Véronique Gingras, and Rémi Rabasa-Lhoret* 245
Transplantation: Pancreatic and Islet Cells *Anissa Gamble, Antonio Bruni, and AM James Shapiro* 259
Hypoglycemic State, Nondiabetic *Pierre J Lefèbvre and André J Scheen* 270

Lipid Metabolism and Atherosclerosis

Classification of Hyperlipidemias and Dyslipidemias *Jesús E Millán Núñez-Cortes and Joaquín J Millán Pérez* 275
Atherosclerosis *Jesus A Araujo and Aldons J Lusis* 282
Atherogenesis *L Badimon and V Llorente-Cortés* 289
Epigenetics, the Vascular Wall, and Atherosclerosis *Gertrud Lund and Silvio Zaina* 303
Primary Mixed Dyslipidemias *Rafael Carmena* 314
Hypercholesterolemia *Sergio Martinez-Hervas and Juan F Ascaso* 320
Low HDL and High HDL Syndromes *Shizuya Yamashita and Yuji Matsuzawa* 327
Hypertriglyceridemias and Their Treatment *José T Real* 340

Obesity

Genetic Basis of Obesity *Dolores Corella and Oscar Coltell* 346
Gut Microbiota; Its Importance in Obesity *Araceli Muñoz-Garach, Isabel M Cornejo-Pareja, and Francisco J Tinahones* 353
Regulation of Food Intake *Albert Lecube and Carolina López-Cano* 363
Adipose Tissue *Xabier Unamuno, Gema Frühbeck, and Victoria Catalán* 370
Comorbidities of Obesity *Vettor Roberto and Di Vincenzo Angelo* 385
Hypothalamic Control of Food Intake and Energy Homeostasis *Luisa M Seoane, Miguel López, and Ruben Nogueiras* 393

Gastrointestinal Hormones and Their Regulation of Food Intake *Luca Busetto, Marco Rossato, and Roberto Vettor* 398

Body Composition *Manfred J Müller, Corinna Geisler, and Anja Bosy-Westphal* 406

Obesity and Food Addiction *Fernando Fernández-Aranda, Trevor Steward, Gemma Mestre-Bach, Susana Jiménez-Murcia, and Ashley Gearhardt* 414

Leptin *Rachel C Morgan and Robert V Considine* 420

Lifestyle and Nutrition *Dragan Micic and Snezana Polovina* 428

Physical Activity and Exercise *Federico Mallo Ferrer* 436

Treatment of Obesity with Bariatric Surgery *Maitane Izaguirre, Gema Frühbeck, and Victoria Catalán* 442

Metabolic Surgery; Indications and Outcomes *Lidia Castagneto-Gissey, James Casella-Mariolo, and Geltrude Mingrone* 459

Treatment: New Drugs *Silvia Garelli, Nicola Salituro, Giulia M Pontesilli, Luigi Ricciardiello, Valentina Vicennati, and Uberto Pagotto* 464

Binge-Eating, Bulimia, and Other Eating Disorders *Zaida Agüera, Núria Mallorquí-Bagué, María Lozano-Madrid, Andreas Stengel, Stephan Zipfel, and Fernando Fernández-Aranda* 473

Lipodystrophy *Marta Giralt, Francesc Villarroya, and David Araújo-Vilar* 482

Gastrointestinal Hormones

GI Hormone Development (Families and Phylogeny) *Anders H Johnsen* 496

GI Tract: General Anatomy (Cells) *George Kontogeorgos* 501

GI Hormones Outside the Gut: Central and Peripheral Nervous Systems *Graham J Dockray* 515

GI Tract: General Pathology of Neuroendocrine Growths *Guido Rindi, Frediano Inzani, and Enrico Solcia* 520

Gastrin *Graham J Dockray* 525

Cholecystokinin (CCK) *Nori Geary* 529

Pancreatic Polypeptide (PP) *Dana K Andersen and F Charles Brunicardi* 534

Peptide YY (PYY) *Peter Holzer and Aitak Farzi* 546

Glucagon and Glucagon-Like Peptides *Daniel M Kemp and Joel F Habener* 555

Glucagon Like Peptide 2 (GLP-2) *Georgios K Dimitriadis and Alexander D Miras* 561

Enterochromaffin-Like Cells *Apostolos V Tsolakis* 565

Substance P *Miguel Muñoz and Rafael Coveñas* 571

Gastrointestinal Hormones in Cancer *Inbal Uri, Kristallenia Alexandraki, and Simona Grozinsky-Glasberg* 579

Somatostatin Receptor Expression in Gastrointestinal Tumors *Eleftherios Chatzellis and Gregory Kaltsas* 587

Gastrointestinal Neuroendocrine Tumor Syndromes (GI NETS) *Robert T Jensen* 597

Gastrinomas *Robert T Jensen* 617

Pancreatic Islet Cell Tumors *Ulrich Knigge, Mikkel Andreassen, Birgitte Federspiel, Carsten Palnæs Hansen, Andreas Kjær, and Seppo W Langer* 626

Peptide Neurotransmitters and Smooth Muscle in the Gut *JR Grider, KS Murthy, and GM Makhlouf* 635

Multi-Organ Endocrine Diseases

Pituitary Tumors Associated With Multiple Endocrine Neoplasia Syndromes *Liliya Rostomyan, Adrian F Daly, and Albert Beckers* 642

Endocrinology of Aging

Aging and Longevity of Human Populations *Diana van Heemst* 648

Animal Models for Aging *EC-H Lee, B Rogina, L Haynes, and GA Kuchel* 653

Oxidative Stress and Aging *Arthur K Balin and RG Allen* 659

Immunology and Aging *Victor Appay* 664

Premature Aging Syndromes *Fabio Coppedè* 669

Hormonal Circadian Rhythms and Sleep in Aging *Georges Copinschi and Anne Caufriez* 675

Circadian Clock, Epigenetic Regulators (Sirtuins), and Metabolism *Mirella L Meyer-Ficca and Ralph G Meyer* 690

Somatotropic Axis in Human Aging *Sabrina Chiloiro, Antonio Bianchi, Antonella Giampietro, and Laura De Marinis* 700

Abnormalities in Water Homeostasis in the Elderly *Laura E Cowen and Joseph G Verbalis* 708

Body Weight, Body Composition, and Aging *Odessa R Addison and Alice S Ryan* 713

Lipid Disorders in the Elderly *Wilbert Aronow* 719

Gonadotropins and Testicular Function in Aging *Fiona Yuen, Peter Y Liu, Ronald Swerdloff, and Christina Wang* 723

Hypogonadism and Testosterone Therapy in Elderly Men *Bu B Yeap* 729

Sexual Function in Aging Men *Giulia Rastrelli, Giovanni Corona, and Mario Maggi* 739

Osteoporosis in the Oldest Old *Evelien Gielen* 748

Aging and the Thyroid Gland *Leonidas H Duntas* 758

Endocrine toxicology and EDCs

Introduction to Endocrine Toxicology and Endocrine Disruption *Jorma Toppari* 762

Toxic Effects of Common Environmental Pollutants in Pancreatic β-Cells and the Onset of Diabetes Mellitus *Paloma Alonso-Magdalena, Eva Tudurí, Laura Marroquí, Ivan Quesada, Robert M Sargis, and Angel Nadal* 764

Endocrine Disruptors and Obesity *Sigal A Willner and Bruce Blumberg* 776

Endocrine Disruptors and Thyroid Function *Josef Köhrle* 787

Neuroendocrine Disruption of Reproduction *Julie Fudvoye, Jean-Pierre Bourguignon, and Anne-Simone Parent* 793

Association of Endocrine Disrupting Chemicals With Male Reproductive Health *Helena E Virtanen, Katharina M Main, and Jorma Toppari* 802

Endocrine Disrupting Chemicals and Behavior *Sheryl E Arambula and Heather B Patisaul* 812

VOLUME 2 – Neuroendocrinology, Pituitary Gland and Diseases, Female Reproduction, and Male Reproduction

Neuroendocrinology

Corticotropin-Releasing Hormone (CRH) *Nicolas C Nicolaides and George P Chrousos* 1

Neurotensin *Arthur Shulkes* 10

Carcinoid Syndrome *Marina Tsoli and Gregory Kaltsas* 13

Catecholamines *Graeme Eisenhofer and Jacques WM Lenders* 21

Pineal Tumors *María-José Barahona and Susan M Webb* 25

Vasopressin *Aoife Garrahy and Christopher J Thompson* 29

Effects of Steroid Hormones on Brain *Anne-Sophie CAM Koning, Russell D Romeo, Bruce S McEwen, and Onno C Meijer* 36

Memory and Epigenetics: Role of Estrogen *Jennifer J Tuscher, Ashley M Fortress, and Karyn M Frick* 42

VIPoma, Glucagonoma, and Somatostatinoma *Wouter T Zandee and Wouter W de Herder* 52

Insulinoma *Wouter T Zandee and Wouter W de Herder* 58

Melatonin *J Arendt* 63

Overview of Neurotransmitters *Floyd E Bloom* 75

Pituitary Gland and Diseases

Anatomy of Hypothalamus *Béla Halász* 81

Pituitary Gland Anatomy and Embryology *Béla Halász* 90

Hypothalamic Disease *Sylvia L Asa and Shereen Ezzat* 97

Diabetes Insipidus *Gary L Robertson* 107

Growth Hormone (GH) *Rikke Hjortebjerg, Gerhard Baumann, and John J Kopchick* 116

Natural and Synthetic Growth Hormone Secretagogues *Giovanna Motta, Stefano Allasia, Marco Zavattaro, Ezio Ghigo, and Fabio Lanfranco* 127

Luteinizing Hormone (LH) *Livio Casarini, Daniele Santi, Gary R Marshall, and Manuela Simoni* 142

Follicle-Stimulating Hormone (FSH) *Daniele Santi, Livio Casarini, Gary R Marshall, and Manuela Simoni* 149

Prolactin: Regulation of Secretion and Action *Filippo Maffezzoni, Gherardo Mazziotti, and Andrea Giustina* 157

Molecular Pathogenesis of Pituitary Tumors *Shereen Ezzat and Sylvia L Asa* 165

Classification of Pituitary Neuroendocrine Tumors (PitNets) *Jacqueline Trouillas, Alexandre Vasiljevic, Emmanuel Jouanneau, and Gérald Raverot* 176

Genetic Causes of Familial Pituitary Tumors *Maria Manuel Costa and Márta Korbonits* 185

Clinical Features of Acromegaly *I Ilie and M Korbonits* 212

Diagnosis of Acromegaly *I Ilie and M Korbonits* 223

Therapy for Acromegaly *Philippe Chanson* 230

ACTH-Secreting Pituitary Tumors *Rosario Pivonello, Maria Cristina De Martino, Davide Iacuaniello, Chiara Simeoli, and Annamaria Colao* 248

TSH-Secreting Pituitary Adenomas *Olympia Koulouri and Mark Gurnell* 261

Surgery for Pituitary Tumors *Pamela Jones and Brooke Swearingen* 267

Clinical Features, Diagnosis, and Management of Nonfunctioning Tumors of Pituitary *Athanasios Fountas and Niki Karavitaki* 271

Surgical Treatment of Nonfunctioning Pituitary Tumors *Michael Buchfelder and Yining Zhao* 281

Pituitary Radiotherapy *Frederic Castinetti and Thierry Brue* 289

Diagnosis and Clinical Management of Aggressive Pituitary Tumors *Gerald Raverot, Emmanuel Jouanneau, and Jacqueline Trouillas* 294

Hypopituitarism, Causes, Diagnosis, Management and Mortality *Athanasios Fountas and Niki Karavitaki* 301

Diagnosis of Prolactinoma and Causes of Hyperprolactinemia *James Ahlquist* 314

Prolactinomas: Clinical Manifestations and Therapy *Anna Scholz and Dafydd Aled Rees* 319

Hypophysitis *Federica Guaraldi, Olivera Casar-Borota, and Marie-Lise Jaffrain-Rea* 325

Radiology of the Pituitary *Jane Evanson* 339

Hyponatraemia *Aoife Garrahy and Christopher J Thompson* 349

Pituitary Disorders Following Traumatic Brain Injury *Anne Marie Hannon and Christopher J Thompson* 365

Female Reproduction

Folliculogenesis *Danielle Monniaux, Véronique Cadoret, Frédérique Clément, Rozenn Dalbies-Tran, Sébastien Elis, Stéphane Fabre, Virginie Maillard, Philippe Monget, and Svetlana Uzbekova* 377

Human Menstrual Cycle *Sophie Christin-Maitre* 399

Implantation *Lechosław T Putowski and M Nowak* 404

Pregnancy Endocrinology *Stefano Palomba and Jessica Daolio* 408

Placental Epigenetics and Outcomes in Children *Patricia Fauque* 418

Endocrinology of Delivery *Silvia Vannuccini and Felice Petraglia* 425

Premenstrual Syndrome (PMS) *M Link* 432

Amenorrhea *Sophie Christin-Maitre* 436

Congenital Hypogonadotropic Hypogonadism in Females *Jacques Young* 439

Functional Hypothalamic Amenorrhea *Sarah L Berga* 444

Polycystic Ovary Syndrome *Stephen Franks* 451

Polycystic Ovary Syndrome: Implications for Cardiovascular, Endometrial, and Breast Disease *HF Escobar-Morreale* 456

Ovarian Androgen-Producing Tumors *Michael DiMattina and Callum Potts* 458

Sport and Menses *Angelica Lindén Hirschberg* 461

Primary Ovarian Insufficiency *Luca Persani* 471

Adult Care of Turner Syndrome *Claus H Gravholt, Mette Viuff, Kirstine Stochholm, and Niels H Andersen* 482

Initial Evaluation of the Infertile Couple *Jean-Marie Antoine and Jacqueline Mandelbaum* 490

Endometriosis *Alain Audebert* 498

Epigenetics of Endometriosis *Daniel Vaiman* 506

Uterine Fibroids and Infertility *Jacques Donnez, Olivier Donnez, Pablo Arriagada, and Marie-Madeleine Dolmans* 513

Environmental Factors and Female Reproduction *Patrick Fénichel and Charlotte Rougier* 525

Miscarriages *Hervé Fernandez and Perrine Capmas* 538

Obesity and Reproduction *Andrés E Ortiz-Flores and Héctor F Escobar-Morreale* 543

Developmental Epigenetics and the Contribution of Parental Diet to Offspring Outcomes *Oliver J Rando and Rebecca A Simmons* 553

Anti-Müllerian Hormone (AMH) in Adults *Agathe Dumont, Geoffroy Robin, Sophie Catteau-Jonard, and Didier Dewailly* 556

Ovarian Stimulation with Clomiphene Citrate *J Gianfortoni* 567

Ovulation Induction With Gonadotropins *Aude Bruyneel, Ralph Papas, and Anne Delbaere* 570

Ovarian Hyperstimulation Syndrome *Basil C Tarlatzis, Julia K Bosdou, and Efstratios M Kolibianakis* 581

Fertility and Pregnancy in Patients With 21-Hydroxylase Deficiency *Virginie Grouthier, Carine Courtillot, Jérôme Dulon, Philippe Touraine, and Anne Bachelot* 588

In Vitro Fertilization (IVF) *Renato Fanchin* 595

Ovarian Failure Treatment Strategies: Egg Donation *Pedro N Barri* 599

Fertility Preservation in Women *Julie Benard, Alexandra Benoit, Charlotte Sonigo, and Michael Grynberg* 603

Female Hormonal Contraception *Genevieve Plu-Bureau* 615

Progesterone Receptor Modulators: Current Applications and Perspectives *Kamila Kolanska, Axelle Pintiaux, Philippe Bouchard, Emile Daraï, and Nathalie Chabbert-Buffet* 622

Diagnosis of Menopause *Tommaso Simoncini, Marta Caretto, Andrea Giannini, and Andrea R Genazzani* 628

Menopausal Treatment *Anne Gompel* 634

Hormonal Treatment of Breast Cancer *Stéphanie Bécourt and Marc Espié* 646

Hormonal Treatment of Male to Female Transgender *Alessandra D Fisher and Louis Gooren* 656

Male Reproduction

Testes Embryology: Cellular Molecular Changes *T Svingen and LJ Pelliniemi* 664

Spermatogonial Physiology and Regulation of the Niche *Stefan Schlatt and Swati Sharma* 670

Male Germ Cell Differentiation *My-Thanh Beedle and Michael D Griswold* 678

Endocrine Control of Spermatogenesis *TM Plant, S Ramaswamy, and Karel De Gendt* 684

Gonadotropin-Releasing Hormone (GnRH) Development and Actions *Margaret E Wierman* 692

Genes and Gene Defects Affecting Gonadal Development and Sex Determination *Dagmar Wilhelm and Stefan Bagheri-Fam* 695

Mutations of the Gonadotropin-Releasing Hormone Receptor Gene *Alfredo Ulloa-Aguirre, Teresa Zariñán, and Saúl Lira-Albarran* 704

Androgen Biosynthesis and Gene Defects *Adina F Turcu and Richard J Auchus* 713

Reproductive and Nonreproductive Actions of Testosterone *Shalender Bhasin and Ravi Jasuja* 721

Hormone Replacement Therapy in Men *Cindy Pham, Christina Wang, and Ronald S Swerdloff* 735

Male Hormonal Contraception *Brian T Nguyen, Ronald S Swerdloff, Frederick CW Wu, and Christina Wang* 741
Estrogen and the Male *Agnė Kadusauskienė and Jonas Čeponis* 751
Gynecomastia *Glenn D Braunstein* 763
Male Sexual Dysfunction *Amarnath Rambhatla and Jacob Rajfer* 767
Androgens and Benign Prostatic Hyperplasia *Maritza Farrant and Stephanie T Page* 775
Prostate Cancer *Timothy McClure, Spyridon P Basourakos, Jaspreet S Sandhu, Peter N Schlegel, and James J Colt* 784
Insulin-Like Peptide 3 (INSL3) *Ravinder Anand-Ivell and Richard Ivell* 793
Epididymis *Maria Christina W Avellar and Barry T Hinton* 807
Fertility in Men With Spermatogenesis Abnormalities *Katherine Rotker and Mark Sigman* 814
Genetics of Male Infertility *Csilla Krausz and Francesca Cioppi* 821
Testicular Tumors *Ewa Rajpert-De Meyts* 831
Male Oncoinfertility *Bernard Robaire and Peter T Chan* 840

VOLUME 3 – Adrenal Glands and Hypertension

Adrenal Glands and Hypertension

Adrenal Cortex; Physiology *Fady Hannah-Shmouni and Christian A Koch* 1
Adrenal Cortex; Development *Typhanie Dumontet and Antoine Martinez* 8
Corticotropin-Releasing Hormone Peptide Family *David W Hogg, Mia Husic, and David A Lovejoy* 16
Regulation of POMC and ACTH Secretion *Dongyun Zhang and Anthony P Heaney* 27
ACTH, Melanocortin Receptors, and MRAP Accessory Proteins *Robert M Dores* 38
Adrenocorticotropic Hormone (ACTH): Physiology and Its Involvement in Pathophysiology *George Mastorakos and Athanasios Antoniou-Tsigkos* 48
Adrenal Steroidogenesis *Daniel B Martinez-Arguelles and Vassilios Papadopoulos* 56
Overview of Glucocorticoids *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 64
Stress and Endocrine Physiology *Nicolas C Nicolaides, Panagiota Pervanidou, and George P Chrousos* 72
Hypothalamic–Pituitary–Adrenal Suppression *Nicolas C Nicolaides and George P Chrousos* 83
Glucocorticoid Metabolism and Activation *Nantia Othonos and Jeremy Tomlinson* 90
Glucocorticoid Receptor *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 104
Glucocorticoids and Immunity *Karen E Chapman* 112
Corticotropin-Releasing Hormone and Inflammation *Markella Nezi, Evangelia Zapanti, and George Mastorakos* 121
Adrenal Insufficiency: Etiology and Diagnosis *Nicolas C Nicolaides and Evangelia Charmandari* 131
Primary Adrenal Hypoplasia and ACTH Resistance Syndromes *Ioannis Kyrou and Constantine Tsigos* 139
Impact of Glucocorticoid Receptor Polymorphisms on Glucocorticoid Action *Mesut Savas and Elisabeth FC van Rossum* 147

Glucocorticoid Resistance Syndromes and States *Nicolas C Nicolaides and George P Chrousos* 157

X-Linked Adrenoleukodystrophy/Adrenomyeloneuropathy *William B Rizzo* 166

Steroid Replacement in Adrenal Insufficiency *Joanne C Blair, Miguel Debono, and Richard Ross* 172

Management of Adult Patients With Congenital Adrenal Hyperplasia Due to 21-Hydroxylase Deficiency *Virginie Grouthier, Jérôme Dulon, Anne Bachelot, and Philippe Touraine* 185

Cushing Syndrome; Screening and Differential Diagnosis *André Lacroix and Lynnette K Nieman* 193

Molecular Genetics of Cushing Disease *Martin Reincke, Marily Theodoropoulou, and Adriana Albani* 205

Pituitary Surgery for Cushing Disease *Pamela Jones and Brooke Swearingen* 215

Evaluation and Follow-Up of Patients With Cushing Disease After Pituitary Surgery *Amandine Ferriere, Claire Cordroch, and Antoine Tabarin* 223

Medical Therapy of Hypercortisolism *Richard A Feelders* 232

Radiation Therapy in Patients With Cushing Disease *Nicholas A Tritos, Jay S Loeffler, and Beverly MK Biller* 237

Bilateral Adrenalectomy for Cushing Disease *Frederic Castinetti* 243

Cushing Syndrome—Unilateral Adrenal Adenoma *Guido Di Dalmazi* 249

Somatic β-Catenin Gene Mutations and WNT Signaling in Adrenal Tumors *Isabelle Bourdeau* 259

Adrenocortical Tumors and *gsp* Mutations *Maria Candida Barisson Villares Fragoso, Isadora Pontes Cavalcante, Leonardo Tadeu Araujo, Helaine Laiz Silva Charchar, Ingrid Quevedo Wanichi, Vania Balderrama, Amanda Meneses Ferreira, and Beatriz Marinho de Paula Mariani* 266

PPNAD, Carney Complex, and Other Micronodular Adrenal Hyperplasia *Stéphanie Espiard and Jérôme Bertherat* 271

Genetics of Familial Forms of Cortisol-Secreting Adrenal Tumors and Hyperplasias *Ludivine Drougat and Constantine A Stratakis* 283

Primary Bilateral Macronodular Adrenal Hyperplasia *André Lacroix* 293

Adrenal Incidentalomas *Massimo Terzolo, Soraya Puglisi, and Giuseppe Reimondo* 303

Adrenocortical Carcinoma: Diagnosis and Therapy *Massimo Terzolo, Soraya Puglisi, Paola Perotti, Mélanie Claps, Elisa Roca, and Alfredo Berruti* 308

Adrenocortical Carcinoma: Genetics and Molecular Markers *Anne Jouinot and Guillaume Assié* 317

Adrenal Surgery *Pavel Nockel, Mustapha El Lakis, and Electron Kebebew* 323

Long-Term Complications of Hypercortisolism *Rosario Pivonello, Davide Iacuaniello, Chiara Simeoli, Maria Cristina De Martino, and Annamaria Colao* 341

Effects of Glucocorticoids on the Brain *Alberto M Pereira, Susan M Webb, and Onno C Meijer* 360

Hypertension; Overview *Morton P Printz and Rebecca L Jaworski* 369

Neurogenic Hypertension *Gino Seravalle, Guido Grassi, and Giuseppe Mancia* 381

Renal Hypertension *Daniele Cusi* 383

Endocrine Hypertension *Inga Harbuz-Miller, Ryan Woodman, and Guido Lastra* 390

Resistant Hypertension *Robert M Carey* 402

Hypertension and Target Organ Damage *Maria Lorenza Muiesan, Anna Paini, Claudia Agabiti Rosei, Fabio Bertacchini, Carlo Aggiusti, Carolina De Ciuceis Damiano Rizzoni, and Massimo Salvetti* 406

Stroke *PCAJ Vroomen and GA Donnan* 415

Normetanephrine and Metanephrine *Jacques WM Lenders and Graeme Eisenhofer* 420

Adrenergic Mechanisms *Peter W de Leeuw and Abraham A Kroon* 425

Novel Insights in β-Adrenergic Receptor Signaling *Guido Iaccarino and Daniela Sorriento* 432

Baroreceptor Responses *AF Sved, EM Stricker, and SD Stocker* 440

Antiadrenergic Agents *Enrico Agabiti-Rosei* 443

Pheochromocytoma and Paraganglioma Syndromes *Vitaly Kantorovich and Karel Pacak* 449

Pheochromocytoma/Paraganglioma: Diagnosis and Treatment *Maurizio Castellano, Mara Giacchè, Luigi Mori, Alessandra Panarotto, and Carlo Cappelli* 455

Malignant Pheochromocytoma *Massimo Mannelli, Gabriele Parenti, Letizia Canu, Giuseppina De Filpo, and Elena Rapizzi* 460

Pheochromocytoma/Paraganglioma: Management, Genetics, and Follow-up *Anne-Paule Gimenez-Roqueplo and Laurence Amar* 469

Renin and Prorenin *Alberto Morganti* 478

Angiotensinogen and Angiotensins *Massimo Volpe and Speranza Rubattu* 483

Kininases *Randal A Skidgel, Ervin G Erdös, and Peter A Deddish* 490

Tissue Ace–Angiotensin–AT_1 Receptor Axis and Repair in the Heart *Yao Sun and Karl T Weber* 497

Hypertension and the Renin–Angiotensin–Aldosterone System *Elena Kaschina, Ulrike M Steckelings, and Thomas Unger* 505

Hyperreninemia *Pierre-François Plouin, Laurence Amar, and Michel Azizi* 511

Renal Vein Renin Measurement as a Diagnostic Tool *Gian Paolo Rossi* 516

Interference With the Renin–Angiotensin System (RAS): Classical Inhibitors and Novel Approaches *Katrina M Mirabito Colafella, Estrellita Uijl, and AH Jan Danser* 523

Aldosterone; Synthesis and Metabolism *John W Honour* 531

Aldosterone; Action and Function *Peter J Fuller and Morag J Young* 540

Aldosterone Receptors *Say Viengchareun, Marc Lombès, and Laetitia Martinerie* 546

Regulation of Potassium Homeostasis *Paola Russo, Fabio Lauria, and Alfonso Siani* 552

Salt-Sensitivity of Blood Pressure *Pasquale Strazzullo, Ferruccio Galletti, and Lanfranco D'Elia* 558

Endogenous Ouabain *Paolo Manunta and Marco Simonini* 564

Atrial Natriuretic Factor and the Family of Natriuretic Peptides *Tsuneo Ogawa and Adolfo J de Bold* 569

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Pathophysiology *John W Funder* 581

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Clinical Aspects *Ellen Marie Freel* 586

Primary Aldosteronism; Epidemiology and Screening *Michael Stowasser* 598

Primary Aldosteronism; Diagnosis and Treatment *Franco Mantero and Maria Verena Cicala* 607

Adrenal Venous Sampling for Primary Aldosteronism *Gian Paolo Rossi* 613

Genetics of Familial Hyperaldosteronism *Silvia Monticone, Martina Tetti, Isabel Losano, Franco Veglio, and Paolo Mulatero* 623

Aldosterone-Producing Adenomas; Genetics *Livia Lenzini, Sofia Zanin, and Gian Paolo Rossi* 631

Apparent Mineralocorticoid Excess *Padiporn Limumpornpetch and Paul M Stewart* 638

Licorice and 11β-Hydroxysteroid Dehydrogenase *Decio Armanini and Chiara Sabbadin* 644

Liddle Syndrome *Ermanno Rossi and Giovanni Maria Rossi* 652

Secondary Hyperaldosteronism *Aleksander Prejbisz and Andrzej Januszewicz* 664

Aldosteronism in Congestive Heart Failure *Yenal I Harper, Oluwaseun A Akinseye, Salem A Salem, Muhammad Shahreyar, and Karl T Weber* 668
Mineralocorticoid Receptor Antagonists *John W Funder* 674
Diuretics *Claudio Ferri and Rita Del Pinto* 681
Calcium Channel Blockers *Stefano Taddei and Rosa Maria Bruno* 689
Pseudohypoaldosteronism Type 1 *Fabio L Fernandes-Rosa* 696
Hyporeninemic Hypoaldosteronism *Shrey Purohit, Dalila B Corry, and Michael L Tuck* 703
Bartter and Gitelman Syndromes *Lorenzo A Calò and Verdiana Ravarotto* 714
Angiogenesis *Lindsay S Cooley and Andreas Bikfalvi* 722

VOLUME 4 – Calcium and Bone, and Thyroid Gland

Calcium and Bone

Bone Cells: Osteoblast/Osteoclast/Osteocyte *Nadia Rucci and Anna Teti* 1
Bone Remodeling *Susan M Ott* 10
Bone Structure and Biomechanics *Fjola Johannesdottir and Mary L Bouxsein* 19
Bone and Bone Marrow; Interactions *Delphine Spruyt, Céline Gillet, and Joanne Rasschaert* 31
Bone Muscle Interactions and Exercise *Jenny E Gunton* 40
Bone as an Endocrine Organ *Gerard Karsenty and Stavroula Kousteni* 47
Calcium Homeostasis in Humans *Roger Bouillon* 52
Calcium-Sensing Receptor *Giuseppe Vezzoli, Teresa Arcidiacono, Lorenza Macrina, Katia Maruca, and Stefano Mora* 58
Phosphate Metabolism, Hyperphosphatemia, and Hypophosphatemia *Seiji Fukumoto* 68
Vitamin D *Ian R Reid* 75
Nutrition and Bone *Peter Burckhardt* 82
Bone Development During Childhood and Adolescence: Peak Bone Mass *Jean De Schepper* 89
Bone Mass Measurement *Paul D Miller and Pierre JM Bergmann* 94
X-Ray Based Imaging Methods to Assess Bone Quality *Klaus Engelke* 102
Bone Turnover Markers *Etienne Cavalier, Richard Eastell, Niklas Rye Jørgensen, Konstantinos Makris, Samuel Vasikaran, and Howard A Morris* 116
Primary Hyperparathyroidism *Claudio Marcocci and Filomena Cetani* 128
Parathyroid Cancer *D Fink and Elizabeth Shane* 139
Parathyroid Surgery *EF Garner and H Chen* 151
Hypercalcemia: Other Causes than Primary Hyperparathyroidism *René Rizzoli* 160
Parathyroid Hormone Related Protein (PTHrP) *Archana Kamalakar, Charity L Washam, and Larry J Suva* 168
Physiology of Calcitonin and Its Therapeutic Uses *Sunil J Wimalawansa* 178
Hypoparathyroidism and Other Causes of Hypocalcemia *Bart L Clarke* 192
Calcitonin Gene-Related Peptide (CGRP) *AA Aubdool, X Kodji, and SD Brain* 204

Epidemiology of Fractures *Nicholas R Fuggle, Elaine M Dennison, and Cyrus Cooper* 213
Pathogenesis of Osteoporosis *Emma O Billington and Ian R Reid* 222
Role of Estrogens and Androgens in Osteoporosis *Michaël R Laurent* 233
Osteoporosis in Premenopausal Women *Serge Rozenberg* 246
Secondary Osteoporosis *Gregory R Emkey* 253
Osteoporosis; Prevention and Ca–Vitamin D Treatment *Bo Abrahamsen* 270
Osteoporosis Treatment: Bone-Forming Agents *Bente L Langdahl* 275
Osteoporosis Treatment: Sequential and Combination Therapy *Benjamin Z Leder and Joy N Tsai* 281
Osteoporosis: Treatment Gaps and Health Economics *Nicholas CW Harvey, Eugene V McCloskey, René Rizzoli, John A Kanis, Cyrus Cooper, and Jean-Yves Reginster* 288
Cancer Treatment-Induced Bone Loss (CTIBL) *Catarina Abreu, Maria R Dionísio, Joana C Silva, and Luís Costa* 296
Bone Metastases; Basic Aspects *Margaux Bernard, Paola Di Mauro, Caroline Reynaud, Chantal Diaz-Latoud, and Philippe Clézardin* 304
Bone Metastases; Clinical Aspects *Steven Wood, Azeez Salawu, Helen Kroening, Stella D'Oronzo, and Janet Brown* 310
Bone Metastases; Medical Treatment *Robert Coleman* 320
Multiple Myeloma Bone Disease *Evangelos Terpos and Maria Gavriatopoulou* 329
Diabetes and Bone *Peter Vestergaard* 341
Paget Disease of Bone *Stuart H Ralston* 350
Heterotopic Ossification and Calcification *Chen Kan, Na Ding, and Lixin Kan* 356
Kidney Stones *S Dizon, EA Iliescu, and A Ross Morton* 365
Pseudohypoparathyroid States *A Tsatsoulis, A Fountas, and E Laspa* 372

Thyroid Gland

Thyroid Gland: Anatomy and Physiology *Salvatore Benvenga, Giovanni Tuccari, Antonio Ieni, and Roberto Vita* 382
Thyroid Gland Development, Molecular Biology *Marina Muzza and Laura Fugazzola* 391
Hypothalamus–Pituitary–Thyroid Axis *Marco Bonomi, Biagio Cangiano, and Luca Persani* 398
Thyroid-Stimulating Hormone (TSH; Thyroptopin) *Leonidas H Duntas* 403
TSH Function and Secretion *Susan R Rose and Janet S Chuang* 408
TSH (Thyrotropin) Receptor *Yuji Nagayama* 416
Thyroid Hormone Metabolism *Josef Köhrle* 420
Sodium/Iodide Symporter (NIS) *Nancy Carrasco and Rachel R Kaspari* 429
Thyroid Peroxidase *Salvatore Benvenga and Roberto Vita* 433
Thyroglobulin *Marina Muzza and Laura Fugazzola* 439
Serum Thyroid Hormone-Binding Proteins *Luigi Bartalena and Eliana Piantanida* 442
Thyroid Hormone Receptors *Claire Briet, Frédéric Illouz, and Patrice Rodien* 448
Thyroid Hormone Action *Yui Watanabe and Roy E Weiss* 452
Resistance to Thyroid Hormone *Gisah Amaral de Carvalho, Tayane Muniz Fighera, and Roy E Weiss* 463

TSH-Producing Adenomas and Resistance to Thyroid Hormones *P Beck-Peccoz, L Persani, and A Lania* 473
Thyroid Function Tests *ER Christ and Albert G Burger* 477
Epidemiology of Thyroid Disease *Mark PJ Vanderpump* 486
Genetic Factors in Thyroid Disease *Marina Muzza and Laura Fugazzola* 496
Environmental Goitrogens *Veena Agrawal, Sana A Ghaznavi, and Ralf Paschke* 506
Iodine Deficiency *Peter Taylor, Onyebuchi Okosieme, Lakdasa Premawardhana, and John H Lazarus* 512
Nontoxic Goiter *Sana Ghaznavi, Kirstie Lithgow, Veena Agrawal, and Ralf Paschke* 524
Thyroid Nodule *Laszlo Hegedüs* 529
Thyroid and Irradiation *Barbara Jarzab, Daria Handkiewicz-Junak, and Jolanta Krajewska* 539
Thyroid Imaging *Luca Giovanella, Giorgio Treglia, and Pierpaolo Trimboli* 545
Thyroid Fine Needle Aspiration Cytology *Ivana Kholová and Camilla Schalin-Jäntti* 565
Thyroid Carcinoma *Rossella Elisei* 573
Medullary Thyroid Carcinoma *Maria Alevizaki, Katerina Saltiki, and Theodora Pappa* 586
Causes of Hypothyroidism *Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen* 600
Diagnosis of Hypothyroidism *Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen* 604
Central Hypothyroidism *Luca Persani and Marco Bonomi* 608
Hashimoto's Thyroiditis *Grigoris Effraimidis and Ulla Feldt-Rasmussen* 613
Systemic Manifestations of Hypothyroidism *Massimo Tonacchera and Luca Chiovato* 616
Treatment of Hypothyroidism *Bernadette Biondi* 624
Myxedema Coma *Leonard Wartofsky* 627
Hypothyroidism, Subclinical *Bettina F Winzeler, Mirjam Christ-Crain, Beat Müller, and Christian Meier* 630
Thyroid Autoimmunity *Ulla Feldt-Rasmussen, Sofie Bliddal, and Claus H Nielsen* 636
Thyrotoxicosis; Overview of Causes *Claudio Marcocci and Roberto Rocchi* 651
Thyrotoxicosis; Diagnosis *Claudio Marcocci and Roberto Rocchi* 657
Thyrotoxicosis; Systemic Manifestations *Claudio Marcocci and Filomena Cetani* 665
Thyrotoxicosis; Treatment *Claudio Marcocci and Filomena Cetani* 673
Subclinical Hyperthyroidism *Bernadette Biondi* 680
Antithyroid Drugs *Jacques Orgiazzi* 683
Radioactive Iodine *Barbara Jarzab and Jolanta Krajewska* 688
Thyrotoxicosis Factitia *Fausto Bogazzi and Enio Martino* 693
Thyrotoxic Storm *Leonard Wartofsky* 695
Graves' Disease *Irene Campi and Mario Salvi* 698
Hyperthyroidism in Graves' Disease *Danila Covelli and Mario Salvi* 702
Pretibial Myxedema *Guia Vannucchi and Mario Salvi* 707
Graves' Orbitopathy *Mario Salvi* 711
Smoking and the Thyroid *Luigi Bartalena and Maria L Tanda* 719

Toxic Adenoma *Kirstie Lithgow, Sana A Ghaznavi, Alexandra Stephenson, Amita Mahajan, and Ralf Paschke* 723
Toxic Multinodular Goiter *Amita Mahajan, Sana A Ghaznavi, Kirstie Lithgow, and Ralf Paschke* 730
Thyroiditis, Infectious and Subacute *Grigoris Effraimidis and Ulla Feldt-Rasmussen* 737
Postpartum Thyroid Dysfunction *Lakdasa DKE Premawardhana and John H Lazarus* 746
Thyroid and Infertility *Sofie Bliddal, Henriette S Nielsen, and Ulla Feldt-Rasmussen* 752
Thyroid Disease and Pregnancy *AM Leung and Jerome M Hershman* 762
Thyroid Disorders in the Elderly *Vafa Tabatabaie and Martin I Surks* 768
Drug Effects and Thyroid Function *Ulla Feldt-Rasmussen and Åse K Rasmussen* 772
Lithium *John H Lazarus* 780
Amiodarone and Thyroid *Fausto Bogazzi and Enio Martino* 782
Thyroid Disease and Bone *Bente L Langdahl* 787
Thyroid Function and Depression *Martin B Jørgensen and Ulla Feldt-Rasmussen* 792
Measuring Impact of Benign Thyroid Diseases on Quality of Life *Torquil Watt* 802

VOLUME 5 – Pediatric Endocrinology

Pediatric Endocrinology

Control and Monitoring of Fetal Growth *Tomas Prior and Christoph Lees* 1
Physiology of Growth Hormone in Fetus and Child *Vijayarangan G Kannian and Fiona J Ryan* 10
Infant, Childhood, and Adolescent Auxology *Gary Butler* 19
Body Proportions *Willem JM Gerver, Bas Penders, and Ralph Brecheisen* 31
Genetic and Hormonal Control of Growth *George Paltoglou, Harshini Katugampola, and Mehul T Dattani* 38
Abnormal Growth: Small for Gestational Age *Kathryn Beardsall, Meera Mallya, and Ajay Thankamony* 55
Growth Hormone Deficiency in Children *Berit Kriström and Elena Lundberg* 66
Growth Hormone Insensitivity *Martin O Savage, Sumana Chatterjee, Vivian Hwa, and Helen L Storr* 81
Tall Stature *Sabine E Hannema and Lars Sävendahl* 94
Growth in Childhood Chronic Conditions *Kung-Ting Kao, Syed Faisal Ahmed, and Sze Choong Wong* 102
Normal Puberty: Somatic Characteristics *Dipesalema Joel and Ieuan Hughes* 118
Genetic and Epigenetic Control of Puberty *Ana Claudia Latronico and Leticia F Silveira* 126
Hormonal Control of Puberty *Lindsey A Loomba-Albrecht and Dennis M Styne* 137
Secular Changes in Puberty *Camilla Eckert-Lind, Alexander S Busch, Elvira V Bräuner, and Anders Juul* 144
Delayed Puberty; Male *Alan D Rogol* 153
Delayed Puberty and Hypogonadism; Female *Sasha Howard and Leo Dunkel* 157

Gonadotropin-Dependent Precocious Puberty; Female and Male *Dick Mul, Wilma Oostdijk, and Stenvert LS Drop* 166

Gonadotrophin-Independent Precocious Puberty; Female and Male *Stenvert LS Drop and Hedi L Claahsen van de Grinten* 175

Organ-Specific Pediatric Endocrine Disorders, Pituitary: Craniopharyngioma *Timothy Shao Ern Tan, John Paul Kilday, and Leena Patel* 186

Hamartoma, Pituitary *G Patti, G Morana, N Di Iorgi, and M Maghnie* 196

Anorexia Nervosa *Maria Teresa Muñoz, Monserrat Graell, and Jesús Argente* 205

Endocrine Late Effects in Childhood Cancer Survivors *Wassim Chemaitilly and Laurie E Cohen* 216

Disturbances of Sodium and Water. Diabetes Insipidus in Children *Rasa Verkauskiene and Ruta Navardauskaite* 235

Obesity, Childhood, and Adolescence *Wieland Kiess* 247

Appetite and Weight *Clare H Llewellyn and Alison Fildes* 260

Management of Obesity in Children and Adolescents: Lifestyle and Exercise Options *James D Nobles and Paul J Gately* 269

Congenital Hypothyroidism: Screening, Early Management, and Outcome *Tim Cheetham* 280

Genetic Causes of Congenital Hypothyroidism *Nadia Schoenmakers* 291

Congenital Hypothyroidism: A Historical Perspective on Cognitive Outcome *Heiko Krude* 308

Hyperthyroidism, Childhood and Adolescence *Scott A Rivkees* 312

Thyroid Tumors in Children *Ari J Wassner* 322

Physiology of Fetal and Neonatal Calcium Metabolism *Jeremy Allgrove* 330

Rickets and Osteomalacia *Suma Uday and Wolfgang Högler* 334

Osteogenesis Imperfecta *Nick Bishop* 350

Hypercalcemia *Justin H Davies and Rebecca J Moon* 361

A Review of Skeletal Dysplasias for the Pediatric Endocrinologist *Sarah M Nikkel and Leanne Ward* 373

Premature Adrenarche *Antonis Voutetakis, Catherine Dacou-Voutetakis, Maria Dracopoulou, and Sarantis Livadas* 380

21-Hydroxylase Deficiency: Clinical and Biochemical Aspects *Anna Nordenström and Svetlana Lajic* 388

Prenatal Diagnosis and Treatment of Congenital Adrenal Hyperplasia *Svetlana Lajic and Anna Nordenström* 401

Steroidogenic Factor 1 (SF-1; NR5A1) *Ken McElreavey and Anu Bashamboo* 410

11β-Hydroxylase Deficiency *Krupali Bulsari and Henrik Falhammar* 416

Human P450 Oxidoreductase Deficiency *Christa E Flück and Amit V Pandey* 426

Pediatric Cushing Disease *Ingrid CE Wilkinson, Martin O Savage, and Helen L Storr* 439

Genetic Control of Fetal Sex Development *Rajini Sreenivasan, Brittany Croft, and Andrew Sinclair* 449

Hormonal Control of Fetal Sex Development *Nadine Hornig, Alexandra Kulle, and Paul-Martin Holterhus* 463

Classification and Presentation of Disorders of Sexual Development (DSD) *Kanthi Bangalore Krishna, Selma F Witchel, Christopher Houk, and Peter Lee* 471

Androgen Biosynthetic Defects: 17β-Hydroxysteroid Dehydrogenadse Type 3 and 5α-Reductase Type 2 Deficiencies *Nathalia L Gomes, Rafael L Batista, and Berenice B Mendonca* 481

Androgen Insensitivity Syndrome (AIS): Complete AIS (CAIS) *Jarmo Jääskeläinen* 487

Androgen Insensitivity: Partial AIS *Rieko Tadokoro-Cuccaro and Ieuan A Hughes* 496

Anti-Müllerian Hormone Deficiency and Resistance *Rodolfo A Rey, Jean-Yves Picard, Nathalie di Clemente, Richard L Cate, and Nathalie Josso* 501

Hypospadiac Genital Tubercle (GT) *Maguelonne Pons, Daniela-Brindusa Gorduza, and Pierre Mouriquand* 513

Undescended Testes *Ritzén E Martin* 521

Human Aromatase Deficiency *Gabriela Guercio, Nora Saraco, Mariana Costanzo, Roxana Marino, and Alicia Belgorosky* 527

Turner Syndrome *Theo CJ Sas, Janielle AEM van Alfen-van der Velden, and Sabine MPF de Muinck Keizer-Schrama* 545

Klinefelter Syndrome *Shanlee M Davis and Judith L Ross* 556

45,X/46,XY Gonadal Dysgenesis, 46,XX/46,XY Chimerism (and Variants), and 46,XX Testicular and Ovotesticular DSD *Martine Cools* 563

Intersexuality: Gender Assignment and Psychosocial Care *Heino FL Meyer-Bahlburg* 570

Ethical and Legal Aspects of DSD/Intersex *Jens M Scherpe and Jameson Garland* 581

Neonatal Diabetes Mellitus *Abdelhadi Habeb and Asma Deeb* 591

Congenital Hyperinsulinism *Indraneel Banerjee, Maria Salomon Estebanez, Karen E Cosgrove, and Mark J Dunne* 602

Beckwith–Wiedemann Spectrum *Eamonn R Maher* 618

McCune–Albright Syndrome *Erica A Eugster* 629

Noonan Syndrome *Michael A Patton and Alistair P Patton* 635

Prader–Willi Syndrome *Urs Eiholzer, Claudia Katschnig, and Annik Hauri-Hohl* 639

History of Endocrinology

Wouter W de Herder, Department of Internal Medicine—Sector of Endocrinology, Erasmus MC - University Hospital Rotterdam, Rotterdam, The Netherlands

The term "endocrinology" is a synthesis of the classical Greek words *endon* (within), *krinein/ekkrinein* (sift), and *logos* (speech, word, telling), denoting logy (a subject of study). Both "endocrine" and "endocrinology" were first used by the French physiologist Maurice-Adolphe Limon in 1904 (Limon, 1904).

In 1905, Ernest H. Starling (**Fig. 1**) first used the term "hormone." He defined hormones as chemical messengers, which are "carried from the organ where they are produced to the organ which they affect by means of the blood stream and the continually recurring physiological needs of the organism must determine their repeated production and circulation from the body" (Starling, 1905). Before that time, the term "internal secretion" had been introduced by Claude Bernard (**Fig. 2**) in 1855 (Bernard, 1879).

As early as 200 BC, the Chinese were already trying to isolate sex and pituitary hormones from the urine and using them for medicinal purposes. Around 655, they identified symptoms of diabetes mellitus, correctly associating it with sugar in the urine and around 1000, they used thyroid extracts to treat goiter (Temple, 2007). Ancient Greek and Roman scientists such as Aristotle, Hippocrates, Lucretius, Celsus, and Galen introduced the humoral approach to understanding biological function and disease. Early anatomists identified most relevant (endocrine) glands and tissues.

In the 19th century, two important endocrine diseases were first described: Robert Graves (**Fig. 3**) reported on a case of goiter with exophthalmos in 1835 (Graves, 1835). In 1840, Karl von Basedow (**Fig. 4**) independently reported on the same constellation of symptoms (Basedow, 1840). Thomas Addison (**Fig. 5**) described Addison disease in 1849 (Addison, 1849).

Already in 1792, John Hunter noted that castration of cockerels caused atrophy of their combs and wattles, but that this could be prevented if the testes were replaced in the abdominal cavity (Forbes, 1947). These experiments were repeated and confirmed in

1849 by Arnold Berthold (Berthold, 1849). It took until 1935 for crystalline testosterone to be isolated (David *et al.*, 1935). At the end of the 19th century, the concept of endocrinology was formally tested in two human experiments: the 72-year-old Charles-Édouard Brown-Séquard (**Fig. 6**) repeatedly injected himself with a watery mixture of blood from the spermatic vein, semen, and the extracted testicles of freshly killed healthy young guinea pigs and dogs. He stated that he had "rejuvenated" himself. He claimed that this therapy increased his physical strength and mental abilities, relieved his constipation, and lengthened the arc of his urine! Brown-Séquard's claim prompted many researchers around the world to pursue this new field of "organotherapy," and for a short period of time it was believed that the "fountain of youth" could be found (Brown-Séquard, 1889a, b). In the same era, George Murray introduced the successful treatment of myxedema with injections of sheep thyroid extract (Murray, 1891).

William Bayliss (**Fig. 7**) and Ernest Starling (his brother-in-law) discovered the first hormone, secretin, in 1902 (Bayliss and Starling, 1902). The most famous hormone, insulin, was discovered in 1921 in parallel by Nicolae Paulescu (**Fig. 8**) and the group of James MacLeod, Frederick Banting, Charles Best (**Fig. 9**), and James Collip (Paulescu, 1921; Banting and Best, 1922; Bliss, 1984). Already in 1889, Joseph von Mering and Oskar Minkowski made the observation that removing the pancreas from a dog resulted in severe and fatal diabetes mellitus (von Mering and Minkowski, 1890).

We know now that the human body has about 79 organs and that approximately 75 hormones circulate in the human body. In 1967, it was discovered that certain hormones could be derived from pro-hormones (Chretien and Mbikay, 2016). The most recently discovered hormone is Asprosin, a fasting-induced glucogenic protein hormone, which is secreted by white adipose tissue and is recruited to the liver. It was discovered in 2016 by the research group of Atul Chopra (Romere *et al.*, 2016). It is impossible

to review the discoveries of all the 75 known hormones, or all endocrine mechanisms in this historical overview. Therefore, only the main discoveries of hormones and/or endocrine mechanisms which led to Nobel Prize awards will be discussed further.

Not surprisingly, the Nobel Prize in Physiology or Medicine 1923 was awarded to Frederick Banting and John Macleod "for the discovery of insulin." Surprisingly, the other team members were not involved. Frederick Banting decided to share his prize money with Charles Best, and John Macleod gave half his award to James Collip (Bliss, 1984). The Nobel Prize in Physiology or Medicine 1936 was awarded jointly to Henry Dale and Otto Loewi "for their discoveries relating to chemical transmission of nerve impulses." Henry Dale and colleagues first identified acetylcholine in 1914 as a possible neurotransmitter (neurohormone), and Otto Loewi showed its importance in the nervous system (Loewi, 1921; Dale, 1914). The Nobel Prize in Chemistry 1939 was divided equally between Adolf Butenandt "for his work on sex hormones" and Leopold Ruzicka "for his work on polymethylenes and higher terpenes." In 1929, Adolf Butenandt isolated oestrone almost at the same time as the winner of the 1943 Nobel Prize for Physiology or Medicine, Edward Doisy (Butenandt, 1931). In 1931, Butenandt isolated androsterone (Butenandt, 1931). Adolf Butenandt, as well as Leopold Ruzicka, and independently of each other, obtained testosterone in 1939, a compound which had been purified from the testes by Ernst Laqueur in 1935 (Butenandt *et al.*, 1939; Ruzicka and Wettstein, 1935). Progesterone was isolated by Adolf Butenandt from the corpus luteum in 1934. The Nobel Prize in Physiology or Medicine 1947 was awarded to Carl Cori and (Gerty) Theresa Cori Radnitz "for their discovery of the course of the catalytic conversion of glycogen," and to Bernardo Houssay "for his discovery of the part played by the hormone of the anterior pituitary lobe in the metabolism of sugar." Bernardo Houssay's main contribution was on the experimental investigation of the role of the anterior pituitary in the metabolism of carbohydrates, particularly in diabetes mellitus. Houssay demonstrated the diabetogenic effect of anterior pituitary extracts and showed that the severity of diabetes decreased after anterior hypophysectomy (Houssay, 1942a,b). These discoveries were instrumental in initiating research into the mechanistic basis of hormonal feedback mechanisms. The Nobel Prize in Physiology or Medicine 1950 was awarded jointly to Edward Kendall, Tadeus Reichstein, and Philip Hench (**Figs. 10–12**) "for their discoveries relating to the hormones of the adrenal cortex, their structure and biological effects." Kendall was mostly recognized for the isolation, identification, and purification of several adrenal steroids. One of these isolated steroids was designated "Compound E," which subsequently became better known as "cortisone" (Mason *et al.*, 1936; Kendall, 1960). Tadeus Reichstein collaborated from 1953 to 1954 with James Tait, Sylvia Simpson Tait, Albert Wettstein, Robert Neher, and Marius Tausk in the isolation and characterization of aldosterone (Tait and Tait, 1998; Shampo *et al.*, 2013). Philip Hench collaborated with Edward Kendall in studies of the effect of Compound E (cortisone) on patients afflicted by rheumatoid arthritis (Hench *et al.*, 1949; Hench and Kendall, 1949). The Nobel Prize in Physiology or Medicine 1977 was divided between Rosalyn Yalow "for the development of radioimmunoassays of peptide hormones" and the other half was given jointly to Roger Guillemin and Andrew Schally "for their

discoveries concerning the peptide hormone production of the brain" (**Figs. 13** and **14**). Roger Guillemin and his research team focused on unraveling the hypothalamic biochemical regulation of anterior pituitary function and secretion. Independent from but also in competition with the research group of Andrew Schally, Roger Guillemin and his coworkers discovered thyrotropin-releasing hormone (TRH), growth hormone-releasing hormone (GHRH), and somatostatin (Guillemin, 1978a,b, 2008; Guillemin *et al.*, 1984; Brazeau *et al.*, 1973; Burgus *et al.*, 1970). In 1955, Andrew Schally and his research group studied corticotrophin-releasing hormone, TRH, luteinizing hormone-releasing hormone, GHRH, bombesin/gastrin-releasing peptide, and somatostatin (Saffran and Schally, 1955; Gual *et al.*, 1972; Kastin *et al.*, 1972; O'Byrne *et al.*, 1994). The Nobel Prize in Physiology or Medicine 1970 was awarded jointly to Bernard Katz, Ulf von Euler, and Julius Axelrod "for their discoveries concerning the humoral transmitters in the nerve terminals and the mechanism for their storage, release and inactivation." Katz and colleagues studied neurotransmitter release; von Euler and his group studied the production and storage of noradrenaline (von Euler, 1933); and Axelrod and coworkers studied the release, reuptake, and storage of adrenaline and noradrenaline (Hertting and Axelrod, 1961; Hertting *et al.*, 1961). Axelrod and his group also discovered and characterized the enzyme catechol-*O*-methyl transferase, which is involved in the breakdown of catecholamines, and studied the body's circadian rhythm, melatonin, and the pineal gland (Wurtman *et al.*, 1963, 1964). The Nobel Prize in Physiology or Medicine 1982 was awarded jointly to Sune Bergström, Bengt Samuelsson, and John Vane "for their discoveries concerning prostaglandins and related biologically active substances" (Raju, 1999). The Nobel Prize in Physiology or Medicine 2010 was awarded to Robert Edwards "for the development of in vitro fertilization." Edwards began his fundamental research on the biology of fertilization in the 1950s. In 1969, a human oocyte was fertilized for the first time in a test tube. Research in the IVF field was continued in collaboration with Patrick Steptoe, and on 25 July 1978, a healthy baby named Louise Brown was born through a Caesarean section after a full-term pregnancy, following

successful IVF (Edwards, 1965; Steptoe and Edwards, 1978) (**Fig. 15**). The Nobel Prize in Chemistry 2012 was awarded to Robert Lefkowitz and Brian Kobilka "for studies of G-protein–coupled receptors." In 1968, Lefkowitz and his team started to use radiolabeled tracers to try to identify cell surface receptors. He and his team managed to unveil several receptors, among which were the ACTH receptor and the β-adrenergic receptor (Lefkowitz *et al.*, 1970a,b; Dixon *et al.*, 1986). In 1980, Kobilka joined the team. He succeeded in isolating the gene encoding for the β-adrenergic receptor and, furthermore, capturing an image of the crystalline structure of the β-adrenergic receptor (Rasmussen *et al.*, 2007; Cherezov *et al.*, 2007; Rosenbaum *et al.*, 2007).

As demonstrated above, the Nobel Prize committee has awarded their prestigious award several times to endocrinologists over almost 100 years. Endocrinology, thereby, has shown that it has always been a front-runner in the field of medicine. Let us hope it will keep this privileged position in the future and will keep on continuously rejuvenating itself. In line with this, it is reassuring that Vladimir Mironov and colleagues have succeeded in producing the first functional 3D bioprinted thyroid for implantation in mice in 2015.

Statistics in Endocrinology: Meta-Analysis Advantages and Pitfalls

Olaf M Dekkers, Leiden University Medical Centre, Leiden, The Netherlands

Introduction

In 2004, the Lancet published a meta-analysis on the potentially increased risk for cardiovascular events in patients using Rofecoxib (Juni *et al.*, 2004). The study showed that Rofecoxib was associated with a more than twofold-increased risk for myocardial infarction compared to other painkillers. In a cumulative meta-analysis, the authors also showed that the evidence for an increased cardiovascular risk could have been known 3 years before the publication if the meta-analysis had been performed earlier.

This Rofecoxib example undoubtedly shows the potential of a meta-analysis: by systematically searching and assessing all the literature published on a specific topic, a robust answer to a research question can be provided. In the Rofecoxib case, all single randomized studies were not designed to show or rule out an effect of Rofecoxib on cardiovascular events. A major advantage of a meta-analysis is that combining estimates increases the precision, which enables the showing of associations that go unnoticed in single (small) studies. This is especially important in the context of side effects, where single randomized studies are by design not designed to detect rare outcomes.

A similar example was a meta-analysis on mortality risk in acromegaly. Although individual studies did not show a statistically increased risk, the combined estimate clearly showed that acromegaly was associated with an increased mortality risk (Dekkers *et al.*, 2008).

Meta-analyses are generally seen to provide high-level evidence. However, it is important to notice that the mere term "meta-analysis" is not a guarantee of high-quality evidence. The main reason is that any meta-analysis ultimately depends on the quality and validity of included studies; and if a meta-analysis is based on low-quality studies with limited internal validity, then the answer provided by the meta-analysis is still not valid; put simply, it is "garbage in, garbage out."

Formally, a distinction can be made between a systematic review and a meta-analysis. A meta-analysis is the mere statistical combining of studies deemed by the authors to be combinable. A systematic review consists of all other important elements of the review such as writing a protocol, a systematic search of the studies, and analysis of bias risk. This means that a systematic review can occur without a meta-analysis, if the authors decide not to combine study effects statistically for any reason. However, a meta-analysis should always be accompanied by a systematic review, as this includes crucial elements such as the systemic search and assessment of bias risk. Yet the distinction between a systematic review and a meta-analysis is not consistently made in literature.

The Research Question

As with other all research, a systematic review starts with a research question. In contrast to randomized trials, for example, research questions for systematic reviews are generally broader. Think of a randomized controlled trial on the treatment of subclinical hypothyroidism. Researchers can decide upfront whether to include only patients with TSH levels >10 mU/L, whether to apply treatment for a period of 1 year or 2 years, and what the target TSH should be. Also, with regard to endpoints, researchers can decide to focus on quality of life, clinical or biochemical parameters, or cardiovascular endpoints.

This is clearly different from a systematic review, where the researcher is ultimately dependent on what is "out there." It is therefore often not meaningful to start with a research question that is narrow or even extremely specified. A systematic review on the effect of 8 weeks of levothyroxine treatment on the quality of life in women with a TSH of 8–15 mU/L will almost certainly reveal no studies on the topic. One approach, and also opportunity, is to define the population under study broadly and not to be restrictive with regard to endpoints considered. This has the advantage that the systematic review provides a broad picture of a treatment effect of a drug (e.g., levothyroxine for subclinical hypothyroidism) or the effect of a risk factor (e.g., Cushing's disease) on a range of outcomes. The downside of such an inclusive approach is that much heterogeneity between studies can be expected a priori, which may hamper firm conclusions.

For systematic reviews on observational studies, the definition of exposure (i.e., the risk factor under study) requires careful consideration. Think of a systematic review on the effect of overweight on cortisol levels. As the researcher is not in control of the data, different ways of classifying body weight may have been used in different studies. Studies may have used BMI, but also waist-hip ratio to classify overweight. In addition, studies may be published using more advanced techniques to measure body fat (MR liver) and researchers should consider first whether it is meaningful to combine studies with different definitions of an exposure in one review. It should be borne in mind that if it is decided at an early stage to be inclusive in the approach, this does not mean that researchers assume a priori that all studies are combinable in one overall effect estimate.

These considerations show that defining a research question for a systematic review is a balancing act: if the question is too narrow, no studies may be eligible; if the question is too broad, between-study heterogeneity may prohibit a meaningful overview.

The Protocol

It is helpful to write a protocol that contains the strategy for the different elements of the systematic review and meta-analysis. Guidance has been published on how to write such a protocol (Shamseer *et al.*, 2015). Publication of the protocol is generally advised, although publication of protocols is still rare (Page *et al.*, 2016).

Although the protocol can be written without knowing what has been published on a specific topic, the researchers doing a systematic review will generally have an idea on what information is available. This prior knowledge should not completely guide the protocol for two reasons: (1) such prior knowledge is fallible, and it might be that important papers only show up after a systematic search; and (2) a negative statement can be an important message from a systematic review. Think again of a systematic review on the effect of levothyroxine treatment in subclinical hypothyroidism based on data from randomized trials. The researchers may consider not including mortality in the protocol, as they assume there are no trials studying this endpoint. It can be argued that mortality as an endpoint should be included in the protocol as, although unlikely, there may be a trial with data on mortality (point 1). However, even if no individual study addresses this important endpoint, the systematic review can come up with an important negative statement that points towards a gap in current knowledge (point 2).

Researchers should consider carefully how much detail to include in the protocol, as some decisions cannot be spelled out in advance in full detail. This may be mainly the case for systematic reviews of observational studies. The statistical analysis of a meta-analysis comparing two different treatment options (A and B) is fairly straightforward, and such an analysis can easily be pre-specified in a protocol. But for other topics, the statistical analysis will depend on what the data structure of included studies will look like. An example is a meta-analysis on the association between IFG1 and mortality risk (Burgers *et al.*, 2011). As different studies provided mortality risks for different IGF1 cut-offs (e.g., tertiles or quintiles), dose response modeling was performed to quantify the IGF1-mortality association. The statistical methods used will depend on how data are reported and whether unadjusted or adjusted relative risks are considered to be more valid. In such a case, the protocol may contain general remarks about dose-response analysis, with details omitted.

Searching and Including Studies

It is generally advisable to search in different electronic databases for eligible studies, since for most systematic reviews, no single database has full coverage of relevant papers (Lemeshow *et al.*, 2005). Commonly, three databases are searched (Page *et al.*, 2016). In addition to using electronic databases, checking key articles for relevant references can be of added value. An additional strategy is to track down important papers by looking into other papers that cite the former.

Searching electronic databases should be done in close collaboration with a trained librarian, for the reason that writing a search string requires knowledge of database-specific terminology and indexing. It is very helpful to define a set of key articles that should be detected by the search strategy for two reasons. Firstly, in this way the sensitivity of the search can be checked, and secondly, the librarian can use the articles to see how a specific topic is indexed in different databases.

In addition to the sensitivity of the search (does the search detect the important articles?), the specificity of the search also requires consideration (how many non-relevant papers are retrieved?). Especially for broadly formulated research questions the specificity of the search can be low, which means that many articles are retrieved, thereby increasing the workload considerably. For example, the search from a systematic review on the association between corticosteroid use and adrenal insufficiency identified 3616 papers, of which finally only 74 were eligible (Broersen *et al.*, 2015). It could be important to consider restrictions in the search to optimize its specificity. For example, if only studies with newer operation or imaging techniques are considered to provide relevant information for the research question, restrictions in calendar time may reduce the workload significantly.

Having two researchers to decide on eligibility may be relevant, because not all decisions may follow automatically from the eligibility criteria and some decisions may require discussion. If researchers restrict the review to studies in adult populations, it may turn out that some studies have included a small number of patients below adult age. If data are presented separately for adults and non-adults, only the data on adults can be extracted. If this is not the case, the researchers should make a decision regarding what proportion of non-adult patients is considered acceptable for a paper to be eligible.

Risk of Bias

A risk of bias analysis is central for every meta-analysis. It provides a judgment on how likely studies included are valid. This is crucial, as individual studies of limited internal validity will pose a direct threat to the validity of the meta-analysis.

Risk of bias is not synonymous with study quality. A high-quality study can be defined as a study that is optimally performed given the research question. But that does not mean that the study can assumed to be at low risk of bias by default. Consider a study on quality of life after two types of operation for an adrenal tumor: laparoscopic versus open surgery. Even in an optimally designed trial, the patients can never be blinded, which places the study at a higher risk of bias. On the other hand, if the sample size of a study is not well calculated, the risk of bias will not automatically be high. Incorrect sample size calculation will often translate into wide confidence intervals, and thus lower weight in the meta-analysis of a study; however, it will not affect risk of bias. In short: there is no direct translation from study quality in risk of bias.

Bear in mind that for a risk of bias analysis, reviewers have to deal with how a study is reported, and the reporting of the study may not always be a perfect measure for how that study is actually conducted. For example, it has been shown that treatment concealment is often well implemented, but not adequately reported (Soares *et al.*, 2004). Although reporting guidelines have improved reporting of studies, empirical studies have shown that reporting is still far from perfect (Poorolajal *et al.*, 2011).

For systematic reviews of randomized trials, a standardized risk of bias approach is generally accepted. This so-called Cochrane tool to assess the risk of bias in randomized trials consists of the following key domains (Higgins *et al.*, 2011).The key elements to be judged for each included study are:

- randomization;
- concealment of allocation;
- blinding of patients and care takers;
- blinding of the outcome assessment;
- incomplete outcome data; and
- selective reporting.

Whereas some elements of trial conduct may introduce bias for a study as a whole (adequate concealment of allocation, for example), other elements (blinding) may apply to specific outcomes only. For example, blinded outcome assessment is crucial for a valid assessment of radiological images, but not for mortality.

Researchers should judge the risk of bias for every study and preferably report the judgment in a transparent way at the level of individual studies. It should be kept in mind that risk of bias focusses on the internal validity, and should not include a judgment about generalizability. The reason is that risk of bias should facilitate the judgment of the study's effect estimate being valid, which is clearly different from a question about how well the results apply to other populations (generalizability) (Dekkers *et al.*, 2010).

For systematic reviews of observational studies on interventions, progress has been made in terms of how to perform a risk of bias analysis (Sterne *et al.*, 2016). However, the application of the published tool requires in-depth understanding of advanced epidemiological concepts. For systematic reviews about etiology, no widely accepted way to judge risk of bias is available; this was underlined by a review identifying 86 different tools (Sanderson *et al.*, 2007). A widely used tool, the Newcastle Ottawa scale, is not well validated (Stang, 2010).

A sensible approach for systematic reviews on etiology is to apply a risk of bias tool that is tailored to the research question under study. Researchers should thus think carefully which design elements can introduce bias in the included studies. Clearly, assessment of confounding is crucial for such a review. In case of confounding baseline imbalances in prognostic variables potentially bias estimated effects, and such confounding is not simply remedied by statistical adjustment. (Bosco *et al.*, 2010).

A specific type of bias that goes beyond individual studies is publication bias. This is the bias that arises when studies with significant results are more likely to get published, which distorts the full picture of the review. A study comparing published to non-published data for antidepressants, for example, showed an overestimation of the positive effect up to 50% when only the published data were taken into account (Turner *et al.*, 2008). Although publication bias is a significant threat to reviews in particular, this form of bias is a problem that can invalidate any overview of the medical literature, whether it is intended to inform guideline policy makers, regulatory instances, or doctors, or whether it is meant for scientific purposes only.

Clinical and Statistical Heterogeneity

For most systematic reviews, some diversity between included studies can be expected a priori. Studies will have included slightly different populations, will have different definitions of exposure or outcome, or may have investigated patients in different settings (primary care versus hospital care, for example). Such differences are an important result of the systematic reviews, and as such should be displayed (Blair *et al.*, 1995). As heterogeneity is an important feature of the review, such heterogeneity can be used for further exploration. Why and in what respect do studies differ? Do these differences translate into differences in effects?

Statistically, there are two measures of heterogeneity: the I^2 statistics and the Cochrane's Q-test. The I^2 statistics (formally not a test) expresses the percentage of variability between studies that cannot be attributed to chance (Higgins *et al.*, 2003). The Q-test tests whether there is evidence for between study heterogeneity; a *P*-value <0.05 is generally considered as evidence for heterogeneity. The problem with the Q-test is its low power to detect heterogeneity in reviews with few studies included (<10 as a rule of thumb); given that almost half of the reviews include fewer studies (Page *et al.*, 2016), this low power should be considered, in which case a non-significant *P*-value provides no evidence for homogeneity.

It is important to note that the absence of obvious heterogeneity is not an argument for the validity of the meta-analysis. The reason is obvious: all studies may for the same reason be biased. This was shown in a meta-analysis on the effect of beta-carotene on cardiovascular events (Egger *et al.*, 1998). Five out of six observational studies showed a consistent protective effect of beta-carotene; only the smallest study showed a null effect. As expected, the meta-analysis of these six studies showed a protective effect. However, as all randomized trials failed to show such a positive effect, the observational studies were likely all biased (healthy user effect).

There is unfortunately no straightforward answer to the question of how much heterogeneity is acceptable when considering a formal meta-analysis. Clearly, too much diversity between included studies can be an argument, and not give an overall pooled

effect. Out of all systematic reviews, a formal meta-analysis was performed in approximately 70% (Page *et al.*, 2016). However, if heterogeneity is considered important, this might also be an argument for subgroup analyses only, or for assessing heterogeneity in a meta-regression framework. Conceptually, a random effects model (see below) does not assume complete homogeneity when combining studies statistically, which can be a reason to use a random effects model in the case of heterogeneity. It should, however, be kept in mind that, although allowing for heterogeneity, the random effects model does not actually explain heterogeneity.

Statistical Analysis

A formal meta-analysis is nothing more complicated than the weighted average of study specific effects. The combined estimate can thus in no way fall outside the range of estimates of studies included in the meta-analysis. Mostly, weighting is performed according to the inverse of the standard error, and as standard errors are closely related to study size, larger studies receive more weight in a meta-analysis.

The forest plot is a graphical display of the effect estimates of individual studies, the weights that individual studies are given in the analysis (often displayed as either a percentage or as a box, with larger boxes representing larger weights), and the weighed combined estimate.

There are two statistical approaches that can be used for a meta-analysis: a fixed effect and a random effects model. The basic difference between these two models relates to the underlying assumption of the model. A fixed effects model assumes that the underlying true effect is the same for all studies, and that differences between studies are due only to chance. This assumption is rather strong, as mostly some heterogeneity will exist, due to either design or patient characteristics. In contrast, a random effects model relaxes this assumption, and assumes that underlying true effects between studies may differ. Especially in the context of observational studies, the random effects assumption may be more realistic (Egger *et al.*, 1997). Statistically, the estimates from the two models are identical if there is no between-study heterogeneity, whereas in the presence of heterogeneity, fixed and random effects models will give different answers. Generally, the confidence intervals of random effects estimates are wider. A second characteristic of the difference is that in a random effects model, the weights become more similar, meaning that smaller studies receive relatively more weight.

There is no ultimate answer to the question of which model to use. However, it seems reasonable to start with a random effects model if heterogeneity is expected.

Network Meta-Analysis

Standard meta-analytic techniques deal with a set of studies that compare two different treatments—for example, levothyroxine and placebo—and the meta-analysis provides a weighted average of study-specific effects. However, these standard techniques cannot account for a situation where more exposures should be compared (e.g., three or more drugs for the same indication). In such occasions a network meta-analysis may be a useful technique.

The basic idea behind network meta-analyses is that if you have the results of a comparison for drug A versus B and also some studies with data on the comparison of A versus C, these data allow the estimation of the effect of B versus C. If the evidence for the B versus C comparison only comes from studies on A versus B and A versus C, than we call the evidence for B versus C "indirect." It might also be that some data also come from studies for B versus C ("direct evidence"), and in this case the network meta-analysis will use both direct and indirect data, combined in "mixed effects." The main assumptions for the validity of a network approach is that results from direct and indirect evidence do not contradict each other, and the studies included are sufficiently similar with regard to clinical and methodological characteristics (Cipriani *et al.*, 2013).

Evolution of Hormonal Mechanisms

Vincent Laudet and Gabriel V Markov, Sorbonne University, Banyuls-sur-Mer, France

Abbreviations

3,5-T2	3,5-Diiodothyronine
AR	Androgen receptor
CO	Carbon monoxide
ER	Estrogen receptor
FSH	Follicle-stimulating hormone
FXR	Farnesoid X receptor
GR	Glucocorticoid receptor
LH	Luteinizing hormone
LXR	Liver xenobiotic receptor
MR	Mineralocorticoid receptor
NO	Nitric oxide
PR	Progesterone receptor
Rev-erb, E75	Nuclear heme-binding receptors
TH	Thyroid hormones
TRIAC	Triiodothyroacetic acid
TSH	Thyroid-stimulating hormone

Glossary

Endocrine signaling Distant intercellular signaling through a body fluid.

Exocrine secretion Secretion of molecules (independent of their physiological role) outside the body cavity, mainly through the digestive system.

Paracrine signaling Local intercellular signaling that does not involves a transport by a body fluid.

Introduction: The Evolution of Hormonal Systems in the Context of Animal Evolution

Hormones are biologically active molecules that are secreted to the blood-stream by a gland, acting remotely and transported to target cells that express specific receptors. Hormones are therefore key messengers of chemical information. The endocrine system, with a wide range of hormones, is the body's second-largest regulatory system, and it works in synergy with the nervous system, which acts very quickly, in a few milliseconds, and whose action does not last much longer. Typically, the endocrine system is much slower, it can take a few seconds or even days to react, but its action can be felt also over a period of several days or even weeks.

The endocrine system fulfills the need of cells and organs to communicate with each other within the body to organize growth, differentiation and cell division in the adult but also during development. The term "hormone" (from a Greek term meaning "set in motion") was adopted by the British physiologist Ernest Starling in 1905 to designate the substances that provide the link between various organs (Sta rling, 1905). They are effectively the key in the coordination of physiological responses in different organs.

There are thousands of different hormones that control virtually all biological processes. Some cause emergency reactions (i.e., adrenaline), others play a regulating role (i.e., insulin, which regulates the glucose level in our blood), still others play a role in the management energy, adaptation to the external environment (temperature for example), the amount of water in the body, salt and ion concentrations, growth, reproduction (the estrogens and androgens that determine female and male sexual characters respectively), blood pressure, digestion etc. Also, some hormones like ecdysone that controls molting in insects or thyroid hormones that control the metamorphosis of a tadpole into a frog, are key regulators of life cycle transitions in animals. Very often, a hormone has several simultaneous effects, and interacts with other substances or hormones and it is more and more important to realize that hormone action is exquisitely regulated at the tissue level by extraordinarily complex and finely tuned mechanisms (Tata, 2005). It is now well demonstrated that controlling the amount of hormone or hormone signaling levels is of critical importance, hence the worry about the widespread presence in the environment of hormonally active pollutants acting as endocrine disruptors (Denver *et al.*, 2009).

Given the variety of hormones and their modes of action, discussing their evolution in general is a challenge. There are, however, a number of general principles that seem valid for all hormones. The first is that at the heart of hormonal systems and their evolution is the hormone/receptor couple. To understand the evolution of this couple we must separate protein or peptide hormones from hormones that are small molecules produced through complex biosynthetic pathways. The second is that the peripheral mechanisms that control the availability of ligands and their activation are extraordinarily important and have been too far neglected. But before we get to the heart of the matter, we need to look at the history of animals in order to have a framework in which we can discuss the evolution of hormonal systems.

More than a century ago, biologists were interested in the origin of animals, which in zoological terms are called the metazoans. They first asked when and how multicellular animals appeared. Paleontology provides some answers and suggests that

 doi:10.1016/B978-0-12-801238-3.64198-3

animals are at least 650 million years old. But it is impossible to know how the first metazoans were built, because the oldest fossils attest a rather long earlier evolution giving almost no clues on the very first metazoans. These fossils are remains of already diversified animals, presenting with several modes of organization. They belong to the so-called Ediacara fauna, named after the Ediacara hills in Australia where they were initially exhumed, before they were also found on other continents. Their burial goes back to 600 million years ago. Therefore there is a deep and partly hidden history of metazoans and we mostly rely on molecular phylogeny, the reconstruction of the history of living Metazoans, to obtain some information on what could have been the first metazoans (Budd and Jensen, 2017).

The formation of metazoans required many innovations. It was necessary to join together cells, allow them to communicate with each other and to specialize. It was also necessary to build with each generation a new organism from a single cell; therefore to invent embryogenesis. Given the major role of hormonal systems in controlling cell differentiation, embryonic development, homeostasis and long-range communications in the body, it is evident that the establishment of the very first hormonal systems were somehow concomitant with the establishment of the first metazoans.

This is why it would be interesting to study in more detail the mechanisms of cellular communication in choanoflagellates, the sister group of metazoans. These are flagellated unicellular organisms that sometimes exhibit a colonial way of life and live either free-swimming in open water or fixed on a substrate. There are more than 125 widely distributed and often abundant species and the inventory is certainly not exhaustive. As, they are considered to be the closest living relatives of early animals they are used by evolutionary biologists as a model for reconstructions of the last ancestor of metazoans (Brunet and King, 2017).

It would be important also to have information about the very first phyla of metazoans. However, this question is very controversial because the phylogeny of basal metazoans is not completely resolved (Simion *et al.*, 2017; Whelan *et al.*, 2017). Depending whether sponges (sessile multicellular organisms with a simple body without obvious symmetry) or ctenophora, also known as comb jellies, (ciliated transparent carnivorous marine organisms with a rotational symmetry) are considered as the most basal metazoan group, the most ancient metazoan organism inferred would be very different. In one case it would be a relatively simple sponge-like inactive animal whereas in the other it would be more active and organized, with a primitive symmetry. We cannot discuss here further the implications of these two visions that are still unresolved but we can however insist on the fact that the resolution of this question will have implication for the level of complexity of global communication devices existing in the first metazoans. Clearly, in both cases, because they lack an internal circulating body fluid, these animals cannot have a classical hormonal system in which hormones are transported in the blood. However this does not mean that there is no intercellular signaling in those animals. Indeed the classical view of hormones defined as internal circulating molecules is changing and the frontier between hormones and growth factors and other paracrine signaling molecules is becoming more and more blurry with the acknowledgment of many short-range functional roles of hormones.

The Evolution of the Hormone/Receptor Couple

At the heart of the hormonal systems is the hormone/receptor couple. According to the classical vision, highlighted in numerous textbooks, hormones specifically turn on their receptors by fitting into a hormone-binding site (also called ligand binding pocket or LBP) as a key fills a lock. However, it is becoming increasingly clear that this view is by far too schematic and that in reality the situation is much more plastic. This should be emphasized as it may have implications at the evolutionary level. This plasticity is well exemplified in the case of nuclear receptors that are ligand-activated transcription factors mediating the effects of numerous hydrophobic hormones such as steroids or thyroid hormones. First, this family of well-conserved receptors illustrates very well that the strong difference we often make between hormones (signaling molecules acting at distance from their origin and transported by blood) and growth factors (signaling molecule acting close to its origin and even sometimes on neighboring cells) do not correspond to the biological reality. Indeed, the nuclear receptors cluster receptors for hormones (e.g., estrogens) but also to growth factors (e.g., retinoic acid) and even active molecules directly derived from food (e.g., fatty acids), and some compounds, such as steroids, can act both as distant hormones and local paracrine signaling factors. All these different classes of compounds act in a very similar fashion by regulating a gene regulatory cascade through a well-conserved superfamily of receptors. Second, the structural variety of ligands acting through nuclear receptors is really impressive and questions the distinction between ligands, that is molecules capable of binding and activating a receptor, and prosthetic group defined as organic molecule maintained permanently in a protein structure and essential for its activity. This is shown by the Rev-erb/E75 receptors that are able to bind heme, the well-known prosthetic group of hemoglobin. In Rev-erb, heme, a large molecule, is also permanently bound in the structure and its redox status controls the activity of the receptor. It is a gas, nitric oxide or carbon monoxide, that controls the redox status and heme and therefore the activity of the receptor. Therefore E75 in *Drosophila*, but also Rev-erbs in vertebrates, are biological sensors for diatomic gasses such as NO and CO (Marvin *et al.*, 2009). This example illustrates very well that hormone receptors can have a much diverse set of ligands than anticipated. Third, and lastly, it is now clear that a given receptor can bind, sometimes with different affinities, a diverse set of ligands that all have clear biological activities. This is well exemplified by the case of vitamin D receptor whose natural ligand is 1,25-dihydroxycholecalciferol regulates calcium metabolism, in particular in the bones. But the same receptor can also be activated in the liver and intestine by a bile acid, lithocholic acid that in fact controls its own degradation as it is a carcinogenic compound (Makishima *et al.*, 2002). Many other nuclear receptors are no longer viewed as highly specific for a small set of ligands that they bind with high affinity but are rather sensors that can be activated by many different compounds on which they bind with a much lower affinity (Sladek, 2010). This is the case for many nuclear receptors

implicated in the control of metabolism (e.g., LXR, FXR etc.…). Therefore the key-lock model although not wrong is an over-simplification and we should keep it in mind when discussing the evolution of hormone-receptor couple.

Being either nuclear receptors that activate a set of target genes or membrane receptors acting through second messengers, the hormonal receptors should of course control a specific response in order to fulfill their physiological need. Insulin must promote the absorption of glucose present in the blood, whereas glucagon, on the contrary causes an increase of the amount of glucose in the blood. Therefore, even if more complex than the key-lock model, specificity is a key concept for the hormone-receptor couple. And this specificity could rely on quite tiny differences. Let's compare the structure of 17β-estradiol and 5α-dihydrotestosterone, the respective ligands of estrogen and androgen receptors responsible of female, and male sex features respectively: one carbon and six hydrogen atoms differ between the two molecules that both harbor the classical steroid skeleton. Therefore, even if somewhat plastic, the receptors must recognize their ligands and not others. This question of specificity is the key in our understanding of the evolution of hormone-receptor couples.

For discussing how the hormone-receptor couple can evolve it is necessary to clearly separate two cases: the receptors for peptide or protein hormones in which both the hormone and the receptors are encoded by genes and the case of receptors for small molecules which are derived from a metabolic pathway that is a series of chemical reactions modifying a precursor compound.

When both hormone and receptor are encoded by genes, the situation is conceptually simple: when a mutation occurs on one of the partners, let say the ligand, a compensatory reaction must occur in the other partner, here the receptor, to allow the binding to be maintained. In case of gene duplication it is therefore quite simple to see how a ligand and a receptor couple can diverge from one another. This has been beautifully illustrated in the 90's by the case of FSH and LH and their respective receptors (Moyle *et al.*, 1994). It has been shown in that case that precise regions of the ligands act as determinants that restrict ligand-receptor interaction, therefore enabling selectivity and explaining binding specificities in a family of homologous ligands and their receptors. This model applies easily to cases where the respective members of the couple belong to the same families and render more easily tractable the structural basis of the selectivity (see Jiang *et al.*, 2014 for glycoprotein hormones). But this is not always the case and in other ligand–receptor pairs (e.g., cytokines) the receptors belong to the same family but their ligands belong to distinct families (Liongue *et al.*, 2016). However this model has well resisted the time (Szkudlinski, 2015) and has been extended to some other ligand-receptor couples such as ghrelin (Tine *et al.*, 2016), oxytocin (Yamashita and Kitano, 2013; Ren *et al.*, 2015) and even outside the endocrine field in the context of protein–protein interactions (Lovell and Robertson, 2010).

The situation is different when the ligand is not encoded by a gene but is a small molecule whose synthesis is controlled by a series of enzymatically-controlled biochemical reactions. This aspect has been studied in more details in the case of steroid receptors. The case is effectively interesting as the five steroid hormone receptors and their respective ligands in humans and other mammals (ER/estrogens, PR/progesterone, AR/androgen, as well as MR and GR/corticoids) arise from the same common ancestor. This raises the question: how did these receptors acquire their specificity with respect to their hormone molecule? As a simple coevolution mechanism obviously cannot operate, alternative models such as the ligand exploitation model (Thornton, 2001) have been proposed to explain how changes of specificity can take place during evolution. According to this model, the terminal ligand in a metabolic pathway has to be the primordial ligand for which a receptor should exist. The existence of this ligand implies the existence of intermediate molecules in the metabolic pathway since however the terminal ligand will not be maintained. In case of duplication of the gene encoding the receptor some duplicated copies can therefore exploit (hence the name of the model) these intermediate compounds. This may explain how novel hormone-receptor pairs can be created.

The ligand exploitation model has been proposed in the case of the estrogen receptors that was considered with its ligand 17β-estradiol to be the primordial steroid-receptor couple (Thornton, 2001). However this model has a fundamental limitation as it considers that the receptors are evolving but that the ligand remains the same across time. We know that this cannot be true and indeed in the case of estrogens this is not true. Detailed comparative genomics have shown that estrogens are a vertebrate specific compound and that the estrogen receptor in invertebrates should therefore have a different endogenous ligand. The fact that some invertebrate estrogen receptors effectively bind 17β-estradiol is therefore a pharmacological effect, unrelated to their endogenous ligand and physiological function that remains unclear.

Even if one cannot speak about direct coevolution, when the receptor is considered, the evolution of the ligand-binding pocket can occur by the slow accumulation of mutations that gradually change the structure of the pocket and its specificity. This has been exquisitely shown for the steroid receptors (Bridgham *et al.*, 2009), but also for retinoid receptors (Gutierrez-Mazariegos *et al.*, 2016) as well as for membrane receptors, in the case of cannabinoid receptors. Here the enzyme implicated in the metabolism of anandamide and 2-arachidonyl glycerol, the two endogenous ligands of cannabinoid receptors, have been shown to follow the evolution of the receptor suggesting some sort of coevolution (McPartland *et al.*, 2007).

Clearly the evolution of small molecules and their receptor should now be scrutinized in greater detail and this is becoming possible. Indeed by scrutinizing on steroidogenesis it has been possible to reconstruct an ancestral receptor-ligand couple (Markov *et al.*, 2017). For this the authors have retraced the history of steroidogenesis using an approach developed for the analysis of universal metabolism (Cunchillos and Lecointre, 2007). The originality of the approach was to use comparative anatomy methods to study evolution at a biochemical level. It is a simple principle: as with animal anatomical features, metabolic pathways are the product of evolution and are modified over the course of time. Using phylogenetic tree construction methods it is therefore possible to infer the evolution of the steroidogenic pathways and to show that, as suggested by comparative genomics approach the five steroid hormones share a unique common ancestor at the basis of vertebrates and are therefore specific to vertebrates. Interestingly, such an evolutionary tree makes it possible to predict the molecules that were present at each evolutionary stage, so it

was possible to determine the structure of the ancestral steroid. This molecule called "paraestrol A" was chemically synthesized and shown to bind and activate an ancestral receptor that was also predicted by molecular phylogeny. This interaction was confirmed by structural modeling, allowing to explain how the receptor specificity to its ligand was reinforced over the course of evolution. This "resurrection" of an ancestral hormone/receptor couple opens up the way to the study of small molecule evolution and is therefore opening a new era, as it will undoubtedly be reproduced in the case of other receptor-ligand couples.

Evolution of Peripheral Control of Hormone Response

Whatever the receptor system, the hormonal response must be carefully regulated both in time and space. The transport of hormones, their entry into target cells when needed, their activation in target tissues, or their degradation after use allows to precisely controlling the duration and magnitude of hormone response. Every step is regulated and therefore every step can be used by natural selection in order to allow the organisms to be in register with their environment, ultimately leading these organisms to be adapted.

The importance of a tight regulation of peripheral hormonal regulation is well exemplified by the case of the early metamorphosis of desert frogs (Buchholz and Hayes, 2005). Living in ephemeral desert pools, the spadefoot toad *Scaphiopus couchii* has the shortest larval period known among frogs, as it must complete its metamorphosis before complete drying of the pool. In this species, differences in TH physiology correlating with larval period differences were identified and are consistent with the notion that selection favoring rapid metamorphosis to avoid desiccation acted, at least in part, through TH physiology that occurred on a tissue-by-tissue level. This suggests that an increase in tissue thyroid hormone content and/or increased tissue sensitivity occurred in the ancestors of *Scaphiopus couchii*. Such a higher tissue response to higher TH levels led to more rapid transformation of metamorphic tissues and therefore to the adaptation to the ephemeral nature of the pond. This example shows very well how an important, and even vital change in larval period duration can be obtained by altered endocrine signaling and beautifully illustrates how change in hormonal response can play an important role. Other recent similar examples, among others also include the central regulation of TH level by TSH in freshwater versus marine sticklebacks (Kitano *et al.*, 2010) or the variation in tooth number controlled by the local production of retinoic acid in cypriniform fishes (Gibert *et al.*, 2015).

Even if given the wide diversity of hormonal systems it is difficult to generalize, it is interesting to note that the enzymes used to regulate in space and time the level of hormone signaling are effectively variable during evolution. Clearly the various enzymes controlling hormone availability vary often in number in different species and are therefore likely contribute to evolutionary innovations in the control of hormone response. For example the 3β-hydroxysteroid dehydrogenase, an essential enzyme involved in the biosynthesis of all classes of steroid hormones, is present in at least six genes in mouse, four in rats, three in hamster and two in humans, all coming from species-specific gene duplications (Simard *et al.*, 2005). Similarly, but in a different scale, the number of deiodinases, essential enzymes that control the tissue availability of triiodothyronine, the active thyroid hormone, is also changing in chordates: there are three deiodinase genes in most vertebrates, but at least five in the cephalochordate amphioxus and only one in sea squirt (Paris *et al.*, 2008). We could multiply the examples: the proteins controlling hormone production and availability in tissues are much more variable than those of the receptors. In addition detailed analysis of their sequence evolution often reveal strong evolutionary pressures in action.

Given these observations, the notion that the ligands are evolving should not come as a surprise. Of course this has been widely accepted since a long time for protein hormones but for obscure reasons this has remained virtually unexplored for small molecules. Strikingly, this was known since a long time for specific cases but never generalized. Indeed rodents and primate do not have the same major corticosteroid: cortisol is the major corticoid in human as well as most other mammals whereas corticosterone is the active compound in rodents. Similarly, in teleost fish the active androgen is 11keto-testosterone a derivative of testosterone. These cases clearly show that hormones are evolving in different species but still; the generalization of this observation is barely recognized by comparative endocrinologists. Because triiodothyronine is the bona fide ligand of thyroid hormone receptors in mammals it should the same in all animals: but this is not the case. In invertebrates, all suggests that the active ligand is not triiodothyronine but TRIAC, a deaminated derivative that is known since a long time but have not been seriously investigated, and the physiological importance of 3,5-T2 in teleost fishes is also gaining increasing recognition (Orozco *et al.*, 2017). The same is true for retinoids or, as discussed above, for estrogens. This is most probably the case in much other systems: it is not because a hormone is present in human that it must be also active in other animals. If there is an area where it is necessary to avoid any anthropomorphism it is indeed the one of hormonal ligands and their receptors.

The Origins of Hormones

If there is one mysterious question, it is the question of the origin of hormonal systems. That the very early metazoans need a system to allow efficient transfer of information from organs to organs in order to synchronize central and peripheral response is accepted since a long time. But how does such a system emerge? This vexing question has not yet received sufficient attention. One reason is that because of anthropomorphism, many people have tried to trace back the origin of human compounds rather to consider animal evolution in an unbiased manner. There is a strong need to biochemically characterize the hormones present in diverging metazoans. The effort that has been made in some systems (e.g., the nematode *Caenorhabditis elegans*) has revealed a

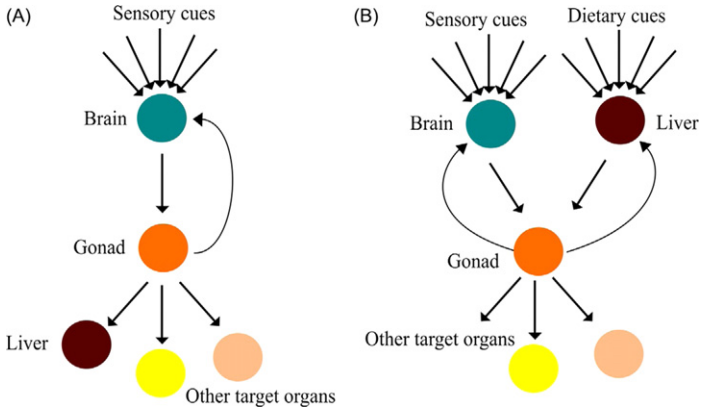

Fig. 1 *For a reappraisal of the integrative role of the digestive system.* (A) A classical textbook hierarchical regulatory model, where the signal goes upside-down -even if retroactions are acknowledged—from the nervous centers to the target organs, among which is the liver. (B) A "pluralistic view," where not only the brain, but also the liver, and possibly the gonad too, are all partial and complementary integration centers.

wide variety of compounds, some related to steroids, but none of them being simplified versions of human hormones, as many would have anticipated. Complexity and diversity are everywhere even in the apparently simplest animals. The analysis of complete genomes has shown that even the most basal metazoans may have surprising sophistication in signaling systems. Clearly, "basal" does not means "primitive" and even morphologically simple animals such as a placozoan or a hydra have the same amount of years of evolution as humans and therefore can be quite elaborate in other aspects of their biology. The unbiased characterization of active compounds (steroids, leukotrienes, prostaglandines etc.…) present in early metazoans will undoubtedly shed light on this important question.

However even in the present paucity of information one can make some interesting observations. Among the many types of hormones some, as the steroids but also the numerous derivatives of fatty acids, are particularly interesting because their chemical structures are conserved outside metazoans (Kushiro *et al.*, 2003). The fact that in such divergent systems similar active molecules are used may be revealing of a deep analogy between the hormonal systems. One reason could be that the biochemical pathways allowing the metabolism of these molecules predates the divergence between, say, animals, fungi and plants (Baker, 1995). This would therefore suggest that evolution has simply used again and again similar enzymatic systems and pathways to diversify an existing class of active molecules. This may explain for example the existence of vertebrate steroids, ecdysteroids of insects and brassinosteroids in plants. Another poorly explored, but quite exciting idea, could be that some structural or chemical properties render these molecules particularly apt to fulfill a hormonal function (Kushiro *et al.*, 2003). Being their hydrophobicity, size, ability to cross membranes, to be buried in protein cores or to be transported in biological fluids, steroids and fatty acid derivatives are apparently more suitable than others to serve as efficient molecules to transport, at long range, specific information. This must be further explored.

Lastly, there is now accumulating evidence than hormones may derive from food-related compounds. This is obvious for leukotrienes and prostaglandins that are fatty-acid derivatives but this is probably also true for steroids or thyroid hormones. The cladistic analysis of steroid hormones discussed above reveals that sex steroids are in fact, biochemically speaking, degradation products of cholesterol, a molecule directly linked to diet. In addition, the phylogenetic analysis of the four main families of steroidogeneic enzymes has revealed that many of these enzymes originate from detoxifying enzymes that hydroxylate toxic compounds targeting them towards degradation pathways. Thyroid hormones are clearly derived from iodinated molecules that were produced in the pharynx of filter-feeding organisms. Indeed many marine organisms filter planktonic particles by gluing them into mucus and it is known that in close vertebrate relatives such as amphioxus and sea squirt, the mucus contains iodinated proteins that help in this process (Holzer *et al.*, 2017). From this an endocrine secretion of iodinated thyroid hormones evolved and it came therefore as no surprise that thyroid hormones promote energy expenditure as their basal exocrine function was probably linked to the signaling of the presence of food. Clearly all these indications reveal a deep, ancient, relationship between nutrition and hormonal signaling. As many hormones are regulating reproduction, one can posit that hormone signaling derived from signaling pathways that were primitively involved in the regulation of the reproductive maturation according to nutritional conditions (Della Torre *et al.*, 2014). This has some important implications on the way we have to look at endocrinology. Classically, as we pointed out in the introduction, hormonal signaling is viewed as a bottom-up cascade from the nervous centers to the target cells, and hormones such as steroids, occupy an intermediary position in the middle of this cascade (see **Fig. 1**A). But our quick journey through metazoan signaling physiology reminds that a significant part of the environmental input is integrated not through the nervous system, but through the digestive system. This is consistent with the recent proposal that the liver may be act as an integrative center complementary to the brain (Della Torre *et al.*, 2011), and with the now well-acknowledged importance of the gut microbiome on the nervous system (Vuong *et al.*, 2017). Therefore we should perhaps now conceptualize a more "pluralistic view," in which not only the brain, but also the liver, the intestine and possibly the gonad too, are all partial and complementary integration centers (**Fig. 1**B). Probably due to the special status of the brain as a "noble organ," being considered

as the supreme integrator of body signals, the nervous system has benefitted from many studies from evolutionary biologists, with many ramifications even out of the strict biological field. Let us hope that the interest in hormones origins will stimulate next generations of scientists to dedicate the same attention to the digestive apparatus and to its functional connections with hormonal signaling.

Take-Home Message for Clinicians

An evolutionary perspective tells us that whatever their chemical nature, both partners in hormone-receptor couples are constantly evolving, as do the fine-tuned mechanisms controlling their availability in time and space. This explains why those systems are so plastic and so difficult to classify. The origin of the hormonal system is deeply rooted into the perception of external nutritional cues, which also explains why it is so sensitive to disruption by environmental chemicals.

General Principles of Endocrine Genetics

Constantin Polychronakos, Research Institute of the McGill University Health Centre, Montréal, QC, Canada

Nomenclature

Lambda S (λ_S) The sibling relative risk. The risk of disease in a sibling of a case, divided by the risk in the general population.

LD Linkage diseqilibrium
MAF Minor allele frequency

Glossary

Aneuploidy An abnormality where the number of copies of genetic material is different from the normal two (or, in the case of sex chromosomes in males, one). Mostly used for whole chromosomes or parts thereof large enough to be seen with the light microscope (approximately >5 Mb). Smaller instances are referred to as CNV (copy-number variation) or indel (insertion-deletion) variants.

Haplotype A string of alleles at adjacent polymorphisms, on one of the two chromosomes of an individual. Example, aBCdeF for adjacent polymorphisms Aa, Bb, Cc, Dd, Ee, Ff. Contrasted to diplotype, that would be a string of two alleles, for example, AA, Bb, cc, Ee, FF in the same example.

Linkage disequilibrium The property of variants located close to each other on the chromosome, to give the same information. Consider a mutational event that created allele *B* in the place of the ancestral allele *b*. This mutation happened on an ancestral chromosome that has, say, allele *A* at the neighboring SNP *A*/*a*. In the immediate progeny of that ancestor, knowing the genotype at *A*/*a* would allow us to confidently infer the genotype at *B*/*b*. With the passage of generations, however, meiotic recombinations occur between the two loci, so that the correspondence no longer applies to 100% of chromosomes and the prediction is no longer absolute but becomes probabilistic. After a sufficiently large number of recombinations, the two loci equilibrate completely and the ability to predict one from the other is lost. In contemporary humans, SNPs in chromosomal proximity may be found in any stage of this process, from complete lack of equilibration (highly correlated, $r^2 = 1$) to fully equilibrated (no correlation, $r^2 = 0$). Meiotic recombinations do not occur uniformly in the genome but tend to concentrate on "hot spots," between which blocks of highly correlated SNPs can be found. The length of these blocks may range from a few kb to a Mb or more.

Mutation A single event that happened in the past and created a DNA sequence variant. Its use as a synonym for "pathogenic variant for a monogenic disease" has been established by usage and will be used in this chapter for convenience.

Locus (plural, Loci) A specific location in the genome usually (but not necessarily) linked to a disease phenotype. Specified as ChrN:p1:p2, where N is the chromosome number, p1 the beginning and p2 the end of the locus, in number of nucleotides counting from the tip of the short arm.

ROC (receiver-operator characteristic) curve Originally developed for the statistical evaluation of enemy-airplane sightings on radar, this curve plots the sensitivity (proportion of cases that score at or above the cut-off) against 1-specificity (proportion of healthy subjects who score likewise). The area under the curve, ranges from 0.5 (test no better than flipping a coin) to 1 (sensitivity and specificity both 100%).

Variant Any DNA sequence difference from the reference human genome. Although in the past it has been used to mean a harmless polymorphism, its modern usage has no connotation of pathogenicity. Phenotypic effects need to be separately determined and stated.

Redefining the Concept of "Genetic Disease"

The importance of genetics in many aspects of endocrinology has been well known for a long time. However, over the past 10 years or so, important breakthroughs in the methodologies of genetic analysis have brought about a redefinition of our understanding of how genetic variance determines endocrine disease, making a new discourse on endocrine genetics timely and topical.

In current usage, the term "genetic disease" is treated as a synonym for what one could more specifically refer to as "Mendelian" or "monogenic" disease: a DNA variant seriously compromising the function of a single gene, suffices to cause the disease. This results in a specific and recognizable pattern of familial inheritance following the patterns established by Mendel. Endocrinology encompasses a large number of such diseases which, although individually rare, collectively account for a nonnegligible part of endocrine practice. However, the bulk of a typical endocrinologist's time is spent caring for diseases not covered by this definition. A correspondingly large part of this discussion will, therefore, be devoted to demonstrating the relevance of genetics in these more complex, multifactorial phenotypes, especially as highlighted by recent discoveries in the past decade. It is not the purpose of this

brief overview to describe individual diseases in any detail but rather to cover the basic principles of how genetic variation can cause (or affect the risk for) endocrine diseases.

Chromosomal Anomalies

Whole-chromosome aneuploidies are compatible with postnatal survival only when they involve the sex chromosomes or Chr21, the smallest human chromosome with the smallest number of genes.

Trisomy of Chr21 causes the distinctive phenotype of Down syndrome which, at the molecular level, must be due to expression of genes on the chromosome at 150% of their normal level (Antonarakis, 2017). The endocrine interest in trisomy 21 is its association with greatly increased risk for autoimmune thyroid disease (Pueschel and Pezzullo, 1985), both thyroiditis and Grave's. Risk of Type 1 diabetes is also increased by as much as an order of magnitude (Anwar *et al.*, 1998). Which specific gene(s) are responsible for this is not currently known but *UBASH3A* (ubiquitin-associated and SH3 domain-containing protein A) is a good candidate for at least part of the effect. A risk variant for type 1 diabetes (T1D) (Grant *et al.*, 2009) and other autoimmune diseases (Zhernakova *et al.*, 2011), is associated with increased *UBASH3A* expression (Dixon *et al.*, 2007) (paralleling the expected effect of the trisomy).

Losses or gains of the X chromosome result in, respectively, the Turner (TS) or Klinefelter (KS) syndromes, both associated with gonadal pathology and infertility.

TS patients are born without gonads and may be thought of as females missing one X (if they carry only the paternal X) or males missing the Y (carriers of a maternal X). In either case, absence of sex hormones results in normal female external and internal genitalia, the hormone-independent default state. Mosaicism and/or partial deletion of ChrX can result in intermediate phenotypes but remarkably short stature is a consistent feature. It is current practice to treat it with growth hormone (GH), which results in an average gain of only 5 cm of adult height (Stephure and Canadian Growth Hormone Advisory, 2005), as usually seen in most conditions involving shortness not due to GH deficiency (Grimberg *et al.*, 2016).

KS due to supernumerary X chromosome(s) in a male, affects mostly the seminiferous tubules and Sertoli cells of the testis, with relatively intact Leydig cells, despite elevated gonadotropin levels. Testosterone treatment is not needed to induce full puberty in most boys with KS and the potential for psychological harm from this intervention has not been investigated. Cognitive improvement from testosterone treatment has been claimed but there is no biological plausibility or credible evidence base to support it.

Since normally one X is inactivated in all cells, both TS and KS must be due to under- or overexpression, respectively, of genes that escape X inactivation. Seven such genes have been discovered to completely escape inactivation, while partial escape is seen in as many as 23% of X-linked genes (Tukiainen *et al.*, 2017).

Monogenic Endocrinopathies

Given the complexity of the endocrine system, it is not surprising that mutations in any one of a very large number of genes cause endocrinopathies, most of them rather rare. General mechanistic principles connecting DNA sequence variation to disease phenotype will be discussed. Individual disorders will be mentioned only as examples to illustrate mechanisms.

Loss of Function of Hormones and Their Receptors and Mediators

Mutations in the actual sequence of peptide hormones themselves is the mechanistically most straightforward cause of monogenic endocrinopathy. They are all transmitted as recessive traits; both copies of the gene must carry loss-of-function variants for the disease to occur. As most of these hormones are subject to feedback regulation, one normal copy of the gene can be upregulated to produce twice the amount of hormone in healthy carriers. The phenotype is as one might predict. Homozygous or compound heterozygous mutations in growth hormone cause growth failure with normal or elevated levels of (bioinactive) hormone but low IGF1 (Phillips and Cogan, 1994). Biallelic loss of function of the beta subunit of either FSH (Matthews *et al.*, 1993) or LH (Weiss *et al.*, 1992), cause hypogonadotropic hypogonadism without anosmia and mutations in the PTH (parathyroid hormone) congenital hypoparathyroidism (Arnold *et al.*, 1990). Such mutations of the hormone itself are, for some reason, rare. Diabetes due to recessive loss-of-function variants of the insulin peptide has not, to my knowledge, been reported.

Deficiency of nonpeptide hormones can result from loss-of-function in the enzymes needed for their synthesis. Classical examples are the various types of thyroid dyshormonogenesis, involving any one of a number of enzymes and transporters needed for thyroxine production (Park and Chatterjee, 2005) and corticosteroid deficiency from loss of function of one of several steroidogenesis enzymes. By far the most common of the latter is deficiency of *CYP21A2* (encoding 21-hydroxylase), required for the production of hydrocortisone and aldosterone. A pseudogene in tandem with the active gene, mapping on Chr6p21.33, invites nonhomologous recombination and explains the high prevalence of this particular problem (White *et al.*, 1984; Higashi *et al.*, 1986). A result of the ensuing hormone deficiency is elevation of the corresponding trophic hormones (TSH and ACTH, respectively, in the above examples). In the case of the adrenal, this results in an additional pathogenetic mechanism, the accumulation of high levels of intermediate products upstream of the block. Their androgenic activity causes virilization of female embryos and premature sexual development. These effects are often the main medical issue, even when the loss of enzymatic function is incomplete and the adrenal can be stimulated enough to produce normal levels of the physiological hormones (simple virilizing congenital adrenal hyperplasia with no manifestations of deficiency).

Mutations in hormone receptors have less predictable phenotypes. Mutations of the TSH receptor do cause the expected simple congenital hypothyroidism (Paschke and Ludgate, 1997) and those of ACTH receptor isolated glucocorticoid deficiency (Tsigos *et al.*, 1993) but mutations in the PTH receptor 1 cause, in addition to hypocalcemia, Bloomstrand chondrodysplasia (Jobert *et al.*, 1998), likely because this receptor also transmits the action of PTHRP (PTH-related peptide).

Finally, a unique and interesting mechanism whereby loss-of-function mutations in a single gene can cause multiple endocrine diseases is seen in the recessively inherited syndrome of autoimmune polyendocrinopathy type 1. It is due to diallelic mutations of *AIRE* (AutoImmune REgulator) (Finnish-German, 1997), the gene that orchestrates the expression of tissue-restricted antigens (including endocrine-gland specific proteins) in the thymus epithelium so that T-cells that react to them can be eliminated through negative selection. In the absence of functional *AIRE*, these proteins are not recognized as self. The parathyroid gland is typically affected but thyroiditis, Addison's disease and type 1 diabetes can also be present.

Dominantly Inherited Endocrinopathies

While recessive mutations always represent loss of function of the gene involved, endocrinopathies can arise through diverse additional mechanisms when only one copy of the gene is mutated.

The simplest of these mechanisms is haploinsufficiency: again loss of function, in situations where 50% expression is not sufficient to maintain normal physiology and (unlike the case with genes encoding peptide hormones) the gene involved is not subject to negative feedback that can upregulate expression from the intact copy. The typical example of a group of such endocrinopathies are the different types of MODY (maturity-onset diabetes in the young), caused by haploinsufficiency of one of a group of dosage-sensitive genes of crucial importance in the development and/or function of the insulin-producing β-cells. The most common forms, MODY1 and MODY3, are due to heterozygous mutations of, respectively, HNF1α and 4α (hepatic nuclear factor 1-alpha and 4-alpha), transcription factors ubiquitously expressed but, apparently, dosage-sensitive only in β-cells (Yamagata *et al.*, 1996). They are important to differentiate from the common forms of diabetes (especially type 1) because they can be very effectively treated with oral sulfonylurea drugs. *IPF1* (insulin promoter factor 1), a transcription factor involved in both pancreatic development and insulin secretion, Glucokinase, the glucose sensor of the β-cells and *RFX6* (Patel *et al.*, 2017), encoding a transcription factor necessary for the specification of the islet endocrine phenotype (Smith *et al.*, 2010), are other examples of genes with obvious functional importance and mutated in, respectively, MODY 5, 2, and 14.

Dominant familial endocrine tumor syndromes are mediated by a special kind of heterozygous loss of function that does not involve haploinsufficiency. In multiple endocrine neoplasia syndromes type 1 and 2, the single intact copy of the mutated gene (respectively *MEN1* and *RET*) (Concolino *et al.*, 2016) is sufficient to maintain normal cellular function. However, somatic mutations are bound to happen during the astronomical number of mitoses that it takes to form each of the affected endocrine glands. If such a mutation destroys the intact copy of the gene in a single cell, this cell and its progeny acquire a proliferative advantage that forms the tumor, according to the Knudson two-hit hypothesis.

Heterozygous mutations may also cause disease through gain of function. This may be an increase in the normal function of a gene or gain of a novel, abnormal function. A typical example of the former is neonatal diabetes due to mutations that increase the function of Kir6.2 or SUR1, the K^+ channel that regulates insulin secretion in β-cells or its controller unit, respectively encoded by the *KCNJ11* and *ABCC8* genes. Such mutations in either gene keep the channel open, preventing the sequence of events that leads to insulin release (Nakhla and Polychronakos, 2005). They also respond to sulfonylureas, which act by binding to and inhibiting SUR1. A large proportion of these mutations are de novo, as might be expected in dominant disease that severely limits survival and reproductive fitness. The exact same mutation often independently recurs in different families, at specific "hot spots"—unlike loss of function, which can be the result of many different mutational events (missense, nonsense, frameshift, splicing), gain of function requires a very specific change. Interestingly, homozygous loss-of-function mutations of either gene cause neonatal hyperinsulinism and severe hypoglycemia.

Another type of neonatal diabetes, due to mutations in the insulin gene, is a good example of gain of abnormal function. Proinsulin peptide, misfolded as a result of a point mutation, accumulates in β-cells and causes apoptosis via an endoplasmic reticulum stress response (Colombo *et al.*, 2008). Through a similar mechanism, heterozygous mutants in Neurophysin II, the precursor that is cleaved into vasopressin and oxytocin, cause familial diabetes insipidus (vasopressin deficiency) by accumulating in and destroying the hypothalamic neurons (Ito *et al.*, 1997) whose projections form the posterior pituitary.

Complex Genetic Traits in Endocrinology; Diabetes as a Paradigm

Recent discoveries have confirmed previous epidemiology pointing to an important role for genetics in such conditions as type 1 or type 2 diabetes (T1D, T2D), Hashimoto's thyroiditis and Grave's disease, short stature, delayed puberty or osteoporosis. More importantly, these studies have come a long way in defining loci in the human genome with variants that measurably increase or decrease risk for each of these diseases. Most of this knowledge was acquired in the past 10 years, thanks to dramatic breakthroughs in human genetics methodology.

Absence of a Mendelian mode of inheritance does not mean that the phenotype is not dependent on genetics. It simply means that the genetic effect is mediated by the cumulative influence of a large number of genetic variants, each of which increases or

decreases disease risk. Most of these variants are single-nucleotide polymorphisms (SNP). Epidemiological evidence indicates that virtually every human phenotype that has been examined has a heritable component.

Genetic Epidemiology

The proportion of disease risk driven by genetic predisposition varies by disease and represents the heritability of the phenotype, defined as the fraction of risk explained by inherited genetic variants. It is assumed that the remaining represents environment but stochastic events may also play a role, as demonstrated in cancer. Heritability is not directly measurable and is context-dependent: uniformity in environmental exposure decreases variance, but a larger proportion of it is explained by genetics, while in the presence of large variation in environmental exposure genetics will explain a smaller fraction of disease risk.

A useful indicator of how much genes contribute to a disease is familial clustering, the simplest measure of which is the sibling recurrence risk (λ_S), the probability of disease in the sibling of a disease case over that in the general population (Risch, 1990). It can vary from less than double to many-fold. How much the λ_S may reflect shared environment, can be determined by twin and adoption studies.

Type 1 Diabetes (T1D)

Among complex traits, T1D (due to autoimmune destruction of the pancreatic β-cells) has one of the highest rates of familial clustering ($\lambda_S = 15$) (Risch, 1990). Concordance in monozygotic twins is >50%) (Redondo *et al.*, 2008), an order of magnitude higher than in dizygotic twins, who are no different from ordinary siblings (Redondo *et al.*, 2004) at about 5%. Therefore little, if any, of the λ_S can be accounted for by shared environment, including intrauterine environment. The term "shared" must be stressed here, to distinguish from population-level exposures which must play an important role: The several-fold increase in T1D incidence over a few generations in most countries studied (Onkamo *et al.*, 1999) can only be explained by environmental changes —but these must be at the population level, thus having no effect on the λ_S. Although cow's milk, viruses, vitamin D sufficiency and many other factors have been proposed, there is no conclusive evidence for any specific one of them.

Even prior to modern molecular genetics, T1D came up as one of the diseases most strongly associated with serological HLA types at the major histocompatibility complex (MHC) locus (Cudworth and Woodrow, 1974). This family of proteins, encoded by a cluster of genes on Chr6p, is associated with most autoimmune diseases. The protein products have a crucial function in adaptive immunity, including self-tolerance development, by presenting antigen to T-lymphocytes. More importantly, they are by far the most polymorphic human proteins and the main reason for allograft rejection. Each gene of class I (HLA − A, − B, − C) or class II (HLA − DP, − DQ, − DR) has hundreds of protein alleles, differing at multiple amino acids. Although not as specific as antibodies or T-cell receptors, the various alleles of each protein do have some selectivity for binding antigenic peptides. By increasing the range of antigenic peptides that can be presented, new mutations at the antigen-binding parts of these proteins have a selective advantage and are tolerated because of the absence of specific function, other than binding arbitrarily different peptides. Studies of large cohorts have mapped T1D risk mostly to alleles on the highly polymorphic exons 2 of DQB and DRB that encode the β-chains of DR and DQ. Because of the tight linkage disequilibrium (LD) between the two genes it is not possible to map T1D risk to one of them but probably both are important. Specific haplotypes of alleles, characterized by a mutation of the highly conserved 57Asp to another amino acid at DQB, confer a relative risk (RR) of 10-fold or more (Erlich *et al.*, 2008), an order of magnitude stronger than most effects in complex-trait genetics, especially given the frequency of these alleles (~15% of Europeans carry at least one). By contrast, the highly protective DQB*0602 (allele index follows asterisk) has a RR <0.1 (Erlich *et al.*, 2008).

The genetic locus conferring the second strongest effect after HLA is at the insulin gene itself at Chr11. A single allele at a common promoter polymorphism (40% of Europeans carry at least one allele) decreases T1D risk to half ($RR = 0.5$) by enhancing AIRE-activated insulin expression in the thymus (Vafiadis *et al.*, 1997), assuring robust self-tolerance to the main T1D autoantigen. Almost equally strong is the effect of the relatively common (9% in Caucasian chromosomes) 620Arg > Trp variant of *PTPN22*, the gene encoding the immune-cell specific LYP phosphatase (Polychronakos and Li, 2011) that modulates T-cell receptor signaling but also affects antigen-presenting cells via less-well understood mechanisms (Li *et al.*, 2017).

In the past decade, technical breakthroughs enabled genome-wide association studies (GWAS) that compare allele frequencies at all common polymorphisms in cases versus controls. This has raised the number of known T1D loci to over 50, but the effect on risk is much lower than described above, the RR ranging from 1.1 to 1.3 (**Fig. 1**). Nevertheless, collective examination of all these genetic effects allows the calculation of a genetic risk score (GRS) (Clayton, 2009) on the basis of which a diagnostic-test ROC (receiver operator characteristic) curve can be constructed (**Fig. 2**). This curve allows us to trade sensitivity versus specificity by choosing a cut-off along the GRS continuum and indicates important potential utility in T1D prediction/prevention. The discovery of an effective immune intervention to prevent T1 is currently pursued by a multitude of clinical trials. If one is found, selection of subjects to treat will be of extreme importance. Autoantibody testing allows quite reliable T1D prediction (Sosenko *et al.*, 2015) but it is logistically not feasible to apply to the entire population with yearly repeats of negative results. Genetic pre-screening can confine the testing to 18% of the population and still capture 80% of future T1D cases (**Fig. 2**).

Risk prediction may not be the most important benefit from these genetic studies. Genetic association loci for complex traits could be a rich source of pathophysiological insights not easily obtainable by conventional research. Examples are the genetics-driven discovery that insulin is expressed in the thymus and modulates risk, which has led to efforts to discover ways of enhancing

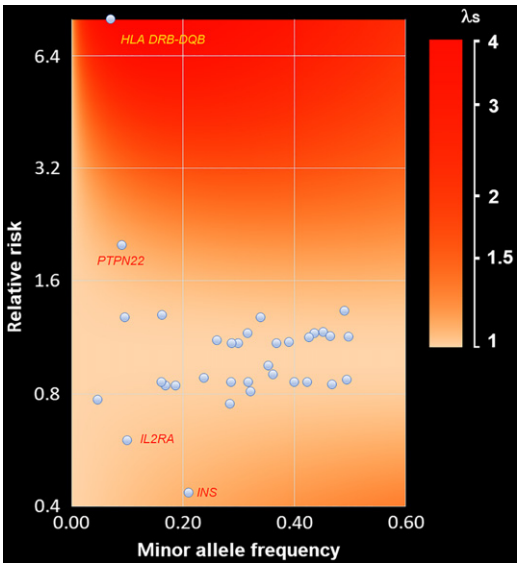

Fig. 1 Genetic loci predisposing to T1D, plotted by minor allele frequency (MAF) and relative risk, the two determinants of their contribution to the sibling recurrence rate (λ_S). The relative risk is based on the odds ratio. The background heat map indicates a locus contribution to the λ_S for any combination of MAF and relative risk.

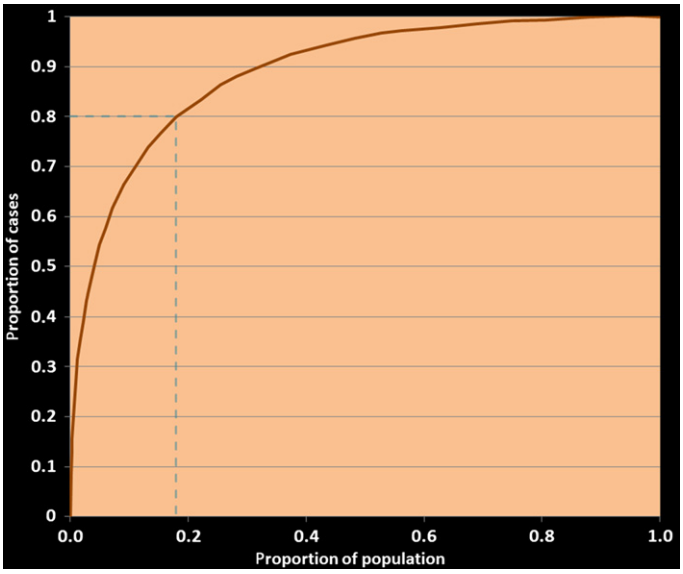

Fig. 2 Receiver operator-characteristic curve for genetic risk score (calculated in Clayton, 2009) based on known T1D loci. It plots the frequency of each risk score value in cases as a function of its frequency in the general population, that is, the sensitivity versus 1-specificity if that value is used as the cut-off. As an illustration of possible practical application, 80% of future diabetics can be predicted from within 18% of the general population.

its thymic expression (Yang *et al.*, 2012), or the discovery that the 620Trp risk allele of LYP confers gain-of-function, leading to a search for inhibitors (He *et al.*, 2013).

Type 2 Diabetes

Concordance in siblings for T2D is much higher than the 5% seen in T1D but because T2D is an order of magnitude more common, the λ_S is actually lower, estimated at two- to threefold over the general population (Hemminki *et al.*, 2010). As might be expected from this, the genetic effects of the well over 100 risk loci discovered by GWAS for T2D are small. The strongest allelic relative risk by a common variant is 1.5 and maps to an intronic SNP in *TCF7L2* (transcription factor 7-like 2) (Grant *et al.*, 2006).

TCF7L2 is a widely expressed transcription factor that regulates the expression of many genes. Its own expression is modulated by the T2D-associated variant but how it determines T2D risk is still unclear and controversial. A large variety of mechanisms have been proposed (reviewed in Florez, 2017) but which of these are true findings, remains to be seen.

Given the weak effects and the much stronger role of the environment in T2D, genetic prediction is not nearly as powerful as that of T1D. A ROC curve based on genetic score only marginally improves prediction based on clinical information (family history, adiposity, physical examination).

Nevertheless, the use the genetic findings to gain valuable functional insights into T2D pathophysiology and advance more specific and effective treatments is an active research field worldwide, stimulated by the high prevalence and devastating long-term morbidity of the disease. The first step toward such effort is to identify the gene and the variant involved in the risk locus. Contrary to the prevailing narrative, GWASs do not discover "disease genes." Most risk variants discovered in these studies are not inside the coding part of a gene and must affect function through effects on transcription. Even if the risk has been mapped to a single variant (a daunting task in itself, because of LD, arising from the historical coinheritance of neighboring variants), it could be affecting the expression of any one of several candidate genes that happen to have expression-regulating elements within the recombination interval (sometimes even if its protein-coding region is outside it). Recent progress in mapping tissue-specific epigenetic changes in the different human cell types by the Encode (Encyclopedia of DNA Elements) consortium and other efforts (Kellis *et al.*, 2014), have produced maps of methylation, histone modification and specific transcription binding sites that can be superimposed on the genetic mapping to drastically narrow down the possible gene-variant candidate pairs (Polychronakos and Alriyami, 2015). Positive identification of the gene involved is the first step towards developing therapeutics to target it. At least two GWAS loci map to genes (DIAbetes Genetics Replication and Meta-analysis (DIAGRAM) Consortium *et al.*, 2014), *PPARγ* and *KCNJ11*, targeted by existing drugs (thiazolidinediones and sulfonylureas) developed by conventional research. This justifies the expectation that many other such drug-gene pairs exist to be discovered starting from genetic rather than functional evidence. This is possible even starting from very weak effects; a weak genetic effect does not necessarily mean that the gene is unimportant in the disease process. It may rather be due to a very weak effect of the polymorphism on a gene extremely important in the disease and an excellent drug target.

The Missing Heritability

Typically, each variant conferring risk to T1D, T2D, or any other complex disease, explains a small part of the heritability. Even collectively, all known variants for each disease leave a substantial part of the heritability unexplained, a situation referred to as the "missing heritability." In T1D, a rare "success story" among complex traits, only about 20%–30% of the heritability remains to be explained. For T2D, this proportion is at best 50%. The missing heritability maps to a very large number of undiscovered genetic loci, each of which confers risk too small to give a signal in genetic studies (Lee *et al.*, 2011). This does not diminish the importance of genetics, it simply highlights the complexity.

Prospects for the Future

It is expected that studies building upon genetic findings in both monogenic and polygenic disease will continue to generate insights that will eventually lead to improved therapies. Although most of these therapies need not include correction of the actual disease-causing genetic variant, gene therapy is a possibility for the future. Like gene therapy for most other types of diseases it must, somehow, overcome the problem of applying it on a very large number of fully differentiated somatic cells and of reversing developmental defects that have already occurred in utero. In the foreseeable future, efforts to develop such approaches are likely to be confined to endocrine diseases for which no satisfactory conventional treatment exists.

Endocrine Epigenetics, Epigenetic Profiling and Biomarker Identification

Virginie Bertrand-Lehouillier, Lisa-Marie Legault, and Serge McGraw, University of Montreal, Montreal, QC, Canada

Introduction

The field of endocrinology investigates the secretion of hormones into the circulation by endocrine glands in response to a stimulus, the signaling of these hormones through the different axes in the body, how hormones influence the body's homeostasis and how abnormalities in endocrine function can lead to diseases. A growing body of evidence now suggests that alterations to the epigenome may be implicated in the pathophysiology or serve as biomarkers of endocrine diseases. Epigenetics is an emerging frontier of science that has provided quantum leap advances in our understanding of mechanisms playing prominent roles in normal developmental processes or in disease etiology. Epigenetics, as a simplified definition, refers to heritable but reversible modifications to the genome that control gene expression without changing the DNA sequence. However, to define how perturbations to the epigenome during one's life could be implicated to the onset of endocrine disorders, we must better understand the complex interactions that exist between genetics, epigenetics, and environmental factors. The scientific interest for epigenetics research has increased over the past decade, in large part because of recent advances in next-generation sequencing technologies that now make high-throughput and quantitative experiments possible. In this introductory article, we will define some of the terms and concepts related to epigenetic modifications, review some next-generation sequencing-based approaches to establish genome-wide epigenetic profiles, as well as provide examples of how dysregulations of epigenetic marks can be used as biomarkers in endocrine disorders.

The Many Faces of the Epigenome

Epigenetic Information and Chromatin Structure

In its original sense, Waddington referred to epigenetics as all molecular pathways modulating the expression of a genotype into a particular phenotype (Waddington, 1968). Over the years, the definition of the word epigenetics gained in complexity as it evolved in parallel with the discovery of additional key players and epigenetic mechanisms. Today, epigenetics can be described as a dynamic machinery that regulates gene expression by shaping the chromatin conformation without modifying the DNA sequence itself. This dynamic machinery comprises the addition of chemical modifications directly on the DNA sequence (e.g., DNA methylation) or on proteins (e.g., histone modifications), or interactions with noncoding RNAs. These epigenetic modifications can either act independently or act in a cooperative manner to regulate gene expression patterns.

To fully grasp the concept of epigenetics requires an understanding of chromatin organization (reviewed in Gilbert *et al.*, 2005; Dillon, 2006; Woodcock and Ghosh, 2010; Hubner *et al.*, 2013). The basic repeating structural and functional unit of the chromatin is the nucleosome, which is formed by the wrapping of 146 bp of DNA around an octamer of histone proteins (2 × H2A, H2B, H3, and H4). These core histone proteins have N-terminal tails, characterized by high lysine content protruding from the nucleosome, that give rise to an overall positive charge and contrasts with the surrounding negative DNA charge. Following nucleosome formation, the chromatin fiber will further compact into higher-order chromatin structures in order to fit inside the nucleus. Chromatin accessibility, nucleosome occupancy and 3D conformation of the genome are also important components of epigenetic mechanisms. Here, we will focus on the chemical modifications that are directly added to the residues of DNA or histone tails, as well as the implication of non-coding RNAs (ncRNAs) in post-transcriptional gene regulation.

DNA Methylation

In mammals, the majority of DNA methylation occurs on cytosines that precede a guanine nucleotide (CpG). Approximatively 30 million CpGs are found across the human genome, with 60%–80% being methylated in somatic cells. The presence of DNA methylation on the genome can directly influence the structure and compaction of the chromatin, thus promoting either activation or repression of transcription depending on the genomic location, background and factor occupancy (reviewed in Zhu *et al.*, 2016). In CpG rich promoters, the presence of DNA methylation correlates with transcriptional repression, whereas gene body DNA methylation was recently linked with active expression (Yang *et al.*, 2014). Methyl groups are added and maintained by enzymes from the DNA methyltransferase family (DNMT) and can be actively removed by ten eleven translocation (TET) enzymes (Bestor, 1988; Okano *et al.*, 1998; Tahiliani *et al.*, 2009; Ito *et al.*, 2010; reviewed in Messerschmidt *et al.*, 2014; Yin and Xu, 2016). DNMT1 is responsible for DNA methylation maintenance through cellular divisions, DNMT2 specifically methylates residues of transfer RNAs (tRNAs), DNMT3A and B catalyze de novo methylation, and DNMT3L, which lacks methyltransferase activity, stimulates de novo methylation and acts as a regulator of maternal imprint establishment (Bourc'his *et al.*, 2001; Reik *et al.*, 2001; Hata *et al.*, 2002; Kaneda *et al.*, 2004; reviewed in Messerschmidt *et al.*, 2014). DNA methylation patterns are established in the first

days of embryonic development during a fundamental reprogramming wave that erases and re-establishes most methylation marks across the genome, except for those at imprinted genes and other specific sequences that are protected from reprogramming (reviewed in Seisenberger *et al.*, 2013; Messerschmidt *et al.*, 2014). An absence of DNMT1 or DNMT3A/B during embryo development is lethal, as methylation profiles will not be established or maintained properly (Okano *et al.*, 1999; Ruchirawat *et al.*, 1987; Kurihara *et al.*, 2008; Arand *et al.*, 2012; McGraw *et al.*, 2013, 2015). The adequate establishment of DNA methylation patterns in early fetal development is of great importance; early perturbations could affect the developing endocrine system leading to a disease later in adulthood, such as obesity and type 2 diabetes (Law *et al.*, 1992; Stocker *et al.*, 2005).

Histone Modifications

Posttranslational modifications (e.g., methylation, acetylation, phosphorylation) on the histone tails can occur to varying degrees and are predominantly added on lysines (K) by histone modifying enzymes, although other residues such as arginine and serine can also be modified. Histone modifications are reversible, for instance, histone acetyltransferases (HATs) add acetyl groups onto lysines whereas histone deacetylases (HDACs) are responsible for their removal. Genome-wide chromatin analyses in mice and humans have shown that commonly repressed regions of the genome overlap with specific histone modifications (e.g., H3K27me3) and DNA methylation marks, whereas active regions containing H3K4me3 and H3K27ac are essentially depleted of DNA methylation (Balasubramanian *et al.*, 2012; Reddington *et al.*, 2013; Cao *et al.*, 2002). Transcriptional activity can also precede the deposition of histone modifications (i.e., H3K4me3 and H3K27me3) as recently observed in mouse embryonic stem cells (Galonska *et al.*, 2015). Although specific histone modifications have been correlated with permissive or repressive chromatin structure (Jenuwein and Allis, 2001; Strahl and Allis, 2000), the dynamic addition and removal of histone marks by histone modifying enzymes is more complex and context-specific than originally thought (reviewed in Henikoff and Shilatifard, 2011).

Non-Coding RNAs

ncRNAs are functional RNA molecules that regulate gene expression at the transcriptional and posttranscriptional level. Their implication in the control of epigenetic pathways goes beyond the classical portrait of epigenetic regulation (reviewed in Peschansky and Wahlestedt, 2014), with many ncRNAs essential for accurate targeting of histone modifying complexes, chromatin remodeling and DNA methylation processes for instance. Epigenetic associated ncRNAs consist of short (<200 nt: microRNAs (miRNAs), short interfering RNAs (siRNAs), and piwi-interacting RNAs (piRNAs)) as well as long (>200 nt: long ncRNAs (lncRNAs)) untranscribed RNA molecules. Many of these ncRNAs exhibit cell-specific, tissue-specific and/or developmental stage-specific expression and have functional roles in promoting or maintaining tissue identity.

Epigenetic Profiling

With the emergence of next-generation sequencing technologies (NGS) combined with in depth bioinformatics analyses, unprecedented advances in genome-wide epigenetic profiling have been accomplished. However, many factors (e.g., amount and quality of sample, required sensitivity and specificity, bioinformatic resources, cost) have to be considered when choosing the most appropriate method in order to produce unbiased results. Recent advances now allow for the processing of low input samples for many of these genome-wide epigenetic approaches, an essential feature when profiling limited quantities of patient material. Furthermore, with the emergence of single-cell technology, many genome-wide epigenetic profiling assays now give single-cell resolution of profiles. Such improvements will further refine our understanding of intercellular heterogeneity at a cell-type specific level in resistant versus non-resistant cells following drug treatment (Kim *et al.*, 2015; Schmidt and Efferth, 2016) or help monitor disease progression (reviewed in Clark *et al.*, 2016). A brief overview of some of these high-throughput NGS techniques will be presented in this section.

DNA Methylation

Sodium bisulfite conversion is still considered to be the gold standard for establishing methylation differences at a single-nucleotide-based resolution. This chemical treatment converts non-methylated cytosines into uracils while methylated cytosines are protected. Amongst the most widespread techniques using bisulfite conversion are Reduced Representation Bisulfite Sequencing (RRBS), Whole Genome Bisulfite Sequencing (WGBS) and Methyl-Seq. As its name suggests, RRBS reduces the portion of the genome that is sequenced by selecting candidate regions of the genome based on methylation-insensitive restriction enzymes to enrich for CpG-containing fragments. The advantages of RRBS include the reduction of genome complexity hence reducing sequencing costs, as well as allowing the profiling of approximately one million CpG dinucleotides located across the genome (e.g., gene promoters, CpG islands, gene bodies, repetitive elements, intergenic regions) (Boyle *et al.*, 2012; Meissner *et al.*, 2008; McGraw *et al.*, 2015). On the other hand, WGBS allows genome-wide DNA methylation profiling of all CpGs, which provides the best alternative to identify all possible differentially methylated regions (DMRs). However, since only a small portion of the genome has the potential to be differentially methylated, sequencing it at a single-base resolution is normally not required.

The associated high sequencing costs still limit the widespread application of WGBS. The Methyl-Seq approach circumvents some of the caveats of RRBS and WGBS by enriching for fractions of the genome that contain only regions of interest by using bait sequences (Ivanov *et al.*, 2013; Wang *et al.*, 2011; Hing *et al.*, 2015). These targeted enrichment approaches (i.e., Methyl-Seq) are fully customizable and can be designed for any reference genome. For now, readily commercially available enrichment kits are limited to humans, mice and rats, and can investigate up to 3.7 million CpGs across the genome (e.g., promoters, CpG islands, shores and shelves, DNaseI hypersensitive sites, RefGenes).

The main disadvantage of sodium bisulfite-based approaches is that they do not discriminate between methylated cytosines (5mC) and hydroxymethylated cytosines (5hmC). To overcome this problem, it is necessary to separate the two modifications and combine classic bisulfite sequencing with oxidative bisulfite sequencing (oxB-Seq) (Booth *et al.*, 2013) or Tet-assisted bisulfite sequencing (TAB-Seq) (Yu *et al.*, 2012) in order to differentiate 5mC from 5hmC. Worth mentioning are the Illumina human methylation arrays, a widely used nonsequencing-based method to detect DNA methylation profiles.

Histone Modifications

For most, the method of choice to define the exact location of histone modifications at a genomic scale is chromatin immunoprecipitation (ChIP) coupled to NGS. Using native or cross-linked chromatin and specific antibodies for the modification of interest (e.g., H3K4me3), chromatin fragments bearing the modification are immunoprecipitated, isolated and used for sequencing library preparation. The genomic localization of the proteins is deduced from the identification of the accompanying DNA molecule, which is achieved by next-generation sequencing (ChIP-seq). This approach can also be used to study the presence and localization of histone variants (Zhang *et al.*, 2005; Barski *et al.*, 2007). With these techniques, the potential for introducing methodological biases is not negligible. The quality/specificity of the antibody directly influences the specificity of the results, while neighboring proteins that could mask the epitope will impact histone/chromatin preparation methods, such as fixation and sample fragmentation (reviewed in Bernstein *et al.*, 2007; Schones and Zhao, 2008).

Non-Coding RNAs

The investigation of ncRNAs is relatively straightforward thanks to reliable whole transcriptome amplification procedures. The sensitivity and specificity of NGS-based approaches are well beyond microarray ('t Hoen *et al.*, 2008; Wang *et al.*, 2009) as they do not rely on target probe hybridization, thus allowing for the identification of variations in length or composition (Jung *et al.*, 2010) of transcripts at a single nucleotide resolution (reviewed in Zhou *et al.*, 2011). Standard RNA isolation methods for transcriptome studies are applied to identify lncRNA transcripts. However, for short ncRNAs, adapted kits for sample processing (e.g., extraction, amplification) need to be used to either capture or enrich. Further steps are usually needed to add length and to introduce a known sequence used for whole transcriptome amplification. It is noteworthy that lncRNA molecules are most often spliced and that some but not all bear a poly(A) tail of unknown length. RNA isolation based on the presence of a poly(A) tail will fraction the population of lncRNAs, as will a downstream reverse transcription primer using an oligo-dT.

Epigenetic Biomarkers

Extensive efforts have been made to identify epigenetic fingerprints that can be used for predictive risk assessment, diagnosis or prognosis/staging for endocrine diseases. Earlier studies relied on targeted approaches using individual genomic regions known or suspected to be implicated in the etiology of the disease of interest. However, such a strategy remained very challenging since it requires prior knowledge about the selection of loci used as candidate regions. The improvement of microarray-based technologies to investigate DNA methylation (e.g., Illumina's Infinium® HumanMethylation450 BeadChip: >450,000 CpGs) provided a more straightforward tool with increased genomic coverage to determine if discrepancies were observable in larger cohorts of patient samples. Using such methodology, a recent study investigated how epigenetic status correlated with aging and alterations in pancreatic islet function. They found an age-related increase in DNA methylation at 241 sites in the genome, with many of these loci previously associated with type 2 diabetes (T2D) (Bacos *et al.*, 2016). Furthermore, these age-related methylation changes partially overlapped with DNA methylation alterations observed in blood samples from prospective cohorts associated with higher insulin secretion and lower risk of T2D. Illumina has now released a new version of this array with enhanced genomic coverage (MethylationEPIC BeadChip; >850,000 CpGs). Still, to investigate all or most CpGs of the genome, WGBS remains the only available tool. Using WGBS to compare islets from diabetic versus control donors revealed 25,820 differentially methylated regions (Volkov *et al.*, 2017). In this comprehensive study, the authors also integrated RNA-seq experiments to further identify novel diabetes-related changes that contribute to islet dysfunction and impaired insulin secretion in T2D.

The potential implication of histone modifications in biomarker discovery in endocrine-related diseases is still a rather unexplored field. In one example, due to the association of endocrine dysfunction and impaired male fertility, it was suggested that alterations in sperm chromatin packaging and abnormal histone modifications could be used as putative markers for the diagnosis and prognosis of idiopathic male infertility (reviewed in Castillo *et al.*, 2015). Using Chip-Seq to investigate genome-wide histone modification profiles, Hammoud *et al.* showed a reduction of H3K4me3 and H3K27me3 on developmental gene

promoters in most infertile men, although the localization of modified histones was unaltered (Hammoud *et al.*, 2011). Furthermore, they showed that five of seven infertile men had randomly distributed histone retention in their sperm. It will be interesting to see if these observations can be extended to a larger cohort of infertile men and if these findings can be related with specific types of male infertility.

Perhaps one of the most promising areas of research regarding epigenetic biomarkers is related to ncRNAs, as many subtypes can be secreted by cells and detected in biological fluids (e.g., serum, plasma, urine) (reviewed in Butz *et al.*, 2016; Amri and Scheideler, 2017; Van Roosbroeck *et al.*, 2013). For example, miRNAs were shown to have an emerging role in the effect of endocrine disruptors (Derghal *et al.*, 2016) and are highly stable and abundant in peripheral blood. Long ncRNAs may possibly serve as non-invasive biomarkers. A recent study demonstrated that lncRNAs are abnormally expressed between sera and tissues of endometriosis patients (Wang *et al.*, 2016). The authors also found a unique set of lncRNAs that was associated with disease severity and progression. Altogether, this subset of observations point to the value of epigenetic modifications as potential new biomarkers for a wide array of endocrine associated diseases and disorders.

Conclusions

Epigenetics is one of the fastest growing fields of scientific research. It provides advanced understanding of the mechanisms at play in various diseases. Examples of potential predictive biomarkers for endocrine-associated diseases can be found throughout the literature. With the considerable improvement in genome-wide epigenetic profiling technologies and the rapid increase in publicly available genome-wide epigenetic data sets, many more of these epigenetic biomarkers will be put forward. However, many challenges will need to be resolved before they can truly be implemented clinically (Garcia-Gimenez *et al.*, 2017a,b). One of the most important and difficult task will be to validate some of these biomarkers in larger cohorts. The future of research on epigenetic biomarkers is very promising, as it will allow for new opportunities in prevention and treatment of endocrine disorders.

Protein and Peptide Hormone Synthesis

Johannes Hofland and Frank H de Jong, Erasmus University Medical Center, Rotterdam, The Netherlands

Introduction

Based on their molecular structure hormones can be categorized into groups of amino acid derivatives, peptide and protein hormones and steroids. Hormone production occurs both in specialized endocrine organs containing differentiated hormone-secreting cells, such as the anterior pituitary gland and pancreatic islets of Langerhans, but also in numerous other tissues spread throughout the human body, for example, fat, muscle, and intestine. This significantly widens the definition of an endocrine gland.

Hormone synthesis is controlled by various biochemical and neural signals that induce (sub-)acute fluctuations or periodic rhythms, leading to hourly, circadian, monthly or seasonal variations. After production, peptide and protein hormones are stored in intracellular secretory vesicles for release upon stimulation. These polypeptides generally interact with cell surface receptors in target organs, producing a wide variety of physiological effects. A key feature of polypeptide hormones is that many affect secondary hormonal systems which can exert negative or positive feedback on synthesis or secretion of the polypeptide hormone itself.

Although there is no official delineation peptides are generally considered to consist of 2–50 amino acids, whereas proteins are comprised of 50 or more amino acids and consequently have more complex three-dimensional structures. With regard to hormones, the peptides and proteins can range from the three amino acid structure of thyrotrophin releasing hormone (TRH) to the 140 kDa homodimeric anti-Müllerian hormone (AMH).

Transcription

Deoxyribonucleic acid, better known as DNA, contains the genetic code of an organism and serves as a molecular template for the construction of the working horses of the cell, the proteins. In order to produce proteins (or peptides) messenger ribonucleic acid (mRNA) precursor is first copied from the DNA by the RNA polymerase II complex; this process is termed transcription. This mRNA is a copy of a specific section of the DNA that is termed a gene and will be used for translation into a protein. In contrast to DNA, RNA is composed of a single string of ribose nucleotides. Its bases are adenine (A), guanine (G), cytosine (C), and uracil (U). The latter is the counterpart of the thymine nucleotide (T) present in DNA. By reading the DNA template strand the RNA polymerase ensures the production of a complementary RNA strand through specific Watson–Crick base-pairing: A–U, C–G, G–C, and T–A (DNA–RNA). As such the RNA bases are identical to the complementary or "sense" DNA strand that is not transcribed, with the exception of the T to U conversion. Bases within the RNA molecule are divided into triplets as these represent specific amino acid sequences that will be incorporated into the ultimate protein structure at translation.

Transcription is initiated after recognition of a conserved start region on the DNA termed promoter by a protein complex containing the RNA polymerase II (Cheung and Cramer, 2012) (**Fig. 1**). Several consensus sequences involved in recognition by

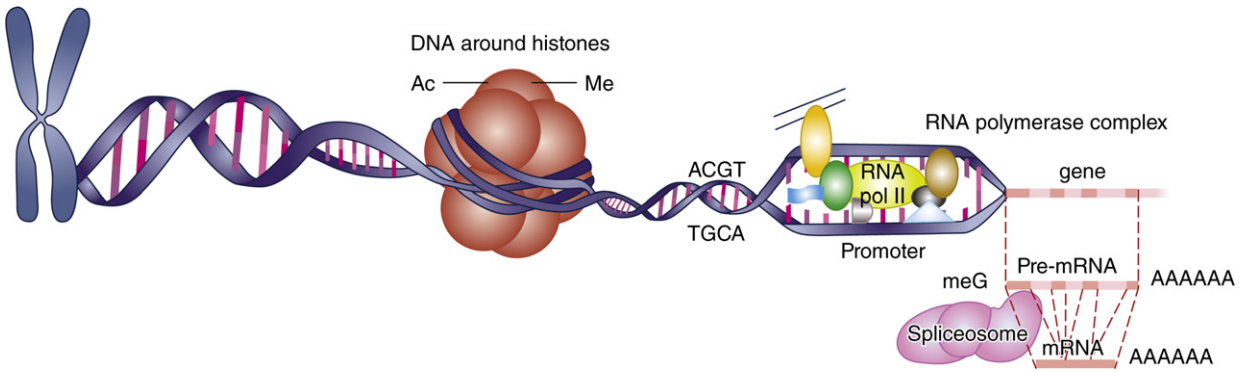

Fig. 1 Transcription. Nuclear DNA is condensed within nucleosomes around histone proteins. In decondensated regions transcription factors can bind to the DNA and guide the RNA polymerase II (RNA pol II) to gene promoter regions. The cumulative interaction between these proteins in the RNA pol II complex leads to induction of transcription and the formation of an RNA molecule that is a copy of the template DNA. The produced pre-mRNA is further processed to include a 5′ methylated guanine cap (meG) and a 3′ poly-adenosine tail (AAAAAA). Large sections of non-coding RNA or introns (white) are removed from the molecule by the spliceosome complex, leading to the mature mRNA molecule.

 doi:10.1016/B978-0-12-801238-3.64286-1

the transcription complex have been described, including the TATA box and the initiator element. The TATA box sequence contains T and A nucleotides and is typically located 25 base pairs (bp) upstream from the transcription start site. Specific proteins termed transcription factors recognize and bind to the TATA box or adjacent DNA sequences. These proteins subsequently recruit other proteins including the RNA polymerase II allowing the transcription initiation complex to be formed. After phosphorylation of the C-terminal domain of the RNA polymerase II an open complex is formed and transcription is started with the unwinding of the double helix of DNA (Grunberg and Hahn, 2013). Individual genes can harbor multiple promoter sites allowing for different start sites for the RNA polymerase II. Consequently a single gene can lead to several different RNA molecules with diversity in the 5′ end. The presence of different cell-specific transcription factors can control the creation of various mRNA molecules from the same gene in different cells.

The elaborate nature of DNA requires resourceful packaging into a compact structure. This is accomplished in chromatin where DNA is tightly coiled around histone proteins. Functional units in which DNA is packaged around a histone are called nucleosomes. Promoter regions are generally not located within nucleosomes, as the presence of DNA-binding proteins prevents DNA coiling around histones in these regions. This enables easier access of the transcription complex to the DNA. Areas of the DNA that are transcriptionally inactive are generally tightly bound around histones; this is visible as dense chromatin. Histone protein modifications, including acetylation and methylation, alter the histone–DNA interaction allowing for (de-)condensation of chromatin. Through these specific histone modifications, particular DNA regions can be made more or less accessible to transcription factors and the transcription complex (Kulaeva *et al.*, 2013).

Despite the presence of the same DNA molecules in every cell in the human body, different proteins or peptides are formed in the panoply of cell types. For instance, the TSH β-subunit is only produced in the thyrotrophic cells in the pituitary gland whereas the dimeric hormone inhibin is only secreted from Sertoli and granulosa cells in the testes and ovaries, respectively. Transcriptional control is the main effector by which individual proteins or peptides are produced within a specific cell type (Reiter *et al.*, 2017). This form of regulation of expression is due to a highly complex interaction between a variety of transcription factors and the transcription complex. The DNA sequences bound by transcription factors can be located far away from the transcription start site and are thought to interact with the RNA polymerase II through looping of the DNA. Depending on whether the transcription factor stimulates or inhibits gene expression at a specific site it is called a transcriptional activator or repressor. Their corresponding DNA sequences or *cis*-regulatory elements are enhancer or silencer regions, respectively. The presence of tissue-specific transcription factors is responsible for the meticulous RNA transcription process and as such the production of specific proteins within the cells.

The activity of transcription factors can be manipulated by external signals, such as hormones, and by intracellular pathways. For instance, steroid hormones bind and activate nuclear receptors that act directly on the DNA as transcription factors in order to stimulate or repress gene expression. Alternatively, protein and peptide hormones induce intracellular signaling cascades by binding to cell-surface receptors. These pathways, frequently involving kinases and phosphatases, regulate the activity and DNA binding of transcription factors in a cell-specific manner.

Another form of transcriptional control is through covalent modification of DNA by methylation. Methylation of the cytosine nucleotide in CG residues is a common mechanism to impair gene transcription, that is, to switch a gene off (Antequera, 2003). Within the genome these residues are overrepresented in promoter regions, which highlights their importance in the regulation of gene expression. CpG island recognition and envelopment by proteins blocks the transcription complex from binding to the transcription start site.

From the double-stranded complementary DNA a single RNA molecule will be transcribed from 5′ to 3′ with the "anti-sense" strand as template in a 3′–5′ direction. The DNA double helix is transiently unwound for about 10 bp at a time to expose the DNA nucleotides to the transcription complex in order to generate RNA. After the initial pairing of the first two ribonucleoside triphosphates the transcription complex migrates along the DNA while unwinding the helix and adding new nucleotides to the growing RNA molecule. This process is termed elongation and is brought about by a series of elongation factors (Kwak and Lis, 2013). Several RNA polymerases can simultaneously bind a single gene allowing the generation of multiple RNA copies at the same time. A specific stop sequence (AAUAAA) termed termination site leads to cessation of RNA transcription by the polymerase at which point the mRNA and transcription complex are released from the DNA (Porrua and Libri, 2015). The DNA region from initiation to termination site is termed the transcriptional unit.

The pre-mRNA product undergoes further processing in the nucleus to prevent degradation and aid transportation and translation. This is accomplished with the help of the phosphorylated C-terminal domain of the RNA polymerase II that once released from the promoter guides proteins towards the transcript in order to facilitate its processing. During transcription the mRNA guanylyltransferase enzyme modifies the 5′ end of the molecule to add a methylated guanine nucleotide. The second modification is the addition of a poly-A tail. First, a polymerase cleaves the 3′ end of the pre-mRNA at approximately 20 nucleotides downstream of the termination site. This is followed by the addition of a poly-adenosine tail to the newly formed 3′ end.

A protein and small nuclear RNA (snRNA) complex termed the spliceosome removes large parts of pre-mRNA that are not used for the production of proteins (Bertram *et al.*, 2017). These non-coding intervening regions constituting the larger part of most mRNA precursors are spliced out and are known as introns. The mature mRNA molecule is constituted by the remaining protein-coding sequences, the exons. Specific coding sequences denote exon–intron boundaries and are recognized by the spliceosome. Precursor mRNA can be processed into different mature mRNA splice variants or isoforms depending on the location of the splice sites. This is not a random process, but is also regulated in a cell-specific manner. Alternative splicing thus adds to protein diversity

starting from a single pre-mRNA molecule. Only mature mRNAs that have undergone 5′ and 3′ modifications and splicing are allowed to enter the cytoplasm.

Translation

Following transport across the nuclear pores mRNA enters the cytoplasm and is free to interact with ribosomes. This intracellular complex with protein production as its main function is composed of proteins and ribosomal RNA (rRNA) molecules (Hinnebusch, 2017). The ribosome binds to the 5′ cap of a cytoplasmic mRNA molecule (**Fig. 2**). It "reads" the base code of the mRNA molecule and travels in 5′–3′ direction until the start triplet or codon (AUG) is encountered. Protein diversity is increased through the use of alternative start codons. Loose scanning by the ribosomal complex can allow skipping of unfavorable AUG codons and subsequent use of an alternative start codon located downstream.

Subsequently, the ribosome facilitates the formation of a protein commencing with the amino acid methionine that is delivered by a transfer RNA (tRNA). Following the start codon the ribosome continues to read the mRNA molecule whilst adding amino acids on the C-terminal end of the protein string as indicated by the codons. The 64 different triplet codons of RNA bases represent the codes for the 20 different amino acids or 3 stop signals. With the exception of methionine and tryptophan, amino acids are encoded by multiple triplets. Variation in codons representing the same amino acids is mostly encountered in the third or wobble base of the triplet. Specific tRNA molecules deliver the amino acids encoded by the triplets through interaction between the codon and complementary anti-codon. Using an ATP-consuming process the carboxyl group of one amino acid is covalently linked to the amino group of the next amino acid by the enzyme peptidyl transferase. The polymerization of amino acids into the elongating polypeptide is continued until a stop codon (UAA, UAG or UGA) is encountered on the mRNA at which point the

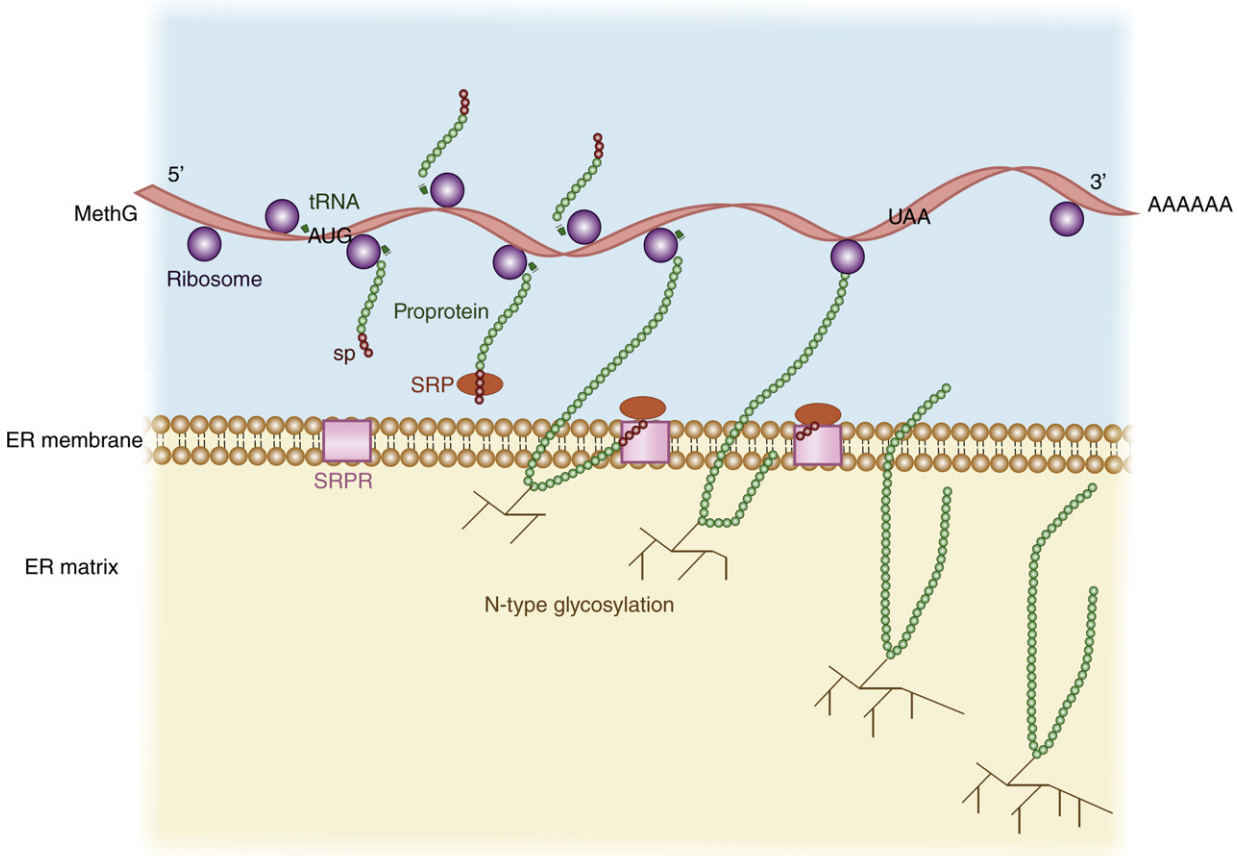

Fig. 2 Translation. Overview of a polysome containing a mRNA strand bound by several ribosomes that travel from 5′ to 3′ and its interaction with the endoplasmatic reticulum (ER). The start codon (AUG) signals the initiation of protein synthesis in which amino acids are successively incorporated into an elongating peptide chain. The emerging signal peptide (sp) is detected by a signal recognition particle (SRP) that guides the protein towards the ER. During translation the protein enters the ER matrix and the signal peptide is cleaved off. Simultaneously, glycosylation occurs at asparagine residues in the protein. Once the ribosome reaches a stop signal (UAA) translation is discontinued and the ribosome dissociates from the mRNA. The complete proprotein translocates into the ER lumen.

protein is released from the ribosome. This leaves the 3′ untranslated region and poly-A tail which are not read for the purpose of protein fabrication. Several ribosomal complexes can simultaneously translate a single mRNA strand, allowing for many copies of protein being produced at the same time in a so-called polysome. The translation process ultimately produces an unprocessed protein called the preprohormone.

Posttranscriptional regulation of protein production is controlled at an additional level through small 21–25 bp RNA molecules that silence translation (Iwakawa and Tomari, 2015). Although previously considered transcriptional noise or non-functioning RNAs, these microRNAs (miRNAs) exert critical, targeted control of up to 30% of protein expression. miRNAs form part of the cytoplasmatic RNA-induced silencing complex (RISC) that pairs to the 3′ untranslated region of mRNA molecules, resulting in their degradation or inhibition of translation.

Given their extracellular communication function protein and peptide hormones need to be secreted from endocrine cells. To that end, newly formed peptide and protein hormones in their prepro-form are prepared for storage in secretory vesicles. The initiation of this pathway towards regulated secretion is accomplished by a 5–10 hydrophobic amino acid signal peptide that is part of the N-terminus of the preproprotein (Nyathi *et al.*, 2013). During ongoing translation this N-terminal specific signal peptide is bound by a cytoplasmic signal recognition particle (SRP). This protein can guide the ribosome with its emerging polypeptide that is being translated towards the SRP receptor on the endoplasmatic reticulum (ER). The ER is a major membrane-enclosed organelle of the cell, which is instrumental in the production of secreted, organelle-bound or trans-membrane proteins and lipids. This guiding process allows for numerous ribosomes being connected to the ER giving it its granular appearance. Following ribosome–ER interaction, the protein will pass the ER membrane through a translocator termed the Sec61 complex and enter the ER. The signal peptide is concurrently cleaved on the luminal side of the membrane by signal peptidase leaving the N-terminal tail of the resulting proprotein inside the ER matrix. Following this co-translational process the production of the proprotein is continued by the ribosome while it protrudes through the ER membrane. After completion of translation the prohormone is released by the ribosome and unlike membrane-bound proteins is completely translocated into the ER lumen. It has now entered the start of the secretory pathway that is required for hormones to function as circulating cell–cell communicators. Meanwhile, the mRNA molecule remains attached to the granular ER as other ribosomes as parts of the polysome remain attached to the ER and continuously use it as a template for translation of new polypeptide chains.

During translation and entrance into the ER and before folding of the protein a cotranslational modification can take place. Many proteins including hormones undergo glycosylation at asparagine moieties, leading to the formation of glycoproteins (Aebi, 2013). A complex oligosaccharide including mannose, glucose and *N*-acetylgalactosamine is transferred from the ER membrane-bound dolichol phosphate to the protein while it is still being synthesized. After transfer further processing of the oligosaccharide chain takes place by glycosidase and glycosyltransferase enzymes. Like other modifications the addition of oligosaccharides has a significant effect on the molecular structure of the protein and its recognition by receptors and other proteins. Also, non-covalent interaction between hormone subunits can arise within the ER and lead to the formation of dimers. For instance, the three anterior pituitary hormones TSH, LH, and FSH all are heterodimers composed of a common glycoprotein hormone α-subunit linked non-covalently to a hormone-specific β-subunit.

Posttranslational Modifications

Once entered into the matrix of the ER prohormones must be transported towards the Golgi apparatus for further processing. In order to execute its main function of protein sorting factory in the cell the Golgi apparatus is composed of several membrane-enclosed compartments called Golgi cisternae (**Fig. 3**). Some peptides or proteins are already matured into end-products within the ER, while others will undergo modification after leaving the ER in downstream sections of the secretory pathway. Transport is accomplished in specialized membrane-enclosed vesicles termed transition elements (Gorelick and Shugrue, 2001). These vesicles bud off from the ER and fuse with the Golgi cisternae. The passage of proteins from the ER to the Golgi apparatus is the rate-limiting step in intracellular transport. Between organelles a highly regulated pathway ensures selective transport of proteins and other luminal molecules. Coat protein complex II (COPII)-coated transition elements make use of surface and target markers, such as the complex Rab protein family and their effectors, to recognize and fuse with their target organelle. Within the budding process of vesicles COPII interacts with acceptor proteins on the outer membrane surface. These acceptor proteins are linked to membrane-bound cargo receptors that bind luminal proteins, like hormones. In this way the transition elements enable specific transport to the Golgi apparatus.

Although the ER exit signals have been elucidated incompletely, the N-type glycosylation can serve as a protein-bound signal for transfer to the Golgi complex. Within the Golgi complex mature hormones are formed. Due to the polarity of the Golgi complex with proteins entering the *cis*-side and leaving through the *trans*-Golgi it is believed that different enzymes work at subsequent sections within the apparatus. In this manner consecutive protein alterations can take place in the functionally distinct compartments of the Golgi complex.

As many peptide and protein hormones are parts of much larger prohormones they need to undergo proteolytic processing. Amino acid residues within the polypeptide, like for instance lysine–arginine or arginine–arginine, mark cleavage sites for the production of active hormones by trypsin-like endopeptidases known as prohormone-converting enzymes (Muller and Lindberg, 1999). Exopeptidases further digest the terminal amino acids of the cleaved products, thereby producing the final length peptide or protein. Within this latter group of enzymes carboxypeptidase E appears crucial in the processing of several peptide hormones,

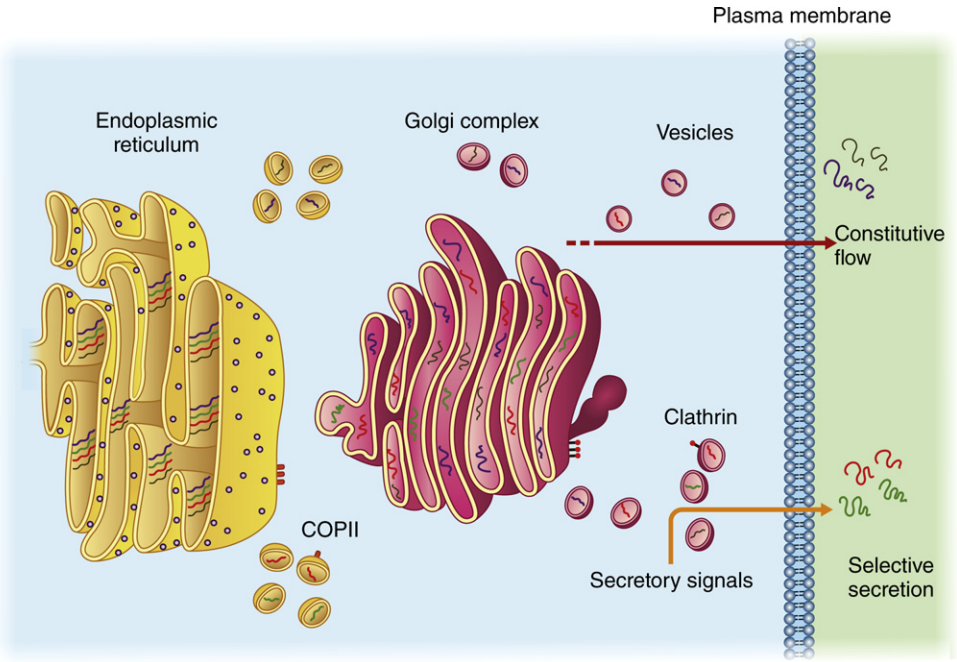

Fig. 3 Posttranslational transport. Proteins destined for secretion are sorted within the endoplasmatic reticulum for transport to the Golgi complex. The hormones are packaged in Coat protein complex II (COPII)-coated vesicles that travel to the Golgi complex and fuse with its membrane. During transport through the Golgi proteins undergo many posttranslational modifications that lead to their final active form. From the trans-Golgi network clathrin-coated vesicles bud off and undergo direct secretion at the plasma membrane in a constitutive flow or alternatively await a secretory signal near the plasma membrane for regulated, selective exocystosis.

such as proinsulin and growth hormone (Ji *et al.*, 2017). In many cases prohormones will give rise to the production of a single peptide or protein product. However, single prohormones can also contain multiple bioactive peptides, leading to the term polyprotein. A prime example of this is the pro-opiomelanocortin (POMC) precursor that contains several peptides, namely adrenocorticotrophic hormone (ACTH), α-, β-, and γ-melanocyte-stimulating hormone (MSH), corticotropin-like intermediate peptide (CLIP), β-endorphin and β-, and γ-lipotropin. For POMC this proteolytic processing occurs quite late in trans-Golgi elements and secretory vesicles. There is a tissue selectivity when it comes to specific cleavage of active peptides from the larger precursor. This is for instance illustrated by proglucagon, which is primarily cleaved into glucagon in the pancreatic α-cell or alternatively into glucagon-like peptide-1 (GLP-1) in the intestinal L cell. Several proteolytic steps might be necessary to convert complex precursors. Interestingly, proteolysis can also produce by-products that can be utilized for stabilization of the end-product. The arginine-vasopressin (AVP) prohormone contains the mature hormone and a protein known as neurophysin II that binds and stabilizes its endocrine counterpart. In the case of the cerebral and adrenomedullary hormone enkephalin a single peptide can also be encoded several times within one gene. Processing of its prohormone releases five copies of the methionine isoform and one copy of the leucine isoform of enkephalin.

During Golgi transport two cysteine residues in a protein can be linked to form a disulfide bridge. This reaction is accomplished by disulfide isomerase and leads to stabilization of the three-dimensional molecular structure. This occurs even in small peptides like the 9 amino acid-containing AVP. For the larger insulin precursor molecule this also constitutes a vital part of processing as this connects the alpha- and beta-chains. The interlinking C-peptide can subsequently be removed at a later stage in the secretory vesicle by proteases that cleave at two sites within the molecule. Disulfide bridges can also be formed at this stage between peptide or protein subunits that are encoded by the same or different genes, ultimately forming homo- or heterodimers or multimers. For instance, linkage of an inhibin βA-subunit to another βA-subunit produces the homodimer activin A, whereas connection of the inhibin βA-subunit to an inhibin α-subunit produces the heterodimer inhibin A.

Besides continued processing of the N-type oligosaccharide chain described earlier, the Golgi apparatus hosts O-type glycosylation of serine and threonine residues. In contrast to N-type glycosylation this only takes place after folding of the protein molecule. Surface-exposed serine and threonine moieties are subject to the addition of *N*-acetylgalactosamine followed by formation of highly diverse branched oligosaccharides by glycosyltransferases. Various *cis*-to-*trans* sections of the Golgi complex contain different membrane-bound enzymes involved in these processes leading to compartmentalization of glycoprotein processing. The oligosaccharides can function as signals for recognition molecules in the Golgi like the lectins. This interaction facilitates selective outbound transport in secretory granules towards the plasma membrane for exocytosis.

Together these posttranslational derivatizations result in significant conformational changes in folding of the polypeptide into a three-dimensional structure (Castro-Fernandez *et al.*, 2005). As such these alterations reveal another level of protein diversity

beyond the code that is encrypted into the DNA. Proteins assume their structure according to their amino acid sequence, known as the primary structure, through noncovalent interactions. The resulting polypeptide will spontaneously fold into the secondary structure that is energetically most favorable under the conditions of the solvent to a state called native conformation. Such rotations in backbone structure can be accomplished among others by the formation of α-helices and β-strands leading to complex motifs. Through a myriad of atomic interactions of the amino acid backbone together with the side chains a three-dimensional or tertiary protein structure is accomplished. Chaperone and chaperonin proteins facilitate this process of folding and limit the assembly of ineffective protein conformations. Quaternary structure only applies to a complex comprised of two or more polypeptides that are non-covalently bound.

Secretion

The trans-Golgi network (TGN) compacts the peptide and protein hormones into small membrane-encapsulated vesicles (Tooze, 1998). These clathrin-coated vesicles secure selective transport of relevant soluble proteins in their lumen through interaction with adaptor proteins and membrane-bound cargo receptors. The vesicles bud off from the Golgi and are transferred to the luminal side of the cellular membrane where they await the action of specific secretagogues triggering exocytosis. The secretory pathway can also be non-selective, as a consequence of bulk flow or constitutive movement. The constitutive exocytic pathway occurs in all cell types and directly targets vesicles to the plasma membrane. Molecules entering this pathway generally lack specific signals that allow them to enter other transport pathways.

Endocrine cells have a high dependence on a regulated exocytic pathway that leads to targeted exocytosis and secretion of hormones. To this end the TGN packages products as secretory vesicles that reside near the plasma membrane and wait for signals to start membrane fusion to release their contents extracellularly (Michael *et al.*, 2006). The formation of the secretory vesicles with their accumulation of specific proteins occurs through unknown mechanisms. Although these vesicles contain unique membrane-bound proteins, the process of targeting proteins for this pathway has not been extensively elucidated. Two proteins, secretogranin III and the above-mentioned carboxypeptidase E, are likely contributors to secretory vesicle formation for polypeptides. For hormones like proinsulin and POMC the membrane-bound exopeptidase can act as a sorting receptor: the pro-form of the hormone binds the carboxypeptidase E in the TGN which is followed by packaging into the secretory vesicles. The enzyme subsequently cleaves the prohormone into the final peptide or protein product during transport. Knockout of this enzyme leads to misdirected flow of several hormones via the constitutive pathway (Ji *et al.*, 2017). After budding from the TGN the content of the vesicle is concentrated up to 200-fold and following microtubule-guided transport to the plasma membrane these dense vesicles await a chemical signal for secretion. This often follows after stimulation of intracellular Ca^{2+} or cyclic AMP due to activation of plasma membrane ion-channels or cell-surface receptors, respectively (Seino and Shibasaki, 2005; Pang and Sudhof, 2010). Vesicles also contain the cleavage products, such as C-peptide in the case of insulin, that are co-secreted together with the hormone at the time of exocytosis.

Conclusion

The production and secretion of peptide and protein hormones is a highly evolved pathway on which many intracellular signals exert their influence. Transcriptional control remains the most critical pathway for regulating protein production, but translation and transport from the ER to the plasma membrane of individual hormones are also dependent on a plethora of stimulatory or inhibitory mechanisms. Aberrations in these physiological mechanisms can lead to changes in peptide or protein hormone levels or function and can ultimately result in clinical disease.

Protein and Peptide Hormone Action

Frank H de Jong and Johannes Hofland, Erasmus University Medical Centre, Rotterdam, The Netherlands

Introduction

The functioning of cells is largely regulated by external factors such as hormones and neurotransmitters. These external factors may be able to enter the cells by diffusion or specialized transport systems, followed by binding to specific intracellular receptors which can then interact with the genome to stimulate or suppress the expression of specific genes. Signaling molecules which are unable to cross the cell membrane can influence cellular function by binding to receptors that directly affect ion channels. Alternatively, the signal of an extracellular protein or peptide hormone can be transferred to the intracellular milieu as the result of binding of the hormone to its specific receptor, which is characterized by a transmembrane domain. This hormone–receptor interaction results in the activation of a large variety of intracellular signal-response cascades, depending on the signal transduction pathway cognate to the receptor. Many of these pathways have been deciphered in terms of the reactions—mostly phosphorylation—and their substrates, which in turn affect specific aspects of cellular function. It is important to realize that the specificity of the binding of a hormone to a receptor is not always absolute; sometimes different hormones can interact with one receptor (**Fig. 1**). Furthermore, specific intracellular pathways may be stimulated or suppressed by more than one hormone–receptor combination.

After binding of the hormone, the hormone–receptor complex will be internalized into the cell, leading to separation of the complex and degradation of part of the proteins, while part of the receptors may also be recycled to the plasma membrane.

The aim of this article is the description of some examples of these pathways, focusing on the diversity of the underlying mechanisms.

G-protein Coupled Receptors

The family of G-protein coupled receptors (GPCRs) is the largest group of receptors known (Fredriksson *et al.*, 2003). It consists of more than a thousand transmembrane proteins, involved in the transduction of signals varying from the detection of light in the retina to interaction with odorous substances in the nasal mucosa and with hormones and neurotransmitters in many organs. These receptors share a structure formed by seven transmembrane α-helices, connected by three intra- and three extracellular loops with an extracellular NH_2-terminus and an intracellular COOH-terminus. The transmembrane helices have a high degree of sequence conservation, whereas the structure and extracellular part of the protein, which interacts with its ligand, the "first messenger," can show a high variety of structure and complexity. This interaction leads to conformational changes in the structure of the GPCR, which are transmitted to the intracellular part of the protein, making interaction of the receptor with one of different guanine nucleotide-binding proteins (G-proteins) possible. These G-proteins convey the signal of the first messenger to the intracellular machinery as "transducers." Until recently, it was supposed that single GPCR molecules combined with G-proteins only after combination with their ligands. However, more recently it was found that GPCRs can exist as homodimers or even heterotetramers in combination with their cognate G-proteins in an inactive state, to be activated after binding of the relevant hormone (Kasai and Kusumi, 2014; Ferré, 2015).

G-proteins

G-proteins are heterotrimers of α-, β-, and γ-subunits, of which the α-subunit can bind guanosine diphosphate (GDP). Upon binding to the intracellular part of the ligand-activated GPCR the GDP molecule will be exchanged for a molecule of guanosine triphosphate (GTP), leading to dissociation of the α-subunit from the $\beta\gamma$-heterodimer (Morris and Malbon, 1999) (**Fig. 2**). After dissociation, both the α-subunit-GTP complex and the $\beta\gamma$-heterodimer may affect the functioning of the cell. The effects depend on the type of subunit: for the α-subunit at least 23 subtypes are known, encoded by 17 genes. These subtypes can be divided in four categories: stimulating adenylyl cyclase ($G\alpha_s$), inhibiting adenylyl cyclase ($G\alpha_{i/0}$), activating phospholipase C ($G\alpha_{q/11}$) and activating Rho guanine exchange factors ($G\alpha_{12/13}$). Interestingly, the subtype of Gα-subunit activated does not need to be specific: multiple coupling of GPCRs to more than one type of Gα-subunit is possible (Hermans, 2003). After the stimulation, the intrinsic GTPase activity of the α-subunit converts the bound GTP back to GDP, enabling recombination with the $\beta\gamma$-heterodimer and ending the actions of the signal transducers.

The β- and γ-subunit are present in at least 6 and 12 different subtypes, respectively. The $\beta\gamma$-dimers can also affect cellular processes, for example, G protein-regulated inward rectifying potassium channels, and may act as coregulators of Gα-effectors such as adenylyl cyclases or phospholipase C (Birnbaumer, 2007).

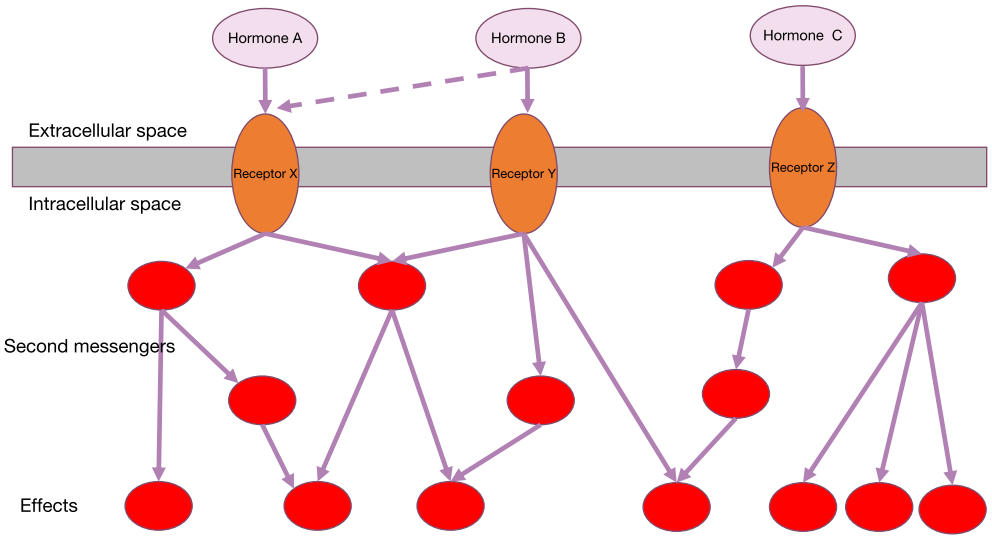

Fig. 1 General scheme for transduction of the signals of protein and peptide hormones into the cell. Hormones can bind to different transmembrane receptors that upon activation induce intracellular signaling cascades. There is a wide variety of second messengers in the cell as well as a multitude of physiological effects that can be regulated by hormones. Often activation of a single receptor or second messenger is transmitted to several downstream targets, thereby amplifying the signal. The large degree of overlap between individual hormonal cascades is caused by the use of the identical receptors or second messenger systems.

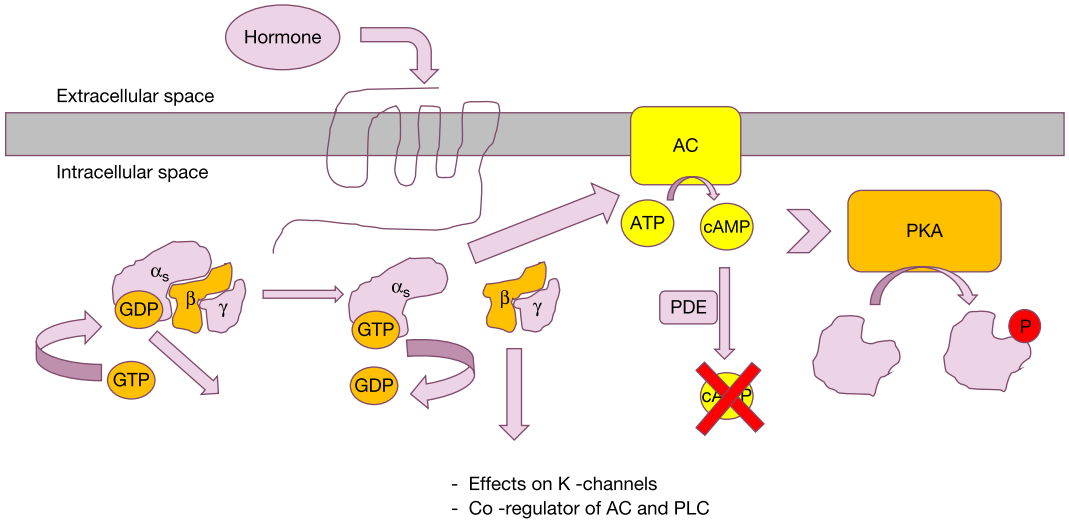

Fig. 2 Signal transduction from GPCR through action on G-protein's α_s- and $\beta\gamma$-subunits to adenylyl cyclase (AC) to production of cAMP to protein kinase A (PKA) to phosphorylation of proteins and effects on potassium channels, respectively.

Effectors of the GPCR-Generated Signals

As mentioned above, membrane-bound adenylyl cyclases can be activated or inhibited by $G\alpha_s$ or $G\alpha_{i/o}$, respectively, stimulating or inhibiting the conversion of ATP to cyclic AMP (cAMP). Nine different subtypes of membrane-bound adenylyl cyclase (ACs 1–9) have been described, each with its own tissue distribution, although many cell types express more than one subtype (Dessauer *et al.*, 2017). In addition, a soluble adenylyl cyclase (AC10) was found mainly in the spermatogenic cells in the testis. Compartmentalization of the different subtypes, in combination with differences in affinity for the various G-protein α-subunits can lead to a specific intracellular localization of the effect of activation of a specific GPCR. cAMP will interact with cAMP-dependent protein kinase (PKA), leading to phosphorylation of specific proteins at specific sites. cAMP response element-binding protein (CREB), a PKA target, can act as a transcription factor upon phosphorylation, controlling the expression of a multitude of target genes. Finally, the effect of phosphodiesterases (PDEs) on cAMP brings the stimulatory action to a halt by breaking the diester bonds between the phosphate and adenylyl groups. The receptor for adrenocorticotrophic hormone (ACTH) is an example of a $G\alpha_s$-protein coupled receptor. Binding of ACTH to this receptor on adrenocortical cells activates the GPCR leading to intracellular

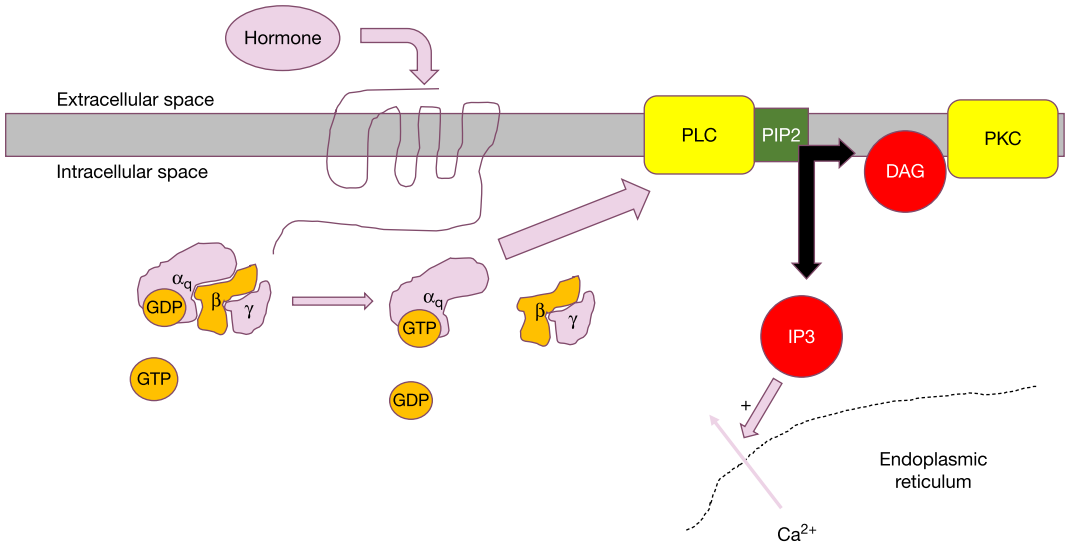

Fig. 3 Signal transduction from GPCR through action on G-protein's α_q-subunit to phospholipase C (PLC), leading to production of diacylglycerol (DAG), stimulating protein kinase C (PKC) and of inositol 1,4,5-trisphosphate (IP_3).

cAMP production. PKA subsequently stimulates adrenocortical steroid synthesis by phosphorylating the steroid acute regulatory protein, which delivers the steroid precursor cholesterol to the mitochondria, and by a CREB-mediated rise in gene expression of multiple steroidogenic enzymes.

Under the influence of $G\alpha_{q/11}$ phospholipase C (PLC) can be activated to cut the phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2) on the glycerol side of the phosphodiester bond resulting in the formation of 1,2-diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3) (**Fig. 3**). IP_3 will promote the release of Ca^{2+} ions from the smooth endoplasmic reticulum, leading to increased intracellular calcium concentrations, while DAG can stimulate protein kinase C (Kadamur and Ross, 2013). The α1-adrenergic receptor is an example of a $G\alpha_{q/11}$-coupled receptor. Activation by its ligands adrenalin and noradrenalin induces smooth muscle contraction through a PLC-dependent mechanism.

Finally, under the influence of $G\alpha_{12/13}$ Rho guanine exchange factors can be activated. Guanine exchange factors (GEFs) are involved in the activation of small GTPases, which act as molecular switches in intracellular signaling pathways and have many downstream targets (Aittaleb *et al.*, 2010).

Recycling and Break-Down of GPCRs

The endocytic pathway tightly controls the activity of GPCRs. Ligand-induced endocytosis can drive receptors into divergent lysosomal and recycling pathways, producing essentially opposite effects on the strength and duration of cellular signaling via G proteins, and may also promote distinct signaling events from intracellular membranes. This ligand-induced endocytosis is mediated primarily by clathrin-coated pits. For the TSH receptor G-protein activation can continue upon internalization, inducing spatially confined signaling pathways within the cytoplasm (Godbole *et al.*, 2017). Lysosomal sorting of a number of GPCRs occurs via a highly conserved mechanism requiring covalent tagging of receptors with ubiquitin. There is increasing evidence that additional, noncovalent mechanisms control the sorting of endocytosed GPCRs to lysosomes in mammalian cells. Recycling of several GPCRs to the plasma membrane is also specifically sorted, via a mechanism requiring both receptor-specific and shared sorting proteins. The current data reveal an unprecedented degree of specificity and plasticity in the cellular regulation of mammalian GPCRs by endocytic membrane trafficking (Hanyaloglu and von Zastrow, 2008).

Kinase-Linked and Related Receptors

The second group of peptide and hormone receptors constitutes the kinase-linked receptors. These divergent and often multimeric receptors are characterized by an extracellular domain capable of binding the ligand, a single transmembrane domain and an intracellular domain with enzymatic activity. This intrinsic kinase activity is stimulated by binding of the hormone to the extracellular part of the receptor and results in phosphorylation of the receptor itself and of downstream messengers. Depending on the enzymatic activity, receptors are classified into tyrosine kinase or serine/threonine kinase families.

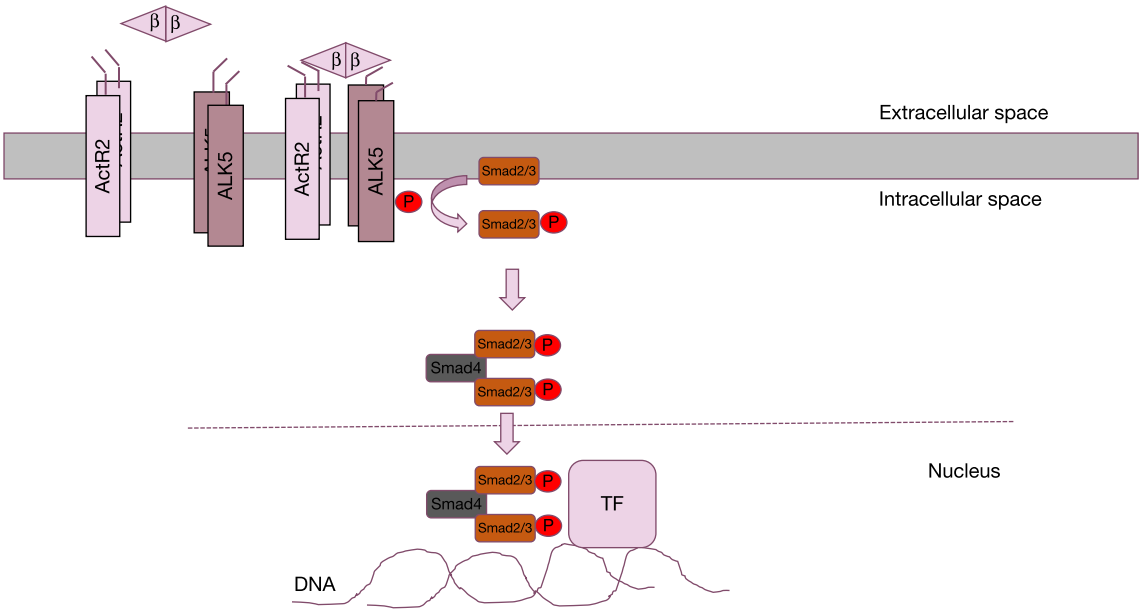

Fig. 4 Mechanism of action of activin on the activity of the activin receptors. Phosphorylation of the type 1 receptor ALK5 leads to phosphorylation of Smad2 or Smad3, which after combination with Smad4 is transported to the nucleus, where it combines with other transcription factors (TF) and regulates transcription of specific genes.

Serine/Threonine Kinase Receptors

Receptors for the TGFβ Superfamily of Growth and Differentiation Factors

The human transforming growth factor β (TGFβ) superfamily of growth and differentiation factors consists of 33 members, most of which are disulfide-bridge linked homodimeric proteins that control developmental processes and adult tissue homeostasis. In addition to TGFβs, this family includes the bone morphogenetic proteins (BMPs), the more restricted subfamily of growth and differentiation factors (GDFs), activins and nodal. TGFβ family members regulate cell growth, differentiation, migration and death, in a developmental context-dependent and cell type-specific manner. For instance, the TGFβs more often inhibit, but sometimes also stimulate, cell proliferation. As TGFβ ligands act multifunctionally in numerous tissue types, they also play complex roles in various human diseases, ranging from autoimmune to cardiovascular diseases and cancer.

All members of this family signal through a comparable sequence of mechanisms (Massagué, 2012) (**Fig. 4**). First, the dimeric growth factor binds to two copies of one of the five type II receptors, all transmembrane proteins with a single membrane spanning domain and a cytoplasmic kinase domain that has serine/threonine kinase activity. Upon binding of the ligand to the type II receptors a heterotetrameric complex is formed, by the additional recruitment of two copies of the appropriate type I receptor; there are 7 known type I receptors. Type I receptors are also known as activin receptor-like kinases (ALKs). Subsequently, the type II receptor phosphorylates the type I receptor, which in turn phosphorylates serine residues in Ser-X-Ser motifs in one of the five specific stimulating (Smad1, -2, -3, -5, or -8) or one of the two inhibiting (Smad6 or -7) receptor-regulated Smad proteins (R-Smads), depending on the type I receptor involved. Two copies of the phosphorylated R-Smad can subsequently be bound to the common Smad4 to form a trimeric complex. Finally, the $(\text{R-Smad})_2$–Smad4 combination enters the nucleus, where it interacts with the chromatin and causes the final signal within the cell by binding to specific sequences in the DNA and enhancing or inhibiting transcription of specific genes.

There are a number of factors, which influence the possible combinations of ligands with the limited number of type II and type I receptors, subsequently leading to specific cellular responses. Finally, the stimulatory effects of the members of the TGFβ-family members ends by dephosphorylation, ubiquitination and proteasome-mediated degradation of the activated R-Smads and activated type II receptors and ALKs (Shi and Massagué, 2003).

TGFβ Signaling

Three highly homologous forms of TGFβ are produced in various cells: TGFβ1, -2 and -3. The mature dimers are secreted noncovalently attached to their pro-peptide (latency-associated peptide, LAP) and are only able to interact with their type II receptor (TGFBR2) after being freed by contacts with cell surface integrins (Shi *et al.*, 2011) provided the TGFβ-coreceptor betaglycan is present in the cell membrane to present the TGFβ-dimer in the right configuration to the receptor (Esparza-López *et al.*, 2001). The TGFβs1, -2 and -3 all signal through binding to the TGFBR2, but the affinities of the three members of the

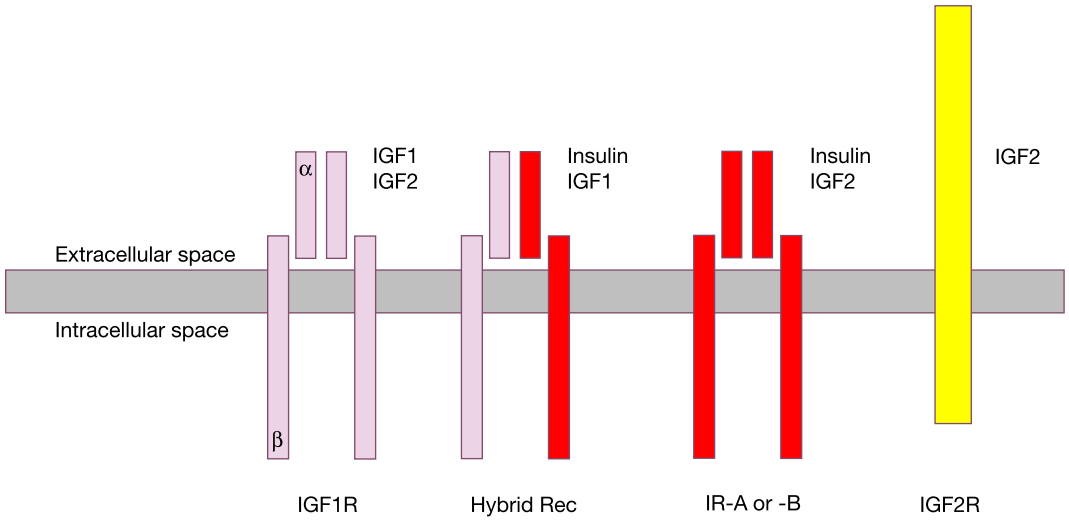

Fig. 5 Structure and combinations of receptors for insulin, IGF1 and IGF2.

subfamily differ. This interaction leads to recruitment of ALK5 into the complex, followed by phosphorylation of R-Smads2 or -3, their combination with Smad4 and the effects on transcription.

In addition to this pathway which is generally used for the signal transduction of members of the TGFβ superfamily, the TGFs can also signal through non-Smad pathways (Moustakas and Heldin, 2009). The TGFBR2 can directly phosphorylate the polarity protein PAR6, which in the end leads to breaking of the tight junctions between mammalian cells, leading to the disintegration of epithelial structure and dedifferentiation of the epithelial cells. An alternative pathway starts by the phosphorylation of proteins by activated ALK5, leading to activation of the mitogen-activated protein kinase (MAPK) signaling cascade, which can regulate cell proliferation or migration.

Signaling by Activin, Inhibin, Nodal, and Myostatin

Activins are combinations of two inhibin β-subunits, βA or βB, connected by disulfide bridges (activin A, activin AB, or activin B). The same β-subunits are part of the inhibin molecule, in which one of the β-subunits is connected to an inhibin α-subunit (inhibin A or inhibin B). Nodal and myostatin (also known as GDF8) are structurally related to activin. Activins, Nodal and myostatin use the Activin-receptors type 2 or type 2B (ActR2 or ActR2B) in combination with ALK4 or ALK5, followed by phosphorylation of Smad2 or -3, which can bind to Smad4 and convey the signal to the nucleus, in the same way as happens with TGFβ. Myostatin is also able to convey information through noncanonical pathways (Walker *et al.*, 2016).

Activin and myostatin can be bound to follistatin in the circulation; this complex is not biologically active. Similarly, Lefty1/2 and Cerberus inactivate Nodal. At the level of the receptor, the inhibins can counteract activin's actions by binding to the ActR2 or ActR2B, but only in the presence of betaglycan, which, apart from acting as a coreceptor for TGFβ, fulfills a similar role for inhibin (Gray *et al.*, 2002).

Signaling by BMPs, GDFs, and AMH

BMPs and the majority of the members of the subfamily of GDFs signal through the activin receptors ActR2 or -2B and the type 2 BMP-receptor BMPR2, combined with ALK1, -2, -3, or -6. GDF1, -3, and -9 signal also through ActR2 or -2B or BMPR2, with ALK4, -5, and -7 as type I receptors. AMH signals by addressing the AMH-receptor type 2 (AMHR2) in combination with ALK2, -3 or -6. Most of these factors use Smad1, -5 and -8 in combination with Smad4 to convey their signal to the nucleus, but GDF1, -3, and -9 signal through Smad2 and -3.

In the circulation, BMPs are bound to the binding proteins noggin and chordin.

Tyrosine Kinase Receptors

The Insulin Receptor Family

Insulin and the insulin-related growth factors (IGFs)1 and -2 signal through the activation of a limited number of receptors: the insulin-receptors (IRs)-A and -B, the IGF type 1 receptor (IGF1R) or the combination of these receptors (**Fig. 5**). An orphan receptor named insulin receptor related receptor (IRR) has also been found. They form a family of highly homologous proteins,

the structure of which is characterized by the presence of an extracellular α-domain, linked by disulphide bridges to a transmembrane β-domain. Both domains are originally synthesized as a single protein, which is cleaved after the formation of the disulphide bridges and subsequently incorporated in the plasma membrane, where they form dimers. IR-A and IR-B are formed from the same gene, where exon 11 can be skipped from its messenger RNA to form IR-A. This leads to the absence of a 12 amino acid sequence from the c-terminal end of the α-domain (Belfiore *et al.*, 2009).

Due to the high homology between the IRs and the IGF1R, they can bind insulin and the IGFs. However, the affinities of the ligands strongly depend on the composition of the receptor dimer: IR-A can bind insulin and IGF2 with high affinity, but IR-B and the hybrid IB-A/IR-B show high affinity binding only to insulin. The IGF1R binds to IGF1 and IGF2, but the hybrid receptor IR/IGF-IR binds both insulin and IGF1. Finally, an unrelated receptor for IGF2, IGF2R, or cation independent mannose-6-phosphate receptor has been described. This receptor consists of a single primarily extracytoplasmic polypeptide chain (Harris and Westwood, 2012) and acts via a G-protein coupled receptor in intracellular transport of lysosomal enzymes. In addition, it sequesters IGF2 from potential receptor activation by internalization and degradation.

Insulin Receptor Signal Transduction

After binding of the ligand to the α-subunit of one of the ligands IR or IGF1R undergo a conformational change inducing activation the kinase activity in the β-domains resulting in transphosphorylation among these subunits and further activation of phosphorylation at tyrosine moieties (Boucher *et al.*, 2014) (**Fig. 6**). This leads to binding and phosphorylation of insulin receptor substrates (IRSs) 1 to 6, which after phosphorylation at multiple tyrosines can bind to intracellular molecules and in turn stimulate their phosphorylation. Subsequently, two main pathways of signal transduction can be activated: one involved in the metabolic actions of insulin (the PI3-kinase/Akt pathway) and the other in cellular proliferation and differentiation (the RAS-MAPK pathway).

Phosphorylated IRS interacts with Src-homology 2 (SH2) docking sites in the regulatory subunit of phosphatidylinositol-(4,5)-bisphosphate 3-kinase (PI3-kinase), activating the catalytic subunit to convert PIP2 to phosphatidylinositol-(3, 4, 5)-trisphosphate (PIP3). PIP3 production leads to activation of several downstream enzymes, including the serine-threonine kinase Akt. Akt activation regulates metabolic enzymes, such as glycogen synthase kinase 3 and 6-phosphofructo-2-kinase, and it is involved in

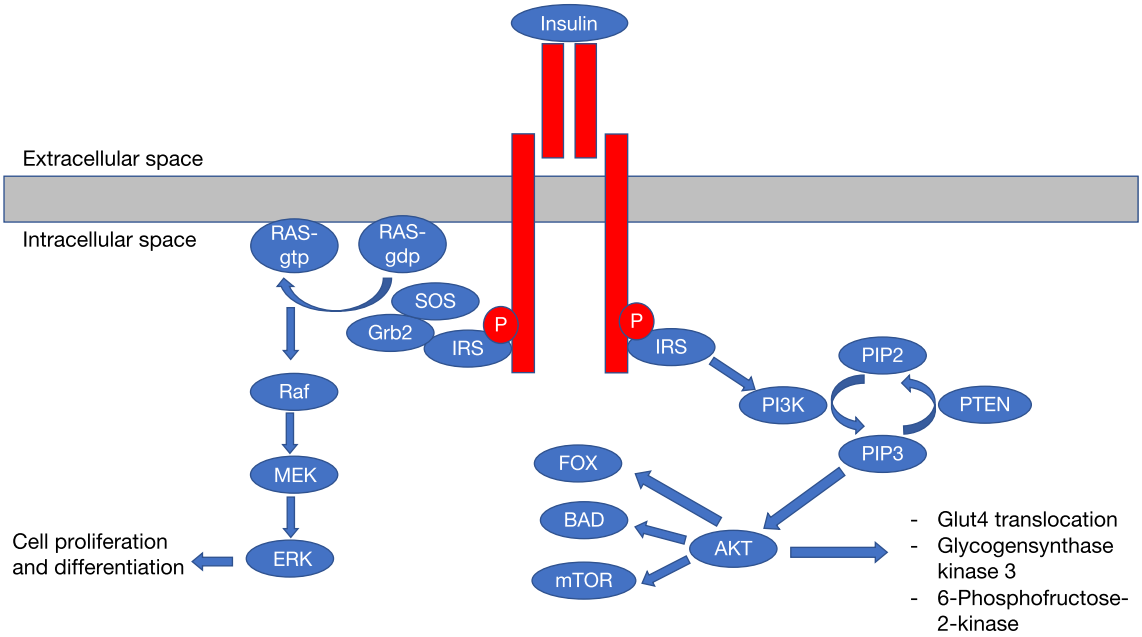

Fig. 6 Mechanism of action of the insulin- and IGF-stimulated receptors. After binding of the ligand, β-subunits are phosphorylated, leading to phosphorylation of insulin receptor substrate (IRS). Phosphorylated IRS stimulates phosphatidylinositol-(4,5)-bisphosphate 3-kinase (PI3-K), activating the catalytic subunit to convert phosphatidylinositol-(4,5)-bisphosphate (PIP2) to phosphatidylinositol-(3, 4, 5)-trisphosphate (PIP3). PIP3 activates Act, which can stimulate a number of other proteins due to its serine-threonine kinase activity. Alternatively, phosphorylated IRS can activate growth factor receptor-bound protein 2 (Grb2). Grb2 activates the Ras guanine nucleotide exchange factor Son of Sevenless (Sos), which is a guanine nucleotide exchange factor for Ras, catalyzing the switch of Ras from the GDP-bound form (Ras-GDP) to the active, GTP-bound form (Ras-GTP). Ras-GTP interacts with and stimulates downstream effectors, such as the serine/threonine kinase Raf, which stimulates its downstream targets MEK1 and 2 that phosphorylate and activate the MAP kinases ERK1 and 2.

glucose metabolism by such activities as induction of glucose transporter (Glut4) translocation from intracellular storage compartments to the plasma membrane. Akt can also phosphorylate a number of other proteins, including BAD and forkhead box protein (FOX), which are involved in inhibition of apoptosis and cell growth. Furthermore, activated Akt can stimulate the mTOR pathway, which is involved in the regulation of mRNA translation into proteins.

The RAS-MAPK pathway is stimulated by IR after binding of growth factor receptor-bound protein 2 (Grb2) to phosphorylated IRS. Grb2 activates the Ras guanine nucleotide exchange factor Sos (Son of Sevenless), which is a guanine nucleotide exchange factor for Ras, catalyzing the switch of membrane-bound Ras from an inactive, GDP-bound form (Ras-GDP) to an active, GTP-bound form (Ras-GTP). Ras-GTP then interacts with and stimulates downstream effectors, such as the serine/threonine kinase Raf, which stimulates its downstream target MEK1 and -2 that phosphorylate and activate the MAP kinases ERK1 and -2. Stimulated ERK1 and -2 play a direct role in cell proliferation or differentiation, regulating gene expression or extranuclear events, such as cytoskeletal reorganization, through phosphorylation and activation of targets in the cytosol and nucleus.

A number of mechanisms play a role in obliteration of stimulated insulin signaling pathways. Since these pathways are stimulated after phosphorylation, phosphatases play an important role at a number of crucial points, starting at dephosphorylation at the level of the receptors and IRSs. Phosphatases like PTEN and SH2 domain-containing inositol 5-phosphatase 2 (SHIP2) dephosphorylate PIP3 at positions 3 and 5. Furthermore, in a number of conditions IR and IGF1R and IRS can be phosphorylated by serine-threonine kinases, leading to downregulation of the activity of the receptors.

The Growth Hormone Receptor Family

The GH receptor (GHR) is part of the larger family of cytokine receptor signal transducers also containing receptors for prolactin, erythropoietin, leptin, thrombopoietin, leukemia inhibiting factor, ciliary neurotrophic factor, oncostatin-M, carditropin-1 and most of the interleukins, together with many of the hematopoietic colony-stimulating factors (Waters, 2016). Members of this family exist in the form of homo- or heterodimers, consisting of proteins with a single transmembrane region. They act upon binding of the ligand by phosphorylation of both the intracellular part of the receptor and other effector proteins. GRHs are preformed homodimers, interacting with two binding sites on the GH molecule, first with a region called site 1, followed by binding of the other monomer with site 2. This binding causes a change in the configuration of the dimer, leading to transphosphorylation of associated Janus kinase 2 (JAK2) molecules on tyrosine residues, resulting in turn in tyrosine phosphorylation of intracellular tyrosines in the GHR providing docking sites or enabling binding of adaptor proteins such as members of the family of Signal transducer and activator of transcription (STATs) (Carter-Su *et al.*, 2016). STAT5 is involved in the stimulation of expression of IGF1 after binding to the promotor regions of these genes. Apart from the phosphorylation of STATs, JAK2 also phosphorylates tyrosine residues on the above discussed insulin receptor substrates (IRSs), causing effects similar to those caused by this branch of insulin signal transduction: the PI3-kinase/Akt pathway and the RAS-MAPK pathway. This explains the metabolic and proliferation/differentiation effects of GH.

Roles of Plasma Binding Proteins in Modulation of Hormone Action and Metabolism

Geoffrey L Hammond, Lesley A Hill, and Phillip W Round, Life Sciences Center, Vancouver, BC, Canada

Abbreviations

SERPIN	Serine proteinase inhibitor	**CBG**	Corticosteroid-binding globulin
DBP	Vitamin D-binding protein	**TBG**	Thyroxine-binding globulin
		SHBG	Sex hormone-binding globulin

Introduction

Small molecular weight lipophylic hormones, steroids and thyroid hormones, are shuttled by plasma proteins from their sites of synthesis to peripheral tissues where they enter cells to act via interactions with intracellular hormone receptors directly or after enzymatic activation. The major plasma hormone-binding proteins (**Table 1**) include albumin that is present in high concentrations and transports a variety of hormones and drugs with μM affinities and limited ligand-binding specificity, the albumin-related vitamin D binding protein that binds vitamin D secosterols with nM affinity, and several low abundance plasma proteins, i.e., corticosteroid-binding globulin, thyroxine-binding globulin and sex hormone-binding globulin, which also bind their ligands specifically with nM affinities. The unique physiochemical properties of these hormone-binding proteins and differences in their plasma concentrations determine the plasma distribution of their ligands between the protein-bound fraction and the "free" fraction that is accessible to tissues and able to enter target cells.

Albumin

Albumin is the most abundant plasma protein. It exhibits a diurnal rhythm, during which the plasma concentrations are lowest in the early hours of the morning (Jones *et al.*, 2017). Albumin is not glycosylated enzymatically, and has a remarkably long plasma half-life of ~19 days (Peters, 1996). Most of the albumin in the body leaves the blood circulation and resides in the interstitial compartments of tissues, apart from the brain, and this is especially pronounced in skin and muscle, which is the major site of albumin catabolism. Albumin is also recycled back into the blood from the interstitial compartments of tissues, multiple times, via the lymph (Peters, 1996), and this dynamic compartmentalization of albumin likely influences the access of its hormonal ligands to cells within tissues.

Albumin binds the thyroid hormones, triiodothyronine (T3) and thyroxine (T4), and steroid hormones with μM affinity. The binding affinity of albumin for T4 is ~4-fold greater than for T3 (Refetoff, 2000), and it displays a preference for estradiol followed by testosterone, progesterone and cortisol (Westphal, 1986). The high concentrations of albumin in plasma provide an unlimited capacity for these hormones, and albumin acts as a reservoir that buffers fluctuations in their plasma levels.

The tertiary structure of albumin comprises three internally similar domains (I-III) each with at least two (A and B) subdomains (He and Carter, 1992). Four binding sites for thyroxine are distributed across subdomains IIA, IIIA and IIIB, which also contain

Table 1 Common names, gene symbols, and properties of the major hormone-binding proteins in human blood

Common names	*Gene Symbol*	*M_r*[a]	*Modifications*	*Levels (M)*	*Affinity Kd*	*Specificity*
Albumin	*ALB*	66.5	Glycation, Cys-34 modifications[b]	500–600 (μM)	1–8 μM	Low
Vitamin D-binding globulin (DBP)	*GC*	52–58	*O-glycosylated* (1–2 sites)	7.0–8.5 (μM)	1–10 nM	High (25-D3 > 1,25-D3)
Corticosteroid-binding globulin (CBG)	*SERPINA6*	60–62	*N*-glycosylated (5 sites)	400–800[c] (nM)	1-10 nM	High (cortisol ≈ corticosterone > progesterone)
Thyroxine-binding globulin (TBG)	*SERPINA7*	54	*N*-glycosylated (4 sites)	180–350[c] (nM)	0.1–1.0 nM	High (T4 > T3)
Sex hormone-binding globulin (SHBG)	*SHBG*	48–50[b]	*N*-glycosylated (2 sites) O-glycosylated (1 site)	10–250[c] (nM)	1–10 nM	High (DHT > testosterone > estradiol)

binding sites for many drugs and fatty acids (Curry *et al.*, 1998), and fatty acids induce conformational changes in albumin that create an additional thyroxine-binding site between domains I and III (Petitpas *et al.*, 2003). However, each molecule of albumin normally binds less than two fatty acids, and the ability of fatty acids to displace thyroid hormones or steroids is therefore limited. The testosterone and progesterone binding sites partially overlap within subdomains IIA and IIB, respectively, and glucocorticoids and other C21 steroids also bind within subdomain IIA (Abboud *et al.*, 2017). In addition, albumin is the main plasma binding protein for steroid hormone precursors and metabolites, as well as conjugated steroids, and it binds sulfated steroids with greater affinity than glucuronidated steroids (Westphal, 1986). Binding of sulfated steroids to albumin is determined primarily by their sulfate moieties, and sulfated steroids are not displaced from albumin by unconjugated steroids, implying that their binding sites are distinct (Westphal, 1986).

Production and Regulation of Plasma Levels

Plasma albumin production by hepatocytes is maintained at the transcriptional level by several liver enriched nuclear factors (Ogawa *et al.*, 1997) including HNF1 (Lichtsteiner and Schibler, 1989), C/EBP-α (Friedman *et al.*, 1989) and C/EBP-β (Descombes *et al.*, 1990). Decreases in plasma albumin levels during acute inflammation are mediated by the pro-inflammatory cytokines, IL-6 (Heinrich *et al.*, 1990) and TNF-α (Buck *et al.*, 2001) that act at the transcriptional level through signaling mechanisms involving C/EBP family members (Poli, 1998). Glucocorticoids enhance the production of albumin by isolated rat heptocytes at the transcriptional level (Nawa *et al.*, 1986), and increase plasma albumin levels in rats (Marinkovic *et al.*, 1989). They also reverse the fall in plasma albumin levels observed after IL-6 treatment (Marinkovic *et al.*, 1989).

Genetic Variants

More than 100 nonsynonymous mutations in the human *ALB* gene are listed in human single nucleotide polymorphism (SNP) databases (http://www.internationalgenome.org). Numerous naturally occurring mutations cause hypoalbuminemia, due to defects in albumin production, and are associated with adverse reactions to drugs (Minchiotti *et al.*, 2008), but there is no evidence that low plasma levels of albumin influence the activities of endogenous ligands like thyroid or steroid hormones. The same is true for individuals with rare cases of analbuminemia who may present with fatigue, edema and hyperlipidemia, but otherwise live and function normally. By contrast, albumin variants with increased affinity for thyroid hormones have been identified in patients with familial dysalbuminemic hyperthyroxinemia (Minchiotti *et al.*, 2008; Greenberg *et al.*, 2014), and the responsible amino acid substitutions have shed light on the main albumin-binding site for thyroxine within domain IIA (Petitpas *et al.*, 2003). Albumin variants with abnormal steroid-binding properties do not influence the levels or activities of steroid hormones. Structural analyses of these variants indicate that key contact points for testosterone are in sub-domain IIA, while progesterone interacts with residues within the helix connecting domains IIA and B (Kragh-Hansen *et al.*, 1990).

Vitamin D-Binding Protein

After the group-specific component of human serum, known as the GC-globulin, was implicated in the antiricketic effects of vitamin D (Thomas *et al.*, 1959), it was renamed as the vitamin D-binding protein (DBP) to reflect its role in the plasma transport of biologically active forms of vitamin D, but *GC* is still currently used as the gene symbol for DBP in genome databases.

Plasma DBP is structurally related to albumin, but domains I-III of DBP adopt a distinct overall shape (Verboven *et al.*, 2002) because a coil fold replaces helix 7 in domain II and its domain III is truncated C-terminally (Cooke and David, 1985). In crystal structures of human DBP, 25-hydroxy D3 hydrogen bonds with amino acids in a hydrophobic cleft between helices 1–6 within domain I. These structures also explain why the additional hydroxyl group of 1,25-hydroxy D3 reduces its binding affinity (Verboven *et al.*, 2002). Plasma DBP also binds the globular form of actin shed by cells after injury, facilitating its removal from the circulation (Mc Leod *et al.*, 1989). Although the actin and vitamin D binding sites overlap, actin and vitamin D bind independently (Otterbein *et al.*, 2002).

The plasma concentrations of DBP are normally at least 100 times lower than those of albumin, but its affinities for vitamin D metabolites exceed those of albumin by 2–3 orders of magnitude (**Table 1**). Importantly, the binding capacity of DBP for both forms of vitamin D exceeds their combined plasma concentrations by at least 20 times, and it exerts a major influence on their plasma distribution, protecting against vitamin D toxicity and acting as a reservoir for 25-hydroxy D3. In human blood, 88% of the 25-hydroxy D3 and 85% of 1,25-dihydroxy D3 is bound to DBP, with only $\sim$0.04 and 0.4%, respectively, being in the free fraction, and the remainder bound mainly to albumin (Delanghe *et al.*, 2015). Although the free concentrations of 1,25-dihydroxy D3 are $\sim$3 orders of magnitude lower than required to saturate the intracellular vitamin D receptor, plasma 25-hydroxy D3 concentrations are normally three orders of magnitude greater than those of 1,25-dihydroxy D3. This means that the amounts of 25-hydroxy D3 that enter cells exceeds those of 1,25-dihydroxy D3 by $\sim$2 orders of magnitude, and this is especially important in cells where 25-hydroxy D3 is converted into the preferred vitamin D receptor ligand, 1,25-dihydroxy D3.

Production and Regulation of Plasma Levels

Plasma DBP is produced by hepatocytes and has a plasma half-life of 2.5 days (Speeckaert *et al.*, 2006). Plasma levels of DBP (**Table 1**), like those of albumin, exhibit a diurnal rhythm, and are maintained within a relatively narrow range throughout life (Jones *et al.*, 2017; Speeckaert *et al.*, 2006). During human pregnancy, it is assumed that estrogens increase maternal plasma 1,25-dihydroxy D3 and DBP levels because similar increases occur after the administration of oral contraceptives (Bouillon *et al.*, 1981). Three HNF1-binding sites within the promoter of the rat gene encoding DBP are key regulators of its basal transcriptional activity. In the liver, HNF1α homodimers interact with these sites in conjunction with the dimerization co-factor of HNF1 to enhance transcription, whereas in the kidney, these sites appear to be occupied by heterodimers of HNF1α and HNF1β (Song *et al.*, 1998). The transcriptional response in kidney cells is much lower than in the liver and it has been attributed to HNF1β acting as a *trans*-dominant inhibitor of HNF1α-mediated enhancer activity. The production of DBP by human liver cells is decreased by TGFβ, while glucocorticoids and IL-6 have the opposite effects, and this explains why plasma DBP levels do not show an acute phase negative response during acute inflammation (Guha *et al.*, 1995).

Genetic Variants

Human DBP is highly polymorphic, with over 120 rare variants identified in different ethnic groups, but three common *GC* allelic variants defined by the nonsynonymous SNPs, rs7041 and rs4588, encode DBP variants that are distinguished by their electrophoretic mobility and *O*-glycosylation status (Borges *et al.*, 2008; Speeckaert *et al.*, 2006). Glycosylation of DBP does not influence its plasma half-life or its vitamin D binding properties, but the common *GC* alleles are linked to differences in plasma DBP and vitamin D levels (Wang *et al.*, 2010) and are associated with susceptibility or resistance to a spectrum of diseases (Speeckaert *et al.*, 2006).

Humans with no plasma DBP have never been identified. Mice that lack plasma DBP because of a gene deletion have undetectable 1,25-dihydroxy D3 in their blood, but they are normocalcemic when maintained on a diet containing vitamin D (Safadi *et al.*, 1999) because their tissue concentrations of 1,25-dihydroxy D are normal (Zella *et al.*, 2008). However, mice without DBP develop secondary hyperparathyroidism and bone abnormalities when fed a vitamin D deficient diet (Safadi *et al.*, 1999). A similar phenotype is observed in megalin deficient mice, and this was attributed to the megalin-mediated endocytosis of DBP in renal tubules, which serves as a means of recovering vitamin D excreted by the kidneys (Nykjaer *et al.*, 1999). Patients with a megalin deficiency have increased DBP in their urine but they are not vitamin D deficient, and megalin does not appear to be functionally important in recovering vitamin D from urine in humans (Storm *et al.*, 2013).

Corticosteroid-Binding Globulin

Plasma corticosteroid-binding globulin (CBG, also known as transcortin or SERPINA6), binds glucocorticoids and progesterone with nM affinity (Westphal, 1986). In human blood, $\sim$85% of cortisol is normally bound by CBG and $\sim$10% is bound by albumin, which together maintain the amount of unbound cortisol in plasma at $\sim$5% (Siiteri *et al.*, 1982; Dunn *et al.*, 1981). In addition to buffering against oscillations in cortisol levels, proteolysis of CBG provides a mechanism for the targeted delivery of its ligands to sites of inflammation or tissue remodeling (Perogamvros *et al.*, 2012; Hammond, 2016).

The primary structure of CBG identifies it as a clade A serine protease inhibitor (SERPINA) family member (Hammond *et al.*, 1987). Most *SERPINA* genes, including *SERPINA6*, are positioned in a syntenic cluster on chromosome 14q32.1. In humans, the CBG precursor includes a signal polypeptide of 22 residues that is removed prior to secretion (Hammond *et al.*, 1987). The mature polypeptide of 383 amino acids contains a single steroid-binding site and six potential *N*-glycosylation sites that are differentially utilized (Sumer-Bayraktar *et al.*, 2011), and glycosylation of N238 in human CBG influences its steroid-binding activity (Avvakumov *et al.*, 1993).

The SERPINs share a common tertiary structure comprising three β-sheets and seven or more α-helices, as well as a functionally important reactive center loop (RCL) that is specifically cleaved by proteases, such as neutrophil elastase that is produced during inflammation (Hammond *et al.*, 1990). Crystallographic analyses have identified structurally and functionally important amino acids within CBG, provided insight into how RCL positioning and integrity influences its steroid-binding activity, and explain how natural mutations effect the biological activities of CBG (Lin *et al.*, 2010).

Production and Regulation of Plasma Levels

Plasma CBG is produced by the liver and its half-life is $\sim$13 h (Seralini *et al.*, 1989). In animal models, *Serpina6* expression in the liver fluctuates in a biphasic manner during fetal life, and also occurs transiently in fetal exocrine pancreas and the developing kidney (Scrocchi *et al.*, 1993a,b; Berdusco *et al.*, 1995). These spatial and temporal changes in CBG production are expected to influence both the systemic and local actions of glucocorticoids at critical developmental stages.

Glucocorticoids influence *SerpinA6* expression differently at specific developmental stages. They increase hepatic CBG production in fetal and early postnatal life but reduce it in adults (Zhao *et al.*, 1997; Berdusco *et al.*, 1995; Pepe *et al.*, 1996), which explains the low plasma CBG levels in patients with Cushing syndrome or after systemic glucocorticoid administration (Schlechte

and Hamilton, 1987). The *SERPINA6* promoter lacks a glucocorticoid response element, and the effects of glucocorticoids on its transcriptional activity may be mediated by interactions between the glucocorticoid receptor and other transcription factors (Verhoog *et al.*, 2014). Cytokines regulate plasma CBG levels in different ways: IL-6 down regulates *SERPINA6* expression in human liver cells, while IL-1β stimulates CBG secretion at a post-translational level (Emptoz-Bonneton *et al.*, 1997).

Plasma Levels in Health and Disease

In humans, plasma CBG levels are similar between sexes (Dunn *et al.*, 1981; Brien, 1981; Ho *et al.*, 2007). Changes in plasma CBG levels occur normally during pregnancy and early development, as well as in patients suffering from acute inflammation caused by infection or tissue trauma, and likely alter the access of glucocorticoids to their target cells (Perogamvros *et al.*, 2012; Hammond, 2016).

In mammals, plasma CBG is transiently produced by fetal hepatocytes after mid-gestation, but declines to low levels shortly before (Scrocchi *et al.*, 1993b; Pepe *et al.*, 1996) or after (Berdusco *et al.*, 1995) birth. The developmental fluctuations in the hepatic production of plasma CBG in the human fetus are unknown but likely reflect those in the baboon (Pepe *et al.*, 1996). Plasma CBG levels in human neonates are low during the first week of life, and gradually rise to adult levels by 12 months of age (Brien, 1981). Low plasma CBG levels in neonates will increase the availability of cortisol to organs such as the lung, the maturation of which is glucocorticoid dependent.

In women, plasma CBG levels increase 2- to 3-fold during the second and third trimesters of pregnancy, along with increased concentrations of its major ligands, cortisol and progesterone (Dunn *et al.*, 1981; Brien, 1981; Ho *et al.*, 2007). Similar increases in plasma CBG occur in women taking synthetic estrogens (Moore *et al.*, 1978), and are presumably mediated by the estrogen receptor. During the final weeks of pregnancy, maternal plasma CBG levels decrease, together with a corresponding increase in free cortisol levels (Ho *et al.*, 2007). Since human CBG binds progesterone almost as well as cortisol, the large amounts of progesterone produced by trophoblasts compete with cortisol for CBG binding at the maternal-fetal interface, and CBG acts as the major determinant of progesterone concentrations in this location (Lei *et al.*, 2015; Hammond, 2016). Low maternal plasma CBG levels are observed in pregnancy-associated disease states, including preeclampsia and gestational diabetes, as well as in gamete recipient pregnancies (Ho *et al.*, 2007).

During inflammation, CBG responds as an acute phase "negative" protein, and reductions in its plasma levels occur in various pathologies involving inflammation and tissue trauma (Zouaghi *et al.*, 1984), including burn injury (Bernier *et al.*, 1998), acute pancreatitis (Muller *et al.*, 2007), sepsis, septic shock and multitrauma (Pugeat *et al.*, 1989; Beishuizen *et al.*, 2001). Pre-symptomatic decreases in plasma CBG have been observed in a rat model of inflammation, demonstrating that CBG is a biomarker of the onset and severity of an inflammatory response (Hill *et al.*, 2016). These reductions in plasma CBG during acute inflammation are attributed to proteolysis of its RCL, as well as a down-regulation of its production by the liver. In this paradigm, proteolysis of CBG occurs early during inflammatory reactions, rendering CBG nonfunctional and promoting the localized release of CBG-bound glucocorticoids at sites of inflammation. Enhanced exposure of tissues to glucocorticoids represses cytokine production and activity, limiting cytokine-mediated tissue damage. At the same time, plasma glucocorticoid levels increase acutely as a result of hypothalamic-pituitary-adrenal activation in response to stress, and synergize with elevations in inflammatory cytokines, such as IL-6, to further reduce plasma CBG production, thereby amplifying free glucocorticoid exposures. During recovery from inflammation, normalization of CBG levels likely plays a role in determining when, and to what extent, glucocorticoids act to restore normal homeostasis (Perogamvros *et al.*, 2012; Hammond, 2016).

Genetic Variants

In a recent genome-wide association study (GWAS), common SNPs in *SERPINA6*, linked to the plasma levels or steroid-binding properties of CBG, were identified as the main determinants of plasma cortisol levels (Bolton *et al.*, 2014). Most CBG variants occur at a low frequency in the general population, but some are enriched in specific ethnic groups. For example, the secretion deficient CBG A51V (rs146744332) occurs at a frequency of ~1:35 in Han Chinese (Lin *et al.*, 2012), Japanese and Kinh Vietnamese (http://www.internationalgenome.org/). In addition, the CBG L93H (rs113418909) and CBG D367N (rs28929488) variants are characterized by reduced affinities for cortisol, and are enriched in individuals of European (Bolton *et al.*, 2014) and Mediterranean/Middle Eastern decent (Emptoz-Bonneton *et al.*, 2000; Cizza *et al.*, 2011; Hill *et al.*, 2012), respectively. Other mutations identified in patients, such as CBG W371S (rs267607282) and CBG G237V (rs754814260), have no detectable cortisol-binding activity (Hill *et al.*, 2012; Perogamvros *et al.*, 2010), while mutations that introduce premature stop codons in the *SERPINA6* coding sequence (e.g., rs777245398) have no CBG in their blood (Torpy *et al.*, 2001; Torpy *et al.*, 2012). Numerous less common nonsynonymous *SERPINA6* SNP have been linked to abnormalities in CBG cortisol-binding activity, production, sensitivity of the RCL to proteolysis, or their immunochemical recognition (Simard *et al.*, 2015).

Many *SERPINA6* mutations that alter the production or function of plasma CBG were discovered in patients presenting with a variety of clinical conditions, including chronic pain, fatigue, depression, hypotension, and excess body weight (Emptoz-Bonneton *et al.*, 2000; Perogamvros *et al.*, 2010b; Hill *et al.*, 2012; Torpy *et al.*, 2001, 2012). However, not all individuals with CBG variants display these clinical features (Hill *et al.*, 2012; Perogamvros *et al.*, 2010b). Patients with CBG deficiencies generally present with low to undetectable serum cortisol levels but normal ACTH levels, and this is because their free cortisol levels in plasma or urine

are normal (Perogamvros *et al.*, 2012; Hammond, 2016). Studies of CBG deficiencies in animal models support a link between lower CBG levels and inflammation susceptibility (Petersen *et al.*, 2006), but most CBG variants that are produced or function abnormally in humans occur rarely, and their clinical consequences have been difficult to establish. Clinical studies of subjects with the secretion-deficient CBG A51V variant that is more common in some ethnic groups may help resolve this. In the only such study to date, pregnancy outcomes and the health of neonates of Chinese mothers with CBG A51V were normal, but a female skewed sex ratio of the offspring was observed (Lei *et al.*, 2015). The biological basis for this is unknown, but CBG deficiency may result in inappropriate cortisol or progesterone exposures during gestation and lead to male fetal demise (Lei *et al.*, 2015).

Thyroxine-Binding Globulin

Plasma thyroxine-binding globulin (TBG, also known as SERPINA7), binds T3 and T4 with nM affinities, but has a preference for T4 (**Table 1**). In human plasma, ~75% of T4 and T3 is bound by TBG. Albumin binds thyroid hormones with ~4 orders of magnitude lower affinity than TBG, and only ~5% of T4 and ~20% of T3 in plasma is bound by albumin. The latter difference reflects the fact that transthyretin also binds T4 with an ~100 fold greater affinity than albumin and has a 10-fold preference for T4 over T3, and as a result transthyretin binds ~20% and ~5% of the T4 and T3 in plasma, leaving <1% of these iodothyronines free in healthy individuals (Pappa *et al.*, 2015).

Unlike most other *SERPINA* members, the human TBG (*SERPINA7*) gene is located on the X chromosome. Human TBG is produced as a 415 amino acid precursor that includes a 20 amino acid signal sequence and four *N*-glycosylation sites (Flink *et al.*, 1986). Plasma TBG and CBG share 42% sequence identity (Hammond *et al.*, 1987), and their tertiary structures are very similar (Zhou *et al.*, 2006). The crystal structure of TBG has identified residues important for ligand binding (Zhou *et al.*, 2006), and provided insight into the functional consequences of TBG variants (Pappa *et al.*, 2015. The RCL of TBG shares little sequence similarity with that of CBG, and appears to move in and out of the main β-sheet A triggering an allosteric mechanism that influences its ligand-binding (Zhou *et al.*, 2006).

Production and Regulation of Plasma Levels

Plasma TBG is produced by hepatocytes and has a half-life of ~5 days (Refetoff, 2000). Several hepatic nuclear factor-binding sites (HNF1α, HNF3α and HNF3β) within the *SERPINA7* promoter, determine its transcriptional activity in hepatocytes (Hayashi *et al.*, 1993). An enhancer located 20 kb downstream of the *SERPINA7* coding sequence also appears to control its expression, because a genetic polymorphism within this region is associated with decreased plasma TBG levels (Ferrara *et al.*, 2015).

Exogenous administration of glucocorticoids reduces TBG levels in humans (Gamstedt *et al.*, 1979) and animal models (Emerson *et al.*, 1993). By contrast, estrogen-dependent increases in TBG in women taking synthetic estrogens or during pregnancy have been associated with increases in sialylation of its *N*-glycans (Ain *et al.*, 1987), and a reduced plasma clearance (Krassas *et al.*, 2010).

Plasma Levels in Health and Disease

A 50% increase in plasma TBG levels in women during pregnancy, accounts for corresponding increases in T3 and T4 levels. In the human fetus, plasma TBG levels gradually increase from 12 weeks of gestation to levels in neonates that are higher than in adults (Williams *et al.*, 2004).

Low plasma TBG levels are found in patients with inflammatory conditions, such as sepsis (Jirasakuldech *et al.*, 2000; Afandi *et al.*, 2000b) or cardiopulmonary bypass surgery (Afandi *et al.*, 2000a). As with CBG, these reductions in TBG levels have been attributed to neutrophil elastase mediated RCL proteolysis that induces a conformational change in TBG and reduces its capacity to bind thyroid hormones at sites of inflammation or tissue trauma (Janssen *et al.*, 2002).

Genetic Variants

Numerous (>50) TBG variants cause a spectrum of TBG deficiencies, from partial to complete, as well as abnormally high plasma TBG levels (Pappa *et al.*, 2015). Biochemically, these TBG deficiencies are caused by nonsense mutations that encode nonfunctional truncated proteins, or missense mutations that alter binding properties and protein expression. By contrast, *SERPINA7* duplication or triplication results in TBG excess (Mori *et al.*, 1995).

Given its chromosomal location, abnormal *SERPINA7* genes are expressed in an X-linked manner. In males, TBG deficits are fully expressed, whereas in heterozygous females, the effects are only partial, although selective X-inactivation in females may result in a complete TBG deficiency (Pappa *et al.*, 2015). The incidence of complete TBG deficiencies varies with ethnicity (Reutrakul *et al.*, 2002; Mandel *et al.*, 1993), for example their incidence in Japanese is 3–10 times higher than in Caucasians. Partial TBG deficiencies occur more frequently in some populations; for example the TBG-A (A191T, rs2234036) variant that has a reduced affinity for thyroid hormones, and susceptibility to inactivation at increased temperature, is present in 40% of Indigenous Australians (Takeda *et al.*, 1989).

Individuals with TBG deficiencies have lower plasma T3 and T4 levels, while the opposite occurs in those with TBG excess, but they are all generally euthyroid because their free T4/T3 levels are within normal ranges, and they do not suffer from major metabolic disturbances (Pappa *et al.*, 2015).

Sex Hormone-Binding Globulin

In humans, sex hormone-binding globulin (SHBG) is the major binding protein for androgens and estrogens in the blood. After removal of a signal polypeptide of 29 residues, SHBG is secreted by hepatocytes as a glycosylated homodimer of 373 residue subunits that comprise tandem laminin G-like domains. Each subunit contains independent steroid-binding sites that bind 5α-dihydrotestosterone (DHT) with the highest affinity, followed by testosterone and estradiol (**Table 1**).

Crystallographic structures have revealed how specific residues interact with steroids. Androgens and estrogens bind in opposite orientations in the binding pocket, and there are steroid-ligand dependent differences in the orientation of a loop region over an entrance to the binding pocket, with estrogens producing a more ordered loop structure (Grishkovskaya *et al.*, 2002). The positioning of this loop is altered by occupancy of a zinc-binding site, which specifically lowers the binding affinity for estrogens (Avvakumov *et al.*, 2000). Crystal structures also identified the binding site for Ca^{2+} that maintains the quaternary structure of the SHBG homodimer and its steroid-binding properties (Grishkovskaya *et al.*, 2000), both of which are adversely affected in frozen and thawed EDTA-plasma (Bocchinfuso and Hammond, 1994).

Production and Regulation of Plasma Levels

Human *SHBG* expression in hepatocytes is under hormonal, nutritional, and metabolic regulation. A nuclear hormone receptor response element positioned near the transcription start site in the *SHBG* promoter binds both HNF4α and COUP-TF, and functions as a transcriptional "on-off" switch, so that HNF4α binding promotes transcription, while COUP-TF binding represses it (Jänne and Hammond, 1998). This competitive relationship between HNF4α and COUP-TF binding at the *SHBG* promoter accounts for most responses observed in relation to the nutritional and metabolic mediators of plasma SHBG levels (Hammond *et al.*, 2012). For instance, hepatic HNF4α levels are increased after thyroid hormone treatment, weight loss or fasting, and this increases hepatic *SHBG* expression and plasma SHBG levels. Conversely, there is evidence that steatosis, pro-inflammatory cytokines and adiponectin all contribute to reductions in hepatic HNF4α levels allowing the "on-off" switch to be occupied by COUP-TF, thereby reducing plasma SHBG production in overweight individuals. A second nuclear hormone receptor-binding site in the *SHBG* promoter interacts with PPARγ to negatively regulate transcription (Selva *et al.*, 2002) or with CAR to increase its activity (Saez-Lopez *et al.*, 2017).

Plasma Levels in Health and Disease

Plasma SHBG levels fluctuate normally throughout life and in response to physiological changes (Hammond *et al.*, 2012), and the plasma half-life of ~1.5 days is influenced by its glycosylation status. During fetal life, changes in plasma SHBG levels likely control the activities of sex steroids during development. Plasma SHBG levels are low at birth and increase during the first few months of postnatal life, presumably in response to the maturation of thyroid hormone actions (Leger *et al.*, 1990). They are maintained at high levels until the onset of puberty, when plasma SHBG levels decrease in both sexes, but to a greater extent in males than females (Aydin and Winters, 2016). Plasma SHBG levels do not fluctuate through the menstrual cycle or change significantly after menopause when anthropometric parameters are taken into account (Pasquali *et al.*, 1997), but increase by as much as 10-fold during pregnancy and in women taking synthetic estrogens (Anderson, 1974), and these increases in plasma SHBG are assumed to be estrogen-dependent. The significance of increased maternal plasma SHBG during late pregnancy is unclear, but it may protect the mother from fetal adrenal androgens (Hogeveen *et al.*, 2002). In healthy normal weight individuals, plasma levels of SHBG in men are about two times lower than in women, a trend that continues through adulthood until old age, when there is an age dependent increase in men (Wu *et al.*, 2008).

Occupancy of the SHBG steroid-binding site varies considerably in relation to these sex and life cycle differences in its plasma levels (Hammond *et al.*, 2012). In young children, SHBG is predominantly unoccupied and this limits tissue exposure to sex steroids until puberty (Hammond, 2011). Steroid occupancy of SHBG also differs markedly between men and women, with SHBG in women being largely unoccupied, allowing it to more effectively limit the access of androgens to target cells (Dunn *et al.*, 1981). This effect is exaggerated in women taking oral contraceptives that increase SHBG levels, and has been exploited pharmaceutically to reduce symptoms of androgen excess (Dewis *et al.*, 1985). By contrast, in men, SHBG is primarily occupied by testosterone and lower plasma levels of SHBG result in proportionally higher amounts of available androgens in men than women (Dunn *et al.*, 1981).

Plasma levels of SHBG are used as a biomarker of a variety of endocrine and metabolic diseases (Hammond *et al.*, 2012). In women, low SHBG levels are commonly associated with clinical manifestations of androgen excess, especially in those who are overweight or present with polycystic ovarian syndrome (Botwood *et al.*, 1995). Plasma SHBG levels are abnormal in patients with thyroid hormone-dependent diseases and can be used to identify patients with thyrotoxicosis due to excessive thyroid hormone

production or availability (Krassas *et al.*, 2010), as well as those with thyroid hormone resistance (Sarne *et al.*, 1988; Krassas *et al.*, 2010). Inverse correlations exist between SHBG levels and body weight, with high levels in patients with anorexia and low levels in obese individuals. These body weight extremes and their associated plasma SHBG levels are linked to increased risk for osteoporosis in lean individuals, and the metabolic syndrome, diabetes and cardiovascular disease in those who are overweight (Hammond, 2017).

Genetic Variants

Polymorphism in *SHBG* influences both the production and function of plasma SHBG (Hammond *et al.*, 2012), and a GWAS has confirmed that SHBG is the major determinant of testosterone levels in men (Ohlsson *et al.*, 2011). A $(TAAAA)_n$ microsatellite located upstream of the *SHBG* promoter influences its transcriptional activity (Hogeveen *et al.*, 2001), as well as plasma SHBG levels (Cousin *et al.*, 2004), and has been associated with age of menarche, and several sex-hormone dependent diseases, including polycystic ovarian syndrome, atherosclerosis and cardiovascular risk, the metabolic syndrome, bone mineral density, and male infertility (Xita *et al.*, 2011; Saltiki *et al.*, 2011; Safarinejad *et al.*, 2011; Xita and Tsatsoulis, 2010; Eriksson *et al.*, 2006). A common SNP (rs1799941) near the *SHBG* transcription start site, as well as others positioned further upstream (rs858518) or downstream of the SHBG coding region (rs727428), are in strong linkage disequilibrium with each other, and are associated with SHBG levels (Thompson *et al.*, 2008). Another SNP located in intron 1 (rs6257) has been associated with low serum SHBG levels and increased risk of type 2 diabetes (Ding *et al.*, 2009) and breast cancer (Thompson *et al.*, 2008).

A nonsynonymous SNP that encodes SHBG D327N (rs6259) introduces a new *N*-glycosylation site (Power *et al.*, 1992), and a reduction in its plasma clearance (Cousin *et al.*, 1999) explains the slightly higher SHBG levels in carriers of this variant, which has been linked to a reduction in hip bone mineral density (Napoli *et al.*, 2009), and a reduced risk for type-2 diabetes (Ding *et al.*, 2009). An association between SHBG P156L (rs6258) and low plasma testosterone levels has been attributed to its reduced affinity for testosterone (Ohlsson *et al.*, 2011). The clinical significance of SHBG P156L and other nonsynonymous SNPs encoding rare SHBG variants with abnormalities in their production, glycosylation, steroid binding, interaction with fibulin family members, or antibody recognition (Wu and Hammond, 2014) is unknown, and may be difficult to determine if they escape detection in routine assays of plasma SHBG (Laurent and Vanderschueren, 2014).

Other Plasma Hormone Binding Proteins

The major plasma hormone binding proteins (**Table 1**) regulate the plasma concentrations of thyroid and steroid hormones, as well as their precursors and metabolites, and influence their metabolic clearance rates and access to target tissues and cells in various ways. However, these lipophylic molecules also bind several other plasma proteins including transthyretin, orosomucoid and apolipoproteins. Transthyretin has only a modest impact on the plasma distribution of thyroid hormones and this is not altered by changes in its plasma concentrations under pathological conditions because only a small fraction (0.5%) of its bindings sites are occupied. Likewise, transthyretin variants with reduced affinity for T3 and T4 have little effect on their plasma distribution, but variants with increased affinity for these iodothyronines are found in a small subgroup of subjects with euthyroid hyperthyroxinemia (Pappa *et al.*, 2015). In addition, the contribution of transthyretin or apolipoproteins to the plasma distribution of thyroid hormones is expected to be greater in individuals with deficiencies in albumin or TBG. Orosomucoid and apolipoproteins (Westphal, 1986) also bind steroids with limited specificity and relatively low affinity, and their impact on the plasma distribution of steroids is limited under normal conditions (Dunn *et al.*, 1981). However, because of their abundance, their effects on the plasma distribution of steroids may be much more significant in individuals with deficiencies in albumin or the plasma proteins that bind steroids specifically with high affinity.

Dynamic Endocrine Rhythms

Thomas J Upton, University of Otago, Dunedin, New Zealand and University of Bristol, Bristol, United Kingdom
Stafford Lightman, University of Bristol, Bristol, United Kingdom

Glossary

Circadian From Latin, circa "about" + dies "day." Refers to biological processes that recur approximately every 24 h. Circadian rhythms are endogenous, entrainable, and stable over a range of physiological temperatures.

Diurnal A general term for a rhythm or process with daily recurrence. The rhythm may or may not be endogenously generated.

Glucocorticoids Steroid hormones, synthesized in the adrenal cortex and responsible for a wide range of physiological effects including metabolic, immune, cognitive and homeostatic. The principal endogenous glucocorticoid in humans is cortisol.

HPA The hypothalamic–pituitary–adrenal axis is defined by complex interactions between the hypothalamus, pituitary and adrenal glands. A highly dynamic system, it regulates circulating glucocorticoid concentrations and plays a crucial role in the neuroendocrine response to stress.

Ultradian Rhythms with a period of less than 1 day but greater than 1 h.

Introduction

The metabolism of all living things is characterized by rhythmic patterns. Fundamental processes such as sleep, temperature regulation, feeding, nutrient digestion, and hormone secretion all exhibit biological rhythms. The period of these rhythms fluctuates from as short as a few minutes, as in the case of insulin secretion, to weeks-long infradian rhythms in case of the human menstrual cycle (Henley *et al.*, 2009a,b; Feng and Lazar, 2012; Waite *et al.*, 2012).

Biological rhythms can be described in terms of their pattern of activity. Diurnal rhythms generally refer to patterns that follow cycles of day and night. Humans and many other species of animal are diurnal creatures as the main period of activity is during daylight hours, with sleep (or other inactivity) at night. Many hormones express diurnal rhythms including thyroid hormones (Russell *et al.*, 2008), testosterone (Walton *et al.*, 2007; Waite *et al.*, 2009; Walton *et al.*, 2007) and prolactin (Van Kerkhof *et al.*, 2015).

Circadian rhythms are more precisely defined. Occurring with a period of approximately 1 day, they are both endogenous and self-sustained. Following these criteria, circadian rhythms may also be diurnal rhythms but not all diurnal rhythms are circadian. Examples of common circadian rhythms include body temperature (Buhr *et al.*, 2010), feeding (Eckel-Mahan and Sassone-Corsi, 2013) and the secretion of hormones, including melatonin (Benloucif *et al.*, 2005) and glucocorticoids (Keller-Wood and Dallman, 1984).

Circadian rhythms are entrained, or synchronized, to external cues. The most powerful environmental stimuli (often called *Zeitgebers*, from the German "time giver") are light and the timing of food (Albrecht, 2012; Asher and Sassone-Corsi, 2015). However, to be true circadian rhythms they must also continue to oscillate even in the absence of synchronizing input.

To accurately measure the endogenous properties of in vivo circadian rhythms, experiments must be conducted under conditions where light and other potential external synchronizers are carefully controlled. In humans, a commonly used protocol, known as "forced desynchrony," requires participants to be admitted to a specialized sleep unit. During this time, bedtime is moved progressively later, eventually resulting in a sleep–wake cycle that occurs within a 28-h "day." Rhythms driven by circadian pacemakers are unable to entrain to this extended day length, and become uncoupled from the sleep-wake cycle. This allows researchers to assess the endogenous "free running" period of the rhythms of interest. Experiments using this protocol indicate that the intrinsic period of cortisol, melatonin, and body temperature ranges between approximately 23.5 and 24.5 h (Czeisler *et al.*, 1999; Wyatt *et al.*, 1999; Gronfier *et al.*, 2007).

Rhythms with a period of less than 1 day but greater than 1 h are termed ultradian. Ultradian rhythms characterize many endocrine rhythms including insulin secretion (Simon and Brandenberger, 2002), growth hormone (Tannenbaum and Martin, 1976), and the reproductive axis (Choe *et al.*, 2013). Of special interest is the ultradian rhythm of glucocorticoids, which will be described in further detail later in this article. In the unstressed state, pulses of cortisol (corticosterone in rats) are secreted every 60–90 min (Veldhuis *et al.*, 1989; Jasper and Engeland, 1991; Windle *et al.*, 1998) on a background circadian rhythm. The complex interplay between the hypothalamic–pituitary pulse generator, the adrenal glands, and environmental stressors creates a dynamic system that if disturbed has important consequences for health and disease.

Intracellular Clocks and the Origin of Circadian Rhythms

Circadian rhythms are generated by the oscillation of intracellular "clocks." Clocks are present in almost all living things including plants, animals, and even single-cell organisms (Roenneberg and Merrow, 2005). In humans and other mammals, a specialized

cluster of cells known as the suprachiasmatic nucleus (SCN) acts as a circadian master clock. The SCN is located in anteroventral hypothalamus, above the optic chiasm and on either side of the third ventricle (Gillette, 1991). Time of day information is transmitted from the eye and the outside world via specialized photosensitive retinal ganglion cells contained within the retinohypothalamic tract. These neurons synapse directly with SCN neurons (Welsh *et al.*, 2010) and entrain the central circadian clock to the timing of light stimulus as well as having direct effects on adrenocortical secretion (Pilorz *et al.*, 2016). However, the SCN continues to function autonomously even when completed isolated from external stimuli. Circadian electrical activity continues within the SCN even when surgically isolated (Inouye and Kawamura, 1979) and in freely moving animals kept in constant darkness (Ono *et al.*, 2015).

The SCN functions as a master clock that coordinates peripheral rhythms. This has been demonstrated in numerous rodent experiments. For example, lesioning the SCN in rats abolishes circadian rhythms of temperature, feeding, movement, and pituitary hormone secretion (Stephan and Zucker, 1972; Abe *et al.*, 1979).

Over the past two decades there have been a number of breakthroughs in the understanding of circadian biology and clock function in mammals. In the late 1990s it was discovered that exposing cultured rat fibroblasts to serum shock induced circadian gene expression (Balsalobre *et al.*, 1998). Further experiments including the demonstration that individual fibroblast cells could function autonomously as circadian oscillators (Welsh *et al.*, 2004) led to the realization that the circadian clock apparatus was present in essentially all body organs and tissues (Hastings *et al.*, 2008; Albrecht, 2012).

These remarkable discoveries have led to a new era in circadian biology. The previous dogma asserting the SCN as the sole circadian pacemaker has been overthrown, replaced by a new model of the SCN as a "master clock" that coordinates and synchronizes rhythms in peripheral tissues (Yamazaki, 2000). Outputs from the SCN project to other brain structures including to the paraventricular nucleus (PVN) of the hypothalamus (Dibner *et al.*, 2010). Connections from the PVN synchronize peripheral clocks to the light/dark cycle via autonomic (parasympathetic and sympathetic) pathways and via hormone signaling (such as cortisol and melatonin) (Yamazaki, 2000; Dibner *et al.*, 2010; Welsh *et al.*, 2010).

The cell clock machinery present both in the master pacemaker neurons of the SCN and in peripheral tissues consists of transcriptional–translational feedback loops. These loops oscillate with a period of approximately 24 h, thereby generating the circadian rhythm. The principal loop is made up of two transcription activators: brain and muscle ARNTL-like protein 1 (BMAL1) and circadian locomotor output cycles kaput (CLOCK). The BMAL1/CLOCK dimer complex activates numerous so-called clock-controlled genes as well as inducing transcription of *Period* (Per) and *Cryptochrome* (CRY). Increasing levels of PER and CRY act via negative feedback to inhibit CLOCK and BMAL transcription. PER and CRY are degraded and the cycle begins once more (see Asher and Sassone-Corsi, 2015; Feng and Lazar, 2012 for excellent reviews). Feedback is also regulated by a number of post-translational mechanisms including phosphorylation and glycosylation of clock proteins (Crane and Young, 2014). When the clock mechanisms are disrupted, so too are circadian rhythms. Deactivating mutations of PER and CRY result in the complete dysregulation of glucocorticoid rhythms and clock gene expression in mice (Dallmann *et al.*, 2006; Oster *et al.*, 2006; Yang *et al.*, 2009).

The Hypothalamic–Pituitary–Adrenal Axis as a Model Dynamic Endocrine Rhythm

Glucocorticoids are synthesized and secreted from the adrenal cortex under control of the hypothalamic–pituitary–adrenal (HPA) axis. Acting through glucocorticoid and mineralocorticoid receptors which are nearly ubiquitously expressed, they regulate growth, metabolism and the response to stress. Glucocorticoids are intrinsically linked to the circadian system through their ability to influence the clock rhythms of multiple tissues (Oishi *et al.*, 2005; Pezük *et al.*, 2012). The potent synthetic corticosteroid dexamethasone alters the circadian phase of gene expression in liver, kidney, and heart but not the SCN (Balsalobre *et al.*, 2000), presumably because glucocorticoid receptors (GR) are not expressed there (Rosenfeld *et al.*, 1993).

The HPA Axis Circadian Rhythm

Basal secretion of cortisol in humans (and corticosterone in rats) is circadian with peak concentrations on waking (Lightman and Conway-Campbell, 2010), anticipating the onset of daily activity. The rhythm is modulated by both stimulatory and inhibitory outputs from the SCN whose axons project into the PVN of the hypothalamus (Kalsbeek *et al.*, 2012). The PVN contains corticotrophin-releasing hormone (CRH) neuroendocrine neurons that in term stimulate adrenocorticotrophic (ACTH) synthesis from the anterior pituitary (Spiga *et al.*, 2014). ACTH released into the peripheral circulation acts at the adrenal cortex to stimulate glucocorticoid synthesis and release (**Fig. 1**).

The adrenal response to ACTH, and thus cortisol secretion, is influenced by inputs from the central nervous system and by intrinsic clock mechanisms within the adrenal itself. Outputs from the SCN connect via a multisynaptic pathway to the autonomic nervous system (Buijs *et al.*, 1999). Branches of the thoracic splanchnic nerve provide extensive sympathetic autonomic innervation to the adrenal glands (Engeland, 1998). Sympathetic input appears to modulate the adrenal-ACTH response in different phases of the sleep/wake cycle. During the awake phase (nighttime in rats) sympathetic drive is highest, increasing ACTH sensitivity and promoting adrenal steroidogenesis (Ulrich-Lai *et al.*, 2006). Conversely, using the same rat model, transecting the

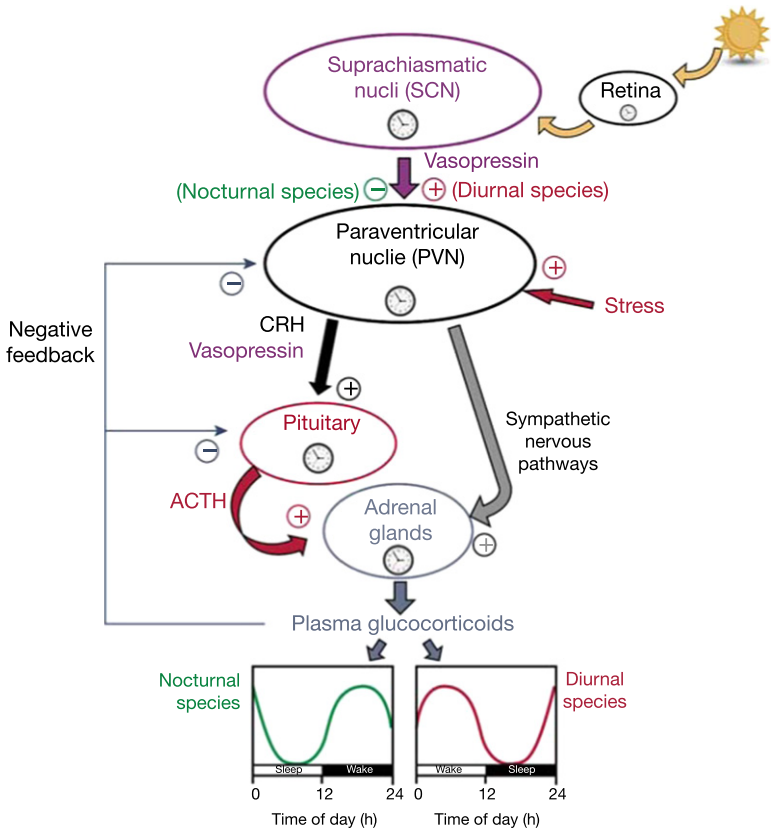

Fig. 1 Representation of the control of circadian glucocorticoid release in mammals. The circadian secretion of GC is dependent on the rhythmic release of ACTH and a gating process by the adrenal clock. *Clock symbols* represent self-sustained oscillators. GC secretion is also modulated by nervous signals coming from the PVN of the hypothalamus via sympathetic nervous pathways. ACTH release is controlled by the rhythmic release of CRH and vasopressin from the PVN. Rhythmic activity of the HPA axis is under the control of the master clock in the SCN, reset by ambient light via the retina. Reproduced from The Functional and Clinical Significance of the 24-Hour Rhythm of Circulating Glucocorticoids, Endocr Rev. 2016;38(1):3–45. doi:https://doi.org/10.1210/er.2015-1080. splanchnic nerve disrupts the normal diurnal variation in CORT levels by attenuating ACTH responsiveness and reducing CORT production at night (Jasper and Engeland, 1994).

Intrinsic properties of the adrenal cell also provide a "gating" mechanism for sensitivity to ACTH. In mouse adrenal slices, which are isolated from external synchronizing inputs, the response to ACTH varies depending on the phase of the circadian cycle (Oster *et al.*, 2006). In vivo experiments in wild-type mice show that ACTH stimulation at the time of zenith CORT results in significantly higher CORT secretion than the same stimulus given at the CORT nadir. However, in mice with mutated non-functioning clock genes, this variation is abolished—the ACTH response at both time points is similar to the "CORT nadir" time point in wild-type animals (Oster *et al.*, 2006).

In summary, glucocorticoids are secreted with a diurnal, circadian rhythm that is entrained by the SCN. The rhythm is modulated at the level of the adrenal by sympathetic nerve inputs from the CNS and by intrinsic adrenal clock mechanisms that "gate" sensitivity to ACTH stimulus depending on the phase of the circadian cycle.

The Ultradian Rhythm and the HPA Axis: Mechanisms and Clinical Significance

Pituitary hormones are not released continuously—rather they are secreted in pulses that vary in amplitude and/or frequency over a 24 h period (Weitzman *et al.*, 1971; Veldhuis *et al.*, 1990). High resolution sampling of blood in both animals (Jasper and Engeland, 1991) and humans (Weitzman *et al.*, 1971; Henley *et al.*, 2009a,b) demonstrate that glucocorticoids are secreted in pulses every 60–90 min (Veldhuis *et al.*, 2008; Spiga *et al.*, 2014). The origin of this ultradian rhythm was previously assumed to be hypothalamic. However, while lesions to the SCN produce the expected abolishment of circadian CORT secretion, they do not disrupt the pulsatile secretion of CORT, which remains ultradian (Waite *et al.*, 2012). This led to the suggestion that the ultradian CORT rhythm is generated outside of the hypothalamus and the convincing hypothesis that the rhythm is intrinsic to the properties of the HPA axis. Mathematical modeling predicts that ultradian oscillations in ACTH and cortisol secretion are a consequence of the dynamic interaction between positive feed-forward from hypothalamic CRH drive and pituitary ACTH

secretion, and negative feedback generated by adrenal cortex secretion of cortisol (Walker *et al.*, 2010). In vivo experiments using rats infused with constant levels of CRH generated ultradian oscillations in both ACTH and CORT (Walker *et al.*, 2012). This supports the premise that pulsatile CRH secretion from the hypothalamus is not required for the generation of the ultradian rhythm. Further, rapid negative feedback by glucocorticoid inhibition on the anterior pituitary must be the crucial factor regulating the dynamic rhythm (**Fig. 2**).

The concept of the pulsatile ultradian hormone rhythm, rather than simply a circadian biphasic rhythm, has become increasingly recognized as physiologically important. Pulsatile exposure to glucocorticoids affects expression of genes and gene transcripts in the liver (Stavreva *et al.*, 2009), brain (Conway-Campbell *et al.*, 2010; George *et al.*, 2017), and many other tissues. In contrast to rats exposed to constant levels of glucocorticoid, CORT given in ultradian pulses induced cyclical GR-mediated gene transcription, or "gene pulsing" (Stavreva *et al.*, 2009). On a behavioral level, responses to stress are blunted in adrenalectomized rats exposed to continuous compared to the normal response when given pulsed CORT replacement (Sarabdjitsingh *et al.*, 2010). These animal studies indicate that pulsatile exposure to glucocorticoids is necessary for normal gene transcription and behavior responses. However, to date very little is known about the implication of these findings in humans. It is proposed that there are likely to be significant biological consequences of altered glucocorticoid pulsatility, alluded to in a few studies of depression (Young *et al.*, 2007), obstructive sleep apnea (Henley *et al.*, 2009a,b), and major cardiac surgery (Gibbison *et al.*, 2013).

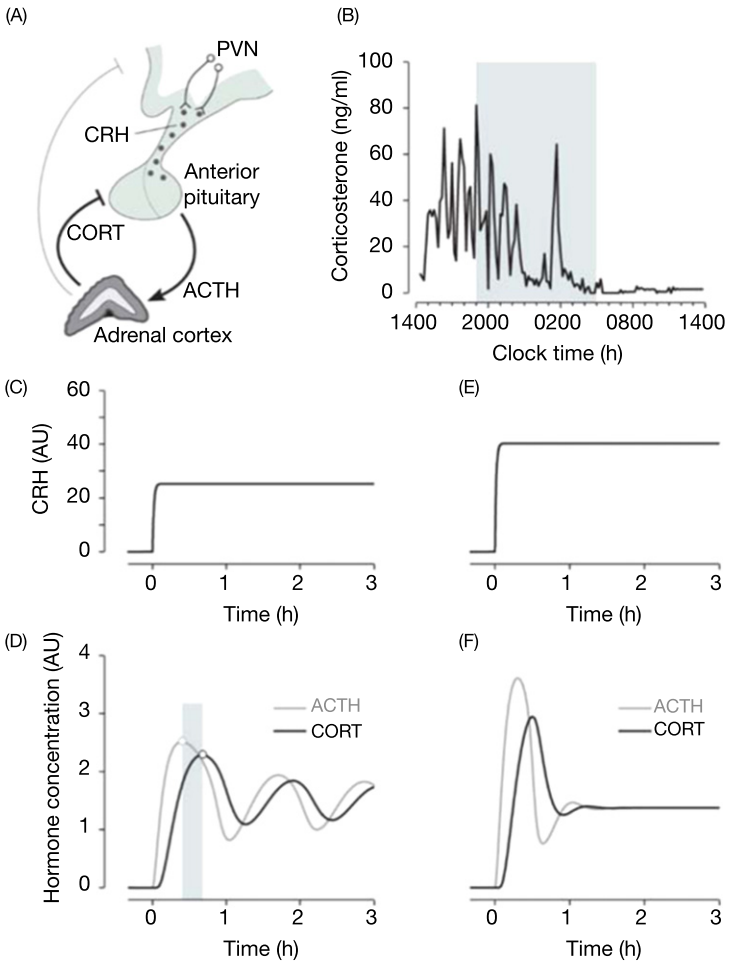

Fig. 2 Regulation of glucocorticoid secretion. (A) Negative feedback in the HPA axis plays a key role in regulating glucocorticoid (CORT) secretion. (B) Ultradian corticosterone (the main glucocorticoid in rodents) oscillations in a freely behaving male Sprague-Dawley rat. Shaded region indicates the dark phase. (C–F) Mathematical modeling predicts that ultradian ACTH and glucocorticoid (CORT) oscillations are regulated by a systems-level negative feedback mechanism in the pituitary-adrenal network, independent of pulsatile hypothalamic activity. Numerical simulations show that the pituitary-adrenal network can oscillate under conditions of constant CRH drive to the pituitary (C–D). Oscillations in ACTH and CORT are characterized by a small phase shift (*shaded region* indicates phase difference between oscillation peaks). For higher levels of CRH drive, the oscillations are rapidly damped to steady-state levels of hormone (E–F). *AU*, arbitrary units. Reproduced from The Origin of Glucocorticoid Hormone Oscillations. PLoS Biol 10(6): e1001341. https://doi.org/10.1371/journal.pbio.1001341.

Rhythms and Endocrine Disease

Endocrinological disorders affect tens of millions of people worldwide with a broad spectrum of manifestations and long-term health effects. Cushing syndrome broadly describes the condition of excess cortisol and may originate from ACTH secreting tumors, typically located in the anterior pituitary, or from excess production by adrenal tumors. When iatrogenic forms (caused by exogenous steroid administration) are excluded, incidence is approximately 0.2–5.0 per million per year, with a population prevalence estimated between 39 and 79 per million (Lacroix *et al.*, 2015). Cushing syndrome causes widespread disease manifestations with increased mortality principally a result of cardiovascular and cerebrovascular disease (Sharma *et al.*, 2015).

The converse of Cushing's, primary adrenal insufficiency, results from the loss or destruction of adrenal tissue and the consequent life-threatening deficiency in adrenal corticosteroid production. Prevalence is around 100–140 per million, and incidence is approximately 1–4:1,000,000/year in Western countries (Bornstein *et al.*, 2016). Even with so-called physiological glucocorticoid replacement, mortality remains twice that of the general population (Bergthorsdottir *et al.*, 2006) and quality of life as measured by subject health scores remains significantly lower than controls (Bleicken *et al.*, 2008).

The diagnostic approach for endocrine disorders is typically to use single-time point measures to demonstrate lack of hormone suppression (in diseases such as Cushing's (Nieman *et al.*, 2008), acromegaly (Katznelson *et al.*, 2014), and primary aldosteronism (PA) (Funder *et al.*, 2016)) or failure to provoke adequate response to stimulation (primary adrenal insufficiency (Bornstein *et al.*, 2016), growth hormone deficiency (Ho, 2007)). Results are often extremely difficult to interpret as the superimposition of circadian and ultradian rhythms results in a wide interindividual variation in the "normal" range (Spiga and Lightman, 2015). Further, variation in measurement methodology makes standardization of results very challenging. Using cortisol as an example, most assays measure total hormone concentrations rather than the free (active) fractions, apart from that measured in the urine and saliva. Salivary cortisol is a noninvasive technique but factors influencing results such as gender, age, and coexisting illness have not been fully characterized (Nieman *et al.*, 2008) and false positive rates may be 20%–40% (Liu *et al.*, 2005). Likewise 24-h urine cortisol collections are cumbersome, often unreliable and subject to multiple extrinsic factors that can falsely affect results (Petersenn *et al.*, 2014).

Studies of circadian or ultradian hormone patterns in humans with endocrine disease are generally limited as the investigative methods are laborious and invasive, requiring inpatient admission and blood sampling typically every 10–20 min. In a study of a small group of patients with primary adrenal insufficiency, blood was sampled every 30–60 min over 24 h. These patients, treated with twice daily oral glucocorticoid replacement, had markedly different profiles of ACTH and cortisol compared with healthy controls (Scott *et al.*, 1978). Now, almost 40 years after that study was published, very little has changed with respect to the regimen of glucocorticoid hormone replacement. So-called physiological doses of glucocorticoid replacement, typically prescribed two to three times per day, do not mimic circadian or ultradian secretion patterns of hormone release. It is therefore perhaps not surprising that quality of life and a wide spectrum of health outcomes remain poor among patients with primary adrenal insufficiency (Andela *et al.*, 2016; Bensing *et al.*, 2016).

Rhythms and Treatment in Hormone-Deficient States

Recent attempts to produce glucocorticoid replacement regimens that mimic endogenous conditions have primarily focused on replicating diurnal CORT rhythms. Once daily dose-modified release preparations of hydrocortisone intend to reproduce "physiological" cortisol profiles (Johannsson *et al.*, 2009, 2016; Mallappa *et al.*, 2015) but do not account for ultradian rhythms. Despite early evidence of some benefit (Quinkler *et al.*, 2015; Giordano *et al.*, 2016), the only prospective long-term study using these medications published to date has reported no improvement in quality of life at 5 years of follow-up (Nilsson *et al.*, 2017). Continuous subcutaneous infusions of cortisol can also mimic diurnal patterns more accurately than oral dosing, but again does not seem to improve quality of life (Gagliardi *et al.*, 2014). Together, these findings support the hypothesis that the ultradian pulsatile rhythm is extremely important and needs to be considered when prescribing replacement glucocorticoids.

Rhythms in Hormone Excess States

High frequency blood sampling in patients with secretory pituitary tumors predictably shows that hormone secretion patterns are manifestly abnormal with marked increases in total hormone secretion compared with controls (Roelfsema *et al.*, 2014). However, it is interesting to observe that secretion remains pulsatile in these conditions. Pulsatile secretion of ACTH and cortisol can be observed in 24-h profiles of patients with pituitary Cushing's disease, although the pattern is disordered with increased pulse frequency and amplitude (Roelfsema *et al.*, 1998). Following successful surgery, secretion profiles returned to normal, matching those of healthy controls (Roelfsema *et al.*, 2011). In a study of 12 patients with adrenal-based Cushing syndrome (where ACTH is suppressed), a similar pattern of abnormal cortisol secretion was observed, with increased pulse frequency and augmented pulsatile secretion (Van Aken *et al.*, 2005). A diurnal rhythm of secretion was maintained, although phase shifted compared with controls. It is likely that alternative outputs from the SCN contributed to this rhythm in the absence of oscillatory ACTH secretion, in addition to gated peripheral ACTH sensitivity mediated by adrenal cell circadian clock rhythms.

Aldosterone secretion is also rhythmic (Wolfe *et al.*, 1966). PA, the inappropriate secretion of aldosterone, is characterized by the development of pathological hypertension (Funder *et al.*, 2016). In a small cohort study comparing 10 patients with PA with

healthy controls, Siragy *et al.* used high frequency blood sampling to observe both circadian and ultradian rhythms of aldosterone secretion. Basal rates and the amplitude of pulsed aldosterone secretion were significantly augmented in PA compared with healthy controls but there was no difference in pulse frequency between the groups (Siragy *et al.*, 1995).

Together, these two conditions provide examples of how rhythms are intrinsic to endocrine processes and the important implications for diagnosis and management.

Ultradian Rhythms: Future Opportunities for Diagnosis and Treatment?

In the setting of adrenal insufficiency, administration of pulsatile subcutaneous glucocorticoid to adrenally suppressed healthy volunteers reproduces a more accurate ultradian rhythm than seen in any other studies in humans (Russell *et al.* 2014). Studies investigating the impact of pulsatile versus twice daily or continuous administration of CORT in patients with adrenal insufficiency are currently being conducted (see http://www.isrctn.com/ISRCTN67193733). A major multicenter clinical trial using ambulatory high frequency hormone sampling (https://clinicaltrials.gov/ct2/show/NCT02934399) aims to provide new information about ultradian endocrine rhythms in both health and disease, with implications for the diagnosis and treatment of these conditions. Paying heed to the ultradian as well as the circadian physiology of conditions such as PA, Cushing's and adrenal insufficiency will ultimately aide clinicians who are limited by the nonspecific, nondynamic set of investigations currently available.

Conclusions

In summary, endocrine hormones are typically secreted in rhythmic patterns with circadian and ultradian pulsatile secretion. Circadian rhythms are established and maintained by cellular clocks, both centrally and in peripheral tissues. Ultradian rhythms modulate processes on shorter time scales influencing gene transcription at the cell level and neurocognitive processes at the behavioral level. Current diagnosis and monitoring typically relies on single time point measurements using unreliable methods, and therefore cannot accurately reflect the true dynamic nature of the disease being studied. Approaches that take into account ultradian as well as circadian physiology promise to provide new insight into the diagnosis and management of endocrine conditions.

Adipose Tissue as an Endocrine Organ

Adipose tissue is not simply an organ that only accumulates and releases lipids, but it is an important endocrine organ that secretes a great variety of substances including steroid hormones, cytokines and growth factors, regulators of lipid metabolism, etc. (Fischer-Posovszky *et al.*, 2007). These factors are called adipokines, and function as part of a complex set of physiological control systems that regulate the local tissue and the physiology of the whole organism. Therefore, adipokines contribute to the regulation of various biological processes including inflammation and immune function, vascular biology, hematopoiesis, cell proliferation and angiogenesis (Radin *et al.*, 2009). Herein, we highlight the adipokines more directly involved in the regulation of energy balance and metabolism.

Leptin

The term leptin comes from Greek (leptos: lean). It is a hormone secreted by the white adipose tissue discovered after the characterization of the effect of the absence of the gene of leptin and its receptor in mice (ob/ob and db/db respectively). These recessive mutations of the obese (ob) gene and the diabetes (db) gene produce in these mice obesity and type 2 diabetes, generating a syndrome similar to morbid obesity in humans (Coleman, 1978; Friedman and Leibel, 1992). The ob/ob and db/db mice have identical phenotypes, weighing three times more than normal mice, showing an increase of up to five times the body fat content. They are hyperphagic, have little locomotive activity and are sexually inactive. Leptin works within a long-term regulatory system, modulating the amount of food consumed in relation to the amount of energy expended (Friedman and Halaas, 1998). It is considered an efferent hormone with a negative feedback function that keeps the adipose tissue mass constant. Leptin is secreted by adipocytes either as a 16 KDa peptide as bound to a soluble form of its receptor (Ob-R). The amount of secreted leptin correlates positively with the amount of fat mass, suggesting that its regulation is linked to a lipid-sensitive mechanism (Maffei *et al.*, 1995). An increase in plasma levels generates a negative energy balance, while the reduction of circulating leptin levels produces a positive energy balance (intake > energy expenditure). Leptin reaches the CNS through the circumventricular organ, crossing the blood-brain barrier in a process dependent on tanycytes (specialized glial cells), which translocate leptin from the blood to the third ventricle, and from there accrete the hypothalamic nuclei (Balland *et al.*, 2014; Langlet *et al.*, 2013). In the hypothalamus, leptin exerts its action on neurons that express their receptor (Ob-R) through a signaling pathway dependent on STAT3 (Ghilardi *et al.*, 1996; Matsuoka *et al.*, 1999). Already in the ARC, leptin depolarizes the POMC neurons, whose anorexigenic response produces a decrease in intake and an increase in energy expenditure (Cowley *et al.*, 2001). On the other hand and simultaneously, leptin inhibits in the arcuate nucleus the neurons with orexigenic effect AgRP/NPY, enhancing the satiating effect of the hormone (van den Top *et al.*, 2004).

Adiponectin

It is a protein secreted and produced exclusively by adipocytes, being one of the most abundant plasma proteins in the bloodstream (Ouchi *et al.*, 2003). It is considered an anti-inflammatory factor, presenting a negative correlation in its plasma concentration with respect to the amount of adipose tissue (Ryo *et al.*, 2004). Therefore, the production of adiponectin is inhibited by pro-inflammatory factors such as tumor necrosis factor alpha (TNFα) and interleukin 6, as well as stress and hypoxia (Hosogai *et al.*, 2007). Numerous clinical studies show a relationship between adiponectin and obesity: adiponectin is reduced in patients with type 2 diabetes, the high concentration of this protein in plasma being a protective factor against diabetes. At the metabolic level, adiponectin increases the oxidation of fatty acids in the muscle and reduces plasma levels of glucose, free fatty acids and triglycerides via the AMP kinase pathway (Fruebis *et al.*, 2001).

Resistin

Resistin is an adipokine belonging to a group of proteins associated with inflammatory processes. Despite being an adipokine, it has been described that this protein is also produced by other tissues such as brown adipose tissue, stomach, intestine, and muscle (Nogueiras, 2003). Its name comes from its effect on the insulin resistance it produces in mice (Steppan *et al.*, 2001); knock-out mice for resistin have lower post-pandrial glucose levels and lower hepatic gluconeogenesis than normal mice (Banerjee *et al.*,

2004). The ability of resistin to modulate insulin resistance is associated with the activation of the suppressor of cytokine 3 signaling (SOCS3), an inhibitor of insulin signaling in adipocytes (Steppan *et al.*, 2005). In rodents, resistin is regulated by metabolic and nutritional status, decreasing in fasting and being increased in states of obesity and type 2 diabetes (Lazar, 2007). Like leptin, the main effects of resistin on energy metabolism are mediated by the hypothalamus; the central administration of resistin reduces the intake and regulates the lipid metabolism of peripheral tissues (Tovar *et al.*, 2005; Vazquez *et al.*, 2008).

Function of White Adipose Tissue on Obesity-Related Diseases

The hypertrophy of adipose tissue in obese organisms also contributes to other disease as type 2 diabetes or the generation of non-alcoholic fatty liver disease (NAFLD). There is a close relationship between hypertrophic adipocytes resistant to insulin, dysregulated immunity in both fat and liver and NAFLD induced by lipotoxicity. The adipocytes and the vascular fraction of the fatty tissue (stroma) secrete many hormones, complement factors, cytokines (TNF-α, interleukins), chemokines and adipokines functioning as an endocrine tissue. As mentioned previously, adiponectin is one of these adipokines, whose reduced secretion of it in obesity alters lipid metabolism and insulin sensitivity in the liver; The administration of adiponectin in obese mice fed a high-fat diet dramatically alleviates hepatomegaly, steatosis and inflammation (Xu *et al.*, 2003). In steatohepatitis, decreased secretion of adiponectin by dysfunctional adipocytes contributes to the formation of NASH (Polyzos *et al.*, 2010).

The macrophages of adipose tissue are an important fraction of the stroma (Halberg *et al.*, 2008; Fuentes *et al.*, 2010). Activation of adipose tissue macrophages plays an important role in fat dysfunction generating insulin resistance, free fatty acid release into the bloodstream and ectopic fatty deposition in the liver (Cusi, 2012). In the stroma there are two types of macrophages: (1) M1 macrophages or classical activation macrophages that play a key role in humoral immunity and in response to pathogens; secrete large amounts of pro-inflammatory cytokines (TNF-α, IL-6, IL-12, …) and low levels of anti-inflammatory cytokines (IL-10); and (2) M2 macrophages or alternative activation with anti-inflammatory function (Lumeng *et al.*, 2007). An increase in M1 macrophages relative to M2 is characteristic of rodents fed a high-fat diet (Lumeng *et al.*, 2007; Odegaard *et al.*, 2008) and obese humans (Lumeng and Saltiel, 2011).

Glossary

Gluconeogenesis Synthesis of new glucose molecules from substrates such as lactate, pyruvate, alanine, glutamine, and other amino acids by reversal of glycolysis.
Glycogen Large intracellular granules made up of polymers of glucose used for storage of carbohydrate mainly in liver and skeletal muscle.
Glycogenolysis Breakdown of glycogen molecules to glucose.
Glycolysis Anaerobic metabolic breakdown of glucose to lactate and pyruvate.
Lipolysis Breakdown of triglyceride molecules, yielding one molecule of glycerol and three free fatty acid molecules.
Triglycerides Fat droplets composed of molecules of three free fatty acids esterified to one molecule of glycerol.

Glucose: From Origins to Fates

Glucose in plasma either comes from dietary sources or can be the product of the breakdown of glycogen in liver (glycogenolysis) or the formation of glucose in liver and kidney from other carbons compounds (precursors) such as lactate, pyruvate, amino acids, and glycerol (gluconeogenesis).

In humans glucose removed from plasma may have different fates in different tissues and under different conditions(e.g., postabsorptive vs. postprandial), but the pathways for its disposal are relatively limited. It may be: (1) immediately stored as glycogen or (2) undergo glycolysis which can be *non-oxidative* producing pyruvate (which can be reduced to lactate or transaminated to form alanine) or *oxidative* through conversion to acetyl CoA which is further oxidized through the tricarboxylic acid cycle to form carbon dioxide and water. Non-oxidative glycolysis carbons undergo gluconeogenesis and the newly formed glucose is either stored as glycogen or released back into plasma (Fig. 1).

Importance of Glucose Homeostasis

Although free fatty acids (FFA) are the main fuel for most organs, glucose is the obligate metabolic fuel for the brain under physiologic conditions. This occurs because of low circulating concentrations of other possible alternative substrates (e.g.,

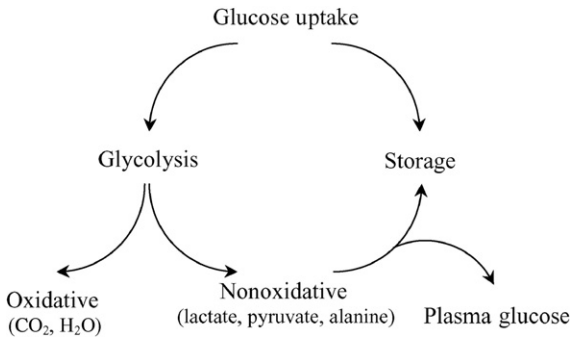

Fig. 1 Routes of post-prandial glucose disposal. From Woerle, H.J., Meyer, C., Dostou, J.M., Gosmanov, N.R., Islam, N., Popa, E., Wittlin, S.D., Welle, S.L. and Gerich, J.E. (2003). ☆*Change History*: October 2017. M. Alsahli and J. E. Gerich updated the text throughout and added new figures.

This chapter is an update of Hans J. Woerle, John E. Gerich, Normal Glucose Physiology, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 263-270.

 doi:10.1016/B978-0-12-801238-3.03827-7

ketone bodies) or because of limitations of transport across the blood-brain barriers (e.g., FFA) (Siesjo, 1988). Brain cannot synthesize glucose or store it as glycogen more than few minutes supply. Thus brain is dependent on a continuous supply of glucose from plasma. Glucose plasma concentrations below 55 mg/dL (3 mmol/L) impair cerebral function (Mitrakou *et al.*, 1991a) whereas more severe and prolonged hypoglycemia cause convulsions, permanent brain damage and even death. Hypoglycemia is associated with multiple other complications. On the other hand, hyperglycemia or diabetes mellitus has its own risks to health.

General Considerations

Relative Changes in Glucose Fluxes

Plasma glucose concentrations are determined by the relative rates at which glucose enters and leaves the circulation. Thus the plasma glucose will increase only if the rate of entry exceeds its rate of exit and, conversely, plasma glucose level will decrease only if rates of exit exceeded the rates of entry. To maintain relatively stable plasma glucose concentrations, increases in rates of glucose delivery into the systemic circulation (e.g., when meal is ingested) require a comparable increase in rates of glucose removal from the circulation (Kelley *et al.*, 1988). For example, during vigorous exercise, fever or trauma when the body's utilization of glucose increases, there is normally a compensatory increase in glucose delivery (Wahren *et al.*, 1978).

Changes in glucose clearance, an index of efficiency of glucose removal from the circulation by itself do not affect plasma glucose concentrations independent of changes in rates of glucose entry and exit.

Factors Influencing Glucose Fluxes

The most important factors on a moment to moment basis are hormones (insulin, glucagon and catecholamines), the sympathetic nervous system activity as well the concentration of other substrates (FFA). On a more prolonged time basis (hours-days), other hormones (cortisol and growth hormone), nutritional factors (e.g., diet composition), exercise and physical fitness, along with concomitant changes in the sensitivity to hormones become important (Gerich, 1993). Cortisol, growth hormone and catecholamines affect glucose homeostasis by altering insulin sensitivity and also by changes in the availability of alternative substrates.

Fasting vs. Postprandial States

The mechanisms delivering glucose into the circulation (i.e., glycogenolysis vs. gluconeogenesis) and the sites for glucose disposal will vary depending on duration of fasting. For example, as fasting is prolonged, the proportion of gluconeogenesis increases and the contribution of hepatic glycogen stores decreases. Moreover, the relative contribution of the kidney increases. In regard to utilization, after an overnight fast, there is no net storage of glucose and all glucose taken up by tissues is either completely oxidized or converted to lactate.

Glucose Transport Pathways

Due to its hydrophilic nature, glucose diffuses slowly across the lipid bilayer of the cell membrane, and needs specific transporter proteins to facilitate its entry into cells. There are two distinct families of transport proteins (Bouche *et al.*, 2004). (1) *Facilitative GLUT family*: These transporters promote facilitated diffusion of glucose, a process that is not energy dependent and that follows Michaelis–Menten kinetics (Gottesman *et al.*, 1984). The high-affinity transporters (GLUT 1, 3, 4) have a Michaelis–Menten constant (K_m) below the normal range of blood glucose concentrations and are capable of providing glucose transport under basal conditions for many cells (Bouche *et al.*, 2004). GLUT1 is present in pancreatic α cells in which glucose entry is the major regulator of their glucagon secretion. GLUT3 is the major neuronal transporter (lowest K_m) whereas GLUT4 mediates insulin-stimulated glucose uptake by skeletal muscle, heart, and adipose tissues. Insulin and exercise promote GLUT3 expression on cell surface (Bouche *et al.*, 2004; Rodnick *et al.*, 1992). The low-affinity transporters (GLUT2) are present on ß cells and in tissues exposed to large glucose fluxes, such as intestine, liver, and kidney (Bouche *et al.*, 2004). (2) *SGLT family*: These transporters utilize the electrochemical sodium gradient to transport glucose against concentration gradients (Bouche *et al.*, 2004; Wright, 2001). SGLT1 is responsible for the dietary uptake of glucose from the small intestine lumen. Both SGLT1 and SGLT2 are present in the renal proximal convoluted tubulae and are responsible for reabsorption of glucose from glomerular filtrate as discussed in detail below (Bouche *et al.*, 2004; Wright, 2001; Bonner *et al.*, 2015; Mueckler, 1990; Cushman and Wardzala, 1980). SGLT2 inhibitors have recently been approved for treatment in patients with T2DM. They have significant glucose-lowering effect by decreasing reabsorption of glucose from glomerular filtrate and inducing glucosuria.

In the kidney, chronic hyperglycemia upregulates SGLT2 expression and activity (Mogensen, 1971; Dominguez *et al.*, 1994). The pathway for this increased expression involves protein kinase A and protein kinase C (Rorsman *et al.*, 2014; Komala *et al.*, 2013) with insulin being the physiologic agonist for this effect (Ghezzi and Wright, 2012). Multiple other factors have also been found to alter the expression of SGLT2 including hepatocyte nuclear factor 1α (HNF1α), serum and glucocorticoid-regulated kinase 1 (SGK1), transforming growth factor ß (TGFß), interleukin-6 (IL-6), and tumor necrosis factor-α (TNF-α) (Komala *et al.*, 2013).

Additionally, treatment with losartan (an angiotensin receptor blocker) reduced renal SGLT2 expression in diabetic rats suggesting that angiotensin II is involved in regulating SGLT2 expression and that changes in renal transporters expression could be important in the development of hypertension in diabetes (Osorio *et al.*, 2009).

Actions of Key Regulatory Factors (Table 1)

Insulin

Insulin regulates glucose metabolism by direct and indirect actions. Through binding to its receptors in the liver, kidney, muscle and adipose tissue, insulin activates its signaling pathway which involves a complex cascade of protein kinases and regulatory proteins of which IRS-1 and IRS-2 are the most important. This causes: (1) suppression of glucose release from liver and kidney (Meyer *et al.*, 1998a), (2) translocation of glucose transporters in muscle and adipose tissue to increase their glucose uptake (Oster-Jorgensen *et al.*, 1990), and (3) inhibition of release of FFA into the circulation due to suppression of the activity of *hormone-sensitive lipase* and a simultaneous increase in their clearance from the circulation (Meyer *et al.*, 1997). Although insulin does not increase glucose transport into liver, it promotes glycogen accumulation by inhibiting *glucose-6-phosphatase*② and *phosphorylase*① (glycogenolysis enzymes) while stimulating *glycogen synthase*③ (Gerich, 2000a).

The effect of insulin on circulating FFA levels indirectly reduces glucose release into circulation and promote glucose removal since FFA stimulate gluconeogenesis and reduce glucose transport into cells (Meyer *et al.*, 1997).

Metabolic processes vary in their sensitivity to insulin and their dose-response characteristics. At basal levels observed in the postabsorptive state ($\sim$5–10 μU/mL), insulin is already inhibiting glucose and FFA release 30%–50% (counteracting the effect of glucagon and the sympathetic nervous system) while having a trivial effect on tissue glucose uptake. Maximal suppression of glucose and FFA release normally is observed with plasma insulin concentrations seen postprandially ($\sim$40–50 μU/mL) whereas maximal stimulation of tissue glucose uptake requires plasma insulin concentrations $>$300 μU/mL levels not seen under normal physiological conditions except in extremely insulin resistant individuals in whom, of course, such level would not produce maximal effect (Gerich, 1993; Stumvoll *et al.*, 2000; Woerle *et al.*, 2003).

The leading regulator of insulin secretion is the plasma glucose concentration: increased plasma glucose after meal ingestion results in 3–4 folds increase in plasma insulin within 30–60 min whereas a decrease plasma glucose below 50 mg/dL ($\sim$2.7 mmol/L) will result in 80%–90% reduction in plasma insulin levels. The main pathway for insulin release is through ATP-regulated potassium (K_{ATP}) channels (Jones *et al.*, 1998). The pathway starts with glucose entry into ß cells. The intracellular glucose is then metabolized in a process that increases intracellular ATP which in turn triggers closure of K_{ATP} channels. The channel closure prevents potassium from leaving ß cells and this causes depolarization of cell membrane and subsequently calcium entry into ß cells through L-type voltage-gated calcium channels. The increase in intracellular calcium activates protein kinases and consequently exocytosis of insulin secretory granules/insulin release (Jones *et al.*, 1998).

Acute increases in amino acids, and to a lesser extent, FFA also increase insulin secretion (Gerich, 1993, 2000a; Stumvoll *et al.*, 2000; Woerle *et al.*, 2003). After meal ingestion, intestinal factors called incretins (e.g., gastrointestinal-inhibitory peptide [GIP], glucagon-like peptide [GLP-1]) augment insulin secretion. This is why plasma insulin concentrations increase to a greater extent after oral glucose load than after intravenous glucose despite identical plasma glucose concentrations (Woerle *et al.*, 2003; Gosmanov *et al.*, 2005).

Glucagon

Glucagon, a hormone secreted from the α cells of the endocrine pancreas, is the major counterpart to insulin in the moment to moment regulation of plasma glucose. Glucagon acts exclusively on the liver where it binds to its receptors and activates *adenylate cyclase*. As a result, intracellular cAMP level increases, enhancing glycogenolysis as a result of phosphorylase stimulation (Magnusson *et al.*, 1995; Gerich, 1981). This response wanes after several hours and is followed by an increase in gluconeogenesis due to a complex process involving both increased substrate uptake and enzyme activation (Gerich, 1993; Gosmanov *et al.*, 2005; Bolli *et al.*, 1984; Gromada *et al.*, 2007; Lecavalier *et al.*, 1989). Thus the main immediate action of glucagon to increase plasma glucose level is through stimulation of hepatic glycogenolysis (Lecavalier *et al.*, 1989).

Table 1 Mechanism of action of key metabolic regulators

	Glucose production	*Glucose utilization*	*Lipolysis*
Insulin	↓	↑	↓
Glucagon	↑	—	—
Epinephrine	↑	↓	↑
Cortisol	↑	↓	↑
Growth hormone	↑	↓	↑
FFA	↑	↓	—

Similar to insulin secretion from ß cells, glucagon secretion is influenced mainly by plasma glucose whereby its secretion is inhibited by hyperglycemia and stimulated by hypoglycemia. In humans, substrates other than glucose (e.g., FFA and amino acids) play less important role. The pathway for glucagon secretions also starts with glucose entry into α cells but the transporters appear to be different than those found in ß cells. The facilitative transporter in α cell is GLUT1 whereas it is GLUT2 in ß cells (Rorsman *et al.*, 2014; Heimberg *et al.*, 1995). More importantly, SGLT1 and SGLT2 transporters were recently also found to be present in α cells whereas they are absent in ß cells and are thought to play a key role in regulating glucagon secretion (Bonner *et al.*, 2015). For example, inhibiting SGLT2 via the SGLT2 inhibitors dapagliflozin (Ferrannini *et al.*, 2014; Merovci *et al.*, 2014) or SLC5A2 (the gene that encodes SGLT2) gene silencing triggers glucagon secretion (Bonner *et al.*, 2015). The exact intracellular pathway that leads to glucagon secretion following glucose entry into α cells is not completely understood. It is established however that the pathway involves ATP-regulated potassium (K_{ATP}) channels and that glucose-induced closure of these channels leads to inhibition of glucagon release (Rorsman *et al.*, 2014; Munoz *et al.*, 2005).

Catecholamines

Catecholamine release is mediated through changes in sympathetic nervous system, being increased during stress and hypoglycemia. Catecholamines inhibit insulin secretion while decreasing insulin action. Acting as both hormones (epinephrine) and neurotransmitters (norepinephrine), they are potent hyperglycemic factors whose actions, unlike those of glucagon, are sustained and affect both glucose release and glucose removal (Bolli *et al.*, 1984; Gerich *et al.*, 1980; Rizza *et al.*, 1980).

For the most part, catecholamines metabolic actions are mediated by beta 2 adrenergic receptors: at the liver they directly increase glycogenolysis via cAMP activation of *phosphorylase* and, to a lesser extent, augment gluconeogenesis indirectly through increasing gluconeogenic substrate availability and plasma FFA (Lecavalier *et al.*, 1989; Rizza *et al.*, 1980). At the kidney level, they are potent stimulators of gluconeogenesis both directly and indirectly as on the liver and are actually more potent stimulators of renal glucose release than hepatic glucose release (Stumvoll *et al.*, 1995). In skeletal muscles, they reduce glucose uptake and stimulate glycogenolysis which results in an increase in release of lactate- the major gluconeogenic precursor. In adipose tissue, catecholamines stimulate lipolysis via activation of *hormone-sensitive lipase* which results in an increase in the release of FFA and glycerol, another key gluconeogenic precursor (Lecavalier *et al.*, 1989; Gerich *et al.*, 1980; Rizza *et al.*, 1980; DeFeo *et al.*, 1991).

Growth Hormone and Cortisol

In contrast to glucagon and catecholamines which act almost immediately, the metabolic actions of growth hormone and cortisol generally take several hours to become evident. These can be summarized as being antagonistic to the action of insulin (i.e., they reduce the ability of insulin to suppress glucose release, stimulate glucose uptake and inhibit lipolysis) (Gerich *et al.*, 1980; Rizza *et al.*, 1982). Both hormones increase the synthesis of gluconeogenic enzymes and reduce glucose transport (Rizza *et al.*, 1982; DeFeo *et al.*, 1989a,b). In addition, cortisol can impair insulin secretion (DeFeo *et al.*, 1989b). Accordingly, the mechanisms for deterioration in glucose tolerance during immunosuppressive glucocorticoid treatment involve induction of insulin resistance and prevention of an appropriate compensatory increase in insulin secretion (DeFeo *et al.*, 1989b).

It is important to note that all of the counterregulatory hormones work via different intracellular mechanisms which reinforce/synergize with one another. Simultaneously small increases in their plasma levels will have greater effect than large increase in plasma level of only one hormone (Mitrakou *et al.*, 1991a).

FFA

FFA are the predominant fuel used by most tissues of the body, the major exceptions being the brain, renal medulla, and blood cells (Fanelli *et al.*, 1993; Cahill, 1970; Havel, 1972). Increases in plasma FFA have many potentially important metabolic consequences (Boden, 1997; McGarry, 1998): stimulation of hepatic and renal gluconeogenesis; inhibition of muscle glucose transport and competition with glucose as an oxidative fuel. The major regulators of circulating FFA levels are the sympathetic nervous system and growth hormone (Fanelli *et al.*, 1993) (which increase plasma FFA levels), insulin (which reduces plasma FFA levels by suppressing lipolysis and increasing FFA clearance) and hyperglycemia. There is evidence for heterogeneity of adipose depots with visceral fat being more metabolically active than subcutaneous fat (Fanelli *et al.*, 1993; McGarry, 1998).

Incretins: (Table 2)

The concept that certain factors secreted from the intestinal mucosa in response to nutrients can stimulate the pancreas to release insulin was first introduced to explain the phenomenon of greater increase in plasma insulin levels in response to oral glucose load compared with the same load of glucose given intravenously. The term *incretin* was used to denote these factors (Baggio and Drucker, 2007). Two main incretins are *gastric inhibitory polypeptide* (GIP) and *glucagon-like peptide-1* (GLP-1) (Baggio and Drucker, 2007; Brown *et al.*, 1975). Both peptides are secreted from intestinal endocrine mucosa (L and K cells) within minutes of nutrient ingestion and have short half-life (minutes) due to the rapid inactivation by a proteolytic enzyme called dipeptidyl peptidase-4 (DPP-4).

GLP-1 and GIP inhibit glucagon secretion (Nauck *et al.*, 2002); only GLP-1 delays gastric emptying and only GLP-1, possibly through a neural mechanism, promotes satiety, decreasing food intake and leads to weight loss (Baggio and Drucker, 2007).

Table 2 Effects of GLP1 and GIP on different tissues

	GLP1	*GIP*
Pancreas	↑ Insulin secretion ↓ Glucagon secretion	↑ Insulin secretion
Peripheral	↓ Hepatic glucose release ↑ Muscle glucose uptake	—
Gastric	Delays gastric emptying	↓ Gastric acid secretion only at supraphysiologic level
CNS	↑ Satiety, ↓ appetite, ↓ weight	—

Upper Gastrointestinal Function and Glycemic Homeostasis

Studies indicate that gastric emptying is a major physiologic determinant of nutrient delivery into the small intestine to the circulation and postprandial glycemia: it accounts for ~35% of the variance in peak blood glucose concentrations after ingestion of oral glucose in healthy volunteers (Rayner *et al.*, 2001; Horowitz *et al.*, 1993) or patients with type 2 diabetes (Rayner *et al.*, 2001; Jones *et al.*, 1996). It is delayed in acute hyperglycemia (Oster-Jorgensen *et al.*, 1990; MacGregor *et al.*, 1976), and accelerated during hypoglycemia (Bjornsson *et al.*, 1994).

Effect of Meal Composition

In healthy humans, adding protein or fat to oral glucose was found to lower postprandial glucose concentrations by slowing the gastric emptying and stimulating incretins. Protein also enhances non-glucose-dependent insulin release (Gentilcore *et al.*, 2006; Gerich *et al.*, 2001).

Gut Microbiota

Gut microbes affect glucose homeostasis through metabolic and immune interactions with the human host (Boulangé *et al.*, 2016; Greer *et al.*, 2016). They increase the density of small intestine villi capillaries and gut motility and also help digest dietary polysaccharides into absorbable sugars and short chain fatty acids (Boulangé *et al.*, 2016; Abrams and Bishop, 1967; Musso *et al.*, 2011; Gibson *et al.*, 2004). Short chain fatty acids in turn are ligands for G protein-coupled receptors including GPR43, the activation of which has been shown in animal studies to reduce fat accumulation, suppress insulin sensitivity in adipose tissues and increase insulin sensitivity in liver and muscle (Boulangé *et al.*, 2016; Backhed *et al.*, 2004). More recently, it has been shown in mice that *Akkermansia muciniphila*, a gut microbe also present in humans, mediate negative effects of interferon gamma (IFNγ) on glucose tolerance (Greer *et al.*, 2016). In IFNγ-deficient mice, *A. muciniphila* is increased and restoration of IFNγ levels reduces *A. muciniphila* in the microbiota. IFNγ-knockout mice whose microbiota has no *A. muciniphila* do not show improvement in glucose tolerance and adding back *A. muciniphila* increased glucose tolerance (Greer *et al.*, 2016). Preliminary data in humans showed that *A. muciniphila* is also linked to IFNγ-regulated gene expression in the human intestine and that individuals without diabetes had higher *A. muciniphila* population within their gut microbiota compared with individuals with type 2 diabetes or with pre-diabetes (Greer *et al.*, 2016).

The Role of Kidney

The kidney is involved in the regulation of glucose homeostasis via three different mechanisms: release of glucose into the circulation (gluconeogenesis), uptake of glucose from the circulation for its energy needs, and most importantly, glucose reabsorption from glomerular filtrate.

In humans, only the liver and kidney contain significant amounts of the enzyme glucose-6-phosphatase and therefore are the only organs that are able to perform gluconeogenesis. Approximately 20% of total glucose output in the normal postabsorptive state can be attributed to the kidney (Gerich *et al.*, 2001). Renal glucose output increases once liver glycogen stores become depleted during fasting (Bjorkman *et al.*, 1980; Ekberg *et al.*, 1999) and in response to hypoglycemia (~100% increase) (Meyer *et al.*, 1999a; Cersosimo *et al.*, 1999a).

The kidney also utilizes circulating glucose for its own energy needs. In the post-absorptive setting after an overnight fast, the kidneys utilize approximately 10% of all glucose utilized by the body (Meyer *et al.*, 2002). Postprandially, renal glucose uptake increases threefold; however, the proportion of systemic glucose disposal to the kidney changes very little as a result of alterations in whole-body glucose disposal (Meyer *et al.*, 2002).

Normally, approximately 180 L of plasma are filtered by the kidneys each day. As the average plasma glucose concentration throughout a 24-h period is ~100 mg/dL (~5.5 mmol/L), ~180 g of glucose is filtered by the kidneys each day. In healthy individuals, virtually all of this is reabsorbed into the circulation and the urine is essentially free from glucose. To put this into perspective, in a typical day, the kidneys produce 15–55 g glucose via gluconeogenesis and metabolize 25–35 g glucose (Gerich, 2010). Therefore, in terms of glucose economy, it is clear that renal reabsorption is the primary mechanism by which the kidney influences glucose homeostasis.

Reabsorption of glucose from glomerular filtrate occurs by means of sodium–glucose co-transporters (SGLT1 and SGLT2) in the proximal convoluted tubulae (Wright *et al.*, 2007). In animal models, approximately 90% of glucose is reabsorbed by SGLT2 and the remaining approximately 10% is mediated by SGLT1 (Wright, 2001; Brown, 2000). Reabsorbed glucose is then released into the circulation through the action of facilitative glucose transporters (GLUTs) at the basolateral membrane of the epithelial cells lining the proximal tubules (Hediger and Rhoads, 1994).

Glucose is freely filtered in the glomerulus, so that, as plasma glucose levels increase, the amount of glucose in the glomerular filtrate increases linearly. Reabsorption of filtered glucose also increases linearly until the maximal reabsorptive capacity is exceeded. This is often referred to as the renal threshold and equates to a filtration rate of 260–350 mg/min per 1.73 m^2 (Zelikovic, 2004), which occurs at plasma glucose concentrations of ~200 mg/dL (~11.0 mmol/L) in healthy adults (Moe *et al.*, 2008). Above this plasma glucose concentration, the percentage of filtered glucose that is reabsorbed decreases and the percentage of the filtered load of glucose that is excreted in the urine increases, resulting in glucosuria.

Glucose Production and Hepatorenal Glucose Reciprocity

A considerable body of evidence indicates that somehow release of glucose by the liver and kidney are interrelated so that a reduction in release by one organ is associated by an increase by the other to further maintain optimal glucose homeostasis. This relationship is referred to as hepatorenal glucose reciprocity (Gerich, 2002).

The kidney is responsible on average for about 20% of glucose released into the circulation in overnight fasted normal human volunteers. Moreover, a number of studies have shown that kidney increased its glucose release (gluconeogenesis) to compensate for restricted (physiologic), or impaired (pathologic) hepatic glucose release (Gerich, 2002; Meyer *et al.*, 1998b; Stumvoll *et al.*, 1998a,b; Cersosimo *et al.*, 1999a,b, 2000a,b; Ekberg *et al.*, 1999; Moller *et al.*, 2001).

Physiologic examples are: postprandially and after prolonged fasting. After meal ingestion, the hepatic glucose release is suppressed ~80% while renal glucose release increases and actually exceeds hepatic glucose release (HGR) for several hours (Meyer *et al.*, 2002) to allow for hepatic glycogen repletion (Gerich, 2002). Also after prolonged fasting (60 h), renal glucose release increases fourfold while hepatic glucose release decreases by ~45% (Ekberg *et al.*, 1999). Examples of renal compensation with pathologic process are: (1) *Hepatic diseases*: Hypoglycemia is extremely uncommon in patients with severe liver disease in the absence of other factors (infection, heart failure). Studies using an animal model for liver failure have demonstrated that there is a compensatory increase in renal glucose release to compensate for the reduced hepatic glucose release (Gerich, 2002; Garcia-Ruiz *et al.*, 1973; Bergman and Drury, 1938; Drury *et al.*, 1950). In humans, during the period of hepatic transplantation when patients have no functioning liver hypoglycemia does not occur; overall glucose release into the circulation either decreases minimally or not at all, and there is an increase in renal glucose release (Joseph *et al.*, 2000; Battezzati *et al.*, 1999). (2) *Acidosis*: Acidosis stimulates renal glucose release (Schoolwerth *et al.*, 1988) while inhibiting hepatic glucose release (Iles *et al.*, 1977). In patients with respiratory acidosis, an increase in net renal glucose release has been demonstrated inversely proportional to blood pH (Aber *et al.*, 1966). (3) *Glucose counterregulation in diabetes*: Patients with type 1 (Gerich, 1988), and prolonged type 2 (Gerich, 2000b) diabetes lose their glucagon response and become dependent on catecholamine responses. Catecholamines are the major hormonal factor responsible for the increase in renal glucose release during hypoglycemia (Meyer *et al.*, 1999b). Consequently, type 1 diabetic patients with both reduced glucagon and epinephrine responses have decreases in both hepatic and renal glucose release during hypoglycemia (Cersosimo *et al.*, 2001). In patients with type 2 diabetes who have reduced plasma glucagon responses, compensatory increases in hepatic glucose release during recovery from hypoglycemia are reduced whereas renal glucose release is increased (Woerle *et al.*, 2001).

The Postabsorptive State

The period after 14–16 h overnight fast is commonly referred to as the postabsorptive state. During this time plasma glucose concentration averages around 70–100 mg/dL (~3.8–5.5 mmol/L) and is relatively stable since rates of glucose release into the circulation approximate the rates of glucose exit from the circulation (~10 μg/kg/min) (Gerich, 1993).

Glucose Production (Table 3)

The liver is responsible for approximately 80% of glucose release into the circulation in the postabsorptive state (Stumvoll *et al.*, 1997). Under these conditions, ~50% of the glucose entering the circulation is due to glycogenolysis and the remainder (~5.0 μmol/kg/min) to gluconeogenesis (Landau *et al.*, 1996). The proportion owing to gluconeogenesis rapidly increases with the duration of fasting, as glycogen stores become depleted; by 24 h from the last meal, gluconeogenesis accounts for about 70% of all glucose released into the circulation, and by 48 h, it accounts for over 90% of all glucose released into the circulation (Landau *et al.*, 1996; Consoli *et al.*, 1987).

The kidney normally contains little glycogen, and renal cells that could make glycogen lack glucose-6-phosphatase. Consequently, virtually all the glucose released by the kidney is the results of gluconeogenesis (Stumvoll *et al.*, 1997). Although the liver releases about four times as much as the kidney under postabsorptive conditions, both organs release about the same amount (2.5–3.0 μmol/kg/min) from gluconeogenesis and the proportion of overall glucose release owing to renal gluconeogenesis increases even further with prolonged fasting (Cersosimo *et al.*, 2000a).

The liver releases glucose both by glycogenolysis and gluconeogenesis and can be considered to be the sole source of glucose due to glycogenolysis. In overnight fasted people, the liver contains about 75 g of glycogen (Nilsson and Hultman, 1973). Thus if it releases glycogen at a rate of 63 mg/min (5 μmol/kg/min), glycogen stores would be totally depleted in about 20 h and the sole source of glucose released into the circulation at this point would be gluconeogenesis (Gerich, 1993).

Regulation of glucose production: Hepatic vs. renal

Glucose release by the liver and kidney are regulated differently. Insulin suppresses glucose release by both organs; (1) directly by affecting enzyme activation/deactivation and (2) indirectly through actions such as limitations of gluconeogenic substrate availability and gluconeogenic activators (e.g., suppression of FFA and glucagon) (Meyer *et al.*, 1998a).

Glucagon, which increases both glycogenolysis and gluconeogenesis in the liver, however, has no effect on the kidney (Stumvoll *et al.*, 1998a). Epinephrine, which can directly activate hepatic glycogenolysis, appears to increase glucose release from the kidney, predominantly by directly stimulating renal gluconeogenesis and, to a lesser extent, by increasing availability of gluconeogenic precursors/activators (e.g., glycerol and FFA) (Stumvoll *et al.*, 1995, 1998b).

Glucose Utilization (Fig. 2)

Although the postabsorptive state is often considered to represent a steady-state, it is actually a pseudo-steady state since rates of glucose removal slightly, and undetectably, exceed rates of glucose release so that if fasting is prolonged, plasma glucose levels gradually decrease; by 20–24 h of fasting they may be 15%–20% lower. However, even after 72 h of fasting, they are usually maintained above 50 mg/dL (~2.8 mmol/L) (Consoli *et al.*, 1987).

In the postabsorptive state, there is no net storage of glucose; consequently, glucose taken up by tissues is either completely oxidized to CO_2 or released back into the circulation as lactate, alanine and glutamine (Perriello *et al.*, 1995) for re-incorporation into glucose via gluconeogenesis (**Table 4**).

Most glucose used by the body can be accounted for by five tissue: the brain (45%–60%), skeletal muscle (15%–20%), kidney (10%–15%), blood cells (5%–10%), splanchnic organs (3%–6%), and adipose tissue (2%–4%) (Gerich, 1993).

Table 3 Summary of postabsorptive glucose release

	Rate (μmol/kg/min)	*% of total*
Overall	10.0	100
A. Hepatic	8.0	80
1. Glycogenolysis	5.0	50
2. Gluconeogenesis	3.0	30
Lactate	1.3	13
Alanine	0.8	8
Other amino acids	0.2	2
Glycerol	0.4	4
Glutamine	0.3	3
B. Renal	2.0	20
1. Glycogenolysis	0	0
2. Gluconeogenesis	2.0	20
Lactate	1.2	12
Glutamine	0.4	4
Glycerol	0.2	2
Other amino acids	0.1	1
Alanine	0.1	1

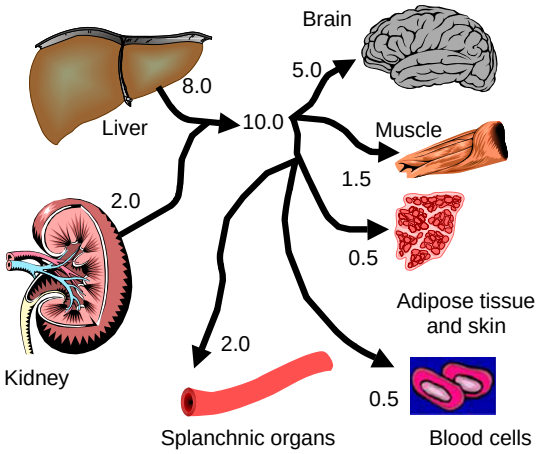

Fig. 2 Glucose utilization and production in the postabsorptive state. The liver and kidney contribute approximately 8.0 and 2.0 μmol/kg/min respectively top the total release of glucose into the circulation (10 μmol/kg/min); the brain, splanchnic tissue, muscle, adipose tissue, and blood cells account for approximately 5.0, 2.0, 1.5, 0.5, and 0.5 μmol/kg/min, respectively. Table 4 Glucose disposal in the postabsorptive state

	Rate (μmol/kg/min)	*% of total*
Overall	10	100
A. Oxidation	~7	~70
B. Glycolysis	~3	~30
Tissues		
Brain	5	~50
Skeletal muscle	2	~20
Splanchnic organs	1	~10
Kidney	1	~10
Adipose tissue	0.5	~5
Blood cells	0.5	~5

Glucose taken up by the brain is completely oxidized whereas that taken up by the kidney, blood cell, splanchnic tissues and muscle mainly undergoes glycolysis. Recall that most of the body energy requirements are met by oxidation of FFA which compete with glucose as the fuel of choice in certain organs (e.g., skeletal muscles, heart and possibly kidney) (Boden, 1997).

Glucose uptake by brain, blood cells, renal medulla, and splanchnic tissue occurs largely independent of insulin, and plasma insulin is low in the postabsorptive state (<10 μU/mL). Under these conditions, amount of glucose removed from the circulation is determined almost exclusively by tissue demands, the mass action effect of the plasma glucose concentration per se, and the number and characteristics of the glucose transporters in specific tissue rather than by insulin. Insulin may be reviewed as playing a permissive role, while counterregulatory hormones that antagonize the action of insulin (e.g., cortisol, growth hormone, epinephrine, and thyroid hormones) can be viewed as modulating the sensitivity of tissue to the effect of insulin on tissue glucose uptake and utilization (Mitrakou *et al.*, 1991a; Gerich, 1993).

Prolonged Fasting (Table 5)

With prolongation of fasting, plasma insulin levels decrease while those of glucagon, catecholamines, growth hormone and cortisol increase. Consequently, plasma FFA, glycerol and the ketone bodies, products of FFA oxidation (beta hydroxybutyrate and acetoacetate) increase. Since hepatic glycogen stores become depleted by 60 h, virtually all of the glucose release at this time is due to gluconeogenesis. Initially hepatic gluconeogenesis decreases while renal gluconeogenesis increases, with an overall result of a decrease in overall glucose release and a slight increase in gluconeogenesis. With more prolonged fasting there is a further decrease in glucose release as gluconeogenesis decreases (Ekberg *et al.*, 1999).

Table 5 Glucose release and disposal after prolonged fasting (~60 h)

	Glucose disposal (μmol/kg/min)	*Glucose release (μmol/kg/min)*	
Overall	6.0	Overall	6.0
Oxidation	4.8	Gluconeogenesis	5.5
Glycolysis	1.2	Glycogenolysis	0.5
Tissues		Tissues	
Brain	3.5	Liver	2.7
Skeletal muscle	1.0	Kidney	2.8
Splanchnic organs	0.5		
Kidney	0.4		
Adipose tissue	0.2		
Blood cells	0.4		

Although more glycerol is available for gluconeogenesis, less lactate is available due to less being produced by glycolysis, and less amino acids are available because of muscle proteolysis decreases. These changes limit gluconeogenesis despite increase in plasma FFA and counterregulatory hormones which promote gluconeogenesis.

Initially during the course of the fast, decreases in glucose release are slightly greater than deceases in glucose uptake so that plasma glucose levels decrease slowly. However, eventually, the rates of uptake and release approximate one another so that a new pseudosteady state is established after 60–70 h with plasma glucose levels usually averaging 55–65 mg/dL (~3–3.6 mmol/L) (Ekberg *et al.*, 1999).

These changes during prolonged fasting are relevant to changes seen in chronically ill patients who often are anorexic, malnourished, and miss meals in hospital because of diagnostic or therapeutic procedures. Because of the limitations on gluconeogenesis, such patients (e.g., those with chronic renal failure, severe liver disease, or heart failure) are prone to develop hypoglycemia during infections or other situations which increase the body's glucose utilization (Gerich, 1993; Ekberg *et al.*, 1999).

The Postprandial State

Complete assimilation of the constituents of a mixed meal containing fat, protein and carbohydrate and restoration of the postabsorptive state takes at least 6 h (McMahon *et al.*, 1989a). Whereas assimilation of a pure carbohydrate load is generally complete within 4–5 h. Despite these time differences, there is little evidence that the fate of ingested carbohydrate differs markedly under the two conditions (Dinneen *et al.*, 1992). Because people usually eat at least three times a day, the majority of the day is spent in the postprandial state.

Various factors can affect the extent of circulating glucose excursions after meal ingestion. These include the time and the degree of physical activity since the last meal, the composition and form (liquid vs. solid), rate of gastric emptying, digestion within the lumen of the small intestine, absorption into the portal vein, extraction by the liver, suppression of endogenous glucose release and finally the uptake, storage, oxidation and glycolysis of glucose in posthepatic tissues (Marin *et al.*, 1992).

From a practical point of view, however, the major factors influencing postprandial glucose homeostasis are those that affect suppression of endogenous glucose release and those that affect hepatic and posthepatic tissue glucose uptake.

Glucose taken up by tissues postprandially can be considered either to be immediately stored or to undergo glycolysis. Therefore, initial direct storage of glucose (glucose to glucose-6-phosphate to glycogen) can be calculated as the difference between whole body glucose uptake and whole body glycolysis. Since postprandial de novo lipogenesis and adipose tissue glucose storage are negligible in humans, virtually all of this storage should represent glycogen formation (McMahon *et al.*, 1989a; Marin *et al.*, 1992).

Of the glucose undergoing glycolysis, some will be oxidized; the remainder will undergo nonoxidative glycolysis leading to the formation of pyruvate, lactate and alanine. These 3-carbon compounds will then be available to undergo gluconeogenesis and either be stored in glycogen via the indirect pathway or be released into plasma as glucose (Woerle *et al.*, 2003).

Fig. 3 depicts the pathways for disposal of a mixed meal containing 78 g of glucose (Woerle *et al.*, 2003). During the 6-h postprandial period, a total of ~98 g of glucose were disposed of. This was more than the glucose contained in the meal due to persistent endogenous glucose release (~21 g): splanchnic tissues initially took up ~23 g, and an additional ~75 g were removed from the systemic circulation. Direct glucose storage accounted for ~32 g and glycolysis ~66 g (oxidative ~43 g and non-oxidative ~23 g). About 11 g of glucose appeared in plasma as a result of gluconeogenesis. This indicates that glycolysis is the main initial postprandial fate of glucose, accounting for ~66% of overall disposal. Oxidation and storage each account for about 45%. The majority of glycogen is formed via the direct pathway (~73%).

Changes in Plasma Hormone and Substrate Concentration (Fig. 4)

After ingestion of 75 g glucose, plasma glucose levels increase to a peak in 30–60 min, usually not exceeding 160 mg/dL (~8.8 mmol/L) and gradually return to or slightly below post absorptive values by 3–4 h. Although plasma glucose levels have

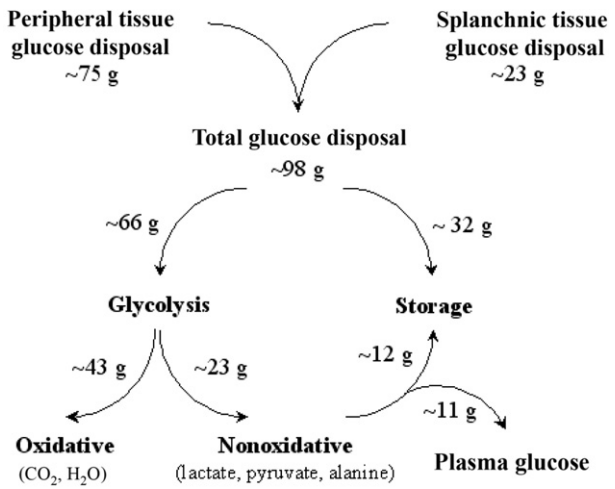

Fig. 3 Summary of sites and routes of postprandial glucose disposal. From Woerle, H.J., Meyer, C., Dostou, J.M., Gosmanov, N.R., Islam, N., Popa, E., Wittlin, S.D., Welle, S.L. and Gerich, J.E. (2003). Pathways for glucose disposal after meal ingestion in humans. *American Journal of Physiology. Endocrinology and Metabolism* **284**, E716–E725, with permission. Fig. 4 Changes in plasma glucose, insulin and glucagon after ingestion of a 75 g oral glucose load in normal volunteers.

returned to postabsorptive levels, glucose fluxes and organ glucose exchange have not. Plasma insulin concentrations follow a similar profile to those of plasma glucose and average only about three to fourfold basal values during this period.

Plasma glucagon concentrations change reciprocally to those of insulin and are generally suppressed about 50%. Early insulin release (i.e., that accruing within 30–60 min) plays a critical role in maintaining normal postprandial glucose homeostasis (Dinneen *et al.*, 1992).

Plasma FFA and glycerol levels decrease due to inhibition of lipolysis while plasma lactate concentration increase as a result of increased glycolysis in liver, muscle, adipose tissue, and kidney. After ingestion of a mixed meal containing protein the circulating concentrations of several amino acids increase (Woerle *et al.*, 2003).

Changes in Rates of Glucose Entry Into and Exit From Plasma (Figs. 5 and 6)

Rates of glucose appearance in plasma represent the sum of orally ingested glucose escaping first pass splanchnic (hepatic) extraction and the residual release of endogenous glucose by liver and kidney. Appearance of ingested glucose in the systemic circulation is detected as early as 15 min, reaches a peak at 60–80 min, and gradually decrease thereafter (Woerle *et al.*, 2003).

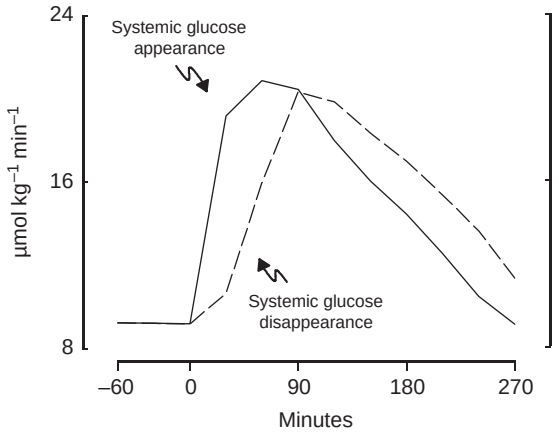

Fig. 5 Changes in rates of glucose entry into and removal from plasma after ingestion of a 75 g oral glucose load in normal volunteers.

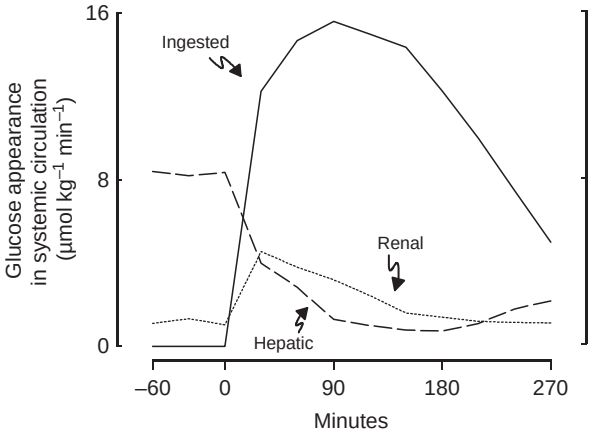

Fig. 6 Changes in rates of entry of glucose into the circulation from ingested glucose, liver and kidney.

On average during a 4–5 h postprandial period about 75% of the glucose molecules in plasma represent those from the meal. Endogenous glucose release by the liver decreases rapidly and is suppressed nearly 80% during the 5-h postprandial period. As a result, nearly 25 g less glucose due to endogenous production reaches the systemic circulation during this interval. In contrast to the liver, recent studies indicate that endogenous renal glucose release in not suppressed and actually increases during this period so that it exceeds hepatic glucose release (Meyer *et al.*, 1999b). This increase in renal glucose release would permit more complete suppression of hepatic glucose release and facilitate more efficient hepatic glycogen replenishment (Meyer *et al.*, 1999b).

Tissues Responsible for Disposal of Ingested Glucose

Based on a survey of published studies, a consensus view of the disposal of a hypothetical meal containing 100 g carbohydrate is depicted in **Fig. 7**. About 30% of the ingested glucose (~33 g) is initially extracted by splanchnic tissues (Kelley *et al.*, 1988, 1994; McMahon *et al.*, 1989a,b; Butler *et al.*, 1991; Ferrannini *et al.*, 1985; Jackson *et al.*, 1986; Mitrakou *et al.*, 1992). Most is taken up by the liver and immediately incorporated into glycogen via "direct pathway" to hepatic glycogen (Beckmann *et al.*, 1993; Petersen *et al.*, 2001). A significant portion of glucose taken up by the liver probably undergoes glycolysis and is released as lactate which is eventually taken up by the liver where it undergoes gluconeogenesis and is subsequently incorporated into glycogen via "indirect pathway" (Kelley *et al.*, 1988; Petersen *et al.*, 2001; Taylor *et al.*, 1996; Mitrakou *et al.*, 1991b). Inhibition of glucose-6-phosphatase causes the glucose-6-phosphate made from this lactate to enter glycogen rather than being released into the circulation as free glucose.

Of the remaining 70 g glucose, which enters the systemic circulation, 25–30 g is taken up by skeletal muscle (Kelley *et al.*, 1988, 1994; McMahon *et al.*, 1989a; Butler *et al.*, 1991; Jackson *et al.*, 1986; Mitrakou *et al.*, 1992; Firth *et al.*, 1986), initially to be oxidized in place of FFA and later (after 2–3 h) to be stored as glycogen (Marin *et al.*, 1992; Taylor *et al.*, 1993). Relatively little of the glucose taken up by muscle is released into the circulation as lactate and alanine (Kelley *et al.*, 1988; Radziuk and Inculet, 1983).

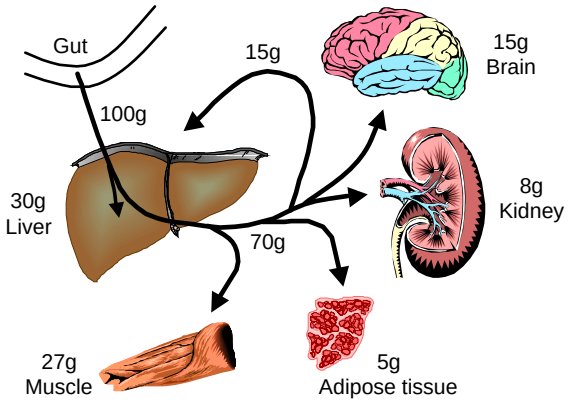

Fig. 7 Postprandial glucose disposal. Of 100 g glucose ingested 30% is taken up by the liver and 70% is released into the systemic circulation. Of this 70 g, 15 g (~20%) is extracted by the liver, 15 g (~20%) is taken up by the brain, 27 g (~40%) is taken up by skeletal muscle, and the remaining 20% is taken up by kidney, adipose tissue, skin, and blood cells.

About 15 g (~20% of the ingested glucose entering the circulation) is taken up by brain as a substitute for the endogenously produced glucose that normally would have been taken up during this period. Recall that endogenous release of glucose from the liver is markedly reduced postprandially.

Another 15 g is extracted from the systemic circulation by the liver either as intact glucose (direct pathway) or as lactate, alanine, and glutamine, whose carbon backbone originated from ingested glucose, for further glycogen formation (indirect pathway) (Taylor *et al.*, 1996). Thus, ultimately splanchnic tissues dispose of nearly half of the ingested glucose (Ferrannini *et al.*, 1980).

The kidney may take up as much as 8 g (~10% of the ingested glucose entering the circulation) (Meyer *et al.*, 1999b). This would leave 5–10 g (7%–15% of the ingested glucose) reaching the systemic circulation) to be taken up by adipose and other tissues (Marin *et al.*, 1992).

Summary

Human plasma glucose concentrations are maintained within a relatively narrow range throughout the day despite wide fluctuations in the delivery (e.g., meals) and removal (e.g., exercise) of glucose from the circulation. This is accomplished by a tightly linked balance between glucose production and glucose utilization regulated by complex mechanisms influenced by the nervous system, several hormones from different types of endocrine cells, and substrates (i.e., free fatty acid concentration and availability of gluconeogenic precursors).

In the postabsorptive stage gluconeogenesis and glycogenolysis contribute equally to glucose release. The liver is responsible for all of glycogenolysis and half of gluconeogenesis. In the postprandial stage almost all endogenous glucose release is via gluconeogenesis. The kidney is involved in the regulation of glucose homeostasis through gluconeogenesis, uptake of glucose from the circulation for its energy needs, and glucose reabsorption. Under a variety of conditions, reciprocal changes occur in hepatic and renal glucose release so as to maintain optimal glucose homeostasis.

Glucose Metabolism and Hormonal Regulation☆

Keith Tornheim, Boston University School of Medicine, Boston, MA, United States

Carbohydrates [named for their empirical formula, $(CH_2O)_n$] include simple sugars (monosaccharides), disaccharides consisting of two linked sugars, and polysaccharides such as the glucose storage polymer glycogen.

Introduction

By definition, simple sugars are aldehydes or ketones with two or more hydroxyl groups; thus, the smallest sugars are the trioses (three-carbon sugars) glyceraldehyde and dihydroxyacetone. Sugars with three to seven carbons are commonly involved in cellular metabolism. Glucose is a hexose (six-carbon sugar) with an aldehyde group at one end; by convention, this is carbon-1. Fructose is also a hexose, but it has a keto group at carbon-2. Sucrose (common table sugar) is a disaccharide of glucose and fructose.

Glucose is the most important of the biological sugars. It is the essential fuel of the brain and thus control of its blood concentration is critical. It is also important in powering intense muscular work. A major metabolic function of the liver is to maintain blood glucose through appropriate release of the sugar from the storage polymer glycogen and through resynthesis of glucose from nonsugar precursors (gluconeogenesis). The blood glucose concentration is under hormonal control, with insulin promoting glucose uptake and storage in muscle and liver and the counterregulatory hormones, such as glucagon and epinephrine, promoting glycogen breakdown as well as gluconeogenesis in liver. Lack of or insufficient insulin is the cause of diabetes, and the resulting chronic elevated glucose levels lead to vascular damage and much of the cases of blindness and kidney disease and increased risk of heart disease. This article discusses the metabolism of glucose in the glycolytic pathway and the production of energy; the storage of glucose in glycogen and its breakdown; the resynthesis of glucose through the pathway of gluconeogenesis; the branch to the pentose phosphate pathway that produces ribose 5-phosphate, which is necessary for DNA and RNA synthesis; and how the metabolism of glucose is linked to the secretion of insulin in the β cells of the pancreatic islets. More details can be found in a basic textbook (Berg *et al.*, 2002) and in the intermediary metabolism book chapter (Ruderman *et al.*, 2001).

Glycolysis

The chemical logic of the glycolytic pathway is the generation of high-energy phosphate compounds that can be used to phosphorylate adenosine diphosphate (ADP) to adenosine triphosphate (ATP). ATP is the energy currency of the cell. The breakdown of ATP is used to power energy-consuming reactions of the cell, from biochemical syntheses to ion pumping to muscular contraction. The early steps in glycolysis actually involve the consumption of two ATPs, but in the later reactions four ATPs are produced, giving a net production of two ATPs per glucose molecule.

Reactions

The reactions of glycolysis are shown in **Fig. 1**. First, glucose is phosphorylated by the enzyme hexokinase ("kinase" means a phosphorylating enzyme) to yield glucose 6-phosphate. Glucose 6-phosphate is isomerized from the aldo sugar to the keto sugar fructose 6-phosphate, which is then phosphorylated at the other end by the key enzyme phosphofructokinase to generate fructose 1,6-bisphosphate. (By current convention, "bis" indicates that the phosphates are on separate carbons, not attached together as in adenosine diphosphate.) Fructose 1,6-bisphosphate is cleaved in the aldolase reaction to two triose phosphates, dihydroxyacetone phosphate and glyceraldehyde 3-phosphate. Since the rest of glycolysis proceeds from the latter, dihydroxyacetone phosphate is converted to glyceraldehyde 3-phosphate by triose phosphate isomerase so that both halves of the glucose molecule can be metabolized. In the glyceraldehyde 3-phosphate dehydrogenase reaction, the aldehyde of glyceraldehyde 3-phosphate is oxidized to a carboxylic acid, but the energy of oxidation is used in part for the uptake of inorganic phosphate (P_i) into a phosphate anhydride in the product 1,3-bisphosphoglycerate. In this reaction, the acceptor of the reducing equivalents is the cofactor nicotinamide adenine dinucleotide (NAD), which becomes NADH with the addition of the hydride (hydrogen with both electrons), whereas a second hydrogen is released simply as a proton in solution. The phosphate anhydride generated at carbon-1 is high energy and thus can be used to phosphorylate ADP to ATP in the phosphoglycerate kinase reaction (so named from the reverse reaction). 3-Phosphoglycerate is then converted to the second high-energy intermediate phosphoenolpyruvate in two steps:

☆*Change History:* October 2017. K Tornheim updated the section on Regulation of Gluconeogenesis (and added "of Gluconeogenesis" to the subheading). This article is an update of Keith Tornheim, Carbohydrate Metabolism and Hormone–Fuel Interrelationships, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, pp. 455-462.

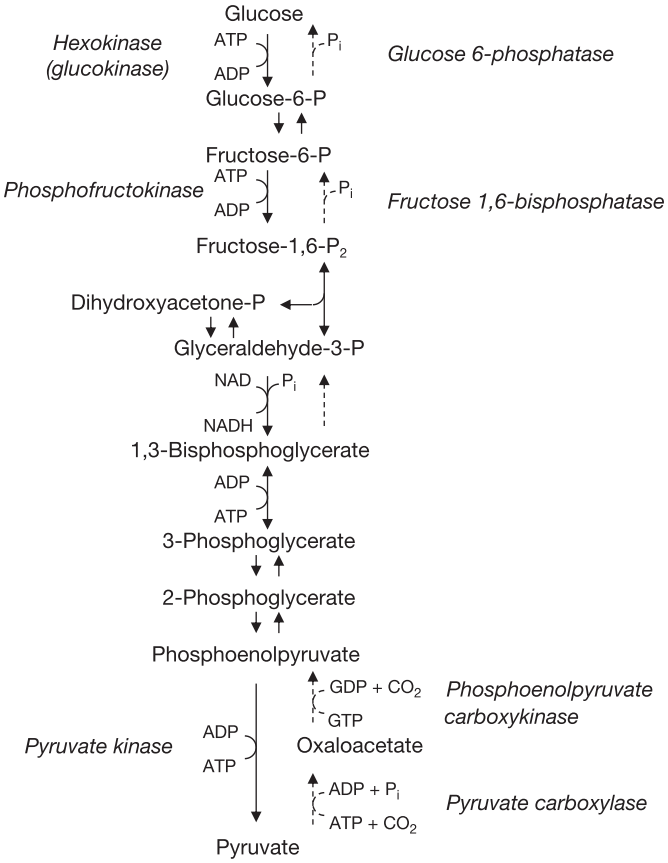

Fig. 1 The glycolytic (glucose breakdown) and gluconeogenic (glucose synthesis) pathways. The purely glycolytic enzymes are listed on the left. All tissues have hexokinase, but liver and pancreatic β cells have the high K_m isoform glucokinase that makes them sensitive to the blood glucose concentration. The purely gluconeogenic enzymes are listed on the right and their reactions are shown with dashed arrows. Liver and kidney have glucose 6-phosphatase, which allows them to produce glucose. All other enzyme reactions shown are used in both glycolysis and gluconeogenesis.

The phosphate is moved from the 3 to the 2 position by phosphoglycerate mutase and then water is removed in the enolase reaction. Phosphoenolpyruvate is then used to phosphorylate ADP to ATP by pyruvate kinase. It is the highly favored conversion of the initial product enolpyruvate to the normal keto form of pyruvate that pulls the reaction forward and causes phosphoenolpyruvate to be a high-energy phosphate donor.

Fate of Pyruvate

The fate of pyruvate depends on the oxidative state of the tissue. For glycolysis to proceed, the NADH produced in the glyceraldehyde 3-phosphate dehydrogenase reaction must be reoxidized back to NAD. Under aerobic conditions, the reducing equivalents from NADH may be transferred to the mitochondrial electron transport chain and ultimately to molecular oxygen. However, if there is insufficient oxygen or insufficient activity of the electron transport chain, then the pyruvate must be used to oxidize NADH and regenerate NAD in the lactate dehydrogenase reaction. This is the reason why strong muscular exercise produces lactate (lactic acid). Yeast lack lactate dehydrogenase and so instead under anaerobic conditions the pyruvate is first decarboxylated to acetaldehyde, which is then used in the alcohol dehydrogenase reaction, generating ethanol in the reoxidation of NADH to NAD. This is why fermentation to produce wine or other alcoholic beverages must be done anaerobically in sealed containers; otherwise, the acetaldehyde would be oxidized to acetic acid (vinegar), making a less palatable drink.

If pyruvate is not needed to be converted to lactate in order to reoxidize NADH, then the pyruvate can enter the mitochondria and be converted to acetyl-coenzyme A (CoA) in the pyruvate dehydrogenase reaction. Acetyl-CoA can be completely oxidized to CO_2 in the citric acid cycle. ATP production by oxidative phosphorylation from the two molecules of pyruvate, together with the reducing equivalents transferred from the two NADHs from the glyceraldehyde 3-phosphate dehydrogenase reaction, is on the order of 15 times greater than the two ATPs produced in glycolysis alone. The details of the citric acid cycle and oxidative phosphorylation are not considered here. If there is excess use of glucose beyond what would be necessary for energy production, then acetyl-CoA can also be used for synthesis of fatty acids.

Regulation of Glycolysis

Phosphofructokinase

The key regulatory enzyme of glycolysis is phosphofructokinase. It is inhibited by ATP and citrate and activated by AMP (and ADP), P_i, and fructose 2,6-bisphosphate. Although ATP is a substrate of the enzyme, it is also an important product of glycolysis, and the inhibition at a regulatory site is an example of classic feedback inhibition. Since ATP usage produces AMP, ADP, and P_i, these activators also signal a need for more ATP production, as would a decrease in ATP. Citrate may serve as an indicator of the sufficiency of alternative fuel, particularly fatty acids that are broken down to acetyl-CoA, which may then increase citrate so that glucose may be preserved for the brain. The importance of fructose 2,6-bisphosphate as an activator has principally been established in liver; it is discussed later in the context of reciprocal regulation of gluconeogenesis and glycolysis. (It is made by phosphorylation of fructose 6-phosphate on the 2 position by a phosphofructokinase-2, distinct from the glycolytic phosphofructokinase.)

Hexokinase and glucose transport

Hexokinase is nominally the first step in glycolysis, but it is not the major point of regulation because glucose 6-phosphate is a branch point leading to glycogen and to the pentose phosphate pathway. Importantly, glucose 6-phosphate is an inhibitor of hexokinase, so if the other pathways are slow and if phosphofructokinase is inhibited, then glucose 6-phosphate will increase and inhibit hexokinase. Conversely, if phosphofructokinase is activated, such as by a decrease in ATP and increase in AMP, then fructose 6-phosphate and glucose 6-phosphate will decrease and hexokinase will be disinhibited. Glucose transport into the cell is also stimulated by insulin in muscle and fat cells, which are tissues that have the insulin-regulated transporter Glut4. In contrast, glucose transport in and out of liver is rapid, catalyzed by Glut2.

Pyruvate Kinase—PKM2 and Cancer

The muscle isoform of pyruvate kinase is essentially unregulated, with weak product inhibition by ATP. The liver isoform is strongly regulated, by allosteric effectors and by phosphorylation, so that it can be inhibited for gluconeogenesis to proceed (see below). Recently there has been increasing interest in PKM2, an alternative transcript of the muscle gene that gives a fetal form of the enzyme but which has also been found in various cancer cell types. PKM2 is also inhibitable, which should allow the accumulation of upstream glycolytic intermediates, such that glucose carbon can be diverted into biosynthetic pathways to make phospholipids for membranes and certain amino acids for protein synthesis, as well as the ribose 5-phosphate for nucleotide synthesis, all needed by these rapidly growing and dividing cells.

Regulation of Pyruvate Dehydrogenase

Regulation of the conversion of pyruvate to acetyl-CoA is of great importance because although pyruvate can be converted back to glucose in the process of gluconeogenesis, there cannot be a net production of glucose from acetyl moieties in animal cells. Pyruvate dehydrogenase is inhibited by its products acetyl-CoA and NADH, and this is countered by the corresponding substrates CoA and NAD; thus, it can be considered that the enzyme is inhibited by high acetyl-CoA/CoA and NADH/NAD ratios. In addition, the enzyme is inactivated by phosphorylation by a specific protein kinase, which is itself activated by high acetyl-CoA/CoA, NADH/NAD, and ATP/ADP ratios. The enzyme can be reactivated by removal of the phosphate by a specific protein phosphatase that is stimulated by high pyruvate levels and by insulin. The pyruvate dehydrogenase reaction is carried out by a multienzyme complex, to which the specific kinase and phosphatase are also bound.

Glycogen Metabolism

Reactions of Glycogen Breakdown

Liver and muscle can contain large amounts of glycogen, a polymer that is a storage form of glucose. It is a branched polymer, with glucose residues largely linked 1–4 but with branches approximately every 10 residues with a 1–6 linkage. The enzyme mainly responsible for breaking down glycogen is phosphorylase (which is short for glycogen phosphorylase because it was the first of its class discovered); it breaks 1–4 linkages by the addition of P_i, releasing a residue as glucose 1-phosphate. However, it can only come within 4 residues of a branch point. Then a "transferase" transfers the branch, except for the penultimate residue, to the end of the main chain; α-1,6-glycosidase cleaves off the final branched residue as free glucose. With the branch removed, phosphorylase can continue.

Interestingly, the phosphorylase reaction can go in both directions, glycogen(n) + P_i ↔ glucose 1-phosphate + glycogen (n − 1), with the equilibrium at [P_i]/[glucose 1-phosphate] = 3.7. Carl and Gerty Cori, the discoverers of phosphorylase, received

the Nobel prize in part for finding the first enzyme that can synthesize a biological polymer since glycogen can be formed in the test tube in the presence of high glucose 1-phosphate. However, in vivo the $[P_i]/[\text{glucose 1-phosphate}]$ ratio is approximately 100, and the enzyme catalyzes glycogen breakdown. This was clearly demonstrated in individuals lacking phosphorylase who have a glycogen storage disease with excess glycogen, not low levels.

Since glucose 1-phosphate is in equilibrium with glucose 6-phosphate through the phosphoglucomutase reaction, the sugar residues released from glycogen can serve as fuel in the glycolytic pathway in muscle. In this context, the fact that glucose 6-phosphate is derived from glycogen phosphorolysis rather than hydrolysis means that there is a net three ATPs produced in glycolysis per glucose residue. In liver, the glucose 6-phosphate produced is generally dephosphorylated to provide blood glucose as needed, along with gluconeogenesis.

Reactions of Glycogen Synthesis

In the synthesis of glycogen by the enzyme glycogen synthase, the glucosyl residue donor is UDP-glucose. UDP-glucose in turn is synthesized from glucose 1-phosphate and UTP, with the release of pyrophosphate (which can be cleaved by pyrophosphatase to pull the reaction). Glycogen synthase resembles phosphorylase in that it makes only 1–4 linkages. The branches in glycogen are made by branching enzyme, which takes a chain of seven residues from the end of a growing chain and attaches it in 1–6 linkage to a glucosyl residue four positions further on.

Regulation of Glycogen Metabolism

The controlling enzymes of glycogen breakdown and synthesis are phosphorylase and glycogen synthase, respectively (Bollen *et al.*, 1998). Their regulation involves allosteric actions by activators and inhibitors as well as phosphorylation and dephosphorylation. The phosphorylation state affects the sensitivity to the allosteric effectors, and the effectors can modulate the phosphorylation state. Hormonal regulation is important to glycogen metabolism. Insulin, a 51-amino acid small protein secreted by the β cells of the pancreatic islets in response to high glucose, promotes glycogen storage. Glucagon, a 29-amino acid peptide secreted by the α cells of the pancreatic islets in response to low glucose, promotes glycogen breakdown in liver as well as gluconeogenesis. Glycogen breakdown in both liver and muscle is promoted by epinephrine, a catecholamine secreted by the adrenal medula in response to nerve impulses, such as when a rabbit sees a fox.

Phosphorylase was originally found to exist in two forms: a nonphosphorylated form (phosphorylase *b*) that required AMP for activity and a phosphorylated form (phosphorylase *a*, with a phosphate on a serine residue of each of its four subunits) that was active in the absence of AMP. Phosphorylase *b* is also inhibited by glucose 6-phosphate and ATP. Glucagon and epinephrine can activate phosphorylase by causing a sequence of reactions (the cascade; **Fig. 2**) that results in the conversion of phosphorylase *b* to *a*. First, these hormones bind to their specific receptors. (Glucagon is only effective on liver and not on muscle because muscle does not have glucagon receptors.) The binding of the hormone causes activation of adenylyl cyclase, which makes cyclic AMP from ATP. This in turn activates the cyclic AMP-dependent protein kinase (PKA), which can then phosphorylate and activate

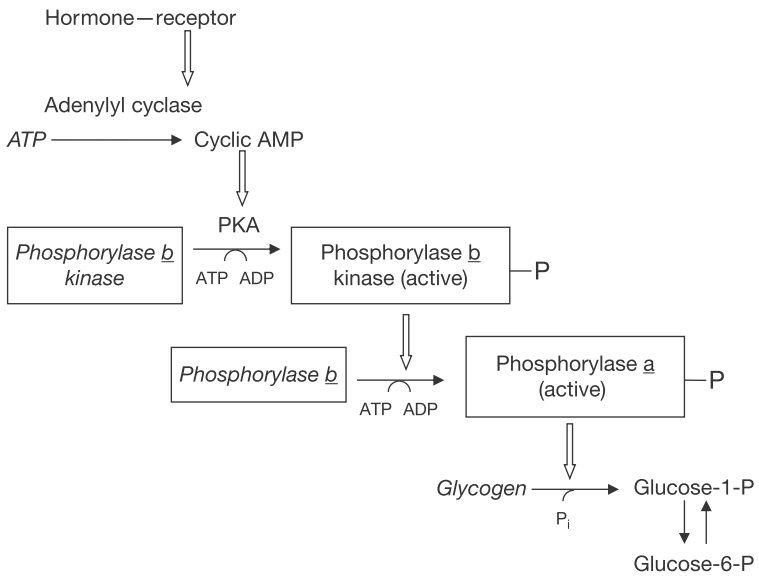

Fig. 2 Stimulation of glycogen breakdown by hormones such as epinephrine and glucagon—the cascade.

phosphorylase *b* kinase. The latter protein kinase then phosphorylates phosphorylase *b*, converting it to phosphorylase *a*, which is more active and breaks down glycogen.

In addition to phosphorylation, phosphorylase *b* kinase can be activated by an increase in intracellular free calcium ion. Thus, when muscular contraction is initiated by a release of calcium from the sarcoplasmic reticulum, the increase in calcium can also trigger glycogenolysis to help provide the needed fuel. Similarly, in liver, the action of epinephrine at low physiological levels to cause glycogen breakdown may be mediated by receptors linked to the release of calcium from the endoplasmic reticulum.

Glycogen synthase is also controlled by phosphorylation/dephosphorylation. In this case, the phosphorylated form is the less active one (originally called glycogen synthase D because it is dependent on glucose 6-phosphate, but now it is called synthase *b* in correspondence with the less active phosphorylase *b*; synthase *a* was originally called synthase I because it is independent of glucose 6-phosphate). The hormonal cascade described previously can cause the phosphorylation of glycogen synthase by PKA, thus inhibiting glycogen synthesis as well as activating glycogen breakdown. However, the situation for glycogen synthase is more complex because there are at least 10 phosphorylation sites that can be phosphorylated by at least nine different protein kinases. The importance or hierarchy of these sites and their kinases remains to be clarified. Insulin's effect in promoting glycogen storage appears to be in part due to inhibition of the action of glycogen synthase kinase 3 (Lawrence and Roach, 1997). Furthermore, insulin can promote the degradation of cyclic AMP via activation of cyclic nucleotide phosphodiesterase. In muscle, insulin's activation of glucose transport (Glut4) and perhaps phosphorylation is a major factor in promoting glycogen synthesis, and deficiency at this step is seen in type 2 diabetic patients and their near relatives.

The protein phosphatases that convert phosphorylase *a* to *b* and glycogen synthase *b* to *a*, particularly the protein phosphatase 1 that has a glycogen-binding subunit, are subject to regulation in several ways. First, binding of allosteric regulators to the protein substrate affects the activity of phosphatases and kinases. Thus, AMP binding to phosphorylase *a* makes it a poor substrate for the phosphatase because the phosphate is tucked in so that it cannot be hydrolyzed, whereas binding of glucose or glucose 6-phosphate causes the phosphate to become accessible. Binding of glucose 6-phosphate to phosphorylase *b* also makes it a poorer substrate for the kinase as well as inhibiting phosphorylase activity. Second, inhibitory proteins can bind to the phosphatase, and the action of these proteins is regulated by their phosphorylation and dephosphorylation. Third, the fact that the same phosphatase works on both phosphorylase *a* and synthase *b* means that when the phosphatase is bound to phosphorylase *a*—and cannot hydrolyze it because the phosphate is tucked in—the phosphatase is prevented from working on glycogen synthase.

Glycogen Storage Diseases

Genetic deficiency of enzymes of the liver related to glycogen breakdown can lead to the engorgement of the liver with glycogen. Thus, patients with Hers disease (type VI) lack liver phosphorylase and must therefore rely on gluconeogenesis to maintain blood glucose. Patients with Von Gierke disease (type I) lack glucose 6-phosphatase, cannot get glucose from either glycogenolysis or gluconeogenesis, and therefore can withstand only limited starvation. Presumably, they have increased glycogen because increased levels of glucose 6-phosphate promote glycogen synthesis and inhibit glycogen breakdown, as described previously. In McArdle disease (type V), muscle phosphorylase is absent (indicating that there are separate muscle and liver isoforms from separate genes) and exercise capacity is limited.

Gluconeogenesis

Gluconeogenesis is the synthesis of glucose from nonsugar precursors, such as lactate, pyruvate, and the carbon skeleton of glucogenic amino acids. This is a major metabolic function of the liver since the brain, in particular, is dependent on glucose as a fuel.

Reactions

In a sense, gluconeogenesis is a reversal of glycolysis, and many of the enzymes are the same for the reactions that are readily reversible. However, specifically gluconeogenic enzymes are needed to reverse three steps in glycolysis that have a large free energy drop. Thus, to reverse the pyruvate kinase reaction, first pyruvate is converted to oxaloacetate by pyruvate carboxylase, a reaction driven by ATP hydrolysis; then the oxaloacetate is decarboxylated and phosphorylated to generate phosphoenolpyruvate by the enzyme phosphoenolpyruvate carboxykinase using GTP (**Fig. 1**). Note that two high-energy phosphate bonds (from ATP and GTP) are needed to produce the very high-energy intermediate phosphoenolpyruvate. The reactions from there to fructose 1,6-bisphosphate occur via reversal of the glycolytic reactions. Then, to generate fructose 6-phosphate, the 1-phosphate is simply cleaved off by the gluconeogenic enzyme fructose 1,6-bisphosphatase (opposing the glycolytic enzyme phosphofructokinase). Fructose 6-phosphate equilibrates with glucose 6-phosphate in the phosphoglucose isomerase reaction as in glycolysis. Finally, glucose 6-phosphate is hydrolyzed to free glucose by glucose 6-phosphatase (opposing the hexokinase isoform glucokinase). Note that synthesis of a molecule of glucose requires the input of six ATP equivalents: the ATP at pyruvate carboxylase, the GTP at

phosphoenolpyruvate carboxykinase, and the ATP at the phosphoglycerate kinase reaction for each of the two halves of the glucose molecule, plus two equivalents of NADH for reversing the glyceraldehyde 3-phosphate dehydrogenase reaction.

Regulation of Gluconeogenesis

Control of net gluconeogenesis involves regulation of the opposing glycolytic enzymes and the corresponding specifically gluconeogenic enzymes. The glucose phosphorylating activity in liver is largely glucokinase, a high K_m (10 mm) isoform of hexokinase that is responsive to changes in the blood glucose concentration in the physiological range. Glucokinase is not inhibited by glucose 6-phosphate because it lacks the regulatory binding domain present in the other hexokinases. On the other hand, glucokinase has a specific inhibitory protein (GKIP) in the nucleus, whose effect is prevented by fructose 1-phosphate and increased by fructose 6-phosphate (Van Schaftingen *et al.*, 1997). (The disinhibition by fructose 1-phosphate explains the stimulation of glucose metabolism by fructose, which in the liver is largely phosphorylated to fructose 1-phosphate by fructokinase.) The liver isoform of pyruvate kinase has several regulatory properties designed to inhibit it so that gluconeogenesis can proceed: (i) strong allosteric inhibition by ATP; (ii) inhibition by alanine, an important gluconeogenic substrate; (iii) dependence on a high level of the activator fructose 1,6-bisphosphate (in order to have the same low K_m for phosphoenolpyruvate that the muscle isoform has with or without fructose 1,6-bisphosphate); and (iv) inhibition by phosphorylation by PKA in response to glucagon. It was originally thought that phosphofructokinase was similarly inhibited by phosphorylation by PKA, but in fact although phosphorylation of phosphofructokinase occurs, it appears to have little effect on the activity of the mammalian enzymes. Instead, PKA phosphorylation of liver phosphofructokinase-2/fructose 2,6-bisphosphatase (PFK2), the bifunctional enzyme that both makes and degrades fructose 2,6-bisphosphate, inhibits the kinase and activates the phosphatase activities, thus reducing the level of fructose 2,6-bisphosphate (Pilkis *et al.*, 1995). Since fructose 2,6-bisphosphate is an activator of the glycolytic phosphofructokinase (sometimes called phosphofructokinase-1 for clarity) as well as an inhibitor of fructose 1,6-bisphosphatase, glucagon can thus reduce glycolytic flux and promote gluconeogenesis at this step as well as at the pyruvate kinase step, in addition to its effect of stimulating glycogen breakdown and inhibiting glycogen synthesis. (Note: In muscle, one would not want epinephrine stimulation of PKA to cause inhibition of PFK2 and hence phosphofructokinase and glycolysis; thus the muscle isoform of PFK2 is an alternative transcript that lacks the PKA phosphorylation site. The cardiac isoform of PFK2, in contrast, has an activating phosphorylation site that is the substrate for AMP-activated protein kinase, and this may be important for increased glycolysis in ischemia.) Fructose 1,6-bisphosphatase is also inhibited by AMP, in contrast to the AMP activation of phosphofructokinase. Recently it has been found that liver PFK2 can have an additional regulatory role: When unphosphorylated, it can bind glucokinase to keep it in the cytosol and hence active. Phosphorylated PFK2 no longer binds glucokinase, which is then released to be bound and inhibited by GKIP (Agius, 2016). Hence, PKA directly or indirectly inhibits all of the key glycolytic enzymes. Pyruvate carboxylase has an absolute requirement for the activator acetyl-CoA; the rationale for this is that gluconeogenesis is quite energy consuming, the required ATP certainly cannot come from glucose metabolism, and the presence of acetyl-CoA would be indicative of sufficient alternative fuel, such as from fatty acids. The fact that phosphoenolpyruvate carboxykinase uses GTP (rather than ATP) may also provide a regulatory link, in that it is using GTP generated by the liver isoform of succinyl-CoA synthetase in the citric acid cycle, so that if there is insufficient citric acid cycle flux, then energy-consuming gluconeogenesis will not be attempted (Stark *et al.*, 2014). Finally, these enzymes are adaptive in that the amount of the glycolytic enzymes glucokinase, phosphofructokinase, and pyruvate kinase is increased by a high-carbohydrate diet, whereas the specifically gluconeogenic enzymes are increased by starvation or a low-carbohydrate diet. Interruption of insulin's normal repression of phosphoenolpyruvate carboxykinase and glucose-6-phosphatase in part explains the inappropriate high glucose output from the liver in diabetic patients, contributing to their elevated blood glucose levels; lack of insulin's normal restraining of adipose lipolysis and fatty acid release to power gluconeogenesis may also be important.

Substrate Cycling

The opposing gluconeogenic and glycolytic enzymes form energy-consuming substrate cycles—that is, if glucokinase and glucose 6-phosphatase were active simultaneously so that glucose were converted to glucose 6-phosphate and back to glucose, the net reaction would be the hydrolysis of ATP to ADP and P_i, and similarly for phosphofructokinase and fructose 1,6-bisphosphatase. If phosphoenolpyruvate were converted to pyruvate and back, there would be production of one ATP but utilization of two equivalents, for a net consumption of one ATP. It was originally thought that such substrate cycling would be a waste of energy (hence the original term futile cycle) and that there should be tight regulation to prevent simultaneous operation of the opposing enzymes. However, sophisticated radiolabeling experiments have shown the occurrence of such substrate cycling. For example, if liver cells undergoing gluconeogenesis are provided with glucose with tritium (a radioactive isotope of hydrogen) attached to carbon-5, then after the glucose is metabolized past the phosphofructokinase reaction, the tritium will be released into water on equilibration of glyceraldehyde 3-phosphate with dihydroxyacetone phosphate in the triose phosphate isomerase reaction. Such experiments have shown a substantial glycolytic rate that is largely reduced by glucagon treatment in order to increase the net gluconeogenic rate. Such substrate cycling has the advantage that there is no "dead" range in which neither glycolysis nor gluconeogenesis is operative and thus there is no control. Furthermore, substrate cycling amplifies cellular signals because changes in activators/inhibitors of glycolysis and/or gluconeogenesis lead to much greater percentage changes in the net rate. Finally, as a

special case, bumblebees have unregulated fructose 1,6-bisphosphatase in their flight muscles so that substrate cycling with phosphofructokinase generates heat to warm up the muscles on cold days to allow flight, much as an electric heater is used to heat a gasoline engine preparatory to start an automobile in very cold climates.

Cori Cycle and Alanine Cycle

There are two important interorgan cycles involving glycolysis in muscle and gluconeogenesis in liver. In the Cori cycle, glucose is metabolized to pyruvate and then to lactate in muscle, the lactate is released into the blood and carried to the liver, where it is reconverted to pyruvate and used for gluconeogenesis, and the resulting glucose is released and travels back to muscle. Lactate is a particularly good gluconeogenic substrate because the reoxidation of lactate to pyruvate in the lactate dehydrogenase reaction also provides the NADH equivalents needed for gluconeogenesis. The alanine cycle is similar to the Cori cycle, except that muscle pyruvate is converted to the amino acid alanine rather than lactate by transamination in the glutamate–pyruvate transamination reaction. A very large proportion of the amino acid put out by muscle is alanine, much more so than its composition in muscle protein, due to the fact that the carbon skeleton derives from glycolytically generated pyruvate. In the liver, alanine is transaminated back to regenerate pyruvate, and the excess amino groups can be disposed of as urea since the urea cycle is also localized to the liver. The importance of alanine as a gluconeogenic substrate in this regard explains why it is a potent allosteric inhibitor of liver pyruvate kinase.

Pentose Phosphate Pathway

The pentose phosphate pathway also branches off from glycolysis at glucose 6-phosphate. It has two important products: ribose 5-phosphate, which is needed for synthesis of nucleotides and nucleic acids (DNA and RNA), and NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate), which provides the reducing equivalents for synthetic reactions such as fatty acid biosynthesis. The first reaction of the pathway, catalyzed by glucose 6-phosphate dehydrogenase, generates one molecule of NADPH from NADP, and the sugar aldehyde group is oxidized to a carboxylic acid. However, since the glucose 6-phosphate substrate is in the pyranose (hemiacetal) ring form with the carbon-5 oxygen linked to carbon-1, the initial product is an internal ester, 6-phosphoglucono δ-lactone, that is then cleaved by lactonase to yield 6-phosphogluconate. 6-Phosphogluconate dehydrogenase produces a second molecule of NADPH from NADP and also releases the carbon-1 carboxyl group as CO_2, leaving the 5-carbon compound ribulose 5-phosphate. The latter (a keto sugar) is converted to ribose 5-phosphate (an aldo sugar) by phosphopentose isomerase. This so-called oxidative branch of the pentose phosphate pathway thus produces two NADPHs and one pentose phosphate. If, however, this gives more pentose phosphate than is needed for nucleotide synthesis, the excess can be converted back to glycolytic intermediates by the non-oxidative branch. Three pentose phosphates (15 carbons total) are converted to two molecules of fructose 6-phosphate and one glyceraldehyde 3-phosphate as follows: First, transketolase transfers 2 carbons from xylulose 5-phosphate (an epimer from ribulose 5-phosphate made by switching the orientation of the carbon-3 hydroxyl by phosphopentose epimerase) to ribose 5-phosphate, thereby producing the 7-carbon sugar sedoheptulose 7-phosphate plus glyceraldehyde 3-phosphate. Second, transaldolase transfers 3 carbons back from sedoheptulase 7-phosphate to glyceraldehyde 3-phosphate, producing fructose 6-phosphate and the 4-carbon sugar erythrose 4-phosphate. Finally, transketolase transfers 2 carbons to the erythrose 4-phosphate from another molecule of xylulose 5-phosphate, producing fructose 6-phosphate and glyceraldehyde 3-phosphate.

Glucose Metabolism and Insulin Secretion

Not only does insulin regulate glucose metabolism but also glucose metabolism in the pancreatic β cells regulates insulin secretion (Prentki *et al.*, 1997). The β cell is responsive to glucose in the physiological range because it has a high K_m glucokinase like liver. In the β cell, the increased glucose metabolism causes an increase in the ATP/ADP ratio, which closes ATP-sensitive K^+ channels in the plasma membrane, causing membrane depolarization and an influx of Ca^{2+} through voltage-sensitive calcium channels that triggers secretion. There are also other glucose concentration-dependent enhancements of secretion that may involve lipid metabolism and signaling pathways, such as via protein kinase C. Interestingly, normal insulin secretion is pulsatile, and it has been proposed that this may be due to underlying oscillations in glucose metabolism.

Insulin Secretion: Functional Biochemical Aspects☆

Willy J Malaisse, Free University of Brussels, Brussels, Belgium

Glossary

cyclic AMP (cAMP) Adenosine-3′,5′-cyclic monophosphate

To maintain normoglycemia, the mammalian organism is dependent on a continuous and continuously adapted supply of pancreatic insulin. A dramatic illustration of such a permanent need for insulin is given by the hyperglycemia seen in normal animals injected with insulin-neutralizing guinea pig anti-insulin serum. In these animals, the rate of endogenous insulin secretion can be calculated from the progressive reduction in the pool of circulating unneutralized antibodies.

Introduction

The insulin-producing B cells are located in small groups of endocrine pancreatic cells known as the islets of Langerhans. Each islet contains up to approximately 2000 cells, with the larger islets having a diameter not exceeding close to 0.2 mm. In addition to insulin-producing cells, the islets of Langerhans contain other endocrine cell types secreting hormones such as glucagon, somatostatin, and pancreatic polypeptide.

Considerable progress in our understanding of the regulation of insulin release was made possible over the past four decades through (1) the development of an immunoassay procedure for the measurement of the low concentration of insulin in plasma (i.e., approximately 0.1 nM), and (2) a technique for the isolation of islets from the pancreatic gland.

This article aims at reviewing briefly the current knowledge on insulin secretion with an emphasis on the following themes: the regulation of insulin release under physiological conditions; the process by which insulin secretagogues, especially D-glucose, are recognized by the islet B cells as insulinotropic agents; the mechanism of coupling between the recognition of secretagogues and more distal steps in the secretory sequence; the participation of a mechanical effector system in the exocytosis of secretory granules; the perturbation of insulin secretion in certain pathological conditions; and the pharmacological tools used to modify insulin secretion in situations of hypo- or hyperinsulinemia.

Physiological Aspects

Under physiological conditions, the release of insulin by the endocrine pancreas is regulated in an immediate and direct manner by a series of circulating nutrients, hormones, and neurotransmitters. It is also modulated in a delayed fashion by dietary, hormonal, and ontogenic factors.

Circulating Nutrients

Circulating nutrients that stimulate insulin release include mainly D-glucose and other monosaccharides, pyruvic and lactic acid, amino acids, unesterified fatty acids, and ketone bodies. Among these nutrients, D-glucose plays an essential role. It is indeed the sole nutrient able to stimulate insulin secretion at its physiological extracellular concentration in the absence of any other exogenous nutrient. The process of glucose-induced insulin secretion is characterized by its sensitivity and rapidity. A sigmoidal curve relates the output of insulin to the concentration of D-glucose in the extracellular fluid. Thus, one may define a threshold concentration for the insulinotropic action of D-glucose (close to 5 mM), a concentration of the hexose yielding a half-maximal secretory response (close to 10 mM), and a maximal velocity of insulin release that is observed at high D-glucose concentrations (approximately 20 mM) and represents about 20 times the basal insulin output.

In response to a rapid increase in D-glucose concentration, the release of insulin exhibits a multiphasic pattern. An almost immediate peak of insulin release is followed by a lower, but higher than basal, insulin output. Thereafter, a progressive rise in the rate of insulin secretion is observed. A high rate of hormonal release is then eventually achieved.

As emphasized in what follows, the insulinotropic action of D-glucose is causally linked to the capacity of the hexose to act as a nutrient and to increase the rate of adenosine 5′-triphosphate (ATP) generation in insulin-producing cells. This fuel concept also

This article is an update of Willy J. Malaisse, Insulin Secretion, Functional and Biochemical Aspects, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 40-44.

applies to the insulin-releasing action of other nutrients mentioned previously. In the case of amino acids, however, the following more nuanced situation prevails. Certain amino acids (e.g., L-leucine, L-glutamine, L-asparagine) also owe their insulinotropic capacity to their role as nutrients in the islet B cells. However, they may also act as allosteric activator of mitochondrial glutamate dehydrogenase and, as a result, facilitate the catabolism of endogenous amino acids in the islet cells. For instance, such is the case for a transported but nonmetabolized analogue of L-leucine. Moreover, other amino acids, which are potent insulin secretagogues, are poor nutrients but stimulate insulin release as a result of their accumulation in the islet cells. Such is the case for cationic amino acids (e.g., L-arginine, L-ornithine), which, through their accumulation inside the islet cells, provoke a depolarization of the plasma membrane and a resulting gating of voltage-sensitive calcium channels.

Immediate and Direct Effects of Hormones and Neurotransmitters

Two examples of the immediate and direct effects of hormones on insulin release are mentioned here. First, adrenaline inhibits insulin secretion evoked by D-glucose or other insulin secretagogues. This effect is suppressed by α-adrenergic blocking agents and coincides with a lowering of the cyclic AMP (cAMP) content in islet cells. It was proposed that, by inhibiting insulin release under conditions of stress and exercise, adrenaline would be better able to mobilize D-glucose from the liver and to mobilize free fatty acids and glycerol from adipose tissue.

Second, certain gastrointestinal hormones, such as glucagon-like peptide 1, potentiates insulin release evoked by D-glucose and other nutrient secretagogues. This is attributable to activation of adenylate cyclase, with a resulting increase in the cAMP content of islet cells. The term 'hormonal enteroinsular axis' was proposed to indicate that the enhancement of insulin secretion by hormones released from the intestinal tract may account for the fact that hyperinsulinemia caused by D-glucose is more marked when the sugar is given orally rather than intravenously.

Likewise, vagal stimulation of insulin release could be a significant feature in the process of food intake and digestion. Cholinergic agents indeed augment insulin secretion evoked by D-glucose. This process involves occupancy of islet cells' muscarinic receptors, activation of phospholipase C, hydrolysis of polyphosphoinositides, and liberation of diacylglycerol and inositol 1,4,5-triphosphate with resulting activation of protein kinase C and mobilization of intracellular Ca^{2+}.

Long-Term Regulation of Insulin Release

Insulin release evoked by D-glucose is decreased in islets prepared from starved animals. It occurs at an abnormally high rate in islets from obese animals. Several hormones also affect the secretory responsiveness of the endocrine pancreas in a delayed manner. This may account for alteration of insulin release in situations such as pregnancy and lactation, acromegaly, hypo- or hypercorticism, and hypo- or hyperthyroidism. Finally, the long-term regulation of insulin release also involves ontogenic factors, as documented by the changes in islet secretory behavior found in fetal and neonatal life or aging.

Recognition of Secretagogues

As alluded to previously, the B cell is equipped with a number of receptors involved in the recognition of adrenergic factors, cholinergic neurotransmitters, and gastrointestinal hormones. By analogy, it had been proposed that each nutrient secretagogue may bind to a specific receptor possibly located at the B-cell plasma membrane. For instance, a previously widespread view postulated the presence of a stereospecific glucoreceptor in islet cells. However, a more pedestrian metabolic hypothesis eventually prevailed, postulating that the insulinotropic capacity of D-glucose is causally linked to its role as a nutrient in islet cells. This was then extended to other nutrient secretagogues and defined as the fuel concept for insulin release.

The key argument in support of this metabolic hypothesis for glucose-stimulated insulin secretion resides in the finding that the α-anomer of D-glucose, which is a more potent insulin secretagogue than ß-D-glucose, is also more efficiently metabolized in pancreatic islets. As a matter of fact, the metabolism of D-glucose in isolated pancreatic cells or in purified islet B cells displays a number of uncommon features, all of which optimize the increase in ATP generation rate resulting from the stimulation of islet cells by this hexose. A few examples of such features follow.

First, the concentration of D-glucose rapidly equilibrates across the plasma membrane of the B cell thanks to the efficiency of the glucose carrier GLUT2 (and GLUT1 in human B cells). Second, the phosphorylation of D-glucose in islet B cells is catalyzed not solely by an ubiquitous low-K_m hexokinase but also by a high-K_m glucokinase. As a result of these two features, the rate of D-glucose phosphorylation increases rapidly and sensibly in response to a rise in the extracellular concentration of the hexose. The regulation of D-glucose phosphorylation in the B cell also involves a number of other mechanisms such as a sequential synarchistic regulation by ATP, induction and repression of glucokinase, feedback inhibition of hexokinase by glucose 6-phosphate, intracellular translocation of glucokinase, intervention of a glucokinase regulatory protein, balance between glucose phosphorylation and dephosphorylation (by glucose-6-phosphatase), and binding of hexokinase isoenzymes to mitochondrial porin, with this process modifying kinetic properties (e.g., sensitivity to glucose 6-phosphate), coinciding with a preferential use of mitochondrial ATP for phosphorylation of D-glucose, and allowing a direct coupling between hexose phosphorylation and mitochondrial respiration.

Second, for the rate of glycolysis to keep pace with the rate of D-glucose phosphorylation, activation of key glycolytic enzymes takes place in glucose-stimulated B cells. For instance, such is the case for the activation of phosphofructokinase by fructose 2,6-bisphosphate. Incidentally, the regulation of phosphofructokinase activity in islet cells also displays the specific feature of an apparent resistance of fructose 6-phosphate,2-kinase to cAMP.

Finally, a preferential stimulation of mitochondrial oxidative events in either isolated islets or purified B cells exposed to increasing concentrations of D-glucose represents an essential feature of the B-cell glucose-sensing device. This phenomenon is attributable mainly to a Ca^{2+}-induced activation of key mitochondrial dehydrogenases such as the FAD-linked glycerophosphate dehydrogenase and 2-ketoglutarate dehydrogenase complex. Therefore, it should be considered as a secondary phenomenon caused by the accumulation of Ca^{2+} in the B cells. It optimizes the yield of ATP generated through the catabolism of D-glucose given that the mitochondrial oxidation of pyruvate provides the major fraction of such an ATP generation and is necessarily coupled with the oxidative modality of glycolysis. It should not be ignored, however, that it was recently documented that insulin-producing cells are equipped with a true sweet-tasting receptor and that activation of this receptor by artificial sweeteners as well as by D-glucose itself results in the stimulation of insulin release mediated by an array of coupling mechanisms.

Coupling Mechanisms

In the process of nutrient-stimulated insulin release, the coupling between metabolic events and more distal events in the secretory sequence appears to be multifactorial. Emphasis is currently placed on the closing of ATP-sensitive K^+ channels caused by the increase in the cytosolic ATP/adenosine diphosphate (ADP) ratio in nutrient-stimulated B cells. The closing of these channels then leads to depolarization of the plasma membrane and the subsequent opening of voltage-sensitive Ca^{2+} channels. The facilitated entry of Ca^{2+} into the B cell and the cytosolic accumulation of this divalent cation then acts as a trigger for the release of secretory granules.

A stimulatory effect of D-glucose on insulin release can still be documented, however, in cells exposed to both diazoxide (to maintain the K^+ channels in their open configuration) and a high extracellular K^+ concentration (to nevertheless cause depolarization of the plasma membrane). This finding points to the participation of other mechanisms in the stimulus–secretion coupling for glucose-induced insulin release. In this perspective, the following considerations should be underlined.

First, an increase in the ATP generation rate might not represent the sole factor coupling the catabolism of nutrient secretagogues to the remodeling of ionic fluxes in the islet cells. For instance, nutrient-induced changes in the redox state of islet cells and their intracellular pH may also participate in nutrient-stimulated insulin release.

Second, the cytosolic accumulation of Ca^{2+} may lead, via calmodulin, to the activation of adenylate cyclase in pancreatic islets. Pancreatic islets indeed contain calmodulin (about 0.1 pmol per islet). This protein binds to a particulate fraction derived from the islets and stimulates adenylate cyclase activity in this subcellular fraction, with both phenomena being activated by ionized calcium. Thus, a calcium-dependent stimulation of adenylate cyclase by endogenous calmodulin may contribute to the accumulation of cAMP evoked by insulin-releasing agents in the islet cells. cAMP should be considered as a modulator of the insulin secretory response to nutrient secretagogues. Its synthesis and breakdown are catalyzed by adenylate cyclase and phosphodiesterase, respectively. cAMP activates a protein kinase, leading to an apparent increase in the responsiveness of the effector system for insulin release to cytosolic Ca^{2+}.

Third, in nutrient-stimulated B cells, as in response to cholinergic agents, breakdown or otherwise accelerated turnover of inositol phospholipids takes place. The accelerated generation of polyphosphoinositides in nutrient-stimulated islet cells may result from a rise in cytosolic ATP production, whereas the stimulation by nutrients of the hydrolysis of inositol-containing phospholipids is currently ascribed to activation of phospholipase C through an increase in the cytosolic Ca^{2+} concentration. Enhanced phospholipid metabolism may then lead to the mobilization of calcium from nonmitochondrial intracellular stores by inositol 1,4,5-triphosphate and activation of protein kinase C by diacylglycerol.

Last, a second key component of the process of nutrient-stimulated insulin release consists in the gating of volume-sensitive anion channels. This concept is mainly based on the following findings. Whislt a rise in D-glucose concentration up to about 6-8 mM decreases the outflow of radioactive rubidium from prelabelled islets, indicating a decrease in potassium conductance, no further decrease in the outflow of radioactive rubidium and, on the contrary, a modest but significant increase is observed at higher D-glucose concentrations, namely in the range of glucidic concentrations provoking the most marked stimulation of insulin release. It seems likely, therefore, that another series of cellular events is responsible for enhancing insulin secretion at these high concentrations of the hexose. The anion channel hypothesis postulates that the entry of D-glucose in insulin-producing cells and the subsequent acceleration of its catabolism results in the intracellular accumulation of metabolites such as lactate and bicarbonate anions. The resulting increase of intracellular osmolarity may then provoke, through increased water uptake, an increase in cell volume and the subsequent gating of volume-sensitive anion channels. In the insulin-producing cells, the gating of these channels may allow the exit of chloride, orthophosphate, lactate and bicarbonate anions and, hence, further depolarization of the plasma membrane and gating of voltage-sensitive calcium channels. This novel concept is supported by a number of findings concerning for instance the stimulation by D-glucose of chloride anion efflux, the nutrient-induced transient increase of inorganic phosphate efflux, a phenomenon referred to as a phosphate flush, and the likely increase in bicarbonate anion outflow during the second and sustained phase of insulin secretion evoked by D-glucose and othet nutrient secretagogues. The latter proposal takes into account the finding that the carbonic anhydrase-catalyzed generation of radioactive bicarbonate from radioactive carbon dioxide itself produced through the oxidative catabolism of the hexose in islets exposed to glucose uniformly labelled with carbon

14 accounts for the majority of the latter production. The anion channel hypothesis also led to investigations concerning the expression in pancreatic islets of the sodium-bicarbonate-cotransporter NBCe1-A and aquaglyceroporin 7.

Effector System

The increase in the cytosolic concentration of ionized calcium caused by D-glucose or other insulin secretagogues triggers the exocytosis of secretory granules by causing the activation of a microtubular–microfilamentous system. The participation of this effector microtubular–microfilamentous system in the process of insulin release has been documented by a number of ultrastructural, biochemical, functional, and cinematographical studies.

Microtubules (21–25 nm in diameter) are considered to represent the cytoskeleton of B cells. They are scattered in the cytoplasm. They can be found between rows of aligned secretory granules. They are thought to provide oriented pathways for back-and-forth saltatory movements of secretory granules. They are also prominent in the ectoplasmic area. At that level, the cell web occupies cytoplasmic areas of variable thickness (50–300 nm) just beneath the plasma membrane and extends into the core of microvillous processes. It consists of a network of actin-like microfilaments (4–7 nm in diameter) generally disposed to form irregularly shaped polygons. This contractile cell web acts as a sphincter, either restricting or favoring the access of secretory granules to their exocytotic site at the plasma membrane.

The tools most commonly used to interfere experimentally with the function of the microtubular–microfilamentous system include mitotic spindle inhibitors (e.g., colchicine, vincristine), microtubule stabilizers (e.g., D_2O), and the microfilamentous modifier cytochalasin B.

At the exocytotic site, the fusion between the limiting membrane of insulin secretory granules and plasma membrane and subsequent fission of the fused membrane seem to involve an anion–osmotic process in which the insertion at the plasma membrane of an anion transport system derived from the limiting membrane of the secretory granules allows for the entry of anions (e.g., Cl^-, OH^-) into the lumen of these granules, followed by their osmotic fission. This process also accounts for the release of several granules aligned along an oriented microtubular pathway, a phenomenon known as the chain release of secretory granules or compound exocytosis.

Pathological Aspects

Defective insulin release is a typical feature of diabetes mellitus. In insulin-dependent diabetes, it results from an autoimmune destruction of insulin-producing cells. In non-insulin-dependent diabetes, the deficiency of insulin release may be caused by a number of distinct site-specific anomalies. Indeed, virtually each step in the process of insulin secretion may be affected by inherited or acquired factors. For instance, a defect in the conversion of proinsulin to insulin and C-peptide may result in the release of large amounts of proinsulin, which is virtually devoid of hypoglycemic action. On the most distal step of the secretory sequence, a defect of the microtubular apparatus may be responsible for a sluggish secretory response to D-glucose in certain animal models of type 2 diabetes.

In most but not all patients with type 2 diabetes, the endocrine pancreas displays a preferential impairment of its secretory responsiveness to D-glucose, as distinct from other nutrient or nonnutrient insulin secretagogues. Site-specific defects responsible for such a situation include (1) a decrease in the number of B cells suitably equipped with sufficient GLUT2 carriers, (2) a nonsense mutation of the glucokinase gene, (3) excessive activity of glucose-6-phosphatase leading to an ATP-wasting futile cycle in the reaction catalyzed by hexokinase isoenzymes and glucose-6-phosphatase, and (4) a deficient activity of the mitochondrial FAD-linked glycerophosphate dehydrogenase, the key enzyme of the glycerol phosphate shuttle. Moreover, glycogen accumulation takes place in the B cell in situations of chronic hyperglycemia. It is held responsible for the secondary process of so-called B-cell glucotoxicity or incompetence. Two typical phenomenological aspects of this process consist in a paradoxical early and transient decrease in insulin release and the perturbation of its anomeric specificity in response to the rapid intravenous administration of D-glucose to patients with type 2 diabetes.

Excessive secretion of insulin can also occur in certain pathological conditions. Such is the case, for instance, in individuals bearing an insulinoma or in patients with persistent hyperinsulinemia during childhood.

Pharmacological Aspects

The therapeutic agents currently used to modify insulin secretion belong to two classes. First, to enhance insulin release in non-insulin-dependent diabetic individuals, either hypoglycemic sulfonylureas (e.g., tolbutamide, glibenclamide) or meglitinide analogues (e.g., nateglinide, repaglinide) are given orally. These antidiabetic agents display a common configuration and act by causing a direct closing of ATP-sensitive K^+ channels without affecting the ATP content of insulin-producing cells.

Second, to prevent excessive insulin secretion in certain pathological conditions, diazoxide and related drugs are used. They cause a direct opening of ATP-sensitive K^+ channels and, hence, inhibit insulin release caused by D-glucose and other secretagogues. This effect of diazoxide is abolished in the presence of hypoglycemic sulfonylureas or meglitinide analogues.

The destruction of insulin-producing cells (e.g., in patients bearing an insulinoma) can be achieved by selective ß-cytotoxic agents, especially streptozotocin.

Insulin is a polypeptide hormone that is secreted from beta cells of the pancreas. It is the primary hormone responsible for regulating glucose uptake and utilization in cells. Insulin is also known as an anabolic hormone and is involved in the synthesis of glycogen, proteins and lipids. A defect in insulin secretion or action leads to aberrant glucose homeostasis and diabetes. Because of its role in the regulation of glucose concentration in the blood and in the pathogenesis of diabetes, an enormous amount of effort has been directed to understand the molecular mechanism of insulin action. In this article we aim to provide an overview on the postreceptor mechanisms which contribute to the key glucoregulatory responses of insulin in its target tissues.

Insulin Receptor and Insulin Receptor Substrates

The first event in insulin action involves the binding of insulin to its receptor. The insulin receptor (IR) is composed of two extracellular α-subunits and two transmembrane β-subunits linked to each other by disulfide bonds. The α-subunit is mostly extracellular and contains the insulin-binding site, while the β-subunit has an intracellular component and possesses an intrinsic insulin-regulated tyrosine kinase activity. Binding of insulin to the α-subunit of IR causes a conformational change, leading to an enhanced protein tyrosine kinase (PTK) activity of the β-subunit by multisite tyrosine phosphorylation (Tyr − 1158, Tyr − 1162, Tyr-1163) (White and Kahn, 1994) (**Fig. 1**). Activated IR-PTK phosphorylates its downstream substrates in tyrosine residues (White, 2003; White, 2006). These substrates include insulin receptor substrates (IRSs), Shc (Src homology and collagen domain) proteins and Grb2 associated binding protein 1 (Gab1). IRSs have multiple tyrosine phosphorylation sites that, once phosphorylated, serve as docking sites for Src homology 2 (SH2) domain-containing signaling molecules (White, 2003; White, 2006). In addition, IRSs have several serine/threonine residues that are phosphorylated by serine/threonine kinases and reduce the binding of these signaling molecules to IRSs. The IRS family has several members (IRS1-IRS6), however, among these, the role of IRS1 and IRS2 has been studied in some detail with regards to their involvement in mediating insulin action and insulin resistance. IRS gene knockout studies in mice have demonstrated that deletion of the IRS1 gene results in normal glucose tolerance despite mild insulin resistance in muscle tissues, whereas deletion of IRS2 was associated with attenuated insulin signaling, insulin resistance and diabetes (Araki et al., 1994; Kubota *et al.*, 2000; Kido *et al.*, 2000; Withers *et al.*, 1998; White, 2006). Consistent with a role of IRS1 in insulin resistance, some mutations in IRS1 have been associated with type 2 diabetes in human subjects (Whitehead *et al.*, 1998; Almind *et al.*, 1996; Burguete-Garcia *et al.*, 2010; Martinez-Gomez *et al.*, 2011), however, a strong association between these mutations and diabetes remains to be established.

Phosphatidylinositol-3-Kinase (PI3K)

As stated earlier, the tyrosine phosphorylated and activated forms of IRSs serve as docking sites for binding with key signaling molecules. These signaling molecules invariably possess SH2 domains and bind to specific phosphotyrosine residues on the IRS proteins. PI3K is one such signaling molecule and is a key mediator of the glucoregulatory and metabolic responses of insulin. PI3K belongs to a family of lipid kinases which catalyze the formation of phosphatidylinositol 3, 4, 5-triphosphate (PIP3) by adding a phosphate group at position 3 of the inositol ring of phosphatidylinositol 4, 5-bisphosphate (PIP2). PI3K family is composed of 3 different members among which class 1A is a heterodimeric protein consisting of a regulatory subunit, p85 and a catalytic subunit p110α. Binding of the regulatory subunit of PI3K to IRS activates the catalytic properties of the p110α subunit resulting in the conversion of PIP2 to PIP3 (Myers *et al.*, 1992). PIP3 then serves as a lipid second messenger for the activation of pleckstrin (PH) domain-containing protein kinases such as three phosphoinositide-dependent–kinase 1(PDK1). PDK1 plays a critical role in activating protein kinase B (PKB) also known as AKT, a downstream effector of PI3K and a critical component of insulin signaling pathway (**Fig. 1**).

 doi:10.1016/B978-0-12-801238-3.95802-1

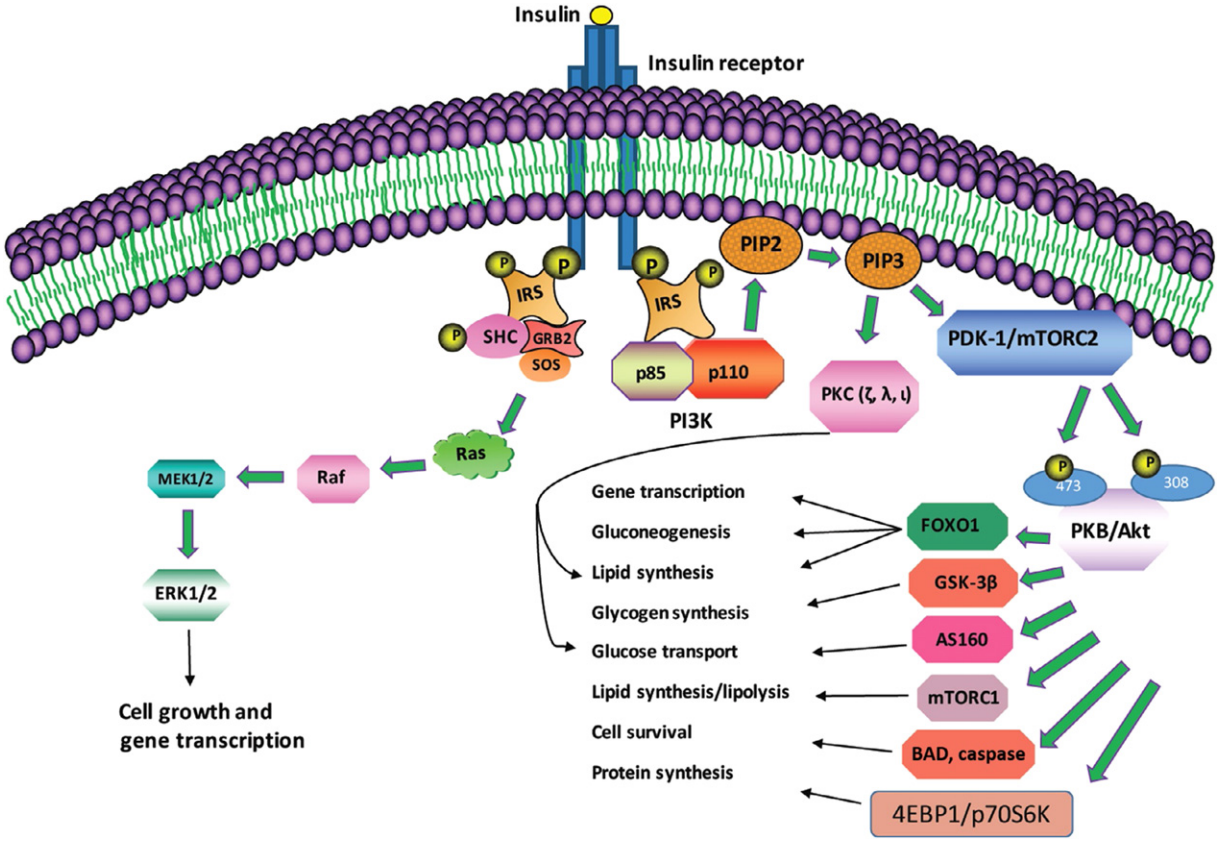

Fig. 1 *Schematic model showing key elements of the insulin signaling pathway.* Insulin-induced tyrosine phosphorylation and activation of IRSs by the PTK of β-subunits lead to the recruitment of SH-2 domain-containing signaling proteins such as Shc, Grb-2-SOS and the p85 regulatory subunit of PI3-K. The IRS-associated complex initiates two main signaling pathways. One pathway, known as the MAPK pathway, consists of Ras/Raf/MEK/ERK1/2. ERK1/2 can be translocated to the nucleus where they can activate transcription by inducing phosphorylation of several transcription factors. The second pathway involves PI3-K activation, which results in the generation of PIP3. PIP3 activates a variety of downstream signaling components, including PDKs, PKB, mTORC1/2, ribosomal protein S-6-kinase (p70s6k), PKCs, GSK-3, and FoxO. PKB and PKC are involved in glucose transport/GLUT4 translocation while mTORC1 regulates protein synthesis via p70s6k. Glycogen synthesis is regulated by PKB via GSK-3. PKB-mediated phosphorylation of FoxO regulates gluconeogenesis by inhibits transcription of PEPCK and G6Pase. mTORC1 controls lipogenesis and lipolysis.

Pkb/Akt and Insulin Action

PKB/AKT is a serine/threonine protein kinase that was originally discovered as a cellular homolog of v-AKT, a retroviral oncogene (Manning and Toker, 2017; Staal, 1987). It has been termed as PKB because of its structural similarities with protein kinase A and protein kinase C (Coffer and Woodgett, 1991). Subsequent studies have led to the identification and characterization of three different homologous isoforms of PKB: PKBα/Akt1; PKBβ/Akt2 and PKBγ/Akt3 (Brazil and Hemmings, 2001; Manning and Toker, 2017). Of these isoforms, PKBβ/Akt2 is highly expressed in insulin responsive tissues and is believed to mediate most of glucoregulatory and metabolic effects of insulin. All isoforms of PKB/AKT, in addition to having a catalytic protein kinase domain, also possess a lipid binding regulatory PH domain which binds to PIP3 generated by PI3K. This binding results in its translocation to the cell membrane where it is activated by its phosphorylation on threonine 308 and serine 473 residues catalyzed by 3-phosphoinositide-dependent protein kinase-1 (PDK-1) and mammalian target of rapamycin complex 2 (m-TORC-2) respectively (**Fig. 1**) (Manning and Toker, 2017).

Glucose Transport

Activated PKB phosphorylates a multitude of downstream substrates that mediate the glucoregulatory responses in insulin target tissues. These substrates include the Akt substrate of 160 kDa (AS160) which is a GTPase activating protein (GAP) and has been suggested to play an important role in insulin-stimulated glucose transport by promoting the translocation of insulin-dependent glucose transporter protein, GLUT4, from the intracellular sites to the plasma membrane (Klip *et al.*, 2014). Although the precise steps that AS160 regulates in GLUT4 trafficking pathway remain elusive, phosphorylation-induced reduction in its GAP activity

appears to be essential for this response because expression of a nonphosphorylatable mutant of AS160 was shown to inhibit insulin-induced GLUT4 translocation (Randhawa *et al.*, 2008; Foley *et al.*, 2011; Klip *et al.*, 2014). Moreover, the results showing that the knock down of AS160 leads to a redistribution GLUT4 from the intracellular sites to the plasma membrane have provided additional support for an implication of AS160 in insulin-induced GLUT4 translocation and glucose transport (**Fig. 1**) (Eguez *et al.*, 2005).

Glycogen Synthesis

Another key physiological response of insulin is the storage of glucose in the form of glycogen in target tissues. Glycogen synthesis in cells is catalyzed by glycogen synthase (GS) and its activity is regulated by a reversible phosphorylation/dephosphorylation pathway (Srivastava and Pandey, 1998). The phosphorylation of GS is achieved by a variety of serine/threonine protein kinases whereas it is dephosphorylated by protein phosphatases. The dephospho-GS is an active form and phospho-GS is inactive, and unable to fully induce glycogen synthesis in response to insulin (Srivastava and Pandey, 1998). One of the protein kinases that phosphorylates and inactivates GS is glycogen synthase kinase-3 (GSK-3) (Srivastava and Pandey, 1998; Roach, 1991). Two isoforms of GSK-3 have been identified in mammalian cells, termed GSK-3α and GSK-3β. In the basal state, GSK-3 remains constitutively active however, PKB/AKT-induced phosphorylation on serine21 in GSK-3α and serine 9 in GSK-3β renders it inactive. Inactivation of GSK-3 results in decreased phosphorylation of GS and thereby enhances its ability to catalyze the synthesis of glycogen in response to insulin (**Fig. 1**). Gene knock out studies as well as use of pharmacological inhibitors have demonstrated that GSK-3 is a critical mediator of insulin-induced glycogen synthesis in both muscle and liver tissues (MacAulay and Woodgett, 2008). In addition, the activation of protein phosphatases can also decrease the phosphorylation of GS and induce glycogen synthesis in response to insulin.

Gluconeogenesis

In addition to stimulating glucose transport and glycogen synthesis, insulin also regulates glucose homeostasis by suppressing hepatic glucose output. This is achieved by the inhibition of gluconeogenesis. In the absence of insulin, the activity of phosphoenol pyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G6Pase), two rate limiting enzymes of gluconeogenic pathway, remains elevated allowing increased production of glucose through this pathway. Insulin inhibits the expression of PEPCK and G6Pase in the liver via PKB-dependent phosphorylation of the forkhead box O (FoxO) family of transcription factors. In the basal state, the FoxOs reside in the nucleus and induce the expression of PEPCK and G6Pase, however, PKB-induced phosphorylation of FoxO results in their binding to 14-3-3 adaptor proteins and nuclear export leading to the downregulation of PEPCK and G6Pase gene expression (**Fig. 1**). Consistent with a critical role of FoxOs in the regulation of gluconeogenesis, genetic deletion of FoxO1 has been reported to inhibit gluconeogenesis in mouse models (Pajvani and Accili, 2015).

Lipogenesis and Lipolysis

Being an anabolic hormone, insulin stimulates lipogenesis and inhibits lipolysis. Sterol-regulatory element binding protein-1C (SREBP-1C), which is a key transcription factor that activates the expression of lipogenic gene transcription program, plays a key role in insulin—induced de novo lipid synthesis. Both mTORC1-dependent and independent pathways regulate the processing and expression of SREBP-1C. A potential role of early growth response-1, a zinc finger transcription factor, in the suppression of insulin-induced lipolysis by inhibiting the expression of adipose triglyceride lipase (ATGL) via mTORC 1 pathway has been suggested (Chakrabarti *et al.*, 2013). While Akt/mTORC1 signaling activates SREB-1C–induced lipogenic program, it suppresses lipolysis (Wang *et al.*, 2015; Kandror, 2017) (**Fig. 1**). Phosphodiesterase 3B (PDE3B) has been shown to play a role in the suppression of lipolysis because adipocytes from PDE3 knockout animals show a reduction in the antilipolytic effect of insulin (Choi *et al.*, 2006).

Ras/Raf/Erk Pathway

In addition to the PI3K/PKB/AKT pathway, insulin also triggers another pathway downstream of IR and IRS-1. In this pathway, SH2 domain-containing proteins Shc (SH2 domain and collagen homologous region) and growth factor receptor binder-2 (Grb-2)/mammalian son of sevenless (SOS) complex results in the activation of Ras-mitogen activated protein kinase (MAPK) signaling. In this cascade, SOS serves as guanine exchange factor for Ras and stimulates the formation of active RAS-GTP complex and activation of a serine/threonine kinase Raf. Raf then phosphorylates MEK (MAPK kinase), which in turn phosphorylates extracellular signal-regulated kinase (ERK1/2) on Thr and Tyr residues located in the activation loop of the kinase (**Fig. 1**). ERKs, via MAPK interacting proteins (MINK1/MINK2), participate in protein synthesis and/or get translocated to the nucleus where they

phosphorylate transcription factors such as c-Jun, CHOP, CREB and MEF-2 to induce gene transcription and contribute to the mitogenic and growth-promoting effects of insulin (Fig. 1).

Calcium and Protein Kinase C in Insulin Signaling

Insulin has been shown to trigger Ca^{2+} influx as well as mediate insulin-induced MAPK and PI3K/AKT signaling cascades in hepatocytes and 3T3-adipocytes (Benzeroual *et al.*, 2000; Benzeroual *et al.*, 1997; Whitehead *et al.*, 2001). In these studies, calcium depletion/chelation, despite blocking PI3K/AKT activation, failed to reduce insulin-stimulated tyrosine phosphorylation of both IR and IRS1, suggesting that Ca^{2+} exerted its effect downstream of IR/IRS. Other cell types, such as L6-myotubes and cardiomyocytes, also exhibit an increase in cytosolic Ca^{2+} in response to insulin via inositol-3-phosphate receptor and ryanodine receptor–mediated events which participate in insulin stimulation of GLUT4 translocation and glucose uptake (Contreras-Ferrat *et al.*, 2014a; Contreras-Ferrat *et al.*, 2014b). An implication of Ca^{2+} in insulin-stimulated AKT phosphorylation and glucose uptake in 3T3-L1 adipocytes has also been reported (Worrall and Olefsky, 2002), establishing a clear role of Ca^{2+} in this process.

The atypical class of PKC family members (PKC ζ, λ and ι) are also important components of the insulin signaling cascade. Atypical PKCs are activated by phospholipids such as PIP3 generated by PI3K activation and require the phosphorylation of a threonine residue in the activation loop for stimulation of their catalytic activity. Once activated, these PKCs participate in insulin-induced glucose transport, GLUT4 translocation as well as lipogenesis by regulating the transcription of SREBP-1C transcription (Fig. 1) (Farese *et al.*, 2014; Farese and Sajan, 2010).

Defects in Postreceptor Insulin Signaling

An aberrant insulin action in insulin resistant states and diabetes has been attributed to defective insulin signaling. This defect can occur at various steps in the insulin signaling pathway and many components of this pathway are subject to negative regulation by serine/threonine protein kinase and protein phosphatases. A series of serine/threonine protein kinases that are activated by free fatty acids, reactive oxygen species and inflammatory cytokines such as TNF-α, that are elevated in insulin resistant sates, catalyze the phosphorylation of IRS-1 on serine residues-301, 307 and 632, dissociate the IRS-1-PI3K complex and reduce PI3K activity, which in turn inhibits insulin action. Protein tyrosine phosphatases (PTPases) also regulate insulin action by dephosphorylating phospho-tyrosines in activated forms of IR and IRS and disabling the downstream signaling at the level of PI3K and PKB/AKT. Ablation of PTB1B, a PTPase with high expression in insulin target tissues, confers protection against high fat diet–induced insulin resistance and improves insulin signaling (Boura-Halfon and Zick, 2009; Morino *et al.*, 2008; Saini, 2010; Boucher *et al.*, 2014).

Summary

Decades of research in many laboratories has helped unravel the signaling pathway induced by IR activation and has identified various components of this pathway that mediate the physiological effects of insulin. As a result, two main pathways have been implicated in mediating the key physiological responses of insulin in insulin target tissues. In one pathway, IRS-associated Shc-Grb2-Sos complex activates the Ras/Raf/MEK/ERK signaling pathway which plays a key role in inducing the mitogenic and hypertrophic responses by initiating protein synthesis and gene transcription. The second pathway that radiates from IRSs involves PI3K activation that generates PIP3. PIP3 recruits PKB/AKT and PDK1 to the membrane where PKB becomes phosphorylated and activated. Activated PKB phosphorylates several downstream substrates such as GSK-3, AS160, FoxO which mediate the effect of insulin in enhancing glucose uptake, GLUT4 translocation, glycogen synthesis and lipogenesis, in the inhibition of lipolysis and gluconeogenesis. Atypical PKCs that are activated by PIP3 also participate in the regulation of GLUT 4 translocation and lipogenesis. PI3K-independent pathways have also been suggested to contribute to insulin–induced responses.

Diagnosis and Classification of Diabetes Mellitus

Jean-Marie Ekoé, University of Montreal, Montreal, QC, Canada

Glossary

Beta cells Cells found in the pancreatic islets of the pancreas that produce insulin.
Glycated hemoglobin Biochemical marker of blood glucose control.
Hyperglycemia High blood sugar level main characteristic of diabetes mellitus.
Insulin Hormone produced by beta cells to control blood glucose levels.
Ketoacidosis Serious complication of diabetes when the body produces high levels of blood acids called ketones due to lack of insulin.
Macrovascular disease Large vessel disease.
Microvascular disease Small vessel disease.
Polydipsia Excessive drinking due to excessive thirst.
Polyphagia Excessive eating.
Polyuria Excessive and frequent production of urine.
Prediabetes Clinical stage preceding diabetes (see below).

Introduction

In the ancient Egyptian papyrus discovered by George Ebers, polyuric states resembling diabetes mellitus were described as early as 1550 BC. The association of polyuria with a sweet-tasting urine was rapidly noted. The term diabetes mellitus, an allusion to the honeyed taste of the urine was used to distinguish it from other polyuric states in which the urine was tasteless.

Diabetes mellitus is now defined as a state of chronic hyperglycemia which may result from many environmental and genetic factors often acting jointly.

Definition of Diabetes and Prediabetes

Diabetes

The usual clinical symptoms of diabetes, polyuria and polydipsia, are the direct consequences of the high blood glucose concentration. Weight loss in spite of polyphagia, ketoacidosis, visual changes, skin and urogenital infections, sepsis and pruritus may be present as well. Mild hyperglycemia is usually symptomless. Almost 50% of persons with diabetes do not present these diabetic symptoms. It is therefore quite clear why diagnosis based solely on symptoms bears a very low incidence.

To study the natural history and pathogenesis of diabetes as a whole, the biochemical definition is the only common and stable factor. Hyperglycemia remains therefore the most important factor required for the diagnosis of diabetes.

The chronic hyperglycemia is due to a defective insulin secretion (relative insulin deficiency) and/or insulin resistance (defective insulin action). Chronic exposure to high blood glucose levels induces specific long-term microvascular complications affecting the nerves, the kidneys and the eyes, as well as an increased risk for macrovascular disease, specifically cardiovascular disease (CVD). The diagnostic criteria for diabetes are based on thresholds of glycemia that are associated with microvascular disease, especially retinopathy.

Prediabetes

Prediabetes is a term referring to impaired fasting glucose (IFG), impaired glucose tolerance (IGT) or a glycated hemoglobin (A1C) of 6.0%–6.4%, each of which places individuals at high risk of developing diabetes and its complications. IFG, IGT, A1c are measured from blood samples at a fasting state (IFG) or 2 h after an oral absorption of a standardized amount of 75 g of glucose, that is, oral glucose tolerance test (OGTT) or at random (A1C).

Diagnostic Criteria

Diabetes

The diagnostic criteria for diabetes are summarized in **Table 1**. They are based on venous samples and laboratory methods. A fasting plasma glucose (FPG) level of 7.0 mmol/L correlates closely with a 2-h plasma (2hPG) value of 11.1 mmol/L or more in a 75 g OGTT, and each predicts the development of retinopathy.

Table 1 Diagnosis of diabetes

FPG $\geq$ 7.0 mmol/L
Fasting = no caloric intake for at least 8 h
or
A1C $\geq$ 6.5% (in adults)
Using a standardized, validated assay, in the absence of factors that affect the accuracy of the A1C and not for suspected type 1 diabetes
or
2hPG in a 75-g OGTT $\geq$ 11.1 mmol/L
or
Random PG $\geq$ 11.1 mmol/L
Random = any time of the day, without regard to the interval since the last meal

2hPG = 2-h Plasma glucose; FPG = fasting plasma glucose; OGTT = oral glucose tolerance test; PG = plasma glucose.

The relationship between A1C and retinopathy is similar to that of FPG or 2hPG with a threshold at around 6.5%. A1C is also a continuous cardiovascular (cv) risk factor and a better predictor of macrovascular events than FPG or 2hPG. Although many people identified by A1C as having diabetes will not have diabetes by traditional glucose criteria and vice versa, there are several advantages to using A1C for diabetes diagnosis. A1C is more convenient than FPG or 2hPG In a 75 g OGTT since it can be measured at any time of day. A1c testing also avoids the problem of day-to-day variability of glucose values as it reflects the average PG over the previous 3 months. In individuals with various hemoglobinopathies, iron deficiency, hemolytic anemias, and severe hepatic and renal disease, A1c may be misleading. Studies of various ethnicities indicate that Africans, African Americans, American Indians, Hispanics and Asians have A1C values that are up to 0.4% higher than those of Caucasian individuals. May be more studies will help to determine if age- or ethnic-specific adjusted A1C thresholds are required for diabetes diagnosis. A1c is not recommended for diagnostic purposes in children, adolescents, pregnant women or those with suspected type 1 diabetes (see classification).

The decision of which test to use for diabetes diagnosis (**Table 1**) is left to clinical judgment.

FPG is a well established standard, fast, easy to perform and only one sample is needed. FPG is also a good predictor of microvascular complications (eye, kidney and nerve disease) Some of its disadvantages to mention are the unstability of the sample, a high day-to-day variability and the fact that it reflects glucose homeostasis at a single point in time.

2hPG is also a well established standard and an excellent predictor of microvascular complications (eye, kidney and nerve disease). The main disadvantages are the unstability of the sample, the high day-to-day variability, its inconveniency and unpalatability as well as its cost.

In the absence of symptomatic hyperglycemia, if a single laboratory test is in the diabetes range, a repeat confirmatory laboratory test must be done on another day.

The use of OGTT as a diagnostic tool has considerably been reduced. OGTT is still or may be used in the following clinical conditions: a random blood glucose is equivocal, as part of special clinical investigation, in pregnancy (diagnosis of gestational diabetes), for experimental and epidemiological purposes and finally to exclude or make the diagnosis of diabetes and impaired glucose tolerance.

In the case of symptomatic hyperglycemia, the diagnostic has been made and a confirmatory test is not required before treatment is initiated. If results of two different tests are available and both are above the diagnostic cutpoints, the diagnosis of diabetes is confirmed. When the results of more than 1 test are available (among FPG, A1c, 2hPG, in a 75 g OGTT) and the results are discordant, the test whose result is above the diagnostic cutpoint should be repeated and the diagnosis made on the basis of the repeat test.

Prediabetes

Table 2 summarizes the diagnostic criteria for prediabetes. The term "prediabetes" refers to IFG, IGT or an A1C of 6.0%–6.4%, each of which places individuals at high risk of developing diabetes and its complications.

IFG is defined as a FPG value of 5.6–6.9 mmol/L. IGT is defined as a 2hPG in a 75 g OGTT plasma glucose value between 7.8 and 11.0 mmol/L. A1C levels between 6.0% and 6.4% are associated with a higher risk for diabetes than lower levels. They are therefore indicative of prediabetes. The cutoffpoints may slightly vary according to different diabetic associations worldwide.

Not all individuals with prediabetes will necessarily progress to diabetes. A significant proportion of them will revert to normoglycaemia probably due to life style modification (increased physical activity and changes in dietary habits).

Classification of Diabetes

There are four main types of diabetes: type 1 diabetes mellitus (DM1), type 2 diabetes mellitus (DM2), gestational diabetes (GDM) and other types of diabetes.

Table 2 Diagnosis of prediabetes[a]

Test	*Result*	*Prediabetes category*
Fasting plasma glucose (mmol/L)	6.1–6.9	Impaired fasting glucose (IFG)
2-h Plasma glucose in a 75-g oral glucose tolerance test (mmol/L)	7.8–11.0	Impaired glucose tolerance (IGT)
Glycated hemoglobin (A1C) (%)	6.0–6.4	Prediabetes

[a]Prediabetes = IFG, IGT or A1C 6.0–6.4% → high risk of developing T2DM.

Type 1 Diabetes

Type 1 diabetes (DM 1) indicates the processes of beta cell destruction that may ultimately lead to diabetes in which insulin is required for survival in order to prevent the development of ketoacidosis, coma and death. This form of diabetes includes cases due to an autoimmune process and those for which the etiology of beta cell destruction is unknown. DM1, previously encompassed by the terms insulin-dependent diabetes, type 1 diabetes, or juvenile-onset diabetes, represents 5%–10% of all cases of diabetes, appears mostly in childhood and adolescence but may be present in adult and elderly individuals. Patients are rarely obese when they present with this type of diabetes. However, the presence of obesity is not incompatible with this form of diabetes. It is strongly associated with certain components of the histocompatibility system, human leucocyte antigens (HLA). The rate of beta cell destruction is quite variable. It can be rapid in children, but a slowly progressive, previously known as latent autoimmune diabetes in adults (LADA), is well described in adults. What triggers the destruction of the beta cells that normally produce insulin has not yet fully been understood. Environmental factors, such as viruses, may play a role in some genetically susceptible individuals.

There are some forms of DM1 which have no known etiologies. Some of these patients have permanent lack of insulin and are prone to ketoacidosis but have no evidence of autoimmunity. This form, known as an idiopathic DM1, is more common among individuals of African and Asian origin. In another form found in Africans, African Americans and Caribbeans and in some other individuals in Latin America, an absolute requirement for insulin replacement therapy in affected patients may fluctuate with time, and come and go, and patients periodically develop ketoacidosis.

Type 2 Diabetes

Type 2 diabetes (DM2) is the commonest form of diabetes (90% of all cases of diabetes). It is a complex metabolic disorder ranging from predominantly insulin resistance with relative insulin deficiency to predominantly an insulin secretory defect with or without insulin resistance. In summary, this type of diabetes previously known as noninsulin-dependent diabetes (NIDDM) or adult onset diabetes, is characterized by a relative insulin deficiency rather than absolute. People with DM2 frequently are resistant to the action of insulin. At least initially, and often throughout their lifetime, these individuals do not need insulin treatment to survive.

Unfortunately DM2 is frequently undiagnosed for many years (lack of symptoms) because the hyperglycemia is not severe enough to provoke noticeable symptoms of diabetes. Nevertheless such patients are at increased risk of developing complications related to diabetes such as eye, kidney, nerves and macrovascular complications. Although the specific etiology of this form of diabetes is not known, autoimmune destruction of the pancreas does not occur. Patients with DM2 are obese and those not obese by traditional criteria, body mass index (BMI) for example, may have an increased percentage of body fat distributed predominantly in the abdominal region. Obesity itself causes insulin resistance. Ketoacidosis seldom occurs in DM2, and when seen it usually arises in association with the stress of another illness such as infection.

The risk of developing DM2 increases with age, obesity and physical inactivity. More and more cases are detected in childhood and adolescence. It occurs more frequently in women with prior gestational diabetes (GDM) the third type of diabetes, in those with hypertension or dyslipidemia, and its frequency in different ethnic groups.

DM2 is often associated with strong familial, likely genetic, predisposition. The genetics of DM2 are quite complex and not yet clearly defined.

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) refers to glucose intolerance with onset or first recognition during pregnancy. The definition applies irrespective of whether or not insulin is used for treatment or the condition persists after pregnancy. Women who become pregnant and who are known to have diabetes mellitus which antedates pregnancy do not have gestational diabetes but have diabetes mellitus and pregnancy and should be treated accordingly before, during and the pregnancy.

Individuals at high risk for gestational diabetes include older women for pregnancy (more than 25 years of age), those with abnormal body weight, those with previous history of prediabetes (IFG and/or IGT) or family history of diabetes, those with a history of large for gestational-age babies, women from certain high-risk ethnic groups such as Hispanic American, African American, Native American, Asian American, Pacific Islander and others and any pregnant woman who has elevated fasting or

casual blood glucose levels. It may be therefore appropriate to screen pregnant women belonging to high-risk populations during the first trimester of pregnancy in order to detect previously undiagnosed diabetes mellitus. If they are found to have GDM at that initial screening, they should be retested between 24 and 28 weeks of gestation.

Formal systematic testing for gestational is usually between 24 and 28 weeks of gestation.

The risk of elevated glucose levels can have adverse effects on the fetus in the first trimester. They can induce fetal malformations. In the second and third trimester there is a high risk of macrosomia and metabolic complications in the presence of elevated glucose levels. It is therefore imperative to make the diagnosis of diabetes during pregnancy.

Diagnosis of Gestational Diabetes

To determine if gestational diabetes is present in pregnant women, a standard OGTT should be performed after overnight fasting (8–14 h). There are two different approaches (**Table 3**). *One step approach*: Perform a diagnostic OGTT without prior plasma or serum glucose screening. This approach may be cost-effective in high-risk patients or populations.

Two-step approach: Perform an initial screening by measuring the plasma or serum glucose concentration 1 h after a 50 g oral glucose load (glucose challenge test: GCT) and perform a diagnostic OGTT on that subset of women exceeding the glucose threshold value on the GCT. With either approach, the diagnosis of GDM is based on OGTT.

Other Types of Diabetes

In this category is included a wide variety of relatively uncommon conditions.

Genetic defects of beta cell function

The diabetic state may be associated with monogenic defects in beta cell function. These forms are characterized by onset of mild hyperglycemia at early age. Patients with these forms of diabetes, formerly referred to as maturity-onset diabetes of the young (MODY), have impaired insulin secretion with minimal or no defect in insulin action.

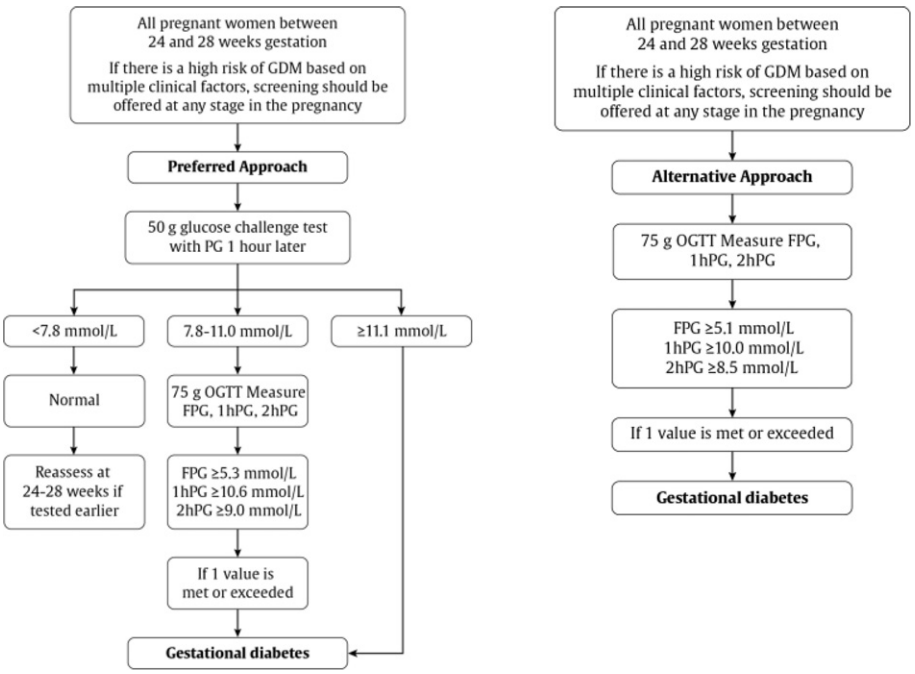
Genetic defects in insulin action

These causes of diabetes are unusual and result from genetically determined abnormalities of insulin action (i.e., mutations of the insulin receptor).

Diseases of the exocrine pancreas

Pancreatitis, trauma, infection, pancreatic cancer and pancreatectomy are some of the acquired processes that can cause diabetes. Any process that diffusely injures the pancreas can cause diabetes.

Table 3 GDM Diagnosis: Two approaches



Endocrinopathies

Insulin action can be antagonized by several hormones. Diseases associated with excess secretion of these hormones can cause diabetes such as acromegaly (growth hormone) or Cushing syndrome (cortisol) etc.

Drug-or chemical-induced diabetes

Insulin secretion may be impaired by many drugs. They may not, by themselves, cause diabetes, but they may precipitate diabetes in persons with insulin resistance.

Infections

Certain viruses have been associated with beta cell destruction. Diabetes occurs for instance in some patients with rubella.

Conclusion

Diabetes is a very common chronic disease with an increasing prevalence and incidence worldwide. There are four main types of diabetes, Type 1, Type 2, gestational diabetes and a final group composed of other types of diabetes. Type 2 is the most common form followed by Type 1, gestational diabetes and other forms most of the time secondary to other clinical situations.

When the symptoms are present the diagnosis is confirmed by elevated blood glucose levels regardless of the time of the day. When symptoms are lacking, measurements made after fasting or after a glucose load may be necessary to confirm or refute the diagnosis of diabetes. An entire investigation is needed if symptoms are questionable. In the case of a medical, obstetrical or family history of diabetes, a single elevated blood glucose measurement may or may not be decisive. An OGTT is indicated in this situation. The OGTT also helps for the diagnosis of prediabetes (IGT). The recent recognition of A1c as a diagnostic tool for prediabetes (IGT) as well as for the diagnosis of diabetes has considerably help to reduce the number of individuals who, otherwise, might have had an OGTT.

Finally, it is of a paramount importance to make the diagnosis of diabetes as early as possible in order to start the treatment without any delay. Early glycemic control is strongly associated with a considerable reduction of acute and long term complications of diabetes.

Glossary

Diabetes Diabetes mellitus is a descriptive term for a heterogeneous group of disorders that are characterized by chronic hyperglycemia due to defects in insulin secretion, insulin action, or both, associated with the development of long-term vascular and neuropathic complications.

Insulin An anabolic hormone produced by the β-cells of pancreatic islets that stimulates glucose uptake by muscle and adipose tissue, glycolysis (glucose metabolism for energy), lipogenesis (triglyceride synthesis), protein synthesis, glycogen synthesis and suppresses gluconeogenesis, glycogenolysis (glycogen breakdown), and lipolysis (triglyceride breakdown). Insulin replacement is necessary for life in type 1 diabetes.

Prediabetes The asymptomatic prodromal period which precedes the clinical manifestation of type 1 diabetes. It may last a few months to several years, during which the autoimmune destruction of the insulin-producing β-cells in the pancreas can be identified.

Introduction

Diabetes mellitus refers to a group of metabolic diseases characterized by chronic hyperglycemia secondary to decreased insulin secretion, insulin action, or both. It is associated with the development of long-term microvascular, macrovascular and neuropathic complications. An expert committee convened by the American Diabetes Association on the diagnosis and classification of diabetes mellitus classified diabetes into four etiologic types. Type 1 diabetes results from either autoimmune mediated or idiopathic destruction of the insulin-producing β-cells of the pancreas, and is characterized by absolute insulin deficiency. Type 2 diabetes is characterized by a combination of insulin resistance and inadequate compensatory insulin secretory response. However, there are some patients that cannot be clearly categorized as type 1 or type 2 diabetes. "Other specific types of diabetes" include genetic defects in β-cell function or insulin action, diseases of the exocrine pancreas, endocrinopathies, drug or chemically induced insulin deficiency, uncommon forms of immune-mediated diabetes, infections and genetic syndromes associated with diabetes. The last form of diabetes is gestational diabetes mellitus.

Type 1 diabetes is most commonly caused by autoimmune-mediated destruction of the pancreatic islet cells. It accounts for 10% of all cases of diabetes mellitus. The incidence of type 1 diabetes tends to be seasonal, with more cases occurring during the autumn and winter months. There is also a worldwide variability in the incidence of the disease with the highest incidence reported in Finland (60–64 cases per 100,000 per year), and the lowest incidences in China, India, and Venezuela (0.1/100000 per year). In the United States, the incidence is estimated at $\sim$21/100,000 per year.

Type 1 diabetes (formerly known as insulin-dependent diabetes or juvenile diabetes) may present at any age. However, approximately 75% of known cases present between the ages of 3 and 18 years with two peaks—one between 5 and 7 years of age, and the other occurring at or near puberty. It is suspected that a similar number of cases actually occur in adults. These cases are often misdiagnosed as type 2 diabetes, and are referred to as latent autoimmune diabetes of adults (LADA). LADA accounts for almost 5%–15% of those diagnosed as type 2 patients. Type 1 diabetes is considered to be a multifactorial autoimmune disease involving both genetic and environmental factors interacting with the immune system, resulting in a T-lymphocyte-mediated destruction of the insulin-producing β-cells in the pancreatic islets. The autoimmune destructive process appears to be more rapid in infants and younger children, and may evolve over several years in older children and adults. There is also an increased recognition of the heterogeneity of type 1 diabetes. An earlier model of the natural history of type 1 diabetes suggested that $<10\%$ of β-cell mass remains at the onset of clinical disease, necessitating the need for lifelong exogenous insulin administration. However, recent studies have shown that almost 40%–50% β-cell function may be present at disease onset and this may be influenced by other factors such as age, body mass index, or physical activity. Thus, functional islets may persist for decades after diagnosis.

☆*Change History*: March 2018. Bimota Nambam William Winter, and Desmond Schatz updated the results of the TRIGR and TEDDY study under "environmental agents," pathogenesis of diabetic ketoacidosis, and sections of prevention studies where results of recent preventive studies have been discussed. There is also an update on current prevention and interventional studies in type 1 diabetes.

 doi:10.1016/B978-0-12-801238-3.03820-4

Genetics of Type 1 Diabetes

The inheritance pattern of type 1 diabetes is complex and does not fit a Mendelian or single gene pattern. In the United States, the risk of developing type 1 diabetes in the general population is 1 in 300. The risk increases to 1 in 20 when individuals have a first degree relative with type 1 diabetes. Children of type 1 diabetes mothers have only a 2% risk of developing the disease; the risk increases to 7% when the father has the disease. The risk is 6%–10% in dizygotic twins while monozygotic twins have a disease concordance rate of approximately 65%, when followed over several decades. However, it never reaches 100%. This discordance suggests that environmental factors, in addition to genetic susceptibility, play a major role in the development of this disease. Additionally, 85% of new cases of type 1 diabetes have no family history.

Approximately 50 genetic loci have been associated with susceptibility to type 1 diabetes. The human leukocyte antigen (HLA) region, located in the major histocompatibility complex (MHC) on chromosome 6p21, accounts for up to 60% of genetic susceptibility. The MHC complex spans a 3.5-megabase region of chromosome 6 and is divided into three regions (Class I–III). HLA class II MHC genes have the strongest association with type 1 diabetes. The majority of patients with type 1 diabetes carry either the HLA-DR3 or HLA-DR4 class II MHC alleles, with approximately 40% being DR3/DR4 heterozygous. Heterozygosity for the DR3/DR4 genotype confers the highest risk for development of type 1 diabetes in Caucasians, followed by DR4 and DR3 homozygosity, respectively. Protective alleles for type 1 diabetes have also been described. One such allele is the class II MHC allele, DQB10602, and has been reported in $<1\%$ of patients with type 1 diabetes. It has been proposed that the degree of susceptibility or protection from the HLA genotype correlates with specific amino acid positions of the DQB1 gene. Position 57 is thought to play a crucial role in determining susceptibility. The amino acid residue at position 57 contributes to the shaping of the antigen-presenting pocket of the molecule, suggesting that the development of diabetes may depend on events surrounding antigen presentation. However, class II MHC genes do not explain all of the HLA association with type 1 diabetes. Class I genes also have been postulated to influence susceptibility and clinical aspects of the disease, such as age of onset and the rate of beta-cell destruction. Other non-HLA susceptibility genes have been mapped, including a region located upstream of the insulin gene that includes variable number of tandem repeats (VNTR). Fewer repeats confer a higher risk while higher numbers of repeats confer a lower risk. However, the overall contribution is low (odds ratio of 1.5). Another non-HLA gene associated with susceptibility to type 1 diabetes is cytotoxic T-lymphocyte associated-4 (*CTLA-4*). This gene encodes a protein that is important for the regulation of T-cell function and immune response to self. Again, the overall risk for development of type 1 diabetes is low. *PTPN22* and *CD25* genes have also been associated with type 1 diabetes risk. The majority of these genes that have been associated with type 1 diabetes risk are involved in immune responsiveness.

Environmental Factors

Due to variability in geographic prevalence rates, an increase in global incidence even in genetically low incidence regions, high disease discordance rates in twins, and rapid assimilation of local disease incidence rates when individuals migrate from low- to high-incidence countries, environmental factors are considered to play a major role in the development of type 1 diabetes.

Traditionally, infectious agents such as rubella have been thought to influence the initiation of the autoimmune process in type 1 diabetes. Approximately 30% of children with congenital rubella develop autoimmune diabetes. Viruses could trigger an autoimmune response either by directly damaging the pancreatic β-cells or by invoking molecular mimicry. At least 14 different viruses have been reported to be associated with the development of type 1 diabetes in human or animal models. Viruses suspected to induce autoimmunity to the β-cells via molecular mimicry include retrovirus, mumps, rubella, cytomegalovirus, and Epstein–Barr virus, whereas viruses that are suspected to induce autoimmunity via direct cytolytic damage to the β-cells include coxsackie-B and other enteroviruses. Enteroviruses as triggers for type 1 diabetes have received much attention. This association has been based on observations of increased enteroviral antibodies in individuals before disease onset, detection of enteroviral particles by immunohistochemistry studies, or viral RNA in autopsy studies of the pancreas in organ donors with type 1 diabetes.

Immunizations have also been implicated in the pathogenesis of type 1 diabetes, although there is little supporting data. An increase in the incidence of type 1 diabetes in Finland was correlated with the initiation of a mandatory immunization program against diphtheria–pertussis–tetanus. There were also reports of an association between vaccination for Hemophilus influenza and an increased incidence of type 1 diabetes. However, in 1998 an expert committee from the National Institutes of Health found no evidence to support these assertions.

Dietary influences on type 1 diabetes autoimmunity, including the protective effects of breast feeding and increased risk of the disease with early exposure to cow's milk have also been debated. Complex proteins in breast or cow's milk such as casein, bovine albumin, or bovine insulin have been implicated in type 1 diabetes development. However, findings from large scale studies such as from "The Environmental Determinants of Diabetes in the Young (TEDDY)" and "Trial to Reduce IDDM in the Genetically at Risk (TRIGR)" study groups do not support a role of complex proteins such as bovine insulin in influencing autoimmunity in those genetically at risk for type 1 diabetes. In fact, infants fed hydrolyzed formula were associated with a higher progression to autoimmunity in both studies.

The role of the gut microbiome and associated changes during early life, in influencing autoimmunity has also been studied over the past few years. Another recent study from the TEDDY group reported a decreased risk of progression to autoimmunity in

infants with the highest risk of type 1 diabetes (HLADR3/4) when fed probiotics in the first 27 days of life. Researchers have also looked into the association between antibiotic use in early life and increased risk for autoimmunity with conflicting results.

Autoimmunity

The detection of islet specific autoantibodies such as islet cell cytoplasmic autoantibodies (ICA), autoantibodies to glutamic acid decarboxylase (GADA), insulin autoantibodies (IAA), insulinoma-associated antigen-2 (IA-2) autoantibodies, and zinc transporter 8 (ZnT8) autoantibodies distinguishes type 1 diabetes from other types of diabetes. Combinations of these autoantibodies have also been found to determine risk for the subsequent development of clinical type 1 diabetes, both in unaffected relatives of individuals with type 1 diabetes and in the general population.

Autoreactive T-cells have been traditionally thought to be mainly responsible for β-cell destruction leading to clinical type 1 diabetes, with islet autoantibodies being formed during the process and having no pathological role in the disease process. This concept has been challenged by recent findings in animal studies, where islet autoantibodies were reported to enhance accumulation of islet-reactive CD4 + T-cells via FcγR mediated pathways. This highlights a possible role of autoantibodies in providing a positive feedback on the dysregulation of autoreactive helper T-cells. Also, short term benefits of rituximab, an anti-CD20 monoclonal antibody that targets B-cells, in preserving β-cell function in new-onset type 1 diabetes patients may also support this concept. Alternatively the benefit of rituximab may result from impairment in B-cell function as antigen-presenting cells to autoreactive T-cells.

Identification of At-Risk Subjects

Identification of individuals susceptible to the development of type 1 diabetes prior to clinical manifestation of the disease can be achieved by genetic screening of newborns with high-risk HLA alleles, and quantification of risk by further autoantibody, genetic, and metabolic testing. Antibody testing is based on the finding that $>90\%$ of patients with new-onset type 1 diabetes have islet autoantibodies. In high-risk individuals, antibodies often develop during childhood with IAA being the first to be detected at around 1 year of age followed by other antibodies. The presence of a single autoantibody imparts an approximate 10% 5-year risk of subsequently progressing to disease, 50%–60% for subjects with two autoantibodies, 70% for those with three autoantibodies, and almost 80% for those with four autoantibodies (without including ICA). The presence of metabolic derangements in addition to serologic markers increases the predictability of screening. Persistent loss of first-phase insulin response during an intravenous glucose tolerance test carries a 50%–70% 5-year risk in autoantibody-positive individuals. Changes in glucose tolerance measured during an oral glucose tolerance test generally occur later in the disease process, indicating significant β-cell destruction. Identification of at-risk individuals has led to a multitude of clinical trials in an attempt to prevent the development of this disease.

Diagnosis

The diagnosis of diabetes is made if any of the following features are present (1) the presence of the classical symptoms of diabetes (polyuria, polydipsia, and unexplained weight loss) with unequivocal hyperglycemia (random plasma glucose 200 mg/dL or 11 mmol/L); (2) 2-h plasma glucose $\geq$200 mg/dL or 11 mmol/L following a 75-g oral glucose challenge in adults (or 1.75 g/kg in children) on two occasions; (3) fasting plasma glucose $\geq$126 mg/dL (7 mmol/L) on two occasions; (4) HbA1c $\geq$ 6.5% on two occasions performed using a validated assay. If two different tests are both above the diagnostic threshold, this also confirms the diagnosis.

Between 20% and 40% of patients with new-onset type 1 diabetes have ketoacidosis at presentation. Unfortunately, the rate of diabetic ketoacidosis at disease onset has not decreased in recent years. Patients with type 1 diabetes have been traditionally viewed as being lean and frankly symptomatic (DKA). However, with increase in obesity rates in patients with type 1 diabetes and ketoacidosis in those with type 2 diabetes, BMI and the presence or absence of ketoacidosis are no longer reliable in distinguishing between the two especially in children and adolescents. When the diagnosis is in doubt, type 1 diabetes can be confirmed by the finding of islet-related autoantibodies. GADA and ICA are found in approximately 70%–80% of new-onset cases, ZnT8A in 63%, IA-2A in 68%, and IAA in 55%. Using all five autoantibodies, $>90\%$ of new-onset type 1 diabetes patients are positive for islet specific antibodies. IAA assays are not valid after 10 days of insulin therapy. Also, following the onset of T1DM, ZnT8A concentrations decline rapidly.

Management

In 1921, Frederick Banting and Charles Best discovered what was thought to be the cure for diabetes—insulin. Prior to the discovery of insulin, type 1 diabetes was a slow but sure death sentence, for which the only treatment was a diet low in

carbohydrates/sugar and high in fats and protein. Of course, insulin is not the cure for diabetes, but rather the vital tool for managing this disease and controlling complications.

The 1993 Diabetes Control and Complications Trial (DCCT) demonstrated a strong relationship between intensive management with good metabolic control and decreased rate of progression of complications. However, intensive therapy should be tailored according to the age of the patient, psycho-social factors including cognitive impairment (especially in the elderly population), presence or absence of frequent hypoglycemia etc. Improved glycemic control should be sought at all ages while avoiding severe hypoglycemia, weight gain, or emotional problems for the patient and the family.

Type 1 diabetes management, both in children and adults is complex, requiring a multidisciplinary medical team including a diabetologist, certified diabetes educator, nutritionist, psychologist, and where needed, a social worker and exercise physiologist. The disease should be approached as affecting the whole family unit and not just the individual with diabetes. The team works together to teach family members (especially for pediatric patients) and involve them in the decision-making process for the patient. Patient empowerment (if done appropriately) is crucial to successful management. A successful management program must be consistent and flexible. A balance must be sought between the needs of the medical establishment (insulin, nutrition, exercise, blood glucose testing, HbA1c tests, lipids, urine microalbumin testing, and complication surveillance) and the lifestyle demands and desires of the patient. Each patient needs individualized therapy based on age, schedule, social environment, and capabilities.

The following are the overall goals of diabetes management:

- Set realistic goals for each child and family: Consider the patient's age, family involvement and social situation, economic factors, and history of hypoglycemia.
- Near normalization of blood glucose levels and HbA1c measurements or, when not possible, improvement on subsequent follow-up.
- Prevention of diabetic ketoacidosis.
- Avoidance of severe hypoglycemia.
- Maintenance of normal quality of life.
- Achievement of normal growth, development, and maturation in children.
- Multidisciplinary support, including nutritional education and psychological support.
- Close surveillance and prevention of microvascular and macrovascular complications.

A variety of insulin regimens are available for use that must be individualized depending on patient compliance, the patient's level of social support, patient's preference based on their lifestyle including dietary and exercise regimens. Today, most patients are placed on basal bolus therapies employing subcutaneous injections of basal (long-acting) insulin with bolus insulin therapy before meals, or insulin pumps. The increased availability of continuous glucose monitoring as well as newer insulin pumps, recently introduced in the market that has the ability to combine data from CGM to automatically adjust basal insulin delivery will not only improve glycemic control, but also the overall quality of life of patients with type 1 diabetes.

Diabetic Ketoacidosis (DKA): Pathogenesis, Definition, and Management

DKA is defined biochemically by the presence of hyperglycemia (blood glucose $>$ 200 mg/dL or 11 mmol/L), venous pH $<$7.3 or bicarbonate $<$15 mmol/L, and ketonemia and ketonuria. Based on the degree of acidosis, DKA can be mild (venous pH $<$7.3 or bicarbonate $<$15 mmol/L), moderate (pH $<$7.2, bicarbonate $<$10 mmol/L), or severe (pH $<$7.1, bicarbonate $<$5 mmol/L).

DKA occurs when there is absolute or relative insulin deficiency combined with the presence of infection, stress, trauma, etc. In addition, there is an increase in circulating counter regulatory hormones such as glucagon, cortisol, growth hormone, and catecholamines. This leads to decreased peripheral glucose utilization, increased glycogenolysis and gluconeogenesis with subsequent hyperglycemia, glycosuria with osmotic diuresis, loss of electrolytes and free water, dehydration, and hyperosmolarity. Hence, patients in DKA are often dehydrated and the degree of dehydration is assumed to be around 10% of total body weight. Although, electrolyte levels in laboratory studies at the time of presentation of DKA are often normal, there is total body depletion of potassium, phosphate, and magnesium. There is also increased lipolysis which increases circulating free fatty acids (FFA) and flux of FFA toward the pathway of hepatic beta oxidation. This leads to increased ketogenesis to form ketone bodies (acetone, acetoacetate, and beta-hydroxybutyrate) which are used as alternative energy sources. Of the three, beta-hydroxybutyrate contributes almost 70% of total circulating ketone bodies during DKA. Ketone bodies are acidic and deplete the alkali reserve in the body. Once the accumulated ketone bodies overwhelm the homeostatic acid–base buffering system, there is ketonuria, and patients develop metabolic acidosis (DKA) which is a life threatening condition. Increased circulating ketone bodies also triggers nausea, abdominal pain and vomiting; this can compound the already existing fluid and electrolyte depleted state. Patients are also tachypneic (Kussmaul respiration) secondary to respiratory compensation of the metabolic acidosis. DKA is a life threatening condition requiring emergency treatment with intravenous fluids and insulin; in severe cases where treatment is delayed, patients can progress to coma and death.

DKA is often seen in patients with new-onset diabetes or when patients with established type 1 diabetes fail to take insulin. New-onset diabetes with DKA is more common in children younger than 2 years of age due to delayed diagnosis and treatment. In

patients with known type 1 diabetes, some of the common risk factors for DKA include noncompliance with insulin regimen, poor family structure and support, lower socio-economic status and limited access to health care.

Many institutions and hospitals have individualized DKA management protocols. Most patients are assumed to have dehydration of 10% and should initially receive a 0.9% NaCl solution intravenous bolus of 10–20 mL/kg given over 1–2 h. The fluid deficit plus maintenance fluids should be administered over 48 h. Normal saline should be used as the initial fluid for the first 4–6 h and if required, switch to a fluid with a tonicity equal to or $>0.45\%$ saline. One of the concerns of using hypotonic fluids in pediatric DKA management is the development of cerebral edema. Hence, many pediatric providers use isotonic fluids for all phases of DKA management. However, this traditional view is being challenged; the ongoing Pediatric Emergency Care Applied Research Network (PECARN) DKA FLUID study is investigating the neurological outcomes of using 0.45% NaCl versus 0.9% NaCl at two different rates in pediatric DKA.

Intravenous insulin should be commenced as soon as fluid replacement has been started at a dose of 0.05–0.1 units/kg per hour, with lower doses used in very young children or in those with marked sensitivity to insulin. Initial intravenous insulin boluses are not recommended since they may increase the risk of cerebral edema (in children) and hypokalemia. Intravenous bicarbonate infusion to correct DKA is also not recommended, as many studies have not found faster resolution of DKA with this method, and there is an increased risk of cerebral edema especially in children. It is only in life threatening cardiovascular instability secondary to severe acidosis that IV bicarbonate should be used cautiously.

Hourly bedside blood glucose checks with 2–4 hourly monitoring of pH, bicarbonate, and electrolytes (sodium, potassium, calcium, and phosphorus) should also be monitored to assess for improvement of acidosis and correction of electrolyte imbalances. Intravenous insulin therapy drives potassium and phosphate into cells, and this can precipitate hypokalemia and hypophosphatemia. Hence, replacement fluids should contain potassium (after patient has had a urine output) and phosphate. Once acidosis has resolved and patient indicates ability to tolerate oral intake, he/she should be transitioned to subcutaneous insulin therapy.

Hyperglycemic Hyperosmolar State (HHS)

Hyperglycemia to >600 mg/dL with hyperosmolarity (>330 mOSm/kg) and minimal ketosis should alert the physician to hyperglycemic hyperosmolar state (HHS). HHS is more common in patients with type 2 diabetes but can also be seen in type 1 diabetes. The distinction between DKA and HHS is important as patients with HHS often are profoundly dehydrated (almost 15% dehydration should be assumed) and need aggressive fluid replacement. The initial normal saline fluid bolus should be ~ 20 mL/kg and if required, additional boluses should be given followed by administration of maintenance and replacement fluid (0.45%–0.75% NaCl) over 48 h. Hyperglycemia improves rapidly with aggressive initial fluid hydration, and low dose insulin at 0.025–0.05 units/kg/h should be initiated when there is no further reduction in blood glucose levels (<50–75 mg/dL/h or 3–4 mmol/L/h) with fluid therapy. Insulin doses must be titrated based on improvement of blood glucose and ketosis. Due to severe hyperglycemia and hypertonicity at presentation, initial intravascular blood volume is often maintained. Once there is reduction in blood glucose and osmolality due to hydration, insulin action, and increased glycosuria secondary to improvement in renal perfusion, there is movement of water from intravascular sites, and this can precipitate a sudden decrease in blood volume leading to hypotensive shock and cardiovascular collapse. If there is nonimprovement or worsening of hemodynamic status, normal saline should be used for fluid replacement even after the first 4–6 h of presentation. The risk of mortality in HHS is much higher compared to DKA.

Search for a Cure and Prevention of Type 1 Diabetes

Type 1 diabetes places a considerable burden on the individual and society with approximately 15 billion dollars spent annually. The ability to identify individuals at high risk of developing the disease, newer understanding of the disease process, together with the tremendous and increasing burden of the disease, has led to the development of multiple studies aimed at the prevention of type 1 diabetes or halting disease progression. Some of the studies are discussed briefly.

A recently completed study by TrialNet investigated the effect of oral insulin (7.5 mg daily) in preventing clinical type 1 diabetes in autoantibody positive, high-risk individuals. This intervention is based on the concept of "inverse vaccination" where repeated exposure of the immune system to exogenous autoantigens leads to long-term tolerance to the specific antigen. The intervention failed to prevent development of type 1 diabetes. As immune responses to antigens vary according to dose, frequency of administration, route of administration, as well as background genetics, it is unclear if the failure was related to these variables. However, a subset of patients with lower insulin secretion had delay in diabetes development by 31 months compared to controls. TrialNet is further investigating immune changes associated with oral insulin intake in another study but with a higher dose (67.5 mg daily vs. 500 mg weekly for 6 months). Of note, the Pre-POINT study recently demonstrated that 67.5 mg oral insulin daily administered for 8 months in children (2–7 years) with high risk HLA-genes, but negative for islet autoimmunity induced a tolerogenic response. This is being further investigated in younger children (6 months–2 years). Another recently completed study (DiAPREV-IT) using GAD-alum vaccine also failed to halt progression of autoimmune process in children with multiple islet autoantibodies. The same study group is conducting another study to evaluate if GAD-alum vaccine in combination with high

dose vitamin D3 (DiAPREV-IT2) can stop disease progression in multiple autoantibody positive children. There are also ongoing/recently completed studies using antigen based therapies such as the MultiPepT1De and use of proinsulin peptide to halt disease progression in new-onset type 1 diabetes.

TrialNet is also conducting two separate studies to evaluate if teplizumab and abatacept can prevent progression of stage 2 of type 1 diabetes (abnormal blood glucose but asymptomatic) to clinical type 1 diabetes. Teplizumab is a humanized anti-CD3 monoclonal antibody which decreases autoreactive T-cells involved in the immune destruction of pancreatic beta-cell while abatacept (CTLA4-Ig), an immunoglobulin that binds to the Cytotoxic T-Lymphocyte Antigen 4 receptor, interferes with the early phases of T-lymphocyte activation, proliferation, and survival which are required for the progression of the disease process of type 1 diabetes.

There are also several studies in newly diagnosed type 1 diabetes subjects which have evaluated the use of immunomodulators and immunosuppressive agents to prolong endogenous insulin secretion after diagnosis. Advances in pancreatic and islet cell transplantation have led to enhanced patient and graft survival. Unfortunately, there are not enough donors to support the vast number of patients with type 1 diabetes. In addition, patients require lifelong immunosuppression to prevent rejection (alloimmunity) and possibly prevent recurrence (autoimmunity). Other promising therapies include stem cell therapy based approaches which are currently being studied in many centers.

Conclusion

The incidence of type 1 diabetes continues to increase placing a heavy economic burden both on individuals and the society worldwide. Despite therapeutic advances and an increased understanding of the disease process, much remains to be uncovered and the quest for prevention and cure still remains a priority.

Type 2 Diabetes☆

Susan L Samson and Alan J Garber, Baylor College of Medicine, Houston, TX, United States

Glossary

Beta cell A cell present in the pancreas islets that synthesizes and secretes insulin.

Glucagon like peptide-1 An incretin hormone released by the intestine after a meal which augments insulin secretion from the beta cell.

Glycated hemoglobin Also called Hemoglobin A1C. A per cent of glycation of hemoglobin as a surrogate measure of average blood glucose.

Insulin A hormone that is secreted from the pancreas in response to glucose levels. Insulin binds its receptor on the cell surface of tissues such as the muscle to promote glucose uptake. Insulin also decreases hepatic glucose production and promotes storage of fatty acids as triglycerides in the adipose tissue.

Macrovascular disease Pertaining to diabetes induced damage to the cardiovascular system that predisposes patients to heart attacks and strokes.

Metabolic syndrome A cluster of physical characteristics that predisposes to the development of type 2 diabetes and cardiovascular disease. Metabolic syndrome includes dyslipidemia, central obesity and glucose intolerance.

Microvascular disease Pertaining to diabetes induced damage to the small blood vessels including capillaries which leads to retinopathy, nephropathy, and neuropathy.

Type 2 diabetes (T2D) results when the pancreatic beta cell is unable to meet increased insulin demands caused by insulin resistance which is usually a result of obesity. With decreased glucose utilization and inappropriate glucose production, hyperglycemia ensues which causes both macrovascular and microvascular complications.

Diagnosis

The diagnostic criteria for T2D originally were based on the glycemic threshold at which retinal complications are manifest. Current criteria include elevated fasting plasma glucose (FPG) ($\geq$126 mg/dL or 7.0 mmoL/L) and/or glucose intolerance with a 2-h plasma glucose level $\geq$200 mg/dL (11.1 mmoL/L) after a standard oral dose of 75 g of glucose (an oral glucose tolerance test or OGTT) (American Diabetes Association, 2018a). A random plasma glucose of $\geq$200 mg/dL (11.1 mmoL/L) also is diagnostic in a patient with symptoms such as thirst, excess urination and/or weight loss.

The National Glycohemoglobin Standardization Program (NGSP) was implemented to align laboratory assays for percent glycated hemoglobin (hemoglobin A1C) with those used in the Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS). In 2009, an international expert committee with representatives from the American Diabetes Association (ADA), the International Diabetes Federation (IDF) and the European Association for the Study of Diabetes (EASD) jointly advocated the incorporation of the A1C threshold of $\geq$6.5% into the diagnostic criteria for T2D (International Expert Committee, 2009). The ADA added A1C criterion in 2010 and the EASD added it in 2013 (the first revision of the guidelines since 2007). However, A1C is inaccurate in certain disease states and it must be used judiciously as a diagnostic tool (Genuth *et al.*, 2017) (**Table 1**). A1C is affected by changes in erythrocyte production or destruction. Levels of glycation also can be increased or decreased in patients with hemoglobinopathies, alcoholism and chronic kidney insufficiency. A1C assay interference occurs with carbamylated hemoglobin from chronic kidney disease, hyperbilirubinemia, alcoholism, and hypertriglyceridemia.

"Pre-diabetes" is a term applied to patients with glucose levels intermediate between normoglycemia and T2D due to the presence of impaired fasting glucose (IFG) and/or impaired glucose tolerance (IGT) by OGTT (American Diabetes Association, 2018a). Many organizations agree that the criterion for IFG is 100–125 mg/dL (5.6–6.9 mmol/L). IGT is defined as a plasma glucose of 140–199 mg/dL (7.8–11.0 mmol/L) during an OGTT, or an A1C of $\geq$5.7% but $<$6.5%. The American Association of Clinical Endocrinologists (AACE) pre-diabetes definition also includes patients who meet metabolic syndrome (MetS) criteria with $\geq$3 of 5 of elevated blood pressure, elevated low density lipoprotein-C (LDL-C), elevated triglycerides, increased waist circumference, and low high density lipoprotein-C (HDL) because of the fivefold risk of developing T2D compared to age and sex matched controls (Samson and Garber, 2014). The rate of progression from the pre-diabetic state to T2D varies widely among different ethnic populations but a crude estimate from published studies is in the range of 4%–9% per year, with body mass index as a strong predictor of progression.

Table 1 Factors affecting the accuracy of Hemoglobin A1C for glycemic status

Increased A1C	
Decreased erythropoiesis	Iron or B12 deficiency
Decreased erythrocyte destruction	Splenectomy
Increased glycation	Alcoholism
	Chronic kidney disease (glucose dialysate)
Assay interference	Chronic kidney disease (carbamylation)
	Hemoglobinopathies
	Hyperbilirubinemia
	Alcoholism
	High dose aspirin
	Chronic opiate use
Decreased A1C	
Increased erythropoiesis	Treatment of iron or B12 deficiency
	Erythropoietin
	Reticulocytosis
Increased erythrocyte destruction	Hemoglobinopathies
	Splenomegaly
	Hemolytic anemias (autoimmune, drugs, mechanical)
	Inherited disorders of the erythrocyte membrane
	Inherited disorders of erythrocyte glycolysis
	Increased disorders that increase erythrocyte oxidative stress (Glucose-6-phosphate dehydrogenase deficiency, glutathione synthetase deficiency)
	Paroxysmal nocturnal hemoglobinuria
Decreased glycation	Vitamin E
	Vitamin C
	Aspirin
	Hemoglobinopathies
Assay interference	Hypertriglyceridemia

Table 2 Diabetes prevalence among ethnic groups in the United States

	Men (%)	*Women (%)*
American Indian/Alaskan Natives	14.9	15.3
Asian	9.0	7.3
Black, non-Hispanic	12.2	13.2
Hispanic	12.6	11.7
White, non-Hispanic	8.1	6.8

Data from 2013 to 2015 National Health Interview Survey and 2015 Indian Health Services National Data Warehouse.

Epidemiology

The prevalence of T2D is increasing at an alarming rate. The worldwide prevalence of adult (age 20–79 years) diabetes, of which T2D comprises >90% of cases, is estimated at 425 million in 2017 with a projection to 629 million by 2045 (IDF, 2017). For Europe and North America the increase in prevalence is predicted to be 16% and 35%, respectively. Even more extreme are 2045 projections for increased diabetes prevalence in Central and South America (+62%), the Middle East and North Africa (+72%), Africa (+156%), and Southeast Asia (+84%). Estimates of prevalence also are complicated by the knowledge that T2D is markedly underdiagnosed, with one-third to one-half of people unaware they have T2D. The prevalence of T2D varies widely among peoples of different ethnicities (**Table 2**), underscoring that the risk for T2D is a combination of epigenetic and genetic factors combined with contributions from lifestyle and environment.

Pathogenesis

The increased prevalence of T2D has followed the trajectory of the prevalence of obesity. Positive energy balance, from excess calories and a sedentary lifestyle, is stored as fat. Visceral fat, in comparison to subcutaneous fat, is associated with higher insulin resistance. If the beta cell cannot compensate, there is relative hypoinsulinemia allowing for lipolysis from visceral fat depots with

Table 3 Available pharmacologic therapies for type 2 diabetes

Drug class	*Available formulations (worldwide)*	*Mechanism*	*Benefits*	*Adverse effects and cautions*
Biguanides	Metformin	Inhibition of hepatic glucose production and promotion of skeletal muscle glucose uptake	Weight loss or weight neutral Decreased progression from prediabetes to diabetes Low cost	Gastrointestinal upset (diarrhea) Lactic acidosis (higher risk with chronic kidney failure) B12 or folate deficiency
Sulfonylureas and meglitinides	Glipizide Gliclazide Glyburide Glimepiride Nateglinide Repaglinide	Depolarization of the beta cell membrane to increase insulin secretion	Low cost	Hypoglycemia Weight gain Acceleration of loss of beta cell function
Thiazolidinediones	Pioglitazone Rosiglitazone	Activation of nuclear receptor peroxisome proliferator activated receptor gamma (PPAR) to increase adiponectin and improve insulin resistance	Decreased progression from prediabetes to diabetes Redistribution of visceral adipose tissue to subcutaneous	Weight gain (fluid and adipose) Fluid retention Chronic heart failure exacerbation Osteoporosis Bladder cancer Suppressed hematopoiesis
Alpha-glucosidase inhibitors	Acarbose Miglitol Voglibose	Inhibition of hydrolysis of starches and carbohydrates in the gut to decrease absorption	Weight loss (decreased absorption of calories) Decreased progression from prediabetes to diabetes (acarbose, voglibose)	Flatulence Abdominal pain Diarrhea
Glucagon like peptide-1 (GLP-1) receptor agonists	Exenatide (twice daily and weekly) Liraglutide (daily) Lixisenatide (daily) Dulaglutide (weekly) Albiglutide (weekly) Semaglutide (weekly)	Activation of the GLP-1 receptor to augment insulin secretion and inhibit glucagon secretion	Weight loss (decreased meal size) Decreased cardiovascular events (liraglutide, semaglutide)	Nausea Subcutaneous injection Contraindicated for patients with a history of pancreatitis, medullary thyroid carcinoma, or multiple endocrine neoplasia type 2 Possible retinopathy progression (semaglutide)
Dipeptidyl peptidase 4 (DPP4) inhibitors	Sitagliptin Vildagliptin Saxagliptin Linagliptin Gemigliptin Anagliptin Teneligliptin Alogliptin Trelagliptin Omarigliptin Evogliptin Gosogliptin	Inhibition of endogenous GLP-1 inactivation to augment insulin secretion and inhibit glucagon secretion	Weight neutral No cardiovascular harm Oral formulation compared to GLP-1 receptor agonists	Nausea Contraindicated for patients with a history of pancreatitis, medullary thyroid carcinoma, or multiple endocrine neoplasia type 2
Amylin analogue	Pramlintide	Slowing of gastric emptying and inhibition of glucagon secretion	Weight loss (decreased meal size)	Nausea Subcutaneous injection
Sodium-glucose cotransporter 2 (SGLT-2) inhibitors	Canagliflozin Dapagliflozin Empagliflozin Ipragliflozin	Inhibition of renal glucose resorption	Weight loss (loss of calories in the urine) Decreased cardiovascular events (empagliflozin, canagliflozin)	Urinary tract infections Genital yeast infections Normoglycemic diabetic ketoacidosis
Dopamine agonists	Bromocriptine quick release	Increased central nervous system sympathetic and dopaminergic tone to decreased hepatic glucose output, lipolysis and insulin resistance	Weight loss	Nausea Asthenia Dizziness Postural hypotension Constipation Rhinitis Exacerbation of psychotic disorders Inhibition of lactation Avoid use with other ergots Effects on CYP3A4 metabolism

(*Continued*)

Table 3 Continued

Drug class	*Available formulations (worldwide)*	*Mechanism*	*Benefits*	*Adverse effects and cautions*
Bile acid sequestrants	Colesevelam	Activation of nuclear receptor activity in the liver and intestines (Farnesoid X receptor, liver X receptor) to improve glucose metabolism and increase GLP-1	Reduction of low density lipoprotein-C levels	Increased triglycerides Flatulence Constipation Dyspepsia Vitamin K deficiency reduced bioavailability of other drugs (oral contraceptives, levothyroxine, phenytoin)

Table 4 Available insulins and insulin analogues with estimated pharmacokinetics

	Insulin products	*Onset*	*Peak*	*Duration of action*
Bolus (Prandial)				
Rapid acting	Lispro[a] Aspart[a] Glulisine[a]	5-15 min	0.5–1.5 h	3–5 h
Short-acting	Regular	0.5–1 h	2–4 h	6–8 h
Basal				
Intermediate acting	Neutral protamine Hagedorn (NPH) Neutral protamine Lispro[a,b] (NPL) Regular U-500	2–4 h 0.5 h	7–8 h 1–3 h	10–12 h 8–24 h
Long acting	Glargine[a] Detemir[a] (>0.8 units/kg)	1–2 h 1–2 h	No peak 6–8 h	24 h 18–24 h[c]
Very long acting	Degludec[a]	2 h	No peak	>40 h

[a]Insulin analogues.
[b]Only as pre-mix with Lispro.
[c]Dose dependent >0.4 units/kg to increase duration.

excess free fatty acid (FFA) production. The increased FFA flux to peripheral tissues, including the liver and skeletal muscle, inhibits insulin signaling. With hepatic insulin resistance and an abundance of FFA substrate, gluconeogenesis is increased, further contributing to hyperglycemia. Skeletal muscle insulin resistance results in decreased glucose disposal peripherally. Over time, the pancreatic beta cell can no longer compensate for the increased insulin demands, and T2D is the unfortunate consequence. The role of beta cell failure in the development of T2D is highlighted by the discovery that many of the genes found to influence T2D risk are linked to beta cell function or maintenance, rather than obesity or insulin resistance.

Treatment

An important pillar of T2D prevention and treatment is lifestyle change, with increased exercise, decreased caloric intake, nutritional modifications and weight loss. The Diabetes Prevention Program (DPP) showed that progression to T2D for patients with IGT was reduced 58% with intensive lifestyle modification during the 2.8 year follow-up (Knowler *et al.*, 2002). Weight loss of 5% can improve glycemia and reduce the need for anti-diabetic medications in patients with T2D. A 500–700 kcal deficit per day is recommended to achieve weight loss (American Diabetes Association, 2018b). Patients with T2D should be counseled on reduction in refined carbohydrates and limitation of dietary fat to 20%–30% of calories with an emphasis on monounsaturated fats. Exercise recommendations from the ADA are 150 min of moderate to vigorous intensity exercise spread over the week, similar to the DPP design. Motivation for continued lifestyle changes can wane and effective programs, such as with the DPP, incorporate "coaches" and continued counseling and encouragement to achieve success.

There is a plethora of non-insulin therapies approved for the treatment of T2D with diverse mechanisms of action (**Table 3**). Often, a combination of medications is required to attain glycemic control initially or with time, as a patient progresses toward complete beta cell failure. In considering a combination, the clinician should choose therapies that will target different defects present in T2D for an additive or synergistic effect on glycemic control. Patient specific factors also need to be weighed—age, weight, hypoglycemia risk, cardiovascular disease, etc.—to derive the maximum benefit and minimize the risks of each medication or combination.

When glycemic control cannot be attained with non-insulin therapies, insulin can be initiated (**Table 4**), as a basal injection of a long-acting or intermediate-acting insulin. Further addition of prandial (bolus) insulin for one to three meals per day may be necessary. The commencement of insulin therapy does not necessitate the discontinuation of all other T2D therapies as there can be continued benefit. For example, the combination of metformin or a GLP-1 receptor agonist with insulin can be insulin sparing.

Complications

Complications are the major cause of morbidity and mortality in T2D and are categorized as microvascular (kidney disease, neuropathy, retinopathy) and macrovascular (cardiovascular disease or CVD). Data from the DCCT (DCCT research Group, 1993), the long-term follow-up study the Epidemiology of Diabetes Interventions and Complications (Nathan *et al.*, 2005), and the UKPDS (UKPDS Study Group, 1998a) provided the primary evidence that glycemic control is the key factor to reduce the progression of diabetic microvascular complications. This has been confirmed by data from more recent trials, Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease (ADVANCE) (Cefalu, 2008). Although A1C is a predictor of CVD risk, the impact of glycemic control on cardiovascular disease prevention for T2D is less clear, although there was a trend to decreased non-fatal and fatal myocardial infarction, but not stroke, in the UKPDS intensive control arm (Kooy *et al.*, 2009; United Kingdom Prospective Diabetes Study (UKPDS) Group, 1998b). Data from the ACCORD trial revealed that intensive glycemic control has to used judiciously with regard to CVD outcomes if implemented in patients with history of hypoglycemia, known CVD, advanced age and a long duration of T2D (ACCORD Study Group, 2008).

The pathogenesis of diabetes complications is complex and not fully elucidated, but several pathologic effects of hyperglycemia are proposed (Forbes and Cooper, 2013). Posttranslational modifications to cell proteins include glycosylation, peroxidation, phosphorylation, nitrosylation and prenylation, with ensuing adverse effects on cellular function and integrity. With excess glucose and fatty acid substrates, there are alterations in cellular respiration leading to mitochondrial dysfunction and respiratory chain uncoupling and, ultimately, a decrease in ATP production for the cell. The presence of excess glucose also activates the pentose phosphate (PP) pathway resulting increased production of UDP *N*-acetylglucosamine which leads to protein glycosylation and alterations in signal transduction and gene expression which go on to promote cell damage. The NAD(P)H produced from the PP pathway further facilitates the conversion of glucose to sorbitol by aldose reductase, increasing oxidative and osmotic stress.

Diabetic retinopathy is the leading cause of blindness in adults (Tan and Wong, 2015). In the early, non-proliferative phase, blood vessel wall pericyte death leads to increased permeability and degeneration. Capillary microaneurysms form and lipid and proteins leak from the vessels to form hard exudates. Cotton-wool spots are evidence of infarcts in the retinal nerve fiber layer. With local hypoxia, angiogenic factors promote neovascularization of the retina during the proliferative stage of retinopathy. The development of fibrovascular changes predispose the patient to retinal detachment and fluid accumulation leads to macular edema. Beyond glycemic control for prevention, management of blood pressure and dyslipidemia are key. In the late stages, retinal photocoagulation treatment of proliferative retinopathy is required and intravitreal injections of anti-Vascular Endothelial Growth Factor (anti-VEGF) are used to treat vision threatening macular edema.

Diabetic nephropathy is the leading cause of kidney failure in developed nations (Forbes and Cooper, 2013). Early in the disease, the kidney undergoes hypertrophy and hyperfiltration is observed. Pathologic changes occur in the glomeruli, where there is expansion of the mesangium and thickening of the basement membrane. There is loss of podocytes which allows protein leakage into the urine. Extracellular matrix is deposited in the tubules leading to fibrosis and loss of glomerular function (glomerulosclerosis). Clinically, nephropathy is diagnosed by the presence of microalbuminuria which can progress to overt proteinuria with nephrotic syndrome. Blood pressure and lipid control along with angiotensin converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARB) can slow the progression of nephropathy.

Peripheral diabetic neuropathy can affect both somatic and autonomic nerves (Marathe *et al.*, 2015). The microvascular contribution to neuropathy is thought to involve local hypoxia due to thickening of the capillary basement membranes (Forbes and Harcourt, 2015). However, there also may be effects on neuron health independent of vascular changes, with direct toxicity of hyperglycemia to glial cells causing nerve fiber degeneration (Forbes and Cooper, 2013). Symptoms of sensory neuropathy include paresthesias, allodynia and loss of proprioception, temperature discrimination and vibration sense. Decreased sensation to touch progresses from the extremities in a "glove and stocking" pattern. Over time, injuries to the skin and joints can abound leading to non-healing skin ulcerations and joint deformities, with increased risk of amputation. Effects on autonomic nerves can cause gastroparesis and other gastrointestinal difficulties, erectile dysfunction, orthostasis, and bladder incontinence.

T2D is a cardiovascular risk equivalent and half of patients with diabetes will die of a CVD event (myocardial infarction or stroke). Premature atherosclerosis develops with immune cell infiltration of vessel walls, proliferation of smooth muscle cells, and accumulation of low-density lipoproteins in macrophages leading to plaque formation (Forbes and Cooper, 2013). Although hyperglycemia contributes to increased inflammation and oxidative stress, atherogenesis is further driven by concomitant dyslipidemia and hypertension as co-components of MetS (Samson and Garber, 2014). Therefore, primary and secondary prevention must include management of LDL-C (HMG-CoA reductase inhibitors or statins), triglycerides (niacin, fibric acid derivatives, omega-3-fatty acids), blood pressure, and aspirin therapy as indicated by age and risk (American Diabetes Association, 2018c). Evidence that available T2D medical therapies have benefit for CVD, beyond glycemic control, has been sparse. However, from UKPDS data, subjects in the intensive arm treated with metformin showed a 36% reduction in all-cause mortality and stroke and a reduction in risk for myocardial infarction (UKPDS, 1998b). The LEADER (Liraglutide Effect and Action in Diabetes: Evaluation of

Cardiovascular Outcome Results) trial enrolled patients with T2D who were high risk for CVD events (>50 years old with known CVD, chronic kidney disease, chronic heart failure or >60 years old with CVD risk factors). After nearly 4 years of follow-up, liraglutide treated subjects had a 20% reduction in major adverse CVD events compared to usual care without liraglutide (Marso *et al.*, 2016b). The long acting GLP-1 receptor agonist, semaglutide, also may have benefit in high risk patients. From the SUSTAIN-6 trial (semaglutide and cardiovascular outcomes in patients with type 2 diabetes), there was a 26% reduction in the primary composite endpoint which was comprised of death from cardiovascular causes, nonfatal MI, and nonfatal stroke (Marso *et al.*, 2016a).

Conclusion

T2D prevalence is increasing throughout the world. It is a significant cause of morbidity and mortality, and pharmacologic treatment and management of complications consumes a large portion of health care costs. Treatment of T2D requires lifestyle and pharmacologic intervention to control glycemia and reduce microvascular and macrovascular complications.

Diabetes Mellitus and Pregnancy

Emily D Szmuilowicz, Charlotte M Niznik, and Boyd E Metzger, Northwestern University Feinberg School of Medicine, Chicago, IL, United States

Introduction

Significance

Normal pregnancy is characterized by multiple metabolic adaptations which enable the fetus to have an ample supply of fuel and nutrients throughout development in utero. Pregnancy is a diabetogenic state; the progressive insulin resistance which develops during pregnancy as a result of placental elaboration of diabetogenic hormones serves to decrease glucose entry into maternal cells and divert fuel to the developing fetus. Gestational diabetes mellitus (GDM) develops during pregnancy in some women whose pancreatic beta-cell function is insufficient to overcome the insulin resistance that occurs during pregnancy. In women who have preexisting diabetes mellitus (DM) who become pregnant, the physiologic metabolic alterations of pregnancy create unique therapeutic challenges, including large changes in insulin requirements over the course of the pregnancy.

The presence of hyperglycemia during pregnancy has wide-ranging health implications for both fetus and mother, beginning at conception and extending many years and decades beyond the pregnancy. Several adverse perinatal outcomes have been associated with diabetes in pregnancy, and treatment reduces risk of many complications for both women and their infants. Hyperglycemia increases risk of excessive fetal growth and neonatal hypoglycemia, and excessive fetal growth in turn can lead to operative delivery, birth trauma, and rarely perinatal mortality. For women with preexisting diabetes that antedates pregnancy, the risk of congenital malformations also increases progressively with increasing severity of periconceptional hyperglycemia, as a result of fetal exposure to maternal hyperglycemia in the early weeks of pregnancy. Furthermore, the hyperglycemia and adverse pregnancy outcome (HAPO) Study has demonstrated that maternal glycemia, even at levels below the range diagnostic of diabetes, is strongly associated with fetal growth, fetal hyperinsulinemia, and fetal adiposity (Metzger *et al.*, 2008; Hapo Study Cooperative Research Group, 2009). Good glycemic control during pregnancy is associated with decreased maternal, fetal, and neonatal complications among women with preexisting DM (Kitzmiller *et al.*, 2008), and two large randomized controlled trials have shown that treatment of GDM decreases birth weight and the frequency of hypertensive disorders of pregnancy (Crowther *et al.*, 2005; Landon *et al.*, 2009). Pregnancy is an opportune time for healthcare providers to counsel, educate and heighten awareness regarding diabetes management strategies.

In addition to the well-known perinatal consequences of hyperglycemia during pregnancy, the altered intrauterine environment carries lifelong health implications for mother and infant which extend well beyond pregnancy. Women with GDM are at significantly increased risk for the future development of type 2 diabetes later in life, even when maternal glucose metabolism returns to normal immediately following pregnancy. In this way, pregnancy may be viewed as a physiologic "stress test" that unmasks a woman's underlying predisposition to chronic disease, and can serve as a valuable window to a woman's future health at a time in her life when targeted preventive strategies may be most effective. Alterations in maternal glucose metabolism in utero can also influence the offspring's long-term risk for obesity and type 2 diabetes later in his or her life.

Categories of Hyperglycemia During Pregnancy

Any type of preexisting DM in a woman of reproductive age may complicate pregnancy. The most common types of preexisting DM are type 1 DM and type 2 DM. Type 1 DM is caused by destruction of the pancreatic insulin-producing beta cells (usually autoimmune in nature), resulting in absolute insulin deficiency. The pathogenesis of type 2 DM is complex; the hallmark pathophysiologic defects are insulin resistance and relative insulin deficiency. GDM is classically defined as "carbohydrate intolerance of varying degrees of severity, with onset or first recognition during pregnancy" (Metzger and Coustan, 1998). However, women with severe hyperglycemia characteristic of previously undiagnosed overt type 2 or (less commonly) type 1 DM who are first diagnosed during pregnancy would be included in this classic definition of GDM. Newer definitions of GDM (International Association of Diabetes Pregnancy Study Groups Consensus Panel *et al.*, 2010; American Diabetes Association, 2017), therefore, distinguish previously-unrecognized overt DM from GDM by excluding those women who meet standard diagnostic criteria for DM. Rarer forms of preexisting DM include glucocorticoid-induced or other drug-induced DM (such as occurs in association with immunosuppressant medications used after organ transplantation or with medications used to treat HIV), DM associated with pancreatic insufficiency (e.g., pancreatitis, cystic fibrosis), and monogenic DM (also known as maturity-onset diabetes of the young; MODY).

GDM is currently defined as diabetes that is first diagnosed during pregnancy that was not clearly overt diabetes prior to gestation (American Diabetes Association, 2017), and refers to the hyperglycemia that transiently results from the pregnancy-induced increase in insulin resistance during the second half of pregnancy.

 doi:10.1016/B978-0-12-801238-3.64972-3

Prevalence

In parallel with the increasing prevalence of obesity and type 2 diabetes in the population as a whole (Shaw *et al.*, 2010; Ogden *et al.*, 2015), the prevalence of pregnancies affected by diabetes has also increased over time and is expected to continue to increase (Hartling *et al.*, 2013). GDM accounts for the vast majority (approximately 85%) of cases, with preexisting DM accounting for the remainder and affecting approximately 1% of all pregnancies (Albrecht *et al.*, 2010). Depending on the population studied and the diagnostic criteria employed, estimates of the prevalence of GDM vary, ranging from 1% to 25% (Moyer and Force, 2014). The number of pregnancies complicated by DM has increased steadily over time; between 1994 and 2004, the relative increase was greatest for pregnancies complicated by T2DM, though pregnancies complicated by all types of DM increased (Albrecht *et al.*, 2010). Multiple factors likely contribute to the increased prevalence observed, including changes in screening and diagnostic criteria, as well as increases in obesity and other diabetes risk factors (such as inactivity and poor diet) that predispose women to both T2DM and GDM.

Metabolic Alterations During Pregnancy

During normal pregnancy, several metabolic adaptations occur to enable a continuous supply of nutrients from the mother to the growing fetus. Glucose is the primary source of energy for the fetus, and diffuses down a concentration gradient from mother to fetus. In addition, amino acids are transported across the placenta from mother to fetus to enable essential protein accretion. Early pregnancy is an anabolic state—maternal fat accumulation results from increased synthesis and deposition of triglycerides in adipose tissues and inhibited lipolysis. During early pregnancy, insulin sensitivity can be increased. Later in pregnancy, the anabolic state gives way to a catabolic state characterized by increased lipolysis. The major metabolic adaptations during later pregnancy have been classically described as a state of "accelerated starvation and facilitated anabolism" (Freinkel, 1980). "Accelerated starvation" refers to maternal adaptive mechanisms during the fasting state that enable continued shunting of fuels such as glucose and amino acids to the fetus even during times of fasting. In addition to the more rapid decrease in plasma glucose which occurs during the fasting among pregnant women, maternal metabolism is more readily diverted toward fat breakdown (in association with increases in free fatty acids and ketones), thus sparing glucose and amino acids for use by the fetus. "Facilitated anabolism" describes the fed state during late pregnancy. Postprandially, there are greater increases in glucose and triglycerides after a glucose load. Glucose is diverted in a concentration-dependent manner toward the fetus and the increased triglycerides provide fuel that can be utilized by the mother and thus further spares glucose for the fetus. The progressive increase in insulin resistance which parallels the growth of the fetoplacental unit is the primary driver of this potential for carbohydrate intolerance, such that by the third trimester insulin sensitivity is 50%–60% lower than in the nonpregnant state (Catalano *et al.*, 1999).

The progressive increase in insulin resistance and insulin secretion that characterizes late pregnancy is thought to be mediated by a number of factors of placental origin, including progesterone, human chorionic somatomammotropin (hCS), placental growth hormone variant, cytokines (Desoye and Hauguel-de Mouzon, 2007), and others; the precise mechanisms remain elusive. In the postpartum period, the marked insulin resistance dissipates immediately.

Pathogenesis of GDM

GDM develops in women who are unable to maintain euglycemia in the face of the diabetogenic changes that occur during normal pregnancy. The relative decrease in insulin sensitivity during late pregnancy is similar among women with and without GDM (approximately 50%–60%), but the starting point differs (Catalano *et al.*, 1999). The initial absolute degree of insulin sensitivity tends to be lower among women with GDM compared to those without; when these women become even more insulin resistant during pregnancy and pancreatic β-cell function is insufficient to compensate for the increased insulin resistance, hyperglycemia occurs. Baseline pregravid metabolic status, therefore, is a major determinant of whether GDM will develop in the face of the more universal relative decrease in insulin sensitivity which occurs during pregnancy (**Fig. 1**). In this way, GDM is a quintessential example of the concept of pregnancy complications as a "window" into a woman's future health (Rich-Edwards *et al.*, 2010). The metabolic stress of pregnancy enables an underlying predisposition to disease (in this case future risk of developing diabetes) to become clinically manifest at a young age, a time when a woman may otherwise be unaware of her future health risks but in many ways may be most poised to enact the lifestyle modifications which could stave off future disease.

Consequences of Hyperglycemia in Pregnancy

The hyperglycemia that occurs as a result of diabetes in pregnancy (regardless of the etiology of the diabetes) can lead to fetal and neonatal consequences, as well as metabolic abnormalities later in life. According to the Pedersen–Freinkel hypotheses (**Fig. 2**), excess maternal fuels (glucose as well as other insulin-dependent fuels such as amino acids and lipids) cross the placenta in a concentration-dependent manner and stimulate the production of excessive insulin and other growth factors in the developing fetus (Pedersen and Osler, 1961; Freinkel, 1980). Increased fetal insulin secretion via increased fetal beta-cell mass (which can be

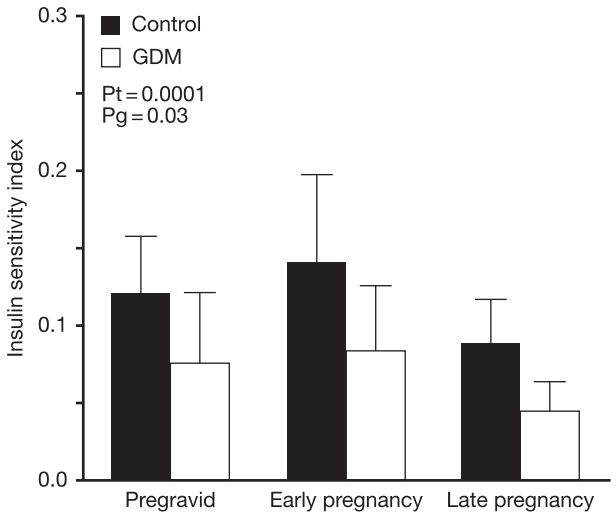

Fig. 1 Longitudinal changes in insulin sensitivity index during 40 mU m^{-2} min^{-1} insulin infusion (mean ± SD). GDM, Gestational diabetes mellitus; Pt, individual longitudinal changes with time; Pg, difference between groups (Catalano *et al.*, 1999).

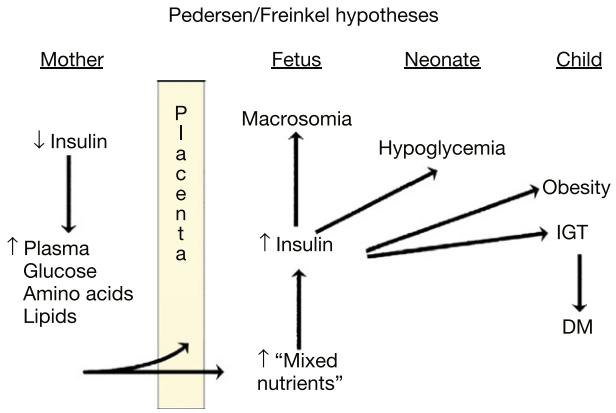

Fig. 2 Effect of maternal fuels on fetal development. The classic hyperglycemia-hyperinsulinemia hypothesis of Pedersen has been modified to show the contribution of other insulin-responsive maternal fuels in addition to glucose. Altered fetal nutrients and fetal hyperinsulinemia are associated with consequences that extend beyond the neonatal period (Silverman *et al.*, 1996).

identified as early as the second trimester) stimulates excessive fetal growth and increased fetal adiposity. The excessive fetal adiposity tends to be disproportionately distributed in the chest and shoulder areas, thereby increasing risks of shoulder dystocia, birth trauma, and operative delivery. In the neonatal period, risk of neonatal hypoglycemia increases as a result of hyperinsulinemia that persists even after cessation of the excess supply of glucose and other nutrients from the mother. Later in life, increased risk of obesity, impaired glucose metabolism, and diabetes result from the altered intrauterine environment (see below).

Preexisting DM

Fetal Implications

In early pregnancy, maternal hyperglycemia significantly increases risk of congenital malformations that develop during the first few weeks of pregnancy when the mother may not yet be aware that she is pregnant. The risk of congenital malformations is estimated to be two- to sixfold elevated among pregnancies complicated by preexisting type 1 or type 2 DM (Landon *et al.*, 2017; Bell *et al.*, 2012; Yang *et al.*, 2006). This risk has been shown to increase linearly with increasing periconceptional A1c above the normal range (Bell *et al.*, 2012; Guerin *et al.*, 2007), though others have observed the increased risk only at higher A1c thresholds (Jensen *et al.*, 2009). Since a large number of pregnancies are unintended (nearly half of pregnancies in the U.S. (Finer and Zolna, 2011)), preconception counseling and optimal glycemic control in women of reproductive age with preexisting DM are of paramount importance in reducing this risk. Optimizing glycemic control as close to normal as is safely possible is the single most

effective strategy to improve pregnancy outcome, and prepregnancy care programs may reduce risk of adverse pregnancy outcomes among women with type 1 and type 2 DM (Murphy *et al.*, 2010). Additional preconception testing is summarized in **Table 1**.

Later in pregnancy, hyperglycemia induces fetal hyperinsulinemia, excess fetal growth and its attendant consequences, and increased future risk of obesity and abnormal glucose metabolism among the offspring (as discussed below under GDM). Risk of perinatal mortality, while low when metabolic control is good, is significantly increased among pregnancies complicated by preexisting type 1 and type 2 DM (Tennant *et al.*, 2014).

Obstetric Complications

Hyperglycemia in early pregnancy increases risk of spontaneous abortion, and the risk increases linearly with increasing periconceptional A1c (Mills *et al.*, 1988). Conversely, early glycemic control achieved through a preconception management program led to significantly decreased rates of early fetal loss (Rosenn *et al.*, 1991). Pregnant women with preexisting DM are also at higher risk for preeclampsia/gestational hypertension, polyhydramnios, preterm delivery, and operative delivery.

Maternal Implications

Women with preexisting DM are at increased risk of hypoglycemia during early pregnancy (Nielsen *et al.*, 2008). Contributors to the increased hypoglycemia risk include the more intensive treatment targets employed during pregnancy, the physiologic decline in fasting glucose, nausea and resulting irregular food intake, difficulty in recognition related to the overlap between symptoms of hypoglycemia and the common symptoms of pregnancy itself (such as nausea, palpitations, sweating, warmth, hunger, inability to concentrate), and most importantly, diminished subjective symptoms of hypoglycemia (Bjorklund *et al.*, 1998).

Risk of diabetic ketoacidosis (DKA) is also increased during pregnancy among women with preexisting DM as a result of the increased insulin resistance and resulting augmentation of lipolysis and ketogenesis which occurs during pregnancy. While fortunately an infrequent complication of pregnancy, a high index of suspicion and low threshold for hospitalization must be maintained for pregnant women who experience symptoms suggestive of DKA (such as nausea, vomiting, abdominal pain, fever, or decreased oral intake) even at moderately increased glucose levels, due to the potentially life-threatening consequences of DKA to the mother and fetus (Sibai and Viteri, 2014). Potential precipitating factors of DKA include intractable vomiting/starvation, infection, insulin deficiency resulting from poor compliance with treatment or insulin pump failure, use of β-sympathomimetic agents for tocolysis, glucocorticoid administration for fetal lung maturation or other medical indications, and gastroparesis (Sibai and Viteri, 2014). Pregnant women should be instructed to test for urine ketones when ill or when blood glucose levels persistently exceed 200 mg/dL (11.1 mmol/L) and to notify the healthcare team when positive values occur.

In general, pregnancy is not considered to increase independently the risk for long-term progression of microvascular complications (Verier-Mine *et al.*, 2005; Diabetes and Complications Trial Research, 2000). Although short-term worsening of retinopathy may occur during and for 1 year after pregnancy, this transient increase in risk did not persist long-term in the Diabetes Control and Complications Trial (DCCT) (Diabetes and Complications Trial Research, 2000). Women without baseline retinopathy are very unlikely to develop severe retinopathy during pregnancy. Among women with moderate or severe retinopathy at

Table 1 Diabetes preconception health checklist

Address family planning and contraception
Optimize glycemic control prior to pregnancy, including A1c $<6.5\%$
Understand meal plan guidelines, recommendations for weight gain, and physical activity during pregnancy
Eat a nutritious meal plan with adequate distribution of carbohydrate, protein, and fat
Evaluation for microvascular complications, including comprehensive eye exam, serum creatinine, and urinary albumin–to–creatinine ratio
Measure thyroid-stimulating hormone (TSH)
Take 400 micrograms of folic acid daily
Discontinue potentially teratogenic medications, including ACE inhibitors, angiotensin receptor blockers, and statins
Smoking cessation
Limit alcohol consumption to less than one drink per day
Stop all alcohol use when actively trying to become pregnant
Gynecological exam and screening for communicable disease
Weight management
Daily physical activity
Seek intervention to address mood disturbances such as depression or anxiety

conception, however, the risk of progression is significant (Chew *et al.*, 1995). Poor glycemic control at conception also increases risk of worsening retinopathy (Chew *et al.*, 1995). Since the transient effect of pregnancy on retinopathy risk persisted for 1 year postpartum in the DCCT, continued frequent ophthalmologic monitoring is warranted for 1 year postpartum (Diabetes and Complications Trial Research, 2000).

Mirroring the patterns noted above for diabetic retinopathy, risk of nephropathy progression also correlates with the degree of baseline disease. Women with no or mild diabetic nephropathy prior to pregnancy are at low risk for durable progression of kidney disease, while those with significant baseline kidney disease are at significant risk of disease progression during pregnancy. While a transient increase in albumin excretion may occur during pregnancy among those with albuminuria at baseline, these changes typically normalize following delivery (Young *et al.*, 2011). In contrast, the minority of women with moderate-to-severe renal insufficiency at baseline are at risk for progression of renal impairment and even development of end-stage renal disease during pregnancy (Purdy *et al.*, 1996). In addition to the potential impact of pregnancy on the progression of diabetic nephropathy, impaired renal function or severe proteinuria at baseline also increases risk of adverse pregnancy outcomes, including preterm delivery, preeclampsia, and fetal growth restriction (Landon, 2007).

Treatment Principles

Good glycemic control throughout pregnancy is associated with the lowest rates of complications for the fetus, pregnancy, and mother (Kitzmiller *et al.*, 2008). While no randomized trials have or will be done to formally evaluate the independent effects of periconceptional and antenatal glycemic control on adverse pregnancy outcomes, multiple observational studies provide strong support for the benefits of excellent glycemic control in reducing these risks. The risk of serious adverse pregnancy outcome (congenital malformations and/or perinatal mortality) was elevated among pregnant women with type 1 DM and periconceptional A1c above 6.9% (Jensen *et al.*, 2009). Similarly, A1c above 6.5% measured in late pregnancy among women with type 1 DM correlated with increased risk of multiple adverse outcomes including preterm delivery, preeclampsia, and neonatal hypoglycemia; A1c above even 6% was associated with increased risk of large for gestational age (Maresh *et al.*, 2015). The risks increased progressively with higher A1c.

Insulin requirements change dramatically over the course of gestation, in parallel with the growth of the placenta and fetus (Garcia-Patterson *et al.*, 2010). In early pregnancy, insulin sensitivity tends to increase, leading to a heightened risk of hypoglycemia at the end of the first and beginning of the second trimester. Subsequently, a progressive increase in insulin resistance occurs, starting at approximately 16 weeks gestational age and peaking in late third trimester (**Fig. 3**). Over the course of the second and third trimesters, a two- to threefold increase in daily insulin requirement typically occurs (Garcia-Patterson *et al.*, 2010), with a disproportionate increase in prandial versus basal insulin (Roeder *et al.*, 2012). Following delivery, the marked insulin resistance disappears immediately, and insulin requirements decrease markedly.

Insulin therapy can be accomplished via multiple daily injections of insulin or insulin pump therapy. Insulin pump therapy offers several advantages, including the ability to provide varying basal rates over the course of the day, to alter the duration of mealtime boluses for foods with varying absorption rates, and to precisely deliver small insulin doses. To date, systematic analysis has not demonstrated significant differences in glycemic control or pregnancy outcomes with insulin pump use compared to

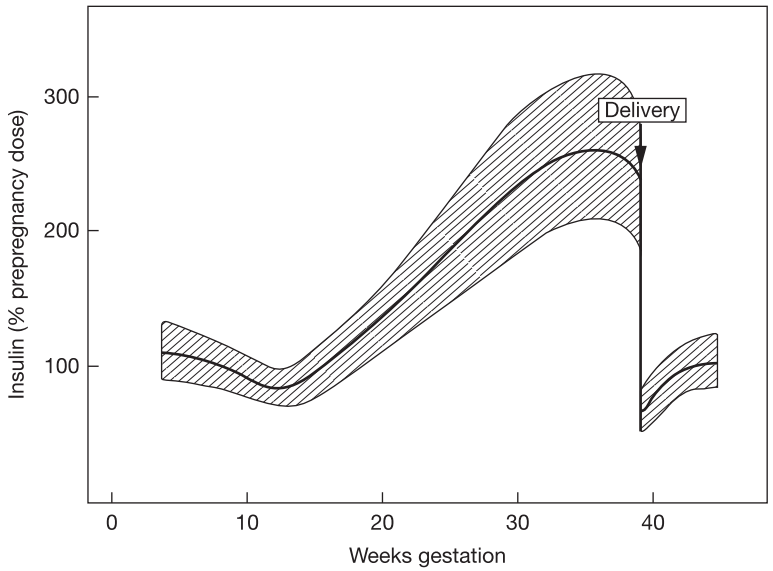

Fig. 3 Schematic representation of varying insulin requirements over the course of pregnancy and after delivery in pregestational diabetes mellitus (Phelps et al., 1988).

traditional multiple daily injections, but many women prefer the flexibility offered by insulin pump therapy in helping them to manage the large and rapidly changing insulin requirements that typically occur over the course of gestation.

Blood glucose targets are fasting glucose ≤90–95 mg/dL (5–5.3 mmol/L) and either 1-h postprandial glucose ≤140 mg/dL (7.8 mmol/L) or 2-h postprandial glucose ≤120 mg/dL (6.7 mmol/L), similar to the targets for GDM discussed below (Blumer *et al.*, 2013; ACOG Committee on Practice Bulletins, 2005; American Diabetes Association, 2017). The recommended A1C target in pregnancy is 6%–6.5%, noting that <6% may be optimal if it can be achieved without significant hypoglycemia, and that <7% may be used if needed to prevent hypoglycemia (American Diabetes Association, 2017).

Continuous glucose monitoring (CGM) systems measure repeated glucose levels in interstitial fluid (which parallel plasma glucose levels) using an electrochemical enzymatic sensor. Many women derive significant benefit from real-time CGM data, which can provide insight into glycemic patterns across the day and night, the degree and duration of postprandial glucose excursion in response to different foods, and the impact of lifestyle factors such as exercise and dietary manipulations on glycemia. This data can be harnessed to inform the frequent insulin dose adjustments which become necessary in the face of continually changing insulin requirements across gestation. CGM systems can also deliver alerts that can warn of hypoglycemia (a valuable safety feature), hyperglycemia, as well as impending hypo- and hyperglycemia. Outside of pregnancy, CGM use has documented benefit in producing glycemic improvement and reduction in hypoglycemia (Beck *et al.*, 2017). Studies evaluating the impact of CGM use during pregnancy on glycemic control and pregnancy outcomes, however, have produced conflicting results to date (Secher *et al.*, 2013; Voormolen *et al.*, 2013; Murphy *et al.*, 2008). One trial demonstrated that improved glycemic control resulted from overnight use of a partially-automated "closed-loop" system that adjusts basal insulin rates in response to glucose levels measured via real-time continuous glucose monitoring (Stewart *et al.*, 2016).

Gestational DM

Diagnosis

The original diagnostic criteria for diagnosis of GDM proposed by O'Sullivan and Mahan were developed more than five decades ago (O'Sullivan and Mahan, 1964). These criteria were developed with the goal of identifying women at increased risk for future development of type 2 DM, rather than those at increased risk for adverse perinatal outcomes. With extrapolation to account for current use of plasma rather than whole blood samples and contemporary laboratory methodology, these criteria remain in use today (**Table 2**). In 2010, the International Association of the Diabetes and Pregnancy Study Groups (IADPSG) proposed a new set of criteria based on data obtained from the landmark HAPO study. The IADPSG diagnostic criteria defined GDM based on the fasting, 1-h, and 2-h plasma glucose levels at which the odds for adverse perinatal outcomes was 1.75 times the corresponding odds of these outcomes at the study population's mean levels (International Association of Diabetes Pregnancy Study Groups Consensus Panel *et al.*, 2010). Therefore, these criteria are unique in that they were the first derived from risk of adverse perinatal outcomes, rather than maternal risk of future metabolic derangement.

Detection of diabetes in early pregnancy (for example, at the first prenatal visit) is recommended among women with elevated risk of type 2 diabetes, including those with a past history of GDM, obesity, or known abnormal glucose metabolism (American Diabetes Association, 2017). The current goal of early screening is to identify women with undiagnosed preexisting (or inter-pregnancy) type 2 DM and its well-established associated risks during pregnancy. How to manage—or label—women with lesser degrees of hyperglycemia in early pregnancy (above normal, but below the diagnostic threshold for overt DM) remains controversial at this time, as the currently-established diagnostic criteria for GDM were not derived from data obtained in early pregnancy, and trials demonstrating incremental benefit of identifying and treating GDM prior to the standard time of diagnosis in late pregnancy are lacking. Women who have negative early testing and all women who have not undergone early testing should

Table 2 Glucose criteria for detection and diagnosis of GDM

	O'Sullivan–Mahan[a,c,e] *(mg/dL)*	*NDDG*[a,c,f] *(mg/dL)*	*Carpenter–Coustan*[a,c,f] *(mg/dL)*	*IADPSG*[b,d,f] *(mg/dL)*
Fasting	90	105	95	92

undergo universal testing at 24–28 weeks gestational age (American Diabetes Association, 2017; Committee on Practice Bulletins-Obstetrics, 2017).

Experts continue to debate the optimal method for GDM diagnosis. In the United States, detection and diagnosis of GDM is most commonly performed using a two-step approach. First, a "glucose challenge test" is administered fasting or non-fasting; a glucose value >130–140 mg/dL (7.2–7.8 mmol/L) 1 h after ingestion of 50 g of glucose is considered a positive screen (with different threshold values within that range imparting varying sensitivities and specificities). Screen-positive women then undergo a 100-g, 3-h oral glucose tolerance test (**Table 1**). More recently, a one-step 75-g, 2-h glucose tolerance test has been proposed by the IADPSG as an alternative approach to detection and diagnosis of GDM, and has been endorsed by some (American Diabetes Association, 2017; International Association of Diabetes Pregnancy Study Groups Consensus Panel *et al.*, 2010; Blumer *et al.*, 2013) but not all (Vandorsten *et al.*, 2013; Committee on Practice Bulletins-Obstetrics, 2017) organizations. Primarily because the IADPSG criteria define a positive diagnostic test as meeting or exceeding one rather than two thresholds, adoption of these criteria leads to a significant increase in GDM prevalence.

While it has been argued that this increased prevalence would have unwanted consequences such as constraints on limited healthcare resources, the higher prevalence of GDM as defined by the outcome-based IADPSG criteria more closely mirrors the prevalence of abnormal glucose metabolism among U.S. women of reproductive age (approximately 30% of U.S. women aged 18–44 years have diabetes or prediabetes based on NHANES data (The International Association of Diabetes & Pregnancy Study Groups (IADPSG) Consensus Panel Writing Group and the Hyperglycemia & Adverse Pregnancy Outcome (HAPO) Study Steering Committee *et al.*, 2012)) and therefore may more accurately reflect the prevalence of pregnancies affected by hyperglycemia and its attendant consequences.

Fetal Implications

The major impact of maternal hyperglycemia on the fetus derives from the basic postulates of the Pedersen–Freinkel hypotheses. Fetal overnutrition and resulting fetal hyperinsulinemia leads to excessive fetal growth (macrosomia), which in turn increases risk of shoulder dystocia and infant birth trauma. Postnatal fetal hyperinsulinemia which persists after cessation of the maternal glucose supply at delivery increases risk of neonatal hypoglycemia and its associated consequences. Other adverse fetal outcomes associated with GDM include neonatal metabolic complications (including hyperbilirubinemia, hypocalcemia, and polycythemia) and very rarely perinatal mortality. Notably, the HAPO study demonstrated that risks of multiple outcomes (macrosomia, fetal hyperinsulinemia, neonatal hypoglycemia, shoulder dystocia or birth injury, preeclampsia and preterm delivery) increased progressively in a continuous manner with increasing fasting, 1-h, and 2-h glucose levels, even within a range currently considered normal (Metzger *et al.*, 2008). In contrast to preexisting DM, GDM is generally not associated with increased risk of congenital malformations, as disease onset is late in pregnancy after organogenesis is complete.

In addition to perinatal consequences, multiple long-term observational studies have demonstrated that maternal history of GDM predicts increased future risk of obesity (Silverman *et al.*, 1991) and impaired glucose tolerance (Silverman *et al.*, 1995) in the offspring. In one large observational study, childhood obesity correlated with amniotic fluid insulin measured during the third trimester of pregnancy (Silverman *et al.*, 1991), bolstering the fundamental hypotheses posited by Pedersen and Freinkel that excess maternal fuel is the key driver of subsequent metabolic derangement. In the Pima Indian population, the prevalence of type 2 DM was dramatically higher among offspring of women who had diabetes during pregnancy, compared to offspring of women without diabetes, even after adjusting for paternal diabetes and offspring weight (Pettitt *et al.*, 1988). Perhaps the strongest line of evidence supporting independent effects of intrauterine exposure to hyperglycemia comes from studies examining discordant sibships. One study examining data from the Pima Indian community found that the risk of diabetes was significantly increased among siblings born after the mother developed diabetes compared to siblings born before maternal DM diagnosis (Dabelea *et al.*, 2000). Since multiple potential confounding factors remain constant between sibling pairs (genetic and most environmental factors), these findings provide strong support for the specific metabolic effects directly attributable to an altered intrauterine environment.

The above relationships set the stage for a vicious transgenerational cycle of diabetes and obesity (Dabelea and Crume, 2011). The fetal overnutrition that results from maternal diabetes increases future risk in the offspring of obesity and abnormal glucose metabolism; female offspring who develop type 2 diabetes or impaired glucose metabolism and become pregnant then impart to their own offspring an increased risk of obesity and diabetes, and the cycle continues.

Obstetric Complications

GDM has been associated with increased risk of multiple adverse obstetric outcomes including preeclampsia, polyhydramnios, operative delivery, maternal birth trauma, and associated morbidities.

Maternal Implications

Women with GDM are at markedly increased risk for future development of type 2 diabetes (Bellamy *et al.*, 2009). Estimates of the cumulative incidence of type 2 diabetes in the postpartum years have varied in different populations and with different lengths of follow-up, ranging 20%–60% or higher at 5–10 years postpartum (Kim *et al.*, 2002; Feig *et al.*, 2008). Since GDM stems from chronic beta-cell

insufficiency, it is not surprising that these women are at high risk for future development of overt diabetes with increasing age and exposure to other risk factors for type 2 DM such as weight gain and physical inactivity. The diagnosis of GDM during a woman's reproductive years, therefore, serves as a crucial window into a woman's future health, and bestows a woman with actionable information at a young age when she might not otherwise be as keenly aware of the need for lifestyle measures aimed at diabetes prevention.

Treatment Principles

The mainstay of treatment for all women with GDM is medical nutrition therapy (MNT), and MNT is sufficient as sole therapy for approximately 80%–90% of women (Crowther *et al.*, 2005; Landon *et al.*, 2009). Lifestyle interventions have been associated with decreased risk of macrosomia and decreased neonatal adiposity, as well as decreased risk of postpartum depression and increased likelihood of achieving postpartum weight goals (Brown *et al.*, 2017; Crowther *et al.*, 2005; Landon *et al.*, 2009). Women are advised to eat three small- to moderate-sized meals and two to four snacks that are balanced in whole-grain carbohydrates, protein, and unsaturated fats. Breakfast is typically smaller than lunch and dinner (for example, 30 g compared to 45–60 g of carbohydrate), as carbohydrate intolerance is commonly more pronounced at the morning meal. Pairing protein with carbohydrate at all meals and snacks is emphasized, not only to increase satiety but also to blunt postprandial carbohydrate-induced glycemic excursion. A bedtime snack is often necessary counteract the tendency toward accelerated starvation (and resulting ketosis) that accompanies the overnight fasting state. When glycemic goals are not met with MNT, insulin therapy is added. Women are asked to monitor capillary blood glucose fasting and 1 h after meals to guide insulin dose adjustments, and to monitor urine ketone levels 1–2 times daily to assess for excessive restriction of carbohydrate intake. Glucose targets are fasting $\leq$95 mg/dL (5.3 mmol/L) and either 1-h postprandial glucose $\leq$140 mg/dL (7.8 mmol/L) or 2-h postprandial glucose $\leq$120 mg/dL (6.7 mmol/L) (American Diabetes Association, 2017; Committee on Practice Bulletins-Obstetrics, 2017).

Treatment of GDM, via MNT with or without insulin therapy, has been shown in two large randomized controlled trials to reduce risk of adverse neonatal outcomes (Crowther *et al.*, 2005; Landon *et al.*, 2009). Specifically, treatment was shown to reduce rates of macrosomia (Crowther *et al.*, 2005; Landon *et al.*, 2009), shoulder dystocia (Landon *et al.*, 2009), neonatal fat mass (Landon *et al.*, 2009), cesarean section (Landon *et al.*, 2009), preeclampsia (Landon *et al.*, 2009, Crowther *et al.*, 2005), and maternal weight gain (Crowther *et al.*, 2005; Landon *et al.*, 2009).

Postpartum Care

Postpartum care for women with diabetes is the springboard to long-term diabetes care, prevention of long-term diabetes complications, and planning for subsequent pregnancies. Postpartum care should be treated as a transition from obstetric to general medical healthcare providers.

Preexisting DM

After delivery, immediate postpartum insulin requirements decrease dramatically among women with preexisting DM due the rapid decrease in placental hormone levels (**Fig. 3**). Maternal insulin requirements for women with type 1 DM usually return to pre-pregnancy levels or lower (Kjos, 2007). Medication requirements vary among women with type 2 DM, depending on the degree of hyperglycemia and the pre-pregnancy treatment regimen. Some may not require medical therapy following delivery and may monitor capillary glucose levels. When medical therapy is indicated, women may resume insulin therapy at reduced doses or oral agents (see breastfeeding considerations below).

Table 3 Metabolic assessments after GDM

Time	*Test*	*Purpose*
Post-delivery (1–3 days)	Fasting or random plasma glucose	Detect persistent, overt diabetes
Early postpartum (around the time of postpartum visit)	75 g 2-h OGTT	Postpartum classification of glucose metabolism[a]
1 year postpartum	75 g 2-h OGTT	Assess glucose metabolism
Annually	Fasting plasma glucose	Assess glucose metabolism
Tri-annually	75 g 2-h OGTT	Assess glucose metabolism
Prepregnancy	75 g 2-h OGTT	Classify glucose metabolism

[a]Classification of glucose metabolism by criteria recommended by the American Diabetes Association. OGTT, oral glucose tolerance test.

Metzger, B. E., Buchanan, T. A., Coustan, D. R., *et al.* (2007). Summary and recommendations of the fifth international workshop-conference on gestational diabetes mellitus. Diabetes Care 30(Suppl 2), S251–260.

GDM

The majority of women with GDM, even those treated with insulin during pregnancy, will have normal glucose levels immediately postpartum. Blood glucose monitoring is required postpartum, however, to exclude the small number of women with unrecognized preexisting type 2 DM (Kjos, 2007). Short- and long-term metabolic assessment after GDM is needed (**Table 3**).

Women should be counseled during both the antepartum and postpartum phases regarding the increased future risk of developing type 2 DM (see "GDM and Maternal Implications" sections). Pharmacologic therapy and lifestyle interventions have been shown to reduce the risk of type 2 DM. In the Diabetes Prevention Program (DPP)/DPP Outcomes Study, metformin and lifestyle changes were equally effective among women with a history of GDM in decreasing progression to diabetes over 10 years of follow-up (Aroda *et al.*, 2015; Nathan *et al.*, 2017). GDM frequently recurs in subsequent pregnancies. Factors which increase risk of recurrence include increased maternal age and parity, and interpregnancy weight gain.

Breastfeeding

Women with both preexisting DM and GDM should be encouraged to breastfeed. Among women with GDM, breastfeeding has been associated with reduced risk of developing type 2 DM in the future (Gunderson *et al.*, 2015). Women should continue a nutrient-dense meal plan, with caloric and nutritional requirements adjusted to meet the additional demands of lactation. Women should be counseled prior to delivery about potential barriers to breastfeeding, including possible post-operative recovery, the possibility of a neonate who requires intensive medical care, and maternal hypoglycemia. There are pros and cons regarding the use of oral medications for treatment of hyperglycemia during breastfeeding. Thus, a decision regarding use of oral agents versus insulin should be made jointly between caregivers and mothers.

Contraception

Ideally, a discussion regarding contraception should take place in the antepartum and immediate postpartum phase. Health care providers should counsel women regarding the need for prevention of unplanned pregnancy with suboptimal glycemic control, metabolic and cardiovascular impact, and individual lifestyle factors. Barrier methods such as condoms, diaphragms, cervical caps, and contraceptive sponges have no adverse systemic effects. Yet couples need to be extremely motivated to ensure proper use due to the high failure rate. Intrauterine devices are commonly recommended for women with DM. Neither the copper IUD nor the levonorgestrel-releasing IUD significantly impact glucose tolerance or lipids. Progestin-only oral contraceptive preparations are not thought to significantly impact diabetes control or blood pressure. Injectable progestin-only contraceptives (depo-medroxyprogesterone acetate, DMPA) may adversely affect lipids, insulin resistance, and weight gain, and is therefore not a first-line choice in this setting (Damm *et al.*, 2007; Xiang *et al.*, 2007). If future pregnancy is not desired, tubal ligation or vasectomy are options.

Diabetes Mellitus; Diagnosis and Treatment in the Elderly☆

Odilia I Bermudez, Tufts School of Medicine, Boston, MA, United States

Glossary

Body mass index (BMI) The measurement of the body mass divided by the square of the stature (total height) of an adult person. BMI is commonly used to assess the nutritional status of adults as low, normal, overweight or obese.

Diabetes mellitus A group of chronic diseases characterized by a deficiency in the production of insulin by the pancreas or by lack of efficiency of the produced insulin, which results in elevated concentrations of glucose concentrations in blood and urine.

Elderly An imprecise term, most often related to the age of retirement, which varies widely across countries. In the United States, older adults or elders are usually considered those aged 65 or more years of age.

Glucose A simple sugar, also known as dextrose, found in blood. Glucose is the main source of energy for the human body.

Glycemia Glucose concentration in the bloodstream. Commonly expressed in the United States as milligrams per deciliter (mg/dL).

Glycosylated hemoglobin Usually referred to as hemoglobin (Hb) AIC, it is a measure of the average glycemic control during a 3- or 4-month period.

Gestational diabetes mellitus (GDM) Diabetes diagnosed in the second or third trimester of pregnancy, without a previous history.

Glycated hemoglobin or hemoglobin A1C (HbA1c or A1c) It reveals the average plasma glucose concentration during the previous 3–4 months. Measurements of A1c are commonly used for screening, diagnosis, and monitoring of diabetes mellitus.

Hyperglycemia Elevated concentrations of glucose in the blood. Fasting hyperglycemia is blood glucose above a desirable level after a person has fasted for at least 8 h.

Hypoglycemia Abnormally low concentrations of glucose in the blood.

Insulin An anabolic hormone produced in the β cells of the islets of Langerhans in the pancreas. It is required for proper glucose, fat, and protein metabolism.

Milligrams per deciliter (mg/dL) It is the measurement unit used to describe the concentration of blood plasma glucose regarding its weight dimension.

Millimole per deciliter (mmol/dL) It is the measurement unit used to describe the concentration of blood plasma glucose regarding its molarity.

Type 1 diabetes (T1D) Autoimmune b-cell destruction, which leads to complete insulin deficiency.

Type 2 diabetes (T2D) Insulin resistance, which leads to a progressive loss of b-cell insulin secretion.

Introduction

The world population is living longer, and this fast-increasing number of older adults is occurring in all world regions, particularly in Asian and African Regions as seen in **Fig. 1**. By the year 2050, it is projected that about one in four of the global population will be an elderly individual of 60 or more years of age (United Nations, Department of Economic and Social Affairs and Population Division, 2017). And, as age is a nonmodifiable risk factor for type 2 diabetes, the number of cases of older adults with diabetes will also increase rapidly. Currently, approximately one of every two cases of diabetes occurs in people older than 55 years of age, and, for example, more than 25% of the United States population aged 65 or older have diabetes, with diabetes-related mortality being higher in this age group (Centers for Disease Control and Prevention, 2017).

This article focuses on the magnitude of diabetes mellitus in the elderly and the relevant epidemiological and clinical aspects associated with this disease, including the identification of risk factors, signs, and symptoms of the disease as well as complications associated with inadequate glycemic control of older people with diabetes. Management therapies, including diet, exercise, and medications that may be used with the special considerations of the geriatric patients in mind, are also discussed.

The aging process is characterized by a gradual decline in function and overall well-being (Lopez-Otin *et al.*, 2013). This aging decline occurs across several organ systems, with a progressive deterioration of physiological functions (de Almeida *et al.*, 2017). Therefore, aging is a risk factor for several diseases including type 2 diabetes, cardiovascular disease, osteoarthritis, dementia, and more. The rapid increases in the size and age structure of the worldwide elderly population, in addition to the extended longevity of this population group, is contributing to increasing numbers of older adults who are affected by chronic diseases, particularly type 2 diabetes and associated comorbidities.

☆*Change History*: March 2018. Odilia I. Bermudez of the first article was involved in the updated chapter. Tables 1, 2 and 7 are new for this chapter. Tables 3, 4, 5, and 6 were in the first chapter and update for this new chapter. The figures 1, 2 and 3 are new additions for the new chapter.

This article is an update of Odilia I Bermudez, Diabetes Mellitus, Diagnosis, and Treatment in the Elderly, In Encyclopedia of Endocrine Diseases, edited by L Martini, Elsevier, New York, 2004, Pages 661–665.

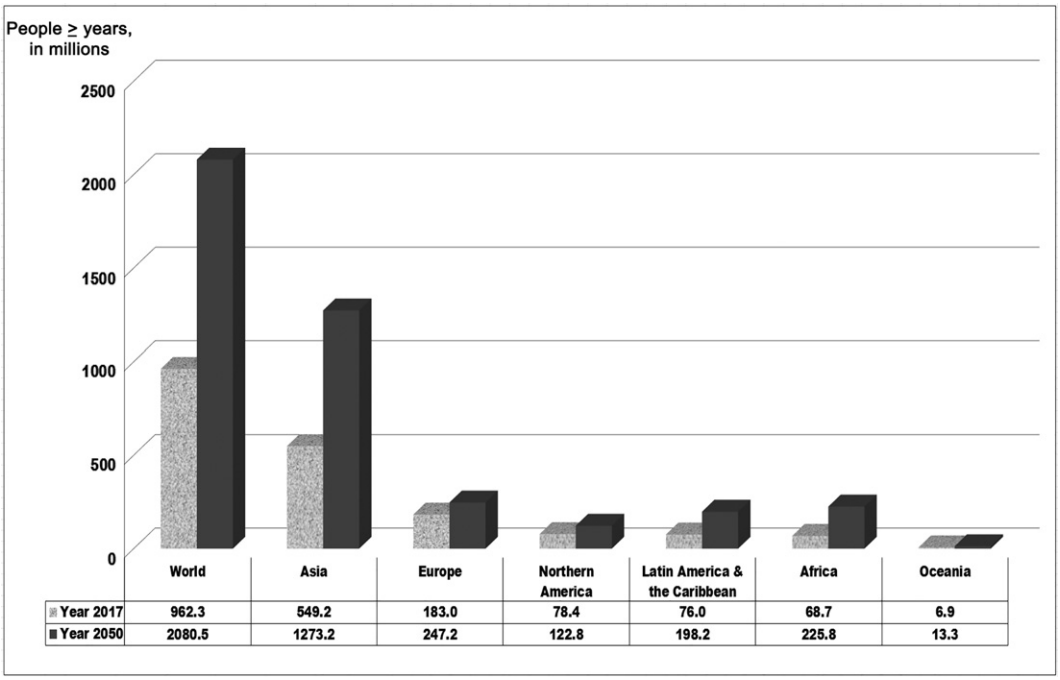

Fig. 1 World population, aged 60 and plus years, by Regions, for the years 2017 and 2050. United Nations, Department of Economic and Social Affairs and Population Division (2017). *World Population Ageing* [Highlights]. New York: United Nations.

Type 2 diabetes, also known as adult-onset diabetes, is the predominant form in older adults. In fact, more than 90% of all cases of diabetes among older adults are type 2. However, evidence shows that up to 12% of individuals older than age 65 with diabetes present islet cell autoimmunity, more similar to type 1 diabetes, and with an elevated risk for hyperglycemia (Pietropaolo *et al.*, 2000). Elders with type 2 diabetes also present at least one or more other major cardiovascular disease risk factors, particularly hypertension, abdominal obesity, and dyslipidemia. The clustering of these conditions has been called the metabolic syndrome, also known as the insulin-resistance syndrome (Oda, 2018).

As mentioned previously, type 2 diabetes is the most common type of the disease in the elderly. Therefore, the remaining sections focus on type 2 diabetes in the elderly.

Prevalence and Incidence of Diabetes Mellitus in the Elderly

According to the International Diabetes Federation (2017), the numbers of the global population between 20 and 79 years of age, affected with type 2 diabetes, is expected to increase from 425 million in 2017 to 629 million in 2045, an overall increase of 148% (see **Table 1**). The largest increase (195%) will occur in the elderly group (65–79 years).

The global burden of diabetes is significant, with large increases in the number of adults living with diabetes. Based on reports of the World Health Organization (WHO), 108 million adults living with diabetes in 1980 and by the year 2014, the number of adults living with diabetes increased to 422 million, which represents an increment of 391% (World Health Organization, 2016).

Similar to the global trends, the prevalence of diabetes among the US population is also increasing across age groups, particularly those in the older groups. As observed in **Fig. 2**, by the year 2015, the US elderly group (>65 years of age) had higher proportions of people with undiagnosed and diagnosed diabetes, as compared to their younger counterparts of 18–44 and 45–64 years of age (Centers for Disease Control and Prevention, 2017). Due to the aging of the US populations, it is expected that the fast growth of the numbers of people with diabetes will continue to grow higher and faster in the elderly groups (**Table 2**). And along with this fast growing, the associated costs of medical care for people with diabetes will also grow at very high levels (Caspersen *et al.*, 2015).

Incidence of Diabetes in the American Adult Population

For the year 2015, the CDC estimated 1.5 million of new cases of diabetes among US adults 18 years or older (Centers for Disease Control and Prevention 2017), which represented seven new cases per 1000 people. From those incident cases, more than half were among middle-aged adults (45–64 years), with equal numbers for men and women. Also, it was reported that incidence of diabetes varied with ethnicity, with higher rates for Hispanics (rate of 8.4 per 1000) and Blacks non-Hispanics (rate of 9.0 per 1000) (Centers for Disease Control and Prevention, 2017). Less than high school education was also identified as a risk factor when compared to lower rates for those with high school or beyond a high school education (**Fig. 3**).

Table 1 Global prevalence of type 2 diabetes and changes (%) between the years 2017 and 2045

Age groups (years)	*2017*	*2045*	*Increases (%)*
20–64	327	438	134
65–79	98	191	195
Total (20–79)	425	629	148

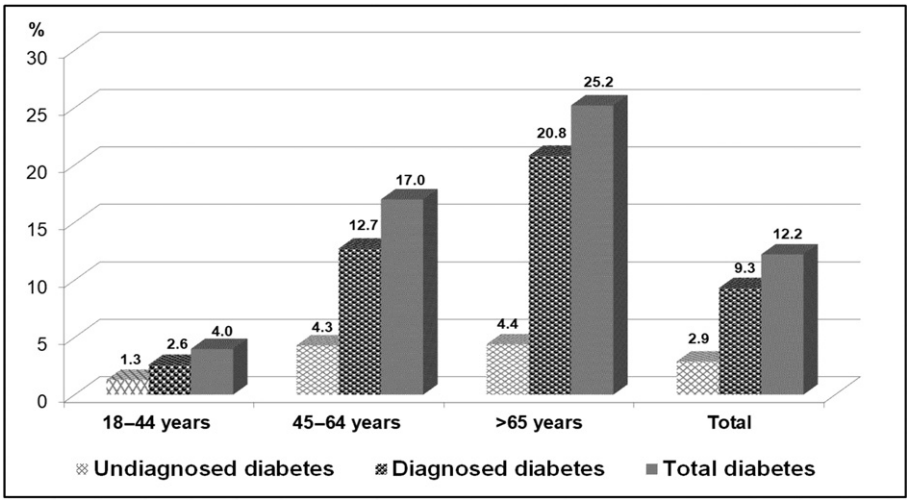

Fig. 2 Percentages of undiagnosed and diagnosed diabetes in US adults for the year 2015. Centers for Disease Control and Prevention (2017). National Diabetes Statistics Report, 2017. Atlanta, GA: Centers for Disease Control and Prevention, U.S. Department of Health and Human Services: p. 20.

Table 2 Numbers (in millions) of US adults (>18 years of age) with undiagnosed or diagnosed diabetes, as estimated for the year 2015

Age groups (years)	*Undiagnosed diabetes (millions)*	*Diagnosed diabetes (millions)*	*Total diabetes (millions)*
18–44	1.6	3.0	4.6
45–64	3.6	10.7	14.3
>65	2.1	9.9	12.0
Total	7.2	23.0	30.2

Centers for Disease Control and Prevention (2017). National Diabetes Statistics Report, 2017. Atlanta, GA: Centers for Disease Control and Prevention, U.S. Department of Health and Human Services: 20.

Risk Factors Associated With Diabetes

There is uncertainty about the specific factors that trigger the development of type 2 diabetes. For example, ethnicity is an important risk factor in the United States. It has been reported that some US ethnic and racial groups are at a higher risk for diabetes than the general population. There it is noted that Asian and Black non-Hispanic adults, as well as Hispanics, have a higher prevalence of diabetes as compared to non-Hispanic whites (Centers for Disease Control and Prevention, 2017).

Growing old is another important risk factor for developing type 2 diabetes (Menke *et al.*, 2015; American Diabetes Association, 2017). It has been estimated that by the year 2050, the number of US older adults (>65 years of age) will grow to 27 million, the equivalent of 55% of all cases of diabetes by that year (Caspersen *et al.*, 2012). There is a positive association between age and developing diabetes beginning after age 30. In fact, being older than 45 years of age is one of the risk factors listed in **Table 3**. And diabetes prevalence will be higher among non-Hispanic black, non-Hispanic Asian, and Hispanic adults as compared to other ethnic groups (Menke *et al.*, 2015).

Evidence also shows that approximately 80% of adults with type 2 diabetes are overweight and physically inactive (American Diabetes Association, 2017). Those with a family history of diabetes are also at increased risk for the disease (American Diabetes Association, 2017). Women who have had gestational diabetes, or who have given birth to a baby weighing more than 9 pounds, are also at higher risk for developing diabetes later in their lives (Daly *et al.*, 2018). Furthermore, there is an elevated risk for diabetes among women with polycystic ovary syndrome (Jaliseh *et al.*, 2017). The risk is also high for those known to have impaired glucose tolerance

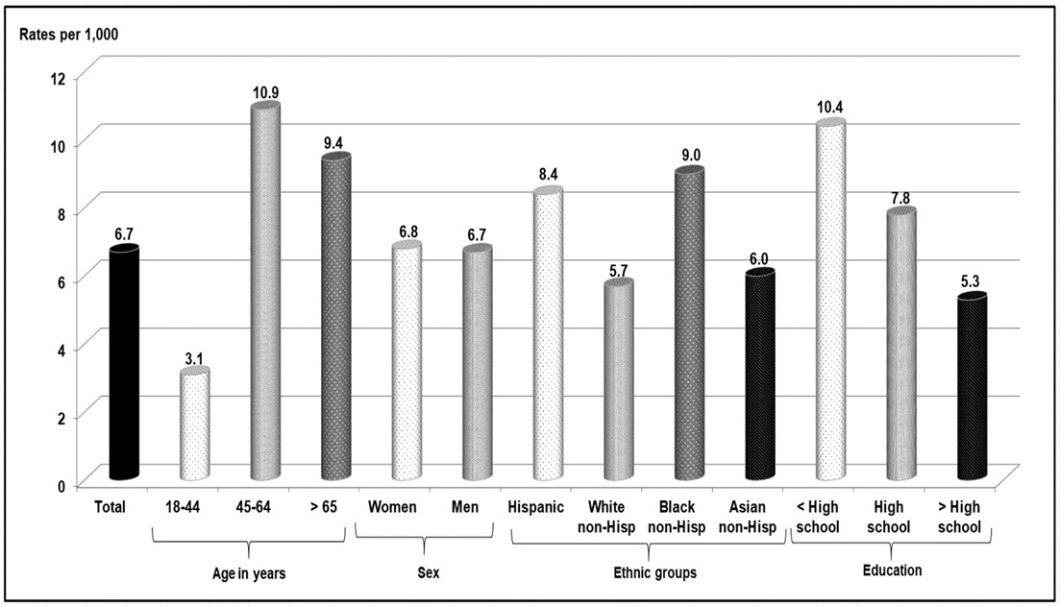

Fig. 3 The incidence of diabetes in the American adult population (>18 years), by age group, sex, ethnicity, and education. Centers for Disease Control and Prevention (2017). National Diabetes Statistics Report, 2017. Atlanta, GA: Centers for Disease Control and Prevention, U.S. Department of Health and Human Services: p. 20.

Table 3 Risk factors for type 2 diabetes

Risk factors
Older than 45 years of age
Ethnicity
Family history of diabetes
Impaired fasting glucose
Impaired glucose tolerance
History of gestational diabetes
Obesity
Hypertension
Dyslipidemia

(IGT) or impaired fasting glycemia (IFG) (American Diabetes Association, 2017), as well as for those who have high blood pressure or signs of heart disease or poor circulation as detailed in **Table 3** (American Diabetes Association, 2017).

Symptoms of Diabetes in the Elderly

Type 2 diabetes has a gradual onset, with signs of the disease developing over the years (Kirkman *et al.*, 2012). The classic symptoms, listed in **Table 4**, are usually subdued or even absent in older individuals, and the disease is often diagnosed several years after its onset when complications are already present. Regular screening for the disease after age 45 is usually the best way to detect early type 2 diabetes and avoid complications associated with the disease later during the senescence period (American Diabetes Association, 2017). Also, diabetes is associated with increased healthcare expenditure in managing diabetes-related hospital admissions and the associated vascular complications.

Diagnosis of Diabetes in the Elderly

Detection of diabetes among older individuals occurs late. It is estimated that onset of type 2 diabetes precedes clinical diagnosis by several years (Kirkman *et al.*, 2012). Compared to younger adults with diabetes, those in the older group have higher rates of myocardial infarction, visual impairment, end-stage renal disease, and lower-extremity amputation (Kirkman *et al.*, 2012). They

Table 4 Symptoms of type 2 diabetes presented in the elderly population

Symptoms of type 2 diabetes
Polyuria (frequent urination)
Polydipsia (excessive thirst)
Weight loss
Severe fatigue and/or nausea
Blurred vision
Frequent and recurrent infections
Slow healing of wounds or sores

American Diabetes Association (2017). Standards of medical Care in Diabetes. *Diabetes Care* 40(*Suppl. 1*), S1–S135.

Table 5 Criteria for the diagnosis of diabetes mellitus

Criteria for diagnosis	*Details*
Fasting plasma glucose (FPG) >126 mg/dL (7.0 mmol/L)	Fasting is defined as no caloric intake for at least 8 h
2-h plasma glucose >200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test (OGTT)	The test should be performed as described by the WHO, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water
Hemoglobin A1c >6.5% (48 mmol/mol)	The test should be performed in a laboratory using a method that is certified by the National *Glycohemoglobin Standardization* Program (NGSP) and standardized to the Diabetes Control and Complications Trial (*DCCT*) assay
In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose >200 mg/dL (11.1 mmol/L)	

American Diabetes Association (2017). Standards of medical Care in Diabetes. *Diabetes Care* 40(Suppl. 1), S1–S135.

are also more likely to present conditions such as depression, cognitive impairment, muscle weakness (sarcopenia), falls and fractures, and physical frailty (Kim *et al.*, 2012).

It has been reported that among people with undiagnosed type 2 diabetes, 10%–29% have retinopathy, 10%–37% have proteinuria, and 9% have neuropathy at the time of diagnosis (Caspersen *et al.*, 2012). These complications, associated with uncontrolled diabetes, take 10 or more years to develop in the presence of the disease. These considerations are very strong justification for the need to look for early symptoms of type 2 diabetes in older adults as early as possible.

The current criteria for the diagnosis of diabetes mellitus are based on the 2017 recommendations of an international expert committee from the American Diabetes Association (2017) and also from the World Health Organization (2016). Based on these recommendations, and according to the 2017 guidelines from the American Diabetes Association (2017), three diagnosis criteria may be used, with confirmation on a subsequent day (see **Table 5**).

Also, and based on the recommendations from ADA, when testing for prediabetes, it is equally appropriate to do fasting plasma glucose or the oral glucose tolerance test or the A1C test, as detailed in **Table 5**. In patients with prediabetes, particularly older adults, the testing or identification of other risk factors for cardiovascular disease is also important to take into consideration (American Diabetes Association, 2017).

Complications of Type 2 Diabetes

Since the metabolic problems associated with diabetes affect the entire body, older adults with this condition face multiple potential complications affecting many different organ systems. If the management of the disease is poorly controlled, if the disease is left untreated, or if the diagnosis is made late, serious complications can occur. Moreover, poor glycemic control among people with diabetes is a major risk factor for end-stage complications of this condition (American Diabetes Association, 2017).

Cardiovascular disease (e.g., coronary heart disease and stroke) is the leading cause of morbidity and mortality among persons with diabetes (Qazi and Malik, 2013; American Diabetes Association, 2017). And cardiovascular disease is two to four times more common in adults with diabetes (Fox, 2010). Also, a chronic kidney disease associated with diabetes is present in about 20%–40% of people with diabetes. This health condition is identified by the elevated excretion of urinary albumin, or by the identification of low rates of glomerular filtration, or by other indicators of kidney impairment (American Diabetes Association, 2017).

Diabetes is also the leading cause of blindness and visual impairment in adults (Danet-Lamasou *et al.*, 2018). Also, nerve damage, combined with peripheral vascular disease, make diabetes the most common cause of lower extremity amputation (Hoffstad *et al.*, 2015). Between 60% and 70% of persons with diabetes have mild to severe forms of diabetic nerve damage, and more than half of lower limb amputations in the United States occur among those people with diabetes (National Institute of Diabetes and Digestive and Kidney Diseases, 2018).

As the evidence indicates, and for all types of diabetes, the risk of developing complications and the progression of the disease, is considerably reduced with tight control of blood glucose levels. Results from the Diabetes Control and Complications Trial Research on type 1 diabetes (Diabetes Control and Complications Trial Research Group *et al.*, 1993), the United Kingdom Prospective Diabetes Study on type 2 diabetes (Ismail-Beigi *et al.*, 2010), and the Kumamoto study (Ohkubo *et al.*, 1995), confirmed that better glycemic control is associated with reductions in both the incidence and the progression of retinopathy and nephropathy in subjects with type 1 and type 2 diabetes mellitus. Available evidence also links macrovascular disease (cardiovascular, peripheral vascular and cerebrovascular disease) to glycemic status (Qazi and Malik, 2013; American Diabetes Association, 2017). Furthermore, subjects with good long-term glycemic control have better survival rates than those with elevated fasting blood glucose (Diabetes Control and Complications Trial Research Group *et al.*, 1993; American Diabetes Association, 2017).

Clinical Management of Diabetes in the Elderly

Older adults with diabetes require careful management of their diabetes condition, with a focus on minimizing long-term vascular complications. Therefore, this should be an important focus in defining glycemic targets.

Careful planning and adherence to the clinical management designed for the elderly with diabetes can provide good glycemic control. The initial clinical management of diabetes in the elderly usually consists of medical nutrition therapy and increases in physical activity. However, few older adults can adhere strictly to the required changes in diet and physical activity, and controlling hyperglycemia becomes a challenge. Therefore, in the vast majority of cases, drug therapy is needed soon after the disease is detected. Drug options include second-generation oral sulfonylureas, metformin, acarbose, insulin, insulin analogs, and combinations of these drugs (American Diabetes Association, 2017). These drugs have demonstrated efficacy in increasing insulin availability, decreasing insulin requirements, or both. Additionally, a combination therapy with dipeptidyl peptidase-4 inhibitor (DPP4i) and sodium-glucose cotransporter type 2 inhibitor (SGLT2i) has been reported to be safe and effective in treating type 2 diabetes (Cho *et al.*, 2018).

Self-monitoring of blood glucose by the elder diabetic, along with clinical diabetes monitoring of hemoglobin AIC are good parameters for monitoring the disease, as it informs the medical team about glucose control during the past 3 or 4 months. A1C lower than 7% is usually the goal of achieving good control (American Diabetes Association, 2017).

The evidence is lacking about the benefits of tight glycemic control in older adults (older than 65 years of age). However, elderly diabetic patients with a prognosis for extended life and who can manage their disease should have the same goals for glycemic control as younger adults, as seen in **Table 6**. For elders with advanced diabetes, disease complications, advanced cognitive or physical impairment, or comorbidities that may reduce their life expectancy, less intensive goals can be pursued. In any case, it is advisable to individualize the clinical management of diabetes among elderly individuals (American Diabetes Association, 2017). In particular, factors like duration of diabetes, age, life expectancy, comorbidities, including CVD or microvascular complications plus other individually-identified considerations, must be taken into consideration (American Diabetes Association, 2017).

Proper clinical and self-management of older adults with diabetes is often difficult and costly due to circumstances associated with aging and comorbidities. Physical ailments, affective or cognitive disorders, psychosocial problems such as depression and living situation can all interfere with the proper management of diabetes in the elderly and potentially exacerbate problems associated with noncompliance with medications, the absence of glucose monitoring, and lack of adequate physical activity (American Diabetes Association, 2017). Additional comorbidities and adverse complications are listed in **Table 7**.

Furthermore, the impact of cardiovascular risk factors is significant among older adults with diabetes. Therefore, the management of diabetes requires tight control of cardiovascular risk factors, including hyperglycemia, hypertension, and dyslipidemia.

Table 6 Goals for glycemic and cardiovascular control of adults

Goal	*Criteria*
For glycemic control	
Hemoglobin A1c	<7% (53 mmol/mol)
Preprandial plasma glucose	80–130 mg/dL (4.4–7.2 mmol/L)
Postprandial plasma glucose	<180 mg/dL (10.0 mmol/L)
For cardiovascular health control	
Blood pressure	Systolic <130 mmHg and/or diastolic <80 mmHg
Lipid profile	
High-density lipoprotein cholesterol	Men: >40 mg/dL (1.0 mmol/L) Women: >50 mg/dL (1.3 mmol/L)
Low-density lipoprotein cholesterol	<100 mg/dL (2.6 mmol/L)
Triglycerides	<150 mg/dL (1.7 mmol/L)

American Diabetes Association (2017). Standards of medical Care in Diabetes. *Diabetes Care* 40(Suppl. 1), S1–S135.

Table 7 Comorbidities and adverse events in older adults with diabetes

Co-existing illnesses
Coronary heart disease
Hypertension
Stroke
Geriatric syndromes
Cognitive impairment
Urinary incontinence
Injurious falls
Polypharmacy
Persistent pain
Adverse health events
Functional disability
Premature death

American Diabetes Association (2017). Standards of medical Care in Diabetes. *Diabetes Care* 40(*Suppl. 1*), S1–S135.

Diabetes needs to be viewed and treated as part of the metabolic syndrome, keeping in mind that the main goals of diabetes management, whenever the circumstances apply, are tight glycemic control and more aggressive management of risk factors associated with cardiovascular disease.

Conclusion

The rapidly increasing rates of diabetes among older adults and the tremendous social and economic impact of the disease require that it be treated as a high-priority public health problem. Prevention of the disease among the growing elderly population is the best strategy to reduce the burden of diabetes. Lifestyle strategies (healthy eating and increased physical activity) are more effective than drugs for preventing the development of diabetes, as indicated results from the Diabetes Control and Complications Trial Research Group *et al.* (1993). These lifestyle changes were particularly successful for people older than age 60.

From this evidence, a strong argument can be made for focusing on the prevention of diabetes in older adults through improvement of the favorable factors, particularly lifestyle factors, associated with diabetes control.

Carbohydrate Metabolism: Diabetes Mellitus, Genomic Aberrations☆

RK Semple, University of Cambridge Metabolic Research Laboratories, Cambridge, United Kingdom

Glossary

Acanthosis nigricans A velvety and pigmented skin rash, usually on the back of the neck, armpits or other flexures.
Autoimmune A condition in which the immune system attacks certain cells, tissues, or organs, resulting in their being damaged or destroyed.
Autosomal dominant The pattern of inheritance of a disease resulting from the inheritance of a single mutated gene that is passed down from one parent, with each child of an affected parent having a 50% chance of inheriting the condition.
Autosomal recessive The pattern of inheritance of a disease resulting from the inheritance of two copies of a mutated gene, one from each parent; there is a 25% chance of conceiving an affected child with each pregnancy from unaffected parents each with a single copy of the mutated gene.
Heterozygous The presence of two different copies of a given gene.
Homozygous The presence of two of the same copies (normal or mutated) of a given gene.
Hyperandrogenism Abnormally high levels of male sex hormones, which in woman can result in abnormal facial hair growth, an enlarged clitoris, and/or irregular or absent menses.
Hypertriglyceridemia Abnormally high levels of triglycerides (fat) in the blood.
Insulin A hormone secreted by beta-cells of the pancreas that promotes the uptake of glucose from the bloodstream into cells where the glucose is used as energy or is stored for future use.
Insulin resistance Decreased ability of insulin to lower blood glucose.
Ketoacidosis A condition in which toxic ketones and acids accumulate in the bloodstream and organs of the body.
Penetrance The likelihood that a mutated gene, when inherited, will result in a disease.
Polygenic The involvement of multiple genes in the development of a disease or condition.

Introduction

Diabetes mellitus is simply defined by an abnormally high blood glucose concentration. The arbitrary diagnostic levels of blood glucose were assigned based on natural history studies establishing the glucose threshold at which hyperglycaemia-related clinical complications start to occur. All forms of diabetes require pancreatic beta cell failure to secrete adequate amounts of insulin. This beta cell failure ranges from the absolute, as in type 1 diabetes, to the relative – that is, insulin secretion persists but is insufficient to maintain normal blood glucose in the face of insulin resistance. In the case of severe insulin resistance insulin secretion may actually be elevated to one or two orders of magnitude above normal, but is nevertheless unable to compensate for the degree of tissue insulin resistance present. The long term complications of hyperglycemia, and those used in setting diagnostic criteria, are eye disease (retinopathy), kidney disease (nephropathy), and nerve disease (neuropathy). Diabetes is also strongly associated with premature atherosclerotic vascular disease (heart attack, stroke, and lower limb amputation), however this is less directly linked to hyperglycemia *per se*, and more directly attributable to other aspects of the metabolic derangement seen in diabetes such as an altered lipoprotein profile.

Diabetes mellitus is divided into many subtypes depending on the underlying aetiology, where known, or on non specific biochemical characteristics such as degree of beta cell failure. Forms of diabetes due to mutations in single genes represent at most a few per cent of all diabetes, but have a high penetrance. At least in the case of monogenic beta cell failure, environmental factors have less influence than in the more common forms of diabetes which are heterogeneous and caused by variation in multiple genes (Fig. 1).

Single-Gene Causes of Diabetes

Traditional family-based genetic studies, or studies of "candidate genes" in patients with rare familial forms of diabetes, particularly in the 1990s, had great success in identifying single gene defects causing diabetes. Since the application of next generation sequencing technologies over the past 10 years, the number of single gene forms of diabetes has increased enormously, although in some cases only a handful of families, or even a single individual have been reported. The genetic basis and characteristic features of a selection of currently known monogenic diabetes syndromes, including all those that are less rare, are summarised in Tables 1–3.

	Sporadic or AR	*ABCC8*		
	AR	*INS*	Proinsulin	c. 15% PNDM
	AR	*GCK*	Glucokinase	
Transient neonatal diabetes (c.50% neonatal DM)	Sporadic or AD with parent of origin effect	*PLAGL1 (ZAC)*	ZAC tumour repressor	Both genes are expressed only from the paternal allele. In TNDM expression is increased due to altered methylation, or due to an extra copy of the paternal allele. Accounts for c. 70% of TNDM.
		HYMAI	HYMAI	
	Sporadic or AD	*KCNJ11*	See above	Mutations generally distinct from those causing PNDM
	Sporadic or AR	*ABCC8*		
	AR	*INS*	Proinsulin	
Maturity onset diabetes of the young (MODY) 1	AD	*HNF4A*	Hepatic Nuclear Factor 4α	Low HDL and high LDL cholesterol common. Sensitive to sulphonylureas
MODY 2	AD	*GCK*	Glucokinase	Mild, non progressive hyperglycaemia only
MODY 3	AD	*HNF1A*	Hepatic Nuclear Factor 1α	Commonest form of MODY; Very sensitive to sulphonylureas; Glycosuria an early feaure
MODY 4	AD	*PDX1*	pancreatic and duodenal homeobox 1	Extremely rare
MODY 5	AD	*HNF1B*	Hepatic Nuclear Factor 1β	Developmental anomalies in kidneys, pancreas and genital trac common. Renal cysts most common
MODY 6	AD	*NEUROD1*	Neuro D1 transcription factor	Extremely rare
Maternally inherited diabetes and deafness (MIDD)	Maternal	*$tRNA^{Leu}$, deletions*	$tRNA^{Leu}$, deletions	Diabetes manifest mostly by decreased insulin secretion and also accompanied by deafness or milder degree of hearing loss

**KCNJ11*, *ABCC8* and *INS* cause up to 1% of MODY cases, but they are far better known for their role in neonatal diabetes (see below). Other genes have also been implicated in MODY including *BLK*, *KLF11* and *CEL1*.

Maturity-Onset Diabetes of the Young (MODY)

Maturity-onset diabetes of the young (MODY) was classically described as autosomal dominantly transmitted diabetes with onset during childhood or early adulthood, lack of obesity (in most cases), and impaired insulin secretion without evidence of antibodies against beta cells. Classical criteria suggested to identify MODY since the 1970s are diagnosis during the first to third decades of life of diabetes in two or more consecutive generations of the same family, with at least one member diagnosed under 25 years of age. More recent screening using modern genetic technologies has shown that some patients with sporadic diabetes also have MODY, and has also allowed a wider view of the phenotypic spectrum. This has lead to the suggestion that the term

Table 2 Selected monogenic forms of insulin resistant diabetes

Syndrome	*Mode of inheritance*	*Gene*	*Gene product*	*Distinguishing features/comment*
Primary Disorders of Insulin Signalling				
Donohue Syndrome (formerly leprechaunism)	AR	*INSR*	Insulin receptor	Extreme insulin resistance, impaired linear growth, paucity of fat and muscle but overgrowth of many other soft tissues. Death usually in infancy.
Rabson–Mendenhall syndrome	AR	*INSR*	Insulin receptor	Milder than Donohue Syndrome, also featuring impaired linear growth, soft tissue overgrowth and extreme insulin resistance. Abnormal dentition and nails, protuberant abdomen, and thick rapidly growing hair usual
Type A Insulin Resistance	Usually AD (may be AR or sporadic)	*INSR*	Insulin receptor	Severe insulin resistance with a normal lipid profile, no fatty liver, and preserved or elevated plasma adiponectin. Acanthosis nigricans, hyperandrogenism,
SHORT Syndrome	AD or sporadic	*PIK3R1*	p85α regulatory subunit of phosphatidylinositol-3-kinase	Short stature, Hyperextensibility or hernias, Ocular depression, Rieger's anomaly, delayed Teething. Lipodystrophy and severe insulin resistance common.
Severe insulin resistance	AD	*AKT2*	Serine threonine kinase AKT2 (protein kinase B)	Severe insulin resistance, found in one family only to date
Lipodystrophies				
Familial partial lipodystrophy (FPLD)	AD	*LMNA*	Lamin A/C	Loss of subcutaneous fat from whole body except head and neck and labia majora
	AD	*PPARG*	Peroxisome proliferator-activated receptor γ (PPARγ)	Lack of fat usually limited to the limbs, and may be subtle; hypertension common
	AD	*PLIN*	Perilipin	Limb lipodystrophy
Congenital Generalised Lipodytrophy (CGLD)	AD	*BSCL2*	Seipin	Mutations in these genes account for 95% of cases of congenital generalised lipodystrophy.
	AR	*AGPAT2*	1-acylglycerol-3-phosphate D-acyltransferase 2	
	AR	*PTRF*		Myopathy. Bone marrow fat may be preserved
	AR	*PCYT1A*	phosphate cytidylyltransferase 1 alpha (PCYT1A)	Also associated with spondylometaphyseal dysplasia + cone-rod dystrophy.

"MODY" be abandoned in favor of precise labeling with the relevant gene name, however the label "MODY" continues to be widely used. There are more than six known forms of MODY defined by the underlying genetic defects.

MODY2 is caused by a mutation in glucokinase, an enzyme produced in pancreatic beta-cells and important for glucose sensing and insulin secretion. Heterozygous loss-of-function mutations in glucokinase lead to an elevated setpoint for blood glucose, with glucose homeostasis otherwise preserved. Hyperglycemia in patients with MODY2 is typically mild, non progressive, and can be treated by diet. Chronic diabetic complications are very rare. MODY1, 3,4,5 and 6, in contrast, are caused by mutations in transcription factors that are expressed in the pancreas and are thought to play a role in beta-cell development and function. These include, most importantly, hepatocyte nuclear factors 4α (MODY2), 1α (MODY3), and 1β (MODY4). HNF1α is the most frequent gene mutated in MODY. Patients with MODY due to mutations in these transcription factors typically have a progressive decrease in insulin secretion with increasing endogenous insulin requirements. Long-term diabetes complications occur with similar frequency to more typical forms of diabetes. In addition, renal cystic disease is a common feature of MODY4 caused by HNF1β mutations.

One of the major challenges in population-wide management of MODY is now to ensure that those affected have access to diagnostic testing, which is particularly important as many patients with transcription factor MODY can safely be managed in the long term on oral sulphonylurea therapy, sometimes even managing to transition from to oral therapy after several years of injected insulin. A variety of different biochemical tests have been employed to aid calculation of MODY risk prior to genetic testing, which has greatly increased rates of diagnosis.

Neonatal Diabetes Mellitus (NDM)

Diabetes presenting in the first 6 months of life is almost invariably non-autoimmune in origin. It is rare and affects 1 in 90000–260000 births. Two subgroups exist, namely Transient Neonatal Diabetes (TNDM), which usually remits by 12 weeks but may relapse after some years and Permanent Neonatal Diabetes (PNDM). Mutations in >20 genes have now been associated with NDM.

Table 3 Selected complex diabetes syndromes

Syndrome	*Mode of inheritance*	*Gene*	*Gene product*	*Distinguishing features/comment*
Insulin-Deficient Diabetes				
Wolfram Syndrome	AR	*WFS1*	WFS1	Optic atrophy, diabetes insipidus, and deafness. Additional features may include renal abnormalities, ataxia, dementia or mental retardation.
Wolcott–Rallison syndrome	AR	*EIF2AK3*	Eukaryotic translation initiation factor 2-alpha kinase 3	Short stature, skeletal dysplasia
Thiamine-responsive megaoloblastic anemia syndrome	AR	*SLC19A2*	Thiamine transporter SLC19A2	Classic triad is megaloblastic anemia, diabetes, and deafness
Histiocytosis-lymphadenopathy plus syndrome (encompassing H syndrome)	AR	*SLC29A3*	Nucleoside transporter SLC29A3	Complex disease spectrum that may include short stature, organomegaly, hypertrichosis, exocrine pancreatic insufficiency, and multisystem inflammation.
Insulin Resistant Diabetes				
Alström syndrome	AR	*ALMS1*	ALMS1	Early onset blindness due to rod-cone dystrophy; sensorineural deafness; cardiomyopathy; obesity; renal failure
MOPDII	AR	*PCNT*	Pericentrin	Primordial dwarfism with skeletal dysplasia
Werner Syndrome	AR	*WRN*	Werner DNA helicase	Loss of peripheral fat and contractures, cataracts, greying hair, atherosclerosis and cancers in the 3rd decade
Bloom Syndrome	AR	*BLM*	Bloom DNA helicase	Short stature, cutaneous photosensitivity, hypogonadism
Primordial dwarfism with severe insulin resistance	AR	*NSMCE2*	NSE2 or MMS21 SUMO ligase	Primordial dwarfism, hypogonadism
Mandibular hypoplasia, Deafness and Progeroid features (MDP) syndrome	AR	*POLD1*	DNA polymerase delta, catalytic subunit	Selective loss of subcutaneous adipose tissue with contractures, sensorineural deafness, male hypogonadism

40% of PNDM is caused by activating mutations in the KCNJ11 and ABCC8 genes, encoding subunits of the pancreatic β-cell potassium-sensitive ATP channel. These mutations lead to severely reduced or absent insulin secretion, but, critically, this may be treated successfully with high doses of sulfonylurea. Some channel mutations also cause psychomotor developmental delay, epilepsy and diabetes, known as DEND syndrome. Insulin (INS) gene mutations cause around 15% of PNDM, leading to ketoacidosis and requiring lifelong insulin treatment. Biallelic inactivating mutations of GCK are a rare cause of insulin-dependent PNDM.

TNDM usually presents in the 1st week of life but disappears by the 12th week, although it recurs later in childhood in around 50% of cases. Insulin treatment is needed but can gradually be weaned. Although TNDM may be caused by mutations in KCNJ11, ABCC8 or INS, in most cases it is caused by abnormally increased expression of the PLAGL1 (also known as ZAC) or HYMAI genes on chromosome 6q24. This region is imprinted, with only the allele inherited from the father being expressed. Diabetes results when an extra copy of the paternal allele is inherited, when two paternal copies but no maternal copies of the locus are found, or when abnormal methylation and thus expression of the maternal allele is seen.

Primary Disorders of Insulin Signalling

Genetic syndromes of extreme insulin resistance may result from mutations in genes encoding key elements of the insulin signaling pathway that transmits the insulin signal into responsive tissues. Mutations in the insulin receptor gene itself, INSR, have been known since the late 1980s, and more than 150 mutations are now known. Mutations impair the ability of insulin to stimulate glucose uptake and use. Characteristically, glucose levels are normal to elevated and insulin levels are very high (due to compensatory increases in beta-cell insulin secretion). At least three distinct clinical syndromes of extreme insulin resistance exist: type A syndrome, Donohue syndrome (formerly known as leprechaunism), and Rabson–Mendenhall syndrome. Donohue and Rabson–Mendenhall syndrome are extremely rare, featuring mutations in both alleles of the receptor gene, and are inherited as an autosomal recessive disorder. Both conditions, as well as extreme insulin-resistant diabetes, feature failure to thrive and impaired linear growth, with soft tissue overgrowth including skin, hair, and viscera. They form a phenoypic spectrum broadly determined by the degree of loss of receptor function. Type A syndrome is considerably more common, and is usually autosomal dominant, being caused by mutations that have the ability to interfere with the function of the co-expressed wild type allele. Type A syndrome most commonly presents as a severe form of "polycystic ovary syndrome" in a lean adolescent girl with acanthosis nigricans, with diabetes and insulin resistance often only discovered during subsequent investigation. Males present much later, and indeed may commonly remain undetected, diagnosed simply as "Type 2 diabetes" in midlife.

The only other form of diabetes caused by a mutation of an insulin signaling gene, and known to affect more than a handful of individuals, is SHORT syndrome. SHORT denotes Short stature, Hyperextensibility or hernias, Ocular depression, Rieger's anomaly (a developmental abnormality of the iris), and delayed Teething. Although not featuring in the acronym, lipodystrophy and severely insulin resistance diabetes are common, although uniquely among lipodystrophic forms of diabetes, lipid profiles are characteristically benign. SHORT syndrome is caused by mutations affecting a regulatory subunit of the enzyme phosphaidylinositol-3-kinase, which is activated in cells by stimulation of the INSR.

Congenital Generalized Lipodystrophy

Congenital generalized lipoatrophic diabetes (CGL), or Berardinelli–Seip syndrome, is a rare, autosomal recessive disorder characterized by the near absence of adipose tissue from birth. This leads to severe insulin resistance with attendant clinical features (glucose intolerance or overt diabetes, hyperandrogenism and early puberty, acanthosis nigricans) as well as hypertriglyceridemia with enlarged, severely fatty liver, and prominent muscles. Mutations in either the BSCL2 gene, encoding an endoplasmic reticulum-associated protein called seipin, or in the AGPAT2 gene, encoding1-acylglycerol-3-phosphate-D-acetyltransferase 2, which plays a key role in triglyceride synthesis, account for around 95% of cases. CGL provide one of the stronges pieces of evidence for the critical importance of fat tissue in metabolic health: without adipose tissue in which to store excess ingested calories safely, lipid and other toxic metabolites accumulates in liver, muscle and elsewhere, blocking insulin action. Severe calorie restriction is an effective though very challenging treatment. Subcutaneous injections of the satiety hormone leptin, which is extremely low or absent in CGL, can blunt he increased appetite often seen in CGL and thereby facilitate dietary restraint, and is now licensed for therapeutic use in some parts of the world including the USA.

Familial Partial Lipodystrophy

Partial lipodystrophy refers to failed or abnormal development of adipose tissue in only some regions of the body. This is often inherited as an autosomal dominant disorder, and is the commonest inherited form of severe insulin resistance with diabetes. The prototypic and commonest form is known as Familial partial lipoatrophic diabetes (FPLD) type 2 (FPLD2), also referred to as Dunnigan-Köbberling familial partial lipoatrophy. It is an autosomal dominant disorder that results from mutations in the lamin A/C gene. Affected patients have apparently normal fat distribution until puberty, when failure of normal pubertal subcutaneous fat tissue accretion in the arms, trunk, and lower extremities unmasks the underlying disorder. The face is typically spared from fat loss, and fat may actually accumulate abnormally in the head and neck, labia majora, and intra-abdominal region. As in CGL, insulin resistant diabetes, dyslipidaemia (often leading to pancreatitis) and severe fatty liver are the norm, and are seen together with features of severe insulin resistance described above.

The second most common form of familial partial lipodystrophy, sometimes known as FPLD4, is caused by mutations in the PPARG gene, which encodes the nuclear receptor that is the target of the thiazolidinedione class of anti-diabetic pharmaceuticals. The degree of subcutaneous fat loss in this condition is often less striking than in FPLD2, with truncal fat often relatively preserved, and indeed in some cases the disorder features only an unusually centripetal pattern of fat mass rather than frank lipodystrophy. Early hypertension and pre-eclampsia appear to be particularly common in this subset of lipodystrophy.

Other Single-Gene Diabetes Syndromes

Many other rare single gene forms of diabetes exist, some of which feature the metabolic disorder only in the context of a much more complex, multisystem disorder. Detailed treatment of these is beyond the scope of this article, however a selection of the disorders is shown in Table 3.

Genetics of Common Forms of Diabetes

The single-gene forms of diabetes described so far constitute no more than 2–5% of cases of diabetes. The more common forms of diabetes are known to have important genetic underpinnings but are not inherited in a predictable pattern. This observation suggests that the common forms of diabetes are likely to be due to several (many) mutant genes that are relatively common in the population. Each gene variant individually is likely to have a modest effect, but together the mutant genes act additively or synergistically. Furthermore, environmental provocations are thought to have important effects on the likelihood that a given gene variant or group of gene variants will express themselves. Thus, the common forms of diabetes are classified genetically as being heterogeneous and complex.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus (T1DM) occurs predominantly in children and adolescents. In the United States, T1DM accounts for approximately 5–10% of all diabetic cases diagnosed. The incidence of T1DM is inexorably rising, but varies greatly worldwide, with the highest reported incidence in Northern Europe and the lowest rates in China, Korea, and Mexico. T1DM is characterized by autoimmune-mediated dysfunction and destruction of the beta-cells of the endocrine pancreas, resulting in insulin deficiency with potential for ketoacidosis,

coma, and death if untreated. The beta-cell loss begins months to years before the actual clinical onset of insulin dependency. Environmental factors such as viral infections and toxins have been suggested to play a key role in the pathophysiology of this disorder. These environmental provocations may activate cells of the immune system (T lymphocytes, B lymphocytes, and natural killer cells), initiating and perpetuating a chronic inflammatory reaction that ultimately leads to beta-cell loss and insulin deficiency.

The greatest genetic risk for T1DM lies in a cluster of genes on chromosome 6, termed the human leukocyte antigen (HLA) locus, which is known to modulate immune function. The presence of certain HLA haplotypes has long been known to predispose individuals to T1DM, whereas other HLA haplotypes appear to be protective. Even before the advent of "next generation" sequencing in the last decade, other genes or chromosomal loci had also been implicated in defining the risk of developing T1DM, including variants near the proinsulin gene and the cytotoxic T-cell lymphocyte associated-4 (CTLA4) gene. Nevertheless it is only with the development of technologies to analyze massive amounts of gene sequence data in parallel, and to compare these between patients with and without T1DM, that major inroads have been made into understanding the nature of the immunological perturbation underlying T1DM. Continuing work is uncovering the precise autoantigens that play a key role in initiation of beta cell autoimmunity, and is gradually elucidating the key role played by cytokines such as IL-2 in the propagation of the immune insult. As this work progresses, so further complementary advances are expected in both risk estimation for individuals, and in development of targeted immunotherapy to delay or halt the disease process.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus (T2DM) is the most common form of diabetes, accounting for at least 90% of all cases. Its prevalence has reached pandemic proportions, with 350 million people estimated to be affected worldwide. Hyperglycemia and overt diabetes result from underlying insulin resistance and impaired insulin secretion secondary to beta-cell dysfunction and failure. Unlike T1DM, the beta cell failure in T2DM is not autoimmune in origin. Both environmental factors (caloric excess and physical inactivity) and genetic predisposition have been implicated in the pathogenesis of T2DM. The strongest evidence for genetic predisposition to T2DM comes from identical twin studies (with 60–90% concordance rates) and studies that show clustering of the disease in families. Current estimates of heritability – that is, the proportion of the prevalence attributable to genetic risk – have ranged from 30–70%. However the underlying genetic risk factors are thought to be heterogeneous.

The first phase of research into the genetic basis of T2DM focused on genetic linkage studies within families, or on detailed study and comparison of candidate genes between affected and unaffected groups. However although such studies led to the identification of several putative T2DM susceptibility genes, not all of these stood up to replication studies, and in retrospect this research approach, limited by the genetic technologies of the time, appears very inefficient. The sequencing of the human genome, and the development of techniques to study common genetic variations across the whole genome in large populations using the so-called genome-wide association study (GWAS) approach, however, has transformed efforts to identify the genes underlying T2DM risk. GWAS-based studies have now identified more than 80 genetic variants associated with T2DM risk. A large minority of these play roles in pancreatic beta cell function or growth, and a smaller number are believed to be involved in insulin action in tissues. The roles played by many of the associations remain to be explained, however.

Despite the excitement around GWAS, only a small amount of the heritability of T2DM has so far been explained, and even the most comprehensive gene-based risk scores perform little better than panels of conventional clinical risk markers. Nevertheless, as the power of next generation sequencing is used in following up these GWAS studies, it is very likely that sufficient insights will be gained into the nature of T2DM susceptibility to make major differences to our understanding of its pathogenesis, and o development of possible novel treatment approaches.

Conclusion

Diabetes mellitus is a heterogeneous group of disorders defined by hyperglycemia. An increasing number of forms of diabetes are known to be caused by mutations in single genes. Although these single-gene forms of diabetes are rare (approximately 2–5% of cases), they have provided important insights into glucose regulation and into the underlying disease process. In some cases discovery of the genetic defect has led to dramatic, mechanism-based changes in the medical care of affected patients, as seen in the use of sulfonylureas in neonatal diabetes and MODY, and the use of leptin in CGL. By contrast, T1DM and T2DM are far more common and are due to the interaction of multiple genes with the environment. Identification of the genes responsible for susceptibility to these common forms of diabetes has been slower, but use of modern genetic technologies in large populations has recently dramatically accelerated elucidation of their genetic "architecture". As this work continues, personalized risk assessments and diabetes treatments based on individual genetic profiles will becomes increasingly practical aims in routine clinical care.

Lifestyle Diabetes Prevention

Ahmad Alkhatib and Jaakko Tuomilehto, Dasman Diabetes Institute, Dasman, Kuwait

Introduction

Diabetes is a known major cause of premature mortality with high economic costs. The future predictions are also gloomy given that 1 in 10 people worldwide are expected to have type 2 diabetes (T2DM) by 2030 (IDF, 2015). The global prevalence of diabetes especially T2DM, is no longer a problem solely for the developed western world such as the UK and US, but there is an emerging trend of increasing prevalence in developing countries, especially in Asia. On the one hand, T2DM continues to rise in most populations around the world. For example, there was a 60% increase in diagnoses in the last 10 years and a 10% rise in National Health Service spend on drugs to manage this condition (Diabetes UK, 2015). On the other hand, Asia is set to become the 'epicenter' of this epidemic with noted proportionally higher levels of young to middle-aged people being diagnosed with T2DM (Shaw *et al.*, 2010). The consequences of diabetes epidemic are alarming, and a diabetes-related mortality event is recorded every 7 s, and unfortunately it is thought that current statistics underestimate the true prevalence, with almost 50% of cases undiagnosed (IDF, 2015).

Common diabetes determinants include excess body fat, poor nutritional habits, physical inactivity, high blood pressure, and family history of diabetes (IDF, 2015). Obesity in particular, is considered a significant contributory factor in the development of T2DM, especially that both obesity and T2DM cases continue to grow in parallel at an alarming rate (WHO, 2016). Despite major steps taken to reverse the trend by public health strategies, there has been increased growth in patient numbers and Diabetes, especially T2DM remains a significant cause of premature mortality in many countries, along with other major non-communicable diseases (NCDs) such as cardiovascular disease (CVD) and cancer (WHO, 2016).

Based on such determinants, appropriate prevention strategies have primarily focused on lifestyle interventions involving physical activity and diet. Diet and exercise prevention strategies focusing on pre-diabetes and high-risk individuals have conclusively shown significant reduction in T2DM incidence rate around the world, ranging from 28% to 58% (Tuomilehto *et al.*, 2001; Knowler *et al.*, 2002; Pan *et al.*, 1997; Ramachandran *et al.*, 2006). Such evidence made essential for more countries to adopt community-based interventions to reduce obesity and T2DM (Diabetes UK, 2015), and emphasizes the role of lifestyle prevention using physical activity and healthy nutritional strategies. However, lifestyle prevention of diabetes also requires a personalized approach and an understanding of the inter- and intra-individual variability in prescribing and promoting a dietary or an exercise intervention. A personalized approach may also play an adjunctive role when applying pharmaceutical therapies in combination with lifestyle to prevent and manage diabetes.

This article discusses the latest research advances in lifestyle prevention of diabetes, with a particular focus on the role of physical activity, innovative nutritional and exercise-based interventions and their single or combined effectiveness. For example, certain functional foods have been scientifically proven to have unequivocal health benefits in preventing T2DM and associated NCDs. The health protective effectiveness of functional foods can be enhanced by a variety of physical activity patterns, including moderate intensity exercise, high-intensity training and strength training. However, the effectiveness of a multi-component lifestyle intervention needs to consider behavioral barriers and associated models to ensure long term adherence. The article will shed some light on how such lifestyle preventative benefits can fit within individualized and localized multi-component T2DM prevention and management models.

Understanding the Lifestyle Determinants of Type 2 Diabetes

Sedentary Lifestyle and Physical Inactivity

Physical activity is defined as any bodily movement produced by the skeletal muscles that use energy. This includes any daily activity such as walking, doing household responsibilities or gardening, or regular physical activities defined as "exercise" and organized physical activities as "sports" such as soccer. Sedentariness has been defined as any waking behavior characterized by an energy expenditure $\leq$1.5 METs (metabolic equivalent of task) while in a sitting or reclining posture such as seated computer use, driving, reading, watching TV or lying down (Sedentary Behavior Research Network, 2012).

Sedentary lifestyle is a major cause of obesity, overweight, and is directly and indirectly linked with major chronic diseases including diabetes and cardiovascular disease (WHO, 2016). The highest prevalence of sedentary behavior exists within the Americas and the Eastern Mediterranean region. Given that 31% of the world's population is physically inactive, amounting for 6% of mortality rates, and that 27% of diabetes cases are attributed to low activity levels (WHO, 2016), it is essential to understand the determinants of both sedentariness and physical inactivity in diabetes prevention.

Sedentary behaviors such as watching TV and prolonged sitting hours are now known causes of diabetes and cardiovascular disease (Hu *et al.*, 2004a,b; Alkhatib, 2016a). Approximately 55% of the waking day is spent in sedentary activity, and individuals

 doi:10.1016/B978-0-12-801238-3.64358-1

who spend >10 h a day sitting have a 34% higher all-cause mortality risk than those who spend just one hour of their waking day sitting (Matthews *et al.*, 2008) which could be either a leisure-based or workplace-based sedentariness (Alkhatib, 2016b; Chau *et al.*, 2012). Epidemiological evidence reported that sitting activities such as one hour of watching TV is associated with 21.8 min reduction in life expectancy (Veerman *et al.*, 2012) whilst TV watching is associated with the risk of T2DM, cardiovascular disease and all-cause mortality, independently of physical activity levels (Grøntved and Hu, 2011). More alarmingly, the sedentary-related health risks, including CVD and mortality risk, may not be reversed by only meeting physical activity guidelines (Biswas *et al.*, 2015). Recent meta-analysis of data from >1 million men and women suggested that physical activity does not attenuate or eliminate the detrimental association of sitting time with mortality (Ekelund *et al.*, 2016), which suggests that sedentary behavior needs to be addressed independently of physical inactivity in T2DM prevention.

Sedentary lifestyle is even more dangerous for those with T2DM, who have been noted to take on average 2000 less steps per day compared to their non-diabetic counterparts (Liese *et al.*, 2013). A dose–response relationship exists between the volume of time of uninterrupted sitting and poor metabolic health (Owen *et al.*, 2010). Measures of glycemic control [insulin resistance, fasting glucose and 2-h postprandial glucose] were all associated with sedentary time and patterns in individuals with T2DM (Sardinha *et al.*, 2017). Recent objective assessment of sedentary and physical activity levels using accelerometers, showed that adults with T2DM were not sufficiently active (<30 min day^{-1} of moderate activity), were highly sedentary (over 9 h day^{-1}), and with their BMI positively correlated with time spent in sedentariness (Mathe *et al.*, 2017). Similar sedentary associations have been reported for hyperglycemia and insulin-resistance levels over 1 year of using concurrent wrist accelerometry and continuous glucose monitoring sensor monitoring T2DM patients (Fritschi *et al.*, 2016). Therefore, reducing sedentary behavior requires further action that is additional to that of promoting physical activity.

Physical activity levels of and exercise capacity are known to be associated with reduced risk of mortality and chronic diseases including diabetes (Myers *et al.*, 2002). Physical activity reduces the risk of several T2DM risk factors especially obesity, and physically active obese appear to have a lower risk of CVD and mortality than lean sedentary individuals (Blair and Brodney, 1999). Several prospective observational studies have reported an association between physical activity and incident diabetes in established cohorts of men and women from different countries (Hu *et al.*, 2004a; Hsia *et al.*, 2005; Wannamethee *et al.*, 2000).

Prospective associations have also been established between physical activity levels in people with T2DM and reduced mortality risk (Church *et al.*, 2005; Hu *et al.*, 2004b), suggesting physical activity levels as a vital prognosis. Evidence from prospective cohort studies and meta analyses involving individuals with diabetes from the EPIC study (European Prospective Investigation Into Cancer and Nutrition) has demonstrated that the lowest mortality risk for people with diabetes was observed in moderately active persons (hazard ratios were 0.60 for all-cause mortality) compared with the physically inactive (Sluik *et al.*, 2012). This suggests that even small amounts of physical activity are beneficial in both prevention and management of diabetes.

Effects of Exercise and Physical Activity on Preventing and Managing T2DM

The role of physical activity training in preventing and managing diabetes is well established through global prospective studies have shown that moderate-to-vigorous physical activity is associated with a 28%–58% reduction in the risk of developing T2DM (Pan *et al.*, 1997; Tuomilehto *et al.*, 2001; Knowler *et al.*, 2002). Both the Finnish Diabetes Study (Tuomilehto *et al.*, 2001) and the US Diabetes Prevention Program (Knowler *et al.*, 2002) have remarkably demonstrated a 58% reduction in T2DM incidence. One showed that moderate exercise, even without achieving target weight-loss induces significant risk-reduction reaching 70% (Tuomilehto *et al.*, 2001; Laaksonen *et al.*, 2005), and the other showed 58% reduced incidence rate compared with taking Metformin (Knowler *et al.*, 2002). More recently the Look Ahead Multicenter Study concluded that enhancements in moderate to vigorous exercise significantly improves the management of cardiovascular diseases risk factors in T2DM participants, and thereby reduces medication use and associated treatment cost (Redmon *et al.*, 2010).

Physical activity levels are often expressed by its main determinant, which is aerobic power or cardiorespiratory fitness, among other environmental and genetic determinants such as age, sex, health status and genetics (LaMonte *et al.*, 2005). Aerobic endurance exercise has been the traditional exercise prescription for those with T2DM, but this have evolved to include resistance training for its added cardio-protective benefits for people with T2DM (Yavari *et al.*, 2012). Current exercise recommendations for adults advocate doing aerobic exercise at a moderate intensity for 30 min on minimally 5 days (but preferably most days) of the week. This should be supplemented with strength-based exercise for the large muscle groups on at least 2 days of the week (IDF, 2015), while an alternative adult exercise prescription of 75 min of vigorous aerobic activity (coupled with two days of strength training) also exists (ACSM, 2009).

Several physiological mechanisms have been found to explain the T2DM adaptations associated with such preventative interventions (Sardinha *et al.*, 2017). These include exercise-stimulated signal transduction, which can restore glucose metabolism in insulin-resistant muscle through both acute activation of glucose transport and by improving insulin sensitivity for up to 48 h after exercise (Sylow *et al.*, 2017), partial or complete remission of T2DM in 11.5% of T2DM diagnosed participants within the first year of intervention and an additional 7% had partial or complete remission of T2DM after 4 years of exercise intervention (Gregg *et al.*, 2012), and potential epigenetic adaptations associated with transient changes in DNA methylation in adult skeletal muscle following acute exercise (Barrès *et al.*, 2012; Hargreaves, 2015), that may improve glucose homeostasis.

There are recent suggestions about similar or superior metabolic health benefits from a shorter duration, more intense physical activity types, and the term "high intensity interval training (HIIT)" has been recently proposed, as a time-efficient strategy for

T2DM prevention (Francois and Little, 2015; Rynders and Weltman, 2014; Gibala, 2009). HIIT training consists of repeated short bouts of intense exercise (usually above 80% of maximal oxygen uptake or age-predicted heart rate) lasting for about 1–4 min in duration, followed by approximately equal periods of low-intensity exercise (Gibala, 2009). Evidence is emerging of HIIT effectiveness across different T2DM patient cohorts including enhanced postprandial glycemic control, hepatic and improved muscle insulin resistance (Francois and Little, 2015). For example, reported effects included, a reduction in 24 h glucose levels and a reduced 3-h postprandial glucose, and increased muscle mitochondrial capacity (citrate synthase activity, protein content) in obese T2DM patients (Little *et al.*, 2011). Others reported a reduced insulin resistance after each session of a 4xHIIT sessions in 40-years old T2DM patients (Shaban *et al.*, 2014). Conversely, others reported no additional benefits for increasing the exercise training intensity when participants with T2DM are matched for their energy cost, suggesting that either intensity is equally effective in lowering blood glycated hemoglobin and increasing whole body and skeletal muscle oxidative capacity in obese T2DM patients (Hansen *et al.*, 1999). Interesting comparison was made between HIIT and resistance-type exercise training for 12-weeks, showing that although HIIT is superior in terms of enhancing mitochondrial capacity (protein synthesis), either HIIT or resistance training improves insulin sensitivity, with better combined effects on both hypertrophy and aerobic and mitochondrial capacity in groups of young and older adults (Robinson *et al.*, 2017), suggesting a combined HIIT and strength training approach. However, research is still needed to demonstrate how to define and implement such a strategy as part of a lifestyle prevention and achieve long-term adherence (Biddle and Batterham, 2015). The generalizability of the outcomes from most of the HIIT studies are often hampered by small sample sizes, acute effects nature, training supervision requirement, participants' adherence and injury, and presumed low levels of fitness in people with T2DM, all factors to be still considered before promoting HIIT compared with lower intensity exercise regimes as a diabetes prevention strategy.

Effective physical activity strategies focus on long-term adherence and behavior management using professional behavioral support with the emphasis on the individual and their needs, utilizing their support networks, and are community-based (Daly *et al.*, 2002; Cooper *et al.*, 1999). This is especially important in the absence of an instructor-led exercise intervention, those who are returning to leisure-time exercise following diagnosis can lack confidence and knowledge regarding starting a routine and lifestyle behavior change has been noted to be challenging for those with T2DM (Simonavice and Wiggins, 2008; Ibrahim *et al.*, 2002).

For high-risk individuals who have been physically inactive or sedentary for a long time, conditioning to physical activity in a safe and progressive exercise prescription is important to adopt and adhere to physical activity (Cooper *et al.*, 1999; Daly *et al.*, 2002). For example, adding on 5 min per day of moderate aerobic exercise each week, till the target goal of 150 min week^{-1} is reached, or simply increasing the volume of walking and reducing the volume of sitting (IDF, 2015). Pedometers are noted to be effective motivational and cost-free tools to advancing volumes of walking-based activity, and a baseline of 3000 steps day^{-1} can be used to build upon, adding a little more within the daily routine until the target 10,000 steps day^{-1} is reached (Minsoo *et al.*, 2009; Yates *et al.*, 2014). Home-based exercise could allow a combined aerobic and resistance-based physical activity routines in a safe environment. For example, resistance-band exercise routines can recruit large muscle groups and positively influence lower limb blood flow, and functional strength in people with T2DM (Egaña *et al.*, 2010). Self-managed home-based routines may be able to demonstrate exercise adherence and strength gains with dropout reduced if there is supported instruction and guidance initially (Chan and Ried, 2013). Furthermore, increased compliance can be achieved partners, friends or relatives can also participate with such exercise interventions (Hammond *et al.*, 1997). There is a merit for home-based exercise for the prevention of T2DM additionally to other efforts within the community and local healthcare settings, especially in terms of adherence and overcoming psycho-social barriers and the individually-adapted approach (Cameron and Alkhatib, 2016).

Role for Nutrition in Diabetes

Poor nutritional habits, including reduced calorific expenditure coupled with excess energy intake (calorie-dense, high sugar, high fat diets) has led to increased proportions of the adult population with reduced insulin sensitivity, most of whom are obese (Edelman, 1998; Lieberman, 2003). Truncal (abdominal) obesity, has been linked to raised levels of plasma leptin, fatty acids and tumor necrosis factor-alpha (TNF-α), all are thought to contribute to insulin resistance. The obesity related peptides or adipocytokines such as resistin, adiponectin and ghrelin can lead to higher baseline levels of *E*-selectin, intra-cellular and extra-cellular adhesion molecules, which increase the likelihood of endothelial cell adhesion, promoting the progression of insulin resistance to type 2 diabetes and endothelial dysfunction to atherosclerosis (Vendrell *et al.*, 2004). There can also be a release of protein kinase, heightening production of basement membrane materials and increasing capillary permeability. This pathophysiology coupled with raised levels of free fatty acids, post-prandial hyperlipidaemia and increased production of free radicals contributes to atherosclerosis and cardiovascular disease (Skilton *et al.*, 2005).

Effective Diets and Nutrition in the Prevention and Management of T2DM

While it is established that dietary intake is a key modifiable factor in the prevention and management of T2DM, variety of food patterns comprising healthy food components have been proposed to have health protective benefits. Those diets include Mediterranean style diet, Nordic diet, vegetarian diet, traditional Korean diet, Japanese diet, Dietary Approaches to Stop Hypertension (DASH) diet, and low-glycemic-index diet, and all have shown various degrees of effectiveness in

preventing T2DM or reducing CVD risk in people with diabetes (Archundia Herrera *et al.*, 2017). Common healthy food ingredients within such diets rely on higher intake of plant-based fruits (e.g. berries), vegetables (leafy green vegetables), legumes (including nuts and seeds), wholegrain (e.g. oat), and seafood-based (fish and shellfish), olive oil and rapeseed oil, and lower intake from dairy and meat products.

The Mediterranean diet (MD) has long been known to be one of the healthiest diets associated with longevity and prevention of metabolic and cardiovascular disease (Willett *et al.*, 1995), and is now an established prevention of mortality (Estruch *et al.*, 2013; Salas-Salvado *et al.*, 2014; Salas-Salvado *et al.*, 2008). A typical MD comprise of high intake of plant-based food items such as fruit, vegetables and legumes, a high intake of olive oil, tree nuts and oily fish, moderate intake dairy products and red wine, and low intake of red wine (Martinez-Gonzalez *et al.*, 2012). It has been suggested that MD components provide a model for their joint effectiveness in prevention and management of T2DM (ADA, 2017). Collectively MD components contain a significant amount of polyphenol compounds from both plant based foods (fruits, vegetables, olive oil, tree nuts), and seafood (e.g. oily fish), which makes some researchers attribute MD health protective benefits to polyphenols (Perona *et al.*, 2006; Urpi-Sarda *et al.*, 2012; Alkhatib *et al.*, 2017). Herbs and spices are included sometimes instead of salt are also rich in polyphenols, among other compounds (Esposito *et al.*, 2017).

Healthy MD components are traditionally consumed in regions bordering the Mediterranean region, where MD was associated with longevity (Willett *et al.*, 1995). However, Adherence to MD is dwindling with the spread of westernized diets in such regions (Sofi *et al.*, 2005; Kontogianni *et al.*, 2008; Jimenez-Redondo *et al.*, 2016). Conversely, MD components are not exclusive to any geographical region, and there are promising findings about the implementation of MD in non-Mediterranean regions (Alkhatib and Klonizakis, 2014; Middleton *et al.*, 2015).

Epidemiological studies have long shown an inverse relationship between MD consumption and incidence of T2DM (Panagiotakos *et al.*, 2005) and more recently a reduced risk of gestational diabetes (Karamanos *et al.*, 2014). Additionally, several recent systematic reviews and randomized controlled trials have demonstrated better T2DM management, and enhanced metabolic state with high-risk individuals, including impaired fasting glucose (IFG), impaired glucose tolerance (IGT) and metabolic syndrome, associated with MD consumption (Salas-Salvado *et al.*, 2014; Esposito *et al.*, 2015; Ley *et al.*, 2014).

Compared with control diets, MD adherence has been shown to reduce glycosylated hemoglobin A1c (HbA1c) levels by 0.30%–0.47% in T2DM patients (Esposito *et al.*, 2017), and longitudinally is associated with 14.7% and 5% reduced reliance on medication 1 and 5 years post-diagnosis, respectively compared with low-fat diet (Esposito *et al.*, 2014). Prospective analysis of the PERIMED study (Prevención con Dieta Mediterránea) results of 1–5 years have also shown an inverse T2DM incidence rate associated with MD consumption compared with low fat diet (Salas-Salvado *et al.*, 2014; Salas-Salvado *et al.*, 2008). Recent meta-analyses have demonstrated that adherence to MD components of fruit, vegetables and legumes (measured by MD 1–9 adherence score, and 136-item food frequency questionnaire) (Martinez-Gonzalez *et al.*, 2012) reduces incidence rates irrespectively of obesity changes (indicated by Body Mass Index; BMI) during 9.5-year follow-up, and suggesting that MD may attenuate the adverse effects of obesity on the risk of T2DM (Eguaras *et al.*, 2017). MD is not necessarily based on caloric restriction or aimed at reducing weight as an outcome, since some of its central elements are high in energy, but rather an effective and easy to adopt method for diabetes prevention and management.

Other healthy diets have also been recommended based on locality, availability of healthy of variety of healthy food components, such as those forming" Nordic diet". Nordic diet is described by higher consumption of locally available plant-based vegetables, fruits such as oat, wholegrain, berries, rapeseed oil, and sea foods such as fish, shellfish from, and reduced intake of sweetened beverages and salt (Bere and Brug, 2009; Olsen *et al.*, 2011). Such foods have been shown to promote decreased improved several biomarkers associated with positive effects on metabolic profile and insulin sensitivity indicated by changes in LDL, HDL, apolipoproteins, and IL-1 Ra levels (Uusitupa *et al.*, 2013). Nonetheless, large diabetes prevention studies have focused more on an overall lifestyle modification, where a hypocaloric or isocaloric intake of common healthy ingredients was the focus (Knowler *et al.*, 2002; Tuomilehto *et al.*, 2001). For example, the Finnish Diabetes Risk Score considers daily consumption of fruits, berries, or vegetables as categorical variables, embedded with other lifestyle determinants such as age, BMI, waist circumference, history of antihypertensive drug treatment and high blood glucose and physical activity (Lindström and Tuomilehto, 2003).

Functional Foods in the Prevention and Management of Diabetes

Irrespective of the dietary approach or diet name, there are common foods with biologically active ingredients that are considered "functional" based on their association with physiological health benefits related to the prevention and management of T2DM (Alkhatib *et al.*, 2017). Regular consumption of functional foods has been linked with numerous positive effects on glycemic control, blood pressure regulation, activation of antioxidant enzymes, gut microbiota and suppression of over-production of pro-inflammatory cytokines during diabetes, suggesting better prevention and management of diabetes and associated complications (Mirmiran *et al.*, 2014).

For example, the components of the MD can be used a model for how various combinations of functional foods induce health protective benefits. Functional foods present within the MD contain polyphenols, terpenoids, flavonoids, alkaloids, sterols, pigments and unsaturated fatty acids play an important role in maintaining wellness, and contribute to preventing T2DM and associated disease including cancer, obesity, asthma, and cognitive decline (Vasto *et al.*, 2014; Alkhatib, 2015). Preventative actions such foods include an enhanced anti-oxidant, anti-inflammatory, insulin resistance and sensitivity and cholesterol lowering properties (Georgoulis *et al.*, 2014).

The benefits of MD components in T2DM have been attributed to specific nutraceuticals within MD food components including monounsaturated fatty acids (MUFA) such as oleic acid in olive oil, polyunsaturated fatty acids omega-3 (alpha-linolenic acid) found in tree nuts such as walnuts (Salas-Salvado *et al.*, 2008), eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) found in oily fish, high amounts of flavonoids and antioxidants found in fruits and vegetables (Muraki *et al.*, 2013), and high amount of fiber found mainly in cereal and whole-grain foods with a low Glycemic Index (GI) (Gil *et al.*, 2011; Tighe *et al.*, 2010). For example, some studies have underlined the importance of olive oil fatty acids, including oleic acid, phytosterols (Beta-sitosterol), antioxidants (alpha-tocopherol), and plant polyphenols in reducing inflammation, oxidation and determining improvements in the endothelial micro- and macro-vascular function (Archundia Herrera *et al.*, 2017, Bahorun *et al.*, 2010). Such effects are known to have preventative roles in both T2DM and CVD. Others highlighted the importance of fruit and vegetable intake to reduce T2DM risk (Muraki *et al.*, 2013, and conversely low intake of such nutrients is linked with and increased disease risk and even mortality (Ezzati and Riboli, 2013).

It is not possible to attribute diabetes risk-reduction benefits to a single functional food or a nutraceutical in MD. Epidemiological studies attempting to link specific MD components to T2DM risk-reduction have found conflicting associations (Ley *et al.*, 2014). For example, omega-3 fatty acids, obtained from fish and seafood were only associated with reduced T2DM risk in Asian populations, but not in European or North American populations (Wu *et al.*, 2012; Ley *et al.*, 2014). Others have also shown that longitudinal adherence to low fat diets did not lower T2DM or CVD risk in postmenopausal women (Tinker *et al.*, 2008). There may be some key functional MD components such as extra-virgin olive oil and tree nuts that have been associated with metabolic mechanistic protective effects such as reducing serum C-Reactive Protein (CRP), interleukin-6 (IL-6) and endothelial and monocyte adhesion molecules in high-risk men and women (Peyrol *et al.*, 2017). Others have also attributed the protective benefits of MD in T2DM (improved insulin resistance, glucose control, and other cardiometabolic risk factors) to the polyphenolic content, especially flavan-3-ols and their food sources (fruits, vegetables, whole grains, and legumes, and also tea, coffee, red wine and cocoa) (Guasch-Ferre *et al.*, 2017).

The latter reviewed a sporadic evidence about the effectiveness of polyphenol lignans-rich foods (such as flaxseeds) in reducing insulin, glucose and CRP levels and improving HOMA-IR in selected patient groups, and a contrasting epidemiological evidence for total flavonoid intake association with T2DM risk was reported (Guasch-Ferre *et al.*, 2017). Polyphenol-rich olive products, including olive leaves, their crude extract, and extra virgin olive oil, were also reviewed elsewhere for their partial effective on aspects of the metabolic syndrome (Saibandith *et al.*, 2017). Whereas, non-flavonoid polyphenolic compound hydroxytyrosol, the main polyphenol of olive oil, has been shown to improve the lipid profile, glycaemia, and insulin sensitivity, and counteract oxidative and inflammatory processes (Peyrol *et al.*, 2017), and resveratrol (found in grapes, grape products) has been shown to increase intra-cellular transport of glucose and reduce insulin secretion, using various animal and tissue models (Szkudelski and Szkudelska, 2011), conferring several benefits for prevention and management of T2DM. Nevertheless, the largest amounts of polyphenols in diets in many populations are derived from coffee, and in Asia from tea, and both of them are inversely associated with reduced risk of T2DM (Matusheski *et al.*, 2012) and reduce low-grade inflammation (Kempf *et al.*, 2010). While each functional food has its own unique characteristics and protective benefits, we recommend following a holistic approach to implement functional foods into variety of dietary approaches within diabetes lifestyle prevention.

Herbal Ingestions and their Protective Role

Herbal ingestions are common among many cultures for centuries. Numerous medicinal plants and natural products have been reviewed for its anti-diabetic functions showing various degrees of effectiveness in preventing and managing T2DM. Examples include fukugetin, palmatine, berberine, honokiol, amorfrutins, trigonelline, gymnemic acids, gurmarin, phlorizin, aloe, banaba, bitter melon, caper, cinnamon, cocoa, coffee, fenugreek, garlic, guava, gymnema, nettle, sage, soybean, green and black tea, turmeric, walnut, and yerba maté (Rios *et al.*, 2015). Reported functions of such ingestions include for instance the inhibition of α-glucosidase and α-amylase enzymes that regulate glucose absorption from the gut, effects on glucose uptake and glucose transporters, modification of mechanisms mediated by the peroxisome proliferator-activated receptor, inhibition of protein tyrosine phosphatase 1B activity, modification of gene expression, and activities of hormones involved in glucose homeostasis such as adiponectin, resistin, and incretin, and reduction of oxidative stress (Rios *et al.*, 2015).

Whilst taking a multi-component to diabetes prevention, it is important to highlight some of the literature around some of the common herbal ingestions, in particular, herbal tea ingestions to prevent and manage T2DM. Several local teas have become popular worldwide because of their popularized health and disease prevention benefits. For example, black and green teas primarily native to south Asian countries are now consumed worldwide, and yerba maté, native to South America is now consumed by millions of people in North America, and parts of Europe and the Levant (Heck and de Mejia, 2007, Zheng *et al.*, 2013).

Tea specific phenolics, particularly green tea includes (+)-catechin and epigallocatechin gallate (ECGC), which suppress oxidative stress, inflammation and cell death, via activation of the nuclear factor erythroid 2-related factor 2 (Nrf2) pathway, leading to the upregulation of antioxidant response element (ARE) gene expression, and enhanced protective enzymes and free-radical scavengers (Zheng *et al.*, 2013). Nrf2 pathway is also influenced by coffee drinking (Carstensen *et al.*, 2013). Antioxidant compounds in green and black tea have been demonstrated to interact with reactive oxygen species and redox active transition metal ions using a multi-antioxidant assay system (Bahorun *et al.*, 2010; Bahorun *et al.*, 2012). In number of randomized and

clinical trials, it was shown that Mauritian black and green tea intake reduces levels of fasting blood glucose (− 18.4%), triglyceride (− 35.8%), LDL/HDL plasma cholesterol ratio (− 16.6%), and C-reactive proteins, and increases plasma antioxidant propensity (Ferric Reducing Antioxidant Power (FRAP): + 418%) in healthy adults (Bahorun *et al.*, 2010; Bahorun *et al.*, 2012). Black and green teas have also been shown to suppress advanced glycation end products formation and their induced oxidative stress in 3T3-L1 preadipocytes, and that consumption of both herbs induces comparable cellular protection against glycation and antidiabetic potential (Ramlagan *et al.*, 2017).

Beyond their significant antioxidant capacity, polyphenols present within cocoa, coffee and yerba maté, include phenolic compounds with different functions. These include caffeoyl derivatives, procyanidins and chlorogenic acid, all have demonstrated ability to influence insulin sensitivity, vascular endothelial function, fat and carbohydrate metabolism, and inflammatory mediators (Mao *et al.*, 2000; Johnston *et al.*, 2003; Rodriguez-Ramiro *et al.*, 2011; Alkhatib and Atcheson, 2017).

For example, several animal studies have suggested that yerba maté can be effective for preventing and treating metabolic disorders including diabetes (Heck and de Mejia, 2007). Only recently, human studies have shown such potential in healthy (Alkhatib, 2014; Alkhatib and Atcheson, 2017), and obese individuals (Kim *et al.*, 2015). The acute yerba maté effects includes 24% augmented fatty acids oxidation, and energy expenditure during exercise compared with exercise alone (Alkhatib, 2014). This was combined by significant positive effects on mood state (focus, energy, and concentration), and appetite and satiety measures (hunger, prospective eating, and desire to eat) in both resting exercise conditions following yerba maté ingestion (Alkhatib and Atcheson, 2017). Chronic ingestion of yerba maté have been shown to enhance weight-loss outcomes after 12 weeks of ingestion in obese individuals (decrease body fat mass, percent body fat and waist to hip ratio) (Kim *et al.*, 2015). Such effects have been explained by thermogenic gene mRNA expression in white adipose tissue (WAT) and decreased fatty acid synthase mRNA expression in WAT, which may be linked to observed decreases in body weight, WAT weight, epididymal adipocyte size, and plasma leptin level (Choi *et al.*, 2017).

These studies suggest that the use of popular herbal teas (e.g. green tea, back tea and yerba maté) have direct and indirect protective outcomes for T2DM. Positive metabolic and behavior adaptations related to herbal intake, especially when combined with physical activity are essential outcomes for designing an optimized lifestyle prevention for metabolic health and diabetes prevention. However, more human studies are needed, and findings need to be integrated into lifestyle intervention studies, involving behavioral components, especially exercise, and to test different the effectiveness and safety of different doses among high-risk populations.

Effects of Combined Physical Activity and Nutritional Interventions, and Multi-Component Models

A multi-component approach which encompasses behavioral and physical aspects is likely to be more effective than a single component diabetes prevention program. Even based on observational studies, it has been found that among older adults (60–80 years), those who consumed MD are more likely to have an active lifestyle compared with those who consume a western diet (Bibiloni *et al.*, 2017). For the prevention of T2DM incidence, it is established that lifestyle interventions combining variety of physical activity patterns with different dietary regimes are more effective than either exercise, diet or medication alone (Knowler *et al.*, 2002; Tuomilehto *et al.*, 2001). The US Diabetes Prevention Program reported significantly better risk reduction benefits (58%) when exercise and diet approach was used compared with 31% when insulin-sensitizing drug Metformin was used (Knowler *et al.*, 2002), and a 15 year follow up still showed that medication did not elicit a better risk-reduction benefit (15 year follow up on DPP).

When a healthy diet, such as the MD, was added to exercise training intervention, combining physical activity with healthy diets such as the MD, is likely to trigger or augment additional protective functions including reduced lipid peroxidation and anti-inflammatory functions, which reflect a better microvascular and macrovascular function and an improved cardiorespiratory capacity in high-risk and older populations (Alkhatib and Klonizakis, 2014; Alkhatib, 2015; Klonizakis *et al.*, 2013). On the one hand, MD added to exercise training as part of short and long term interventions combining MD with moderate-to-heavy exercise, produced a better increase in endothelial vascular activity and cardiorespiratory capacity than exercise alone (Alkhatib and Klonizakis, 2014; Klonizakis *et al.*, 2014). On the other hand, adding a weight-loss program (strength training) to a MD adherence program, doubled the protective immunological protective functions in high-risk postmenopausal women (Richard *et al.*, 2013). A 26% reduction in C-reactive protein (CRP) concentrations and a 10% reduction in an arbitrary inflammatory score that included, interleukin-6 (IL-6), IL-18, and Tumor necrosis factor (TNF)-α when the group followed MD only, while when a weight loss program was combined with MD, the reduction in inflammatory markers was almost doubled for plasma IL-6 (− 21%) and IL-18 (− 15.6%) compared with the control diet, and with no significant impact on CRP concentration (Richard *et al.*, 2013). Another study in people with metabolic syndrome, has also shown that a combined hypocaloric MD with 12 weeks of moderate-to-heavy exercise training, is more effective than MD alone in enhancing physical aspects (weight loss, physical fitness and improvement of metabolic syndrome risk factors) and mental domains of health-related quality of life measures (vitality, general physical health, emotional role, and self-perception of health) (Landaeta-Diaz *et al.*, 2013).

The role of pharmacological therapies may also play an adjunctive role in combination with lifestyle to prevent diabetes. Glucose-lowering agents such as metformin, sulphonylureas, thiazolidinediones, insulin, newer incretin-based therapies and sodium glucose co-transporter 2 inhibitors have been commonly reported in diabetes prevention trials with varying success (Chatterjee *et al.*, 2018). Non-glucose-lowering therapies such as orlistat and renin angiotensin system blockers can also prevent

diabetes, whereas statins are associated with slightly increased risk, but can be effective in personalized patient circumstances and phenotypic profile (Chatterjee *et al.*, 2018).

Personalized Lifestyle Diabetes Prevention

Designing an individualized and locally-tailored lifestyle and physical activity recommendations to prevent, treat and manage diabetes, considering innate and environmental factors. The personalized profiling of individuals' molecular characteristics such as genetics (DNA sequence), epigenetics (DNA modification), transcriptomics (gene expression), proteomics (protein products of coding genes), metabolomics (metabolite products of metabolic pathways) and microbiome (bacteria species interacting with host) at different levels has been coined as "OMICS" or "Personalized Medicine" (Chen and Snyder, 2013; de Toro-Martin *et al.*, 2017), also called as "precision medicine". Utilizing the personalized approach in a comprehensive lifestyle diabetes prevention strategy, requires a wider understanding of the behavioral as well as the biochemical and genetic factors governing diabetes, as recently proposed (Alkhatib *et al.*, 2017), and updated (**Fig. 1**).

For example, determining the responders vs. non-responders to diabetes intervention can rely on lifestyle factors determining long-term adherence such as exercise enjoyment (self-selected exercise), physical activity training intensity (individualized prescription based on individuals' cardiorespiratory and metabolic response during exercise), and age and gender-specific risks (e.g. post-menopause related risks) (Alkhatib and Klonizakis, 2014). It can also rely on cellular metabolomics and transcriptomics mediators (e.g. IL-6, TNF-α, GRP78) and genes expression (e.g. DUSP1), which have been linked to differential responses to exercise intervention in obese individuals (Tiss *et al.*, 2014; Khadir *et al.*, 2015). The latter found that IL-6, TNF-α, and DUSP1 were all decreased in some but not all obese individuals who followed a 12-week exercise intervention, and similarly only some subjects displayed an improvement in the profile of lipids (LDL, HDL, TG, cholesterol) and glucose (HbA1c and fasting blood glucose), despite no BMI overall change.

Integrating a personalized approach for preventing and managing T2DM should consider both biological and behavioral models, and embed nutrition education and counseling as part of lifestyle diabetes prevention studies. For example, understanding the barriers to changing sedentary behavior, increasing physical activity or diet requires studying the barriers and facilitators to changing behavior and considering the psycho-social determinants such as the importance of purpose, motivation, and attitudes associated with changing behavior, which meets the needs of the individual, family and local community (Aitaoto *et al.*, 2017). Such approach can be effective in enhancing specific outcomes associated with nutritional interventions, such as assisting individuals in adopting new dietary approaches, such as adherence to non-geographical dietary style (Alkhatib and

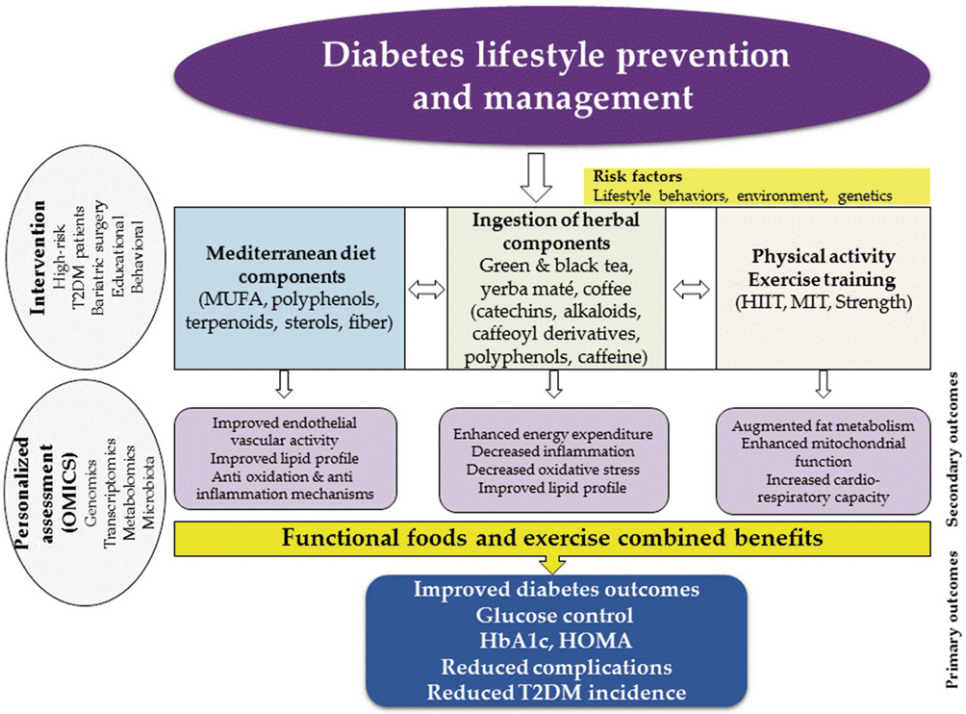

Fig. 1 Integration model of diabetes lifestyle prevention and management to understand biological processes and improve clinical outcomes. MUFA (monounsaturated fatty acids), HIIT (high intensity interval training), MIT (moderate intensity training), HbA1c (glycosylated hemoglobin A1c) HOMA (homeostatic model assessment), T2DM (type 2 diabetes mellitus).

Klonizakis, 2014; Middleton *et al.*, 2015, Martinez-Gonzalez, 2016; ADA, 2017). It can also be effective with those who follow an invasive metabolic and bariatric surgeries (Moize *et al.*, 2016; Eickhoff, 2017). Nonetheless, adapting individualized tools to make combined behavioral and biological changes as part of lifestyle diabetes prevention requires further research.

Overweight and Obesity

Obesity is a complex, adiposity-based chronic disorder, and the major risk indicator for T2DM.

The global prevalence of both overweight and obesity is now widely recognized as the major epidemic of the 21st century. Assessment of overweight and obesity in the clinical setting is done by calculating the body mass index (BMI): overweight is defined as a BMI of 25–29.9 kg m^{-2} and 22–27.9 kg m^{-2} in individuals with an Asian ethnic background whereas obesity is defined as a BMI >30 and $\geq$ 28 kg m^{-2} in individuals with an Asian ethnic background. It has been suggested that the BMI cutoff of $\geq$23 kg m^{-2} is an optimal criterion for screening in East and South Asian ethnicities based on correlations with cardiometabolic risk (Jensen *et al.*, 2014).

Obesity usually arises from the interactions between genetic and environmental factors and is associated with weight-related complications which cause significant rates of morbidity and mortality. People can easily monitor their weight, but it is also important to record weight at health service encounters for people considered overweight or obese.

Meta-analyses have assessed the association between obesity and diabetes (Abdullah *et al.*, 2010, NCD Risk Factor Collaboration, 2017). Vazquez *et al.* (2007) examined 32 studies conducted in multiple countries between 1985 and 2004 and found that the relative risk for incident diabetes was 1.87 (95% CI, 1.67–2.10) for every standard deviation increase in BMI. In addition to baseline BMI, several studies have shown that weight gain represents an important risk factor for diabetes in adult populations. Both, the Nurses' Health Study (Colditz *et al.*, 1997) and the Health Professionals Follow-up Study reported that individuals who gained 5.0–9.9 kg when compared to those who maintained their weight within 2 kg of their weight as young adults had 1.5–3 fold increased risks of diabetes, coronary heart disease, and hypertension. These increases in risk were greater in adults with greatest weight gain. In the Finnish Diabetes Prevention Study (DPS) in overweight people with IGT, weight reduction was associated with prevention of T2D in a linear fashion; a 5% weight reduction resulted in a 66% risk reduction in T2D incidence (Lindström *et al.*, 2005). One should however remember that weight reduction is a result from changes in diet and/or physical activity.

Central Obesity

Intra-abdominal fat is recognized as a driver for the progression of metabolic risk factors independently of BMI. We also know that ectopic visceral, intra-abdominal fat distributed around organs in the peritoneal cavity and retroperitoneal around the kidneys are not necessarily correlated with BMI. Increased waist circumference in the presence other metabolic risk factors is not the perfect measure but identifies the presence of intra-abdominal fat and is an important parameter in assessing cardiovascular risk in routine clinical practice (Chalasani *et al.*, 2012).

A recent analysis comprising individual-level data from 21 studies with 155,000 participants and over 9000 compared data on BMI, waist circumference (WC), waist-hip and waist-height ratio (WHtR) for risk of incident diabetes (Lee *et al.*, 2017). Each of the measures had a positive association with incident diabetes. A one standard deviation increment in each of the measures was associated with 64%–80% higher diabetes risk. WC and WHtR were more strongly associated with risk than BMI, but there was no appreciable difference between the four measures in the predictive accuracy for diabetes at five years. Thus, any of these measures would suffice to assist in primary diabetes prevention efforts.

Conclusion

Diabetes is a major cause of morbidity and is associated with increased risk of major non-communicable disease and mortality, and placing a significant burden on the healthcare system and economy. Preventing diabetes especially T2DM is possible through understanding and addressing lifestyle determinants, especially physical activity and diet. The increased prevalence of sedentary lifestyle is linked with several NCDs including diabetes and is independently associated with mortality risk. This makes it important to consider prevention strategies which focus on interrupting sitting times in addition to increasing work and leisure-time physical activity levels. Appropriate physical activity patterns increase the effectiveness whether moderate, vigorous aerobic training or strength-type exercise have all been shown various degree of effectiveness in preventing and managing T2DM. Emerging evidence about the benefits of HIIT is encouraging but longitudinal and prospective cohort studies are required before such approach is recommended as a public health strategy. There is also a significant emerging evidence about T2DM risk-reduction benefits associated with functional foods such as components of the MD and popular herbal ingestions because of their role in enhancing immunological and cardio-metabolic functions. Innovative laboratory and field-based approaches have made it possible to objectively assess the various risks associated with T2DM and to individualize the prevention strategy at different genetic, molecular, tissue and whole-body levels. Nonetheless,

it is essential that any lifestyle prevention to consider combined approaches integrating physical activity, diet, medication and education for sustainable risk-reduction outcomes.

Hyperglycemic Hyperosmolar State☆

J Maletkovic and A Drexler, UCLA School of Medicine Los Angeles, Los Angeles, CA, USA

Definition and Epidemiology

Hyperglycemic hyperosmolar state used to be named hyperglycemic hyperosmolar nonketotic coma, but this term was not applicable to all patients as it was found that it frequently presents without coma. It was also named hyperglycemic hyperosmolar nonketotic state, but findings of moderate ketonemia in some patients lead to the acceptance of its updated term hyperglycemic hyperosmolar state (HHS). This is a potentially fatal hyperglycemic crisis that occurs as acute complication of uncontrolled diabetes mellitus.

HHS is most frequently encountered in middle-aged or elderly subjects with type 2 diabetes however it has also been reported in type 1 diabetes as a simultaneous occurrence with diabetic ketoacidosis (DeFronzo *et al.*, 1994; Rosenbloom, 2010). The mortality rate from HHS is still high and approaches 20% (Wachtel *et al.*, 1991). On the other hand, the incidence of HHS is less than 1 case per 1000 person-years.

Pathophysiology

The syndrome is characterized by severe hyperglycemia with glucose concentrations frequently greater than 600 mg dl^{-1}, dehydration and invariably elevated osmolality to above 320 mOsm kg^{-1}. By convention, significant hyperketonemia and metabolic acidosis are absent but the syndrome is considered to overlap with diabetic ketoacidosis in about one-third of cases (Wachtel, 1990). Patients with previously undiagnosed diabetes account for approximately 20% of cases.

Hyperosmolar state develops as a result of osmotic diuresis caused by hyperglycemia, which then creates severe fluid loss. The total body deficit of water is usually about 7–12 l in HHS, which represents a loss of about 10%–15% of body weight. Although mild ketosis can be seen with HHS, it is generally absent in this state. It is considered that patients with HHS with type 2 diabetes still do have enough insulin to be protected from exaggerated lipolysis and the consequent abundance of FFA (Kitabchi *et al.*, 2009). They do not, however, have enough insulin to prevent hyperglycemia (Smiley *et al.*, 2011).

Insulin Deficiency

There is relative, rather than absolute, insulin deficiency in patients with type 2 diabetes. This permits acceleration of hepatic glycogenolysis and gluconeogenesis. The net result is an increase in hepatic glucose production that, in the presence of elevated counterregulatory hormones, leads to a progressive rise in blood glucose concentration.

Insulin Resistance

Intercurrent illness (e.g., severe sepsis, acute myocardial infarction) is associated with elevations of circulating counterregulatory hormone concentrations. Hyperglycemia is exacerbated via direct and indirect tissue actions of these hormones, i.e., exacerbation of accelerated hepatic glucose production and antagonism of insulin-mediated glucose disposal in muscle. High levels of catecholamines (epinephrine and norepinephrine) inhibit endogenous insulin secretion, thereby compounding the preexisting defect in patients with type 2 diabetes. As hyperglycemia develops, the renal threshold for reabsorption of glucose – approximately 180 mg dl^{-1} but often higher in the elderly - is exceeded. This results in renal losses of glucose that provide temporary partial protection against more severe hyperglycemia. Renal losses of electrolytes (sodium, potassium, phosphate, and magnesium) accompany the osmotic diuresis. Subsequent contraction of intravascular volume causes a fall in renal perfusion. The absence of significant ketosis may reflect the presence of endogenous insulin secretion sufficient to restrain lipolysis, the latter process being suppressed at lower insulin concentrations than those required to stimulate glucose disposal.

Clinical Features

Symptoms of progressively intense thirst and polyuria reflecting hyperglycemia and dehydration develop over several days or even weeks. Many patients are in a moribund state of severe dehydration by the time they are admitted to hospital. Elderly or infirm patients who have been unable to maintain adequate oral fluid intake are at particular risk. Most patients with HHS will have some

Table 1 Guide to initial treatment of hyperglycemic hyperosmolar state in adults

Fluids and electrolytes

Volumes
- 1 l per hour × 2–3, thereafter adjusted according to the degree of hydration and taking continuing polyuria into account. N.B. Use caution in patients with known renal disease or cardiovascular insufficiency; consider central venous pressure monitoring.

Fluids
- Isotonic saline (0.9%, 150 mEq l^{-1} sodium chloride) initially.
- Hypotonic saline (0.45%, 75 mEq l^{-1} sodium chloride) if serum sodium exceeds 150 mEq l^{-1} (restrict to 1–2 l in total and consider use of 5% dextrose with increased insulin if marked or worsening hypernatremia).
- 5% Dextrose at 1 l every 4–6 h replaces saline when blood glucose has fallen to 250 mg dl^{-1} until patient is eating and drinking again.

Potassium replacement
- No potassium chloride added to the first liter of fluid, unless initial plasma potassium <3.5 mEq l^{-1}.
- Measure serum potassium every 2 h initially (see below: other measures)
- Thereafter, add dosages below to each liter of fluid:

If plasma K^+:
- <3.5 mEq l^{-1}, add 40 mEq potassium chloride (severe hypokalemia may require more aggressive replacement with careful monitoring of serum potassium concentration).
- 3.5–5.5 mEq l^{-1}, add 20 mEq potassium chloride.
- >5.5 mEq l^{-1}, add no potassium chloride to the infusion.

Insulin
- 5–10 U h^{-1} (average 6 U h^{-1} in adults) by continuous intravenous infusion initially until blood glucose has fallen to 250 mg dl^{-1}. Thereafter, adjust rate (usually 1–4 U h^{-1} required in the absence of severe infection) together with dextrose infusion to maintain serum glucose between 100 and 200 mg dl^{-1} until patient is eating and drinking again.
- Thereafter, change to an appropriate subcutaneous insulin regimen.
- Review continuing need for insulin therapy 2–3 months after full recovery.

Other measures
- Search for and treat precipitating cause (e.g., infection, myocardial infarction).
- Systemic hypotension usually responds to adequate fluid replacement with crystalloids.
- Pass bladder catheter if level of consciousness is impaired or no urine is passed within 2 h of the start of therapy.
- Continuous electrocardiographic monitoring may warn of hyperkalemia or hypokalemia (serum potassium should be measured hourly if <3.5 or >5.5 mEq l^{-1}).
- Consider cranial computed tomography imaging to exclude other pathology (e.g., cerebral hemorrhage, venous sinus thrombosis) if the level of consciousness remains impaired following correction of hyperosmolar state.
- Treat acute thrombo-embolic complications with anticoagulant doses of heparin.
- Update clinical and biochemical progress using a purpose-designed flowchart.

degree of neurologic disturbance. If osmolality is normal and patients show severe neurologic deficit, further workup is indicated to rule out underlying neurologic pathologic condition. Elderly patients are particularly susceptible to these disturbances. Some neurologic presentations include irritability, restlessness, stupor, muscular twitching, hyperreflexia, spasticity, seizures, and coma (Arieff, 1984; Butts, 1987). The clinical signs and symptoms reflect the severity of the hyperosmolality (Palevsky, 1998).

Precipitating Factors

Respiratory and urinary tract infections are common precipitants; others include myocardial infarction, pulmonary embolism, and acute pancreatitis. Patients can present with symptoms of the preceding illness, such as infection or myocardial ischemia. Certain antihypertensive drugs, including high-dose diuretics and beta-blockers, have been implicated; diuretics may exacerbate dehydration and potassium depletion. Other drugs include phenytoin, cimetidine, and chlorpromazine. High-dose corticosteroids have potent effects on carbohydrate and lipid metabolism, readily precipitating metabolic decompensation in predisposed individuals.

Diagnosis

Evaluation of volume status is one of the initial assessments of patients with HHS.

Urinalysis reveals marked glycosuria with a "negative" or "trace" ketone reaction using semiquantitative nitroprusside-based test strips. Blood glucose concentration is markedly elevated, i.e., >500 mg dl^{-1}. Blood urea nitrogen is elevated and hematocrit is raised. The serum osmolality is determined by the concentrations of the different solutes in the plasma. In normal subjects, sodium salts, glucose, and urea are the primary circulating solutes. Increased serum osmolality to more than 320 mOsmol kg^{-1} is seen in patients with neurologic abnormalities and is typical for HHS. Rarely, serum osmolality can be more than 400 mOsm

kg^{-1}. The formula for the calculation of serum osmolality is given below (Rasouli and Kalantari, 2005; Worthley *et al.*, 1987).

$$\text{Serum osmolality} = (2 \times \text{serum [Na]}) + (\text{glucose, in mg dl}^{-1})/18 + (\text{BUN in mg dl}^{-1})/2.8$$

(where BUN is serum urea nitrogen)

The formula with all units in millimoles per liter is the following:

$$\text{Serum osmolality} = (2 \times \text{serum [Na]}) + (\text{glucose}) + (\text{urea})$$

Most patients will present with hyponatremia. (Each 100 mg dl^{-1} of the glucose level more than normal lowers the serum sodium level by about 1.6 mEq L^{-1}.) An additional decrease in serum sodium is present with confounding pseudohyponatremia that occurs with hyperlipidemia or hyperproteinemia with some laboratory assays (Dhatt *et al.*, 2012; Weisberg, 1989). In some cases of HHS, patients may present with hypernatremia secondary to osmotic diuresis and more severe dehydration (Liamis *et al.*, 2000; Milionis *et al.*, 2001). Hypernatremia indicates a profound degree of water loss. Arterial plasma pH is >7.30 and bicarbonate is >15 mEq l^{-1}. However, a degree of acidosis may result from impaired renal excretion of H^+ ions allied to tissue hypoperfusion. Serum potassium is frequently paradoxically elevated despite the total body deficit in HHS. Treatment with insulin shifts potassium into the cell and causes a rapid decrease of the serum potassium levels. Hypokalemia is frequently encountered after starting insulin treatment (Maletkovic and Drexler, 2013).

Treatment and Complications

The management of HHS consists of fluid and electrolyte repletion, insulin administration, and the treatment of the precipitating cause if one can be identified. Patients should be admitted to a monitored unit where close observation of mental status, blood pressure, heart rate and rhythm, and urine output can be done (**Table 1**).

Complications and Outcomes

Nontraumatic rhabdomyolysis in patients with greater degrees of hyperosmolarity may precipitate acute renal failure. There is a high frequency of thrombo-embolic complications. The average mortality rate is approximately 15%, higher than for patients with diabetic ketoacidosis. The acute outcome tends to be worse for individuals of advanced age or with serious comorbidity.

Hypoglycemia☆

Darleen A Sandoval, University of Michigan, Ann Arbor, MI, United States and University of Cincinnati School of Medicine, Cincinnati, OH, United States
Elizabeth M Lamos, Lisa Younk, Maka S Hedrington, and Stephen N Davis, University of Maryland School of Medicine, Baltimore, MD, United States

Glossary

Hypoglycemia Mild: blood glucose levels between 50 and 70 mg dL^{-1}. Severe: blood glucose levels <50 mg dL^{-1} that requires resuscitation.

Hypoglycemia associated autonomic failure (HAAF) A situation in which previous episodes of hypoglycemia (or exercise) blunt autonomic, neuroendocrine, metabolic and symptomatic response to subsequent episodes of hypoglycemia.

Type 1 diabetes mellitus An autoimmune disorder in which the patient's body cannot make insulin, and consequently requires exogenous insulin administration.

Type 2 diabetes mellitus A disorder of insulin resistance and progressive beta-cell dysfunction resulting in hyperglycemia, and consequently requiring oral and/or injection therapy including exogenous insulin.

Introduction

Typically, blood glucose levels are tightly regulated between 70 and 150 mg dL^{-1} in healthy man. Hypoglycemia (blood glucose levels of <70 mg dL^{-1}) occurs as a consequence of fasting (>24 h) or different disease conditions including diabetes mellitus, insulinomas, inborn errors of metabolism such as galactosemia, persistent hyperinsulinemic hypoglycemia of infancy and hereditary fructose intolerance, postbariatric surgery, and severe prolonged exercise. While the incidence of hypoglycemia has historically been considered to be associated with type 1 diabetes mellitus (T1DM), the prevalence of hypoglycemia in type 2 diabetes mellitus (T2DM) also increases greatly as endogenous insulin secretion fails and treatment is shifted to insulin and/or insulin secretagogues. Imbalances of exogenous insulin with food intake and physical activity create challenges in the maintenance of glucose homeostasis in T1DM and T2DM.

Maintenance of Blood Glucose

Blood glucose homeostasis is maintained by the complex interplay of factors regulating glucose absorption from the gut, glucose production by the liver (glycogenolysis and gluconeogenesis), and glucose uptake in tissues such as muscle, liver and brain. Once the gut absorbs glucose it enters the portal circulation where it is first taken up by the liver. In the postabsorptive state, the liver will release glucose into the circulation via the process of glycogenolysis. After an overnight fast, gluconeogenesis becomes the primary source of endogenous glucose production. The fate of glucose taken up by the tissues (stored or metabolized) depends on the type of tissue and energy status. The majority of glucose uptake in the fasting state is by the central nervous system as glucose is the brain's primary fuel. The brain has limited glucose stores and thus, is dependent on endogenous (primarily hepatic) glucose output for its glucose supply. Glucose is transported into the tissues by a specific family of proteins called glucose transporters. Different tissues usually have distinct isoforms of these transporters. For example, GLUT-1 and GLUT-3 isoforms are located in the brain, GLUT-2 is located in the liver and pancreas, GLUT-4 is located in muscle and adipocytes and GLUT-5 is located in the epithelial cells of the jejunum. Both the autonomic nervous system (ANS) and the endocrine system regulate glucose homeostasis. Insulin lowers plasma glucose by (1) suppressing endogenous glucose production (both by direct action on the liver and indirect actions to reduce substrate flux such as lactate, pyruvate, glycerol, and free fatty acids to the liver) and (2) increasing glucose uptake into peripheral tissues (predominantly muscle). Glucagon increases plasma glucose via direct regulation of gluconeogenesis and glycogenolysis to increase hepatic glucose production.

☆*Change History*: March 2018. Davis et al. made the following changes: Hypoglycemia and Diabetes has been updated to include data on type 2 diabetes. Negative Cardiovascular Effects of Hypoglycemia has been added. Strategies to Reduce Hypoglycemia has been added. The glossary has been updated. Additional reading citations have been updated and added. M Hedrington and S Davis made the following changes: The abstract has been revised. Hypoglycemia and Diabetes has been updated. Effects of Hypoglycemia on the Quality of Life has been added. Hypoglycemia Risk Reduction and Patient-Centered Considerations has been added. Additional reading citations have been added.

This article is an update of Darleen A. Sandoval and Stephen N. Davis, Hypoglycemia, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 636-640.

Physiological Response to Hypoglycemia

The physiological response to hypoglycemia involves the ANS and many neuroendocrine and metabolic processes (Tables 1 and 2). The initial defense is a reduction in endogenous insulin secretion, which occurs when plasma glucose is in the low normal range (80–70 mg dL^{-1}). Glucagon and epinephrine secretion are activated at glucose levels just below normal (70 mg dL^{-1}), and, together with inhibition of endogenous insulin secretion, are the primary defenders against hypoglycemia. Glucagon is a powerful and quick acting stimulus for hepatic glucose production. The increase in hepatic glucose production is primarily through glycogenolysis but gluconeogenesis becomes more important as hypoglycemia is prolonged. Epinephrine increases heart rate, cardiac contractility, and lipolysis and inhibits glucose uptake, while also increasing endogenous glucose production, primarily from the liver but also from the kidney. Glucagon responses are absent within 5 years duration of T1DM and in long-duration T2DM, increasing reliance on epinephrine for defense against hypoglycemia. Growth hormone, from the pituitary gland, cortisol, from the adrenal cortex, and norepinephrine spillover from the sympathetic nervous system also increase in response to moderate hypoglycemia but have modest metabolic effects. Pancreatic polypeptide, an index of parasympathetic nervous system activity, oxytocin, vasopressin, thyroid hormone, aldosterone and adrenocorticotropic hormone are also released during hypoglycemia but do not appear to have discernable acute metabolic effects.

Symptoms of Hypoglycemia

The symptoms of hypoglycemia can be separated into those that are neurogenic (autonomic) and those that are neuroglycopenic. Examples of autonomic symptoms experienced when glucose levels fall below 60 mg dL^{-1} are tremulousness, palpitations, anxiety, sweating, and dry mouth. These symptoms are autonomic in origin and stem from increased sympathetic drive. For example sweating is cholinergically mediated via sympathetic nerve fibers and tremor is correlated with increased circulating levels of epinephrine. Symptoms that are neuroglycopenic generally occur at glucose levels of 50 mg dL^{-1} or less, result directly from brain glucose deprivation, and include difficulty in thinking, confusion, weakness, fatigue, paresthesias, seizures, coma and death. Impairment of cognitive function occurs at glucose levels of about 45 mg dL^{-1} and is implicated as a cause for fatal accidents occurring in patients.

Hypoglycemia and Diabetes

Type 1 Diabetes Mellitus

Persistent hyperglycemia has been determined to be the cause of long-term microvascular complications associated with T1DM. The Diabetes Control and Complications Trial (DCCT), a landmark multicenter randomized clinical trial, was developed to determine the risks and benefits of tight glucose control. The results showed that tight glucose control, defined as an HbA_{1c}

Table 1 Effects of a 120-min hyperinsulinemic hypoglycemic clamp on neuroendocrine and autonomic responses in overnight fasted men

	Basal	*Final 30 min of the clamp*
Norepinephrine (pg mL^{-1})

Data are means ± SE.

≤ 7.2%, obtained by using either multiple insulin injections or continuous subcutaneous insulin infusion prevented or delayed the progression of diabetes complications as compared to conventional treatment (HbA_{1c} ≥ 9.0%). However, patients with tight glucose control also suffered a threefold increase in the incidence of severe hypoglycemia (requiring outside assistance to recover) and coma. In fact, 90% of all patients with T1DM experienced mild to moderate hypoglycemia.

Type 2 Diabetes Mellitus

Similar to findings from the DCCT, the UK Prospective Diabetes Study found that in patients with T2DM, intensive blood glucose control (HbA_{1c} 7.0%) reduced microvascular complications by 25%, compared to conventional blood glucose control (HbA_{1c} 7.9%). Again though, improved glucose control, primarily in patients who use insulin, is associated with a higher incidence of hypoglycemia in T2DM, occurring in 70% of participants in recent trials. Moreover, in addition to tight glucose control (HbA_{1c} < 6.0%), poor glucose control (HbA_{1c} ≥ 9.0%) is also associated with an increased risk of hypoglycemia in T2DM. In large trials, patients with higher HbA_{1c} levels that have been randomized to conventional glucose control have poorer outcomes in association with severe hypoglycemic episodes than patients randomized to intensive control. Overall, nearly equivalent rates of severe hypoglycemia have been reported in T1DM and insulin-treated T2DM (11.5 and 11.8 events per 100 patient years, respectively). Recently, three large randomized controlled trials (ACCORD (Action to Control Cardiovascular Risk in Diabetes), ADVANCE (Action in Diabetes and Vascular Disease), and VADT (Veterans Affairs Diabetes Trial)) have demonstrated that individuals with T2DM are particularly susceptible to the adverse consequences of hypoglycemia. In all three trials, episodes of severe hypoglycemia were associated with serious adverse cardiovascular events and increased mortality.

In diabetes, hypoglycemia is initially caused by insulin excess but can be potentiated by lack of food intake, physical activity, and autonomic dysfunction. Hypoglycemia associated autonomic failure (HAAF) is an acute failure of the autonomic response to hypoglycemia that is induced by prior episodes of hypoglycemia in both T1DM and T2DM. This creates a situation where the patient has reduced capability to defend against impending hypoglycemia. Unfortunately hypoglycemia is the complication of diabetes most feared by insulin-requiring diabetics. Consequently, the increased prevalence of hypoglycemia is the major roadblock preventing patients from realizing the benefits of tight glucose control.

Hypoglycemic Unawareness

One component of HAAF is hypoglycemic unawareness. Hypoglycemic unawareness occurs when an individual has a reduced or complete loss of symptoms that indicates the presence of hypoglycemia. The pathogenesis of hypoglycemic unawareness is multifactorial but includes a shifting of the glycemic threshold. That is, symptoms only occur at progressively lower glucose levels. If this threshold occurs

below a critical level, hypoglycemic symptoms may not be activated and a patient may slip into a coma with little or no warning. Importantly, hypoglycemia unawareness can be reversed by meticulous avoidance of iatrogenic hypoglycemia.

Role of Antecedent Stress in Incidence of Hypoglycemia

Many studies have demonstrated the importance of antecedent hypoglycemia in the pathogenesis of HAAF. Patients with tight glucose control typically have low glycemic thresholds due to the repeated exposure to prior hypoglycemia. Prior episodes of hypoglycemia cause a shift in the glycemic threshold, which results in a progressive diminution of autonomic and neuroendocrine responses to subsequent episodes of hypoglycemia. As stated above, the autonomic and neuroendocrine responses to hypoglycemia are necessary to stimulate the liver to release more glucose and inhibit peripheral uptake of glucose in an attempt to defend against the falling glycemia. With these defenses reduced, combined with the absence of glucagon, the T1DM patient is left particularly vulnerable to repeated hypoglycemia. Tables 3 and 4 contain data from healthy subjects exposed to either day 1 clamped euglycemia or hypoglycemia followed by a subsequent bout of hypoglycemia on day 2. These data clearly demonstrate the blunted day 2 neuroendocrine and autonomic nervous system responses after day 1 hypoglycemia and reveal the considerably greater amounts of glucose that had to be infused during the day 2 experiments to maintain the desired level of hypoglycemia. The phenomenon of blunted counterregulatory responses to recurring hypoglycemia has been extended to T2DM as well. Mild antecedent hypoglycemia (60 mg dL^{-1}) blunted autonomic nervous system responses to subsequent hypoglycemia in participants with T2DM that were randomized to either suboptimal (HbA_{1c} ~10.0%) or intensive glycemic control (HbA_{1c} ~6.7%).

Exercise is important in the maintenance and well-being of individuals with diabetes. Physical activity improves insulin sensitivity, helps in body weight maintenance and can reduce postprandial hyperglycemia. Unfortunately, exercise is also associated with increased hypoglycemia in T1DM patients. This may be due in part to the fact that prior episodes of hypoglycemia also reduce the autonomic and neuroendocrine response to a subsequent bout of prolonged exercise. The reverse is also true, prior prolonged exercise blunts autonomic and neuroendocrine responses to next day hypoglycemia. Also, one bout of exercise in the morning blunts neuroendocrine and metabolic counterregulatory response to a second bout of exercise in the afternoon. Thus insulin delivery (reduced) and carbohydrate intake (increased) during exercise following a hypoglycemic episode may have to be modified in order to prevent further hypoglycemia.

The mechanism(s) responsible for the blunting effect of prior episodes of hypoglycemia are not fully understood but likely involve several interactive pathways. Cortisol is known to blunt sympathetic nervous system (SNS) responses to stress in both animal and human experimental models. Therefore prior increases in cortisol during hypoglycemia or exercise could be one factor that causes blunted SNS responses to subsequent episodes of hypoglycemia or bouts of exercise. Additionally, within the CNS, several studies found decreases in expression and activity of glucokinase (a rate-limiting enzyme of glycolysis) and AMP-activated kinase (a highly conserved fuel-sensing enzyme), as well as changes in neurotransmitter level or activity. For example,

Table 3 Effects of Day 1 hypoglycemia on neuroendocrine and autonomic responses to Day 2 hypoglycemia in overnight fasted men and women

	Basal	*Final 30 min of Day 2 hypoglycemic clamp*
Norepinephrine (pg mL^{-1})

γ-aminobutyric acid (an inhibitory neurotransmitter), corticotrophin-releasing factor, and urocortin are all reduced in level or activity and these changes are associated with blunted responses to hypoglycemia. Insulin, lipid, and neuropeptide signaling, as well as alterations in brain fuel selection (i.e., monocarboxylic acid utilization), uptake and/or metabolism may also be involved in modulation of counterregulation during repeated episodes of hypoglycemia.

Negative Cardiovascular Effects of Hypoglycemia

In several large-scale clinical trials, improved management of hyperglycemia has not led to improved cardiovascular outcomes in patients with T2DM. The reason for this is unclear, but the increased rate of hypoglycemia with increased glycemic control may be one confounding factor. Limited evidence exists to suggest that hypoglycemia can induce acute EKG abnormalities, such as atrial and ventricular ectopic beats, ST-segment depression, QT-interval prolongation, and P- and T-wave abnormalities, which could lead to dangerous arrhythmias. However, the more ubiquitous mechanisms by which hypoglycemia exerts long-term damaging cardiovascular effects likely involve promotion of inflammation, oxidative stress, leukocytosis, endothelial dysfunction, and prothrombogenic and atherogenic pathways. Patients with a history of recurring hypoglycemia have been found to have increased inflammation and intima-media thickness and reduced flow-mediated arterial dilation.

Effects of Hypoglycemia on the Quality of Life

Even a single bout of hypoglycemia has a considerable impact on the quality of life in type 1 as well as T2DM. Studies have shown that a hypoglycemic episode of only 1 h duration the night before markedly affected the individual's sense of well-being the next day. Various trials have also demonstrated that hypoglycemia is associated with increased anxiety, symptoms of depression, reduced alertness during driving and diminished ability to function at work.

Strategies to Reduce Hypoglycemia

Special attention to an individuals' regimen, age and comorbidities allows the practitioner to individualize treatment plans and glycemic goals. The dosing and timing of insulin and insulin-secretagogue therapy to meals and exercise should be reviewed. Antihyperglycemic agents that are not routinely associated with hypoglycemia (i.e., GLP-1 agonists, DPP-4 inhibitors, acarbose, metformin), may result in unanticipated hypoglycemic events when combined with insulin. Strict avoidance of hypoglycemia by tolerating a higher average glucose for 2–3 weeks can improve hypoglycemic symptom awareness.

Newer, basal insulin analogs have also been demonstrated to lower rates of hypoglycemia, particularly during the night. Glycemic variability is reduced with the addition of sensor-augmented insulin pump therapy compared to multidaily insulin injections. And, glycemic goals are more likely to be achieved without increasing the rate of hypoglycemia. A continuous glucose monitor can improve glucose monitoring and alert individuals to a rapidly falling glucose. These devices when used in combination with insulin pumps equipped with features to suspend insulin delivery can reduce nocturnal hypoglycemia without increasing HbA_{1c} values.

Hypoglycemia Risk Reduction and Patient-Centered Considerations

The degree of importance for reducing the risk of hypoglycemia and associated difficulties vary among people with diabetes. Thus, each patient should be approached with individualized treatment strategies and glycemic targets. Factors that need to be taken into consideration are patient's age and life expectancy, any existing comorbidities and likely consequences of hypoglycemia on the patient's life. For example, an aggressive target might be appropriate for an active, healthy individual with diabetes who has preserved awareness of hypoglycemia and uses real-time CGM with sounding alarms.

Adverse consequences of hypoglycemia often outweigh the benefits of tight glycemic control in children, older individuals, patients with comorbidities and/or shorter life expectancy. Children with T1DM have high risk of hypoglycemia since eating and activity patterns are usually hard to predict, which makes insulin-dosing challenging. In addition, children with T1DM often lack ability to recognize symptoms of hypoglycemia.

Severe hypoglycemia is common in older adults with diabetes. Factors that contribute include geriatric syndrome, comorbidities, polypharmacy, decline in renal and hepatic function, impaired counterregulatory responses to hypoglycemia, hypoglycemia unawareness. Even mild hypoglycemia can cause dizziness and blurry vision, which in older adults dramatically increases the likelihood of falls. The latter, according to the CDC is the leading cause of injury and death in older Americans. Additionally, elderly patients with diabetes are particularly vulnerable to hypoglycemia associated malignant ventricular arrhythmias that can be life threatening. Thus, American Diabetes Association and American Geriatric Society recommend avoiding hypoglycemia in older adults by targeting HbA1c $\sim$7.3% for individuals with good functional status and few comorbidities and 8%–9% for ailing patients with multiple comorbidities and limited life expectancy. It remains undecided whether hypoglycemia per se increases the risk of dementia.

Real-time CGM allows people with diabetes to not only view their glucose level almost immediately, but also identify direction and speed of change. The studies have shown that real-time CGM use can reduce number and duration of hypoglycemic episodes, improve HbA1c and reverse hypoglycemia unawareness. Current CGM models (RT-CGM) also offer an integrated alarm system that is triggered when glucose level reaches a preset value and the direction of change projects hypoglycemia.

Hypoglycemia is of course always a subject of concern when diabetes is treated with insulin. Analog insulins have been designed to more closely mimic normal insulin profiles. Besides improved HbA1c and fasting plasma glucose, insulin analogs are also associated with markedly reduced risk of hypoglycemia. And each subsequent generation seems to have even better safety profile than the one preceding it. One current example is insulin degludec, which has been demonstrated to be noninferior to insulin glargine in trials studying type 1 as well as type 2 diabetic patients. Degludec has also been associated with significantly lower rates of nocturnal hypoglycemia compared to insulin glargine and insulin detemir.

Medtronic's MiniMed 670G—a hybrid closed loop insulin delivery system is the first FDA approved artificial pancreas. The closed loop system combines a CGM, an insulin pump and sophisticated predictive algorithms embedded on an external processor (e.g., on a smartphone). The processor receives information from the CGM and after performing algorithmic calculations, sends insulin-dosing signals to the pump. The studies have demonstrated that using this system in a controlled as well as in unmonitored (in-home) environment considerably increases the time, in which glycemia is in the target range, improves HbA1c and reduces hyper and hypoglycemia. Several companies are working on adding a glucagon pump to this system, which would further reduce hypoglycemia.

Conclusions

A vicious cycle is generated for T1DM patients when intensive control results in iatrogenic hypoglycemia. An increased frequency of hypoglycemia leads to lower glycemic thresholds, blunted neuroendocrine and autonomic nervous system responses, hypoglycemia unawareness and unfortunately further episodes of hypoglycemia. Patient-centered treatment that focus on preventing hypoglycemia but allow maintenance of optimal control of blood glucose levels can add significantly to the quality of life for the T1DM and T2DM patient.

Glycation- and/or Polyol Pathway-Inducing Complications☆

Naila Rabbani and Paul J Thornalley, University of Warwick, Coventry, United Kingdom

Glossary

Advanced glycation endproduct (AGE) A stable, endstage product formed in glycation reactions.
Early-stage glycation adducts Schiff's bases and fructosamines.
Glycation The nonenzymatic reaction of glucose, α-oxoaldehydes and other saccharide derivatives with proteins, nucleotides and lipids.
Glycoxidation Glycation processes involving oxidation.
Polyol pathway A metabolic pathway converting glucose to fructose via sorbitol.

Early-Stage Glycation—Formation of Fructosamine: Glycated Hemoglobin and Glycated Albumin

Glycation of lysyl side chain and N-terminal amino groups of proteins by glucose was the first major glycation process studied. Glucose reacts with these amino groups initially to form a Schiff's base which undergoes an Amadori rearrangement to form *N*-(1-deoxy-D-fructos-1-yl)-amino acid or fructosamine, on lysine residues forming fructosyl-lysine (FL) and N-terminal amino acids to form N-terminal fructosyl-amino acid residues (Rabbani and Thornalley, 2012b)—**Fig. 1**A. The major glycation adduct of glycated hemoglobin HbA1c (A1C) is the *β*-chain N-terminal fructosyl-valine residue with a secondary important glycation site at α-chain lys-61 (Delpierre *et al.*, 2006; Zhang *et al.*, 2001) and the major sites of glycation by glucose in human serum albumin (HSA) are, in order of reactivity: N-terminal aspartate and lys-525, lys-199 and lys-439 residues (Barnaby *et al.*, 2011). FL and related fructosamines are early-stage glycation adducts which are repaired and removed from cellular proteins enzymatically by fructosamine-3-phosphokinase (F3PK) (Delpierre *et al.*, 2000)—**Fig. 1**B. Gene deletion of F3PK produces marked increases in FL without evidence of pathogenesis or decreased lifespan (Veiga-Da-Cunha *et al.*, 2006), suggesting that glycation by glucose to fructosamine does not, per se, contribute to pathology. Indeed, studies with high dose thiamine therapy in experimental diabetes showed that diabetic nephropathy, retinopathy and neuropathy could be prevented without correction of increased FL content of the kidney, retina and nerve (Karachalias *et al.*, 2010; Thornalley, 2005). The likely explanation is that formation of FL and N-terminal amino acid fructosamine residues do not markedly impair protein function—fructosamine formation does produce loss of charge of the glycated residue, for example, and lysine and N-terminal amino acid residues have a relatively low probability of location in functional domains of proteins, compared to arginine residues – the major site of location of AGEs (Gallet *et al.*, 2000; Rabbani and Thornalley, 2014). Levels of early-stage glycation adducts are rather directly linked to extent and duration of hyperglycemia and therefore their measurement finds use as biomarkers of glycemic control—including, recently, for A1C, a criterion for diagnosis of diabetes (Bonora and Tuomilehto, 2011).

Protein Glycation in Monitoring Glycemic Control

Fructosamine concentrations change in response to hyperglycemia; they respond strongly to persistent hyperglycemia and weakly to short-term postprandial hyperglycemia. The assay of fructosamine residues is a diagnostic marker of medium term glycemic control in diabetes mellitus. Approximately 6%–15% of the HSA is glycated with a fructosamine in vivo. Glycated HSA reflects glycemic control in the 2–3 weeks preceding analysis. Glycated hemoglobin accounts for c. 7.5% of total hemoglobin in normal healthy human subjects. The different forms are designated HbA_{1a1}, HbA_{1a2}, HbA_{1b} and HbA_{1c} (A1C). A1C is the most abundant of the minor components in human red blood cells in vivo, accounting for approximately 5% of total hemoglobin. It too is a mixture of mostly the fructosamine adducts of the *β*-val-1 (60%) and α-lys-61 (40%)—see above. HbA_{1a1} and HbA_{1a2} are the *β*-chain N-terminal adducts of fructose-1,6-bisphosphate and glucose-6-phosphate, respectively. HbA_{1b} is thought to result from a deamidation in the *β*-chain of HbA_{1c}. The measurement of A1C reflects glycemic control over the 6–8 weeks preceding analysis. In diabetes mellitus, the concentration of fructosamine of serum proteins is typically increased 2-fold, relative to those of normal human subjects (c. 5 vs. 2 nmol/mg protein). A1C has become an important clinical chemistry marker of glycemic control in diabetes: 6.0%–6.9% good control, 7.0%–7.9% moderate control, and ≥8.0%, poor control. A1C is also a screening marker for diagnosis of diabetes (AIC ≥6.5%) and prediabetes state of impaired glucose tolerance (IGT; A1C 5.7%—6.4%)

This chapter is an update of Paul. Thornalley, Glycation- and/or Polyol Pathway-inducing Complications, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 275-278.

 doi:10.1016/B978-0-12-801238-3.03829-0

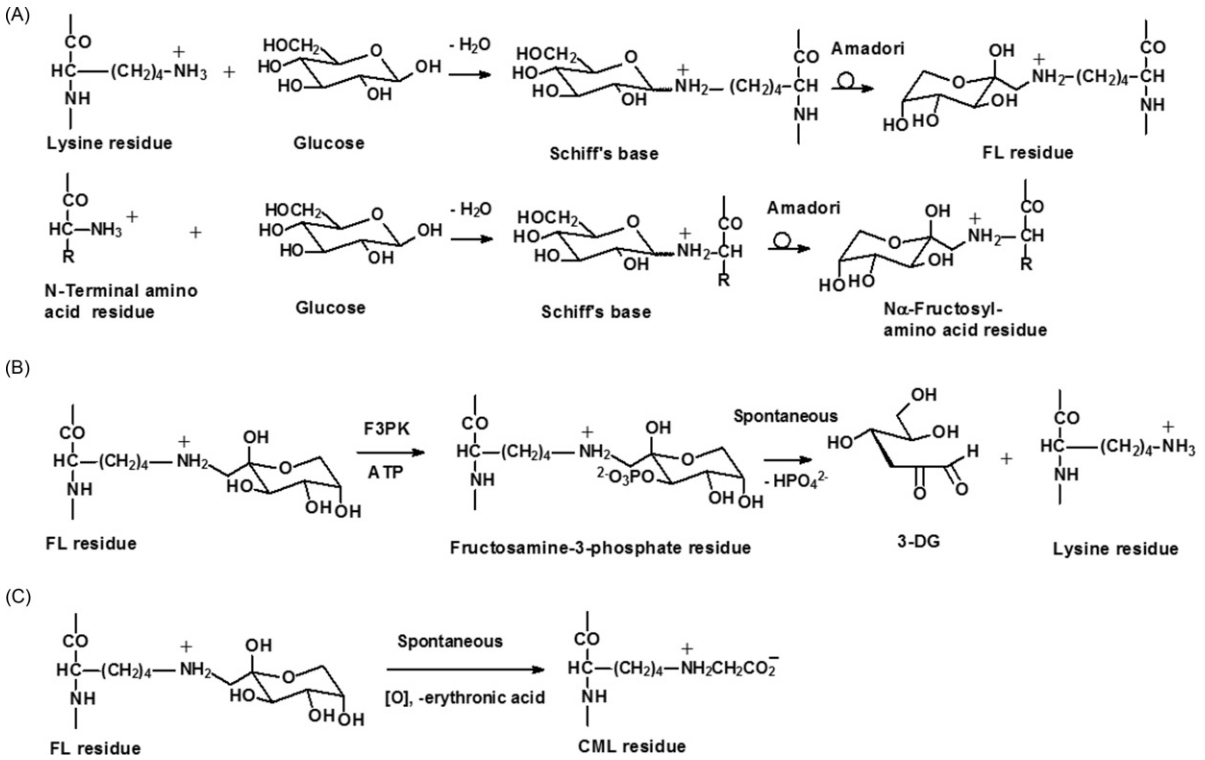

Fig. 1 *Glycation of proteins on lysine and N-terminal residues—formation and metabolism of fructosamines by glycation of protein with glucose.* (A) Reaction of glucose with lysine residues to form a Schiff's bases with Amadori rearrangement to a fructosamine, fructosyl-lysine (FL). Similar reactions occur with N-terminal amino acid residues, for example, β-val-1 of hemoglobin in A1C. (B) Deglycation of fructosamine residues by fructosamine-3-phosphokinase (F3PK). (C) Oxidative degradation of fructosyl-lysine to form the AGE, N_ε-carboxymethyl-lysine (CML). FL and CML adduct residues are shown with the peptide backbone –CO-CHR-NH- shown on the left. For the corresponding free adducts at physiological pH, the N-terminal amino group is protonated $-NH_3^+$ and the C-terminal carbonyl is a carboxylate $-CO_2^-$ moiety.

(American-Diabetes-Association, 2014; Bonora and Tuomilehto, 2011). A1C is routinely measured by cation exchange chromatography (Sacks, 2012).

Formation of Advanced Glycation Endproducts

FL and other fructosamine residues also degrade to form AGEs. The major AGEs formed from FL degradation are N_ε-carboxymethyl-lysine (CML) and glucosepane—the latter producing a crosslink with a neighboring arginine reside (**Fig. 1**C). Reactive dicarbonyl metabolites, glyoxal, methylglyoxal (MG), 3-deoxyglucosone (3-DG) are also important precursors of AGEs in vivo—**Fig. 2**A. Glyoxal is formed by lipid peroxidation and the nonenzymatic oxidative degradation of glucose and proteins glycated by glucose, MG is formed mainly by the degradation of triosephosphates, and 3-DG is formed by degradation of fructosamine-3-phosphate in the repair of early glycated proteins, the degradation of fructose-3-phosphate and the slow, non-enzymatic oxidative degradation of glucose and proteins glycated by glucose (Rabbani and Thornalley, 2012a). Unlike glucose, glycation by dicarbonyls is directed to arginine residues—for example, glycation of arginine residues by MG forms a stable hydroimidazolone, N_δ-(5-hydro-5-methyl-4-imidazolon-2-yl)ornithine (MG-H1)—**Fig. 2**B. MG and glyoxal are metabolized mainly by the glyoxalase 1 (Glo1) of the cytoplasmic glyoxalase system—**Fig. 3**A. Clinical homozygous frameshift mutation of the GLO1 gene is embryonically lethal, indicating that glycation by dicarbonyl substrates of Glo1—particularly MG—is a highly physiologically damaging form of glycation (Rabbani and Thornalley, 2014; Rabbani *et al.*, 2014b).

Quantitative assessments of AGEs show that major protein AGEs are: MG-H1, CML and the crosslink glucosepane (Ahmed *et al.*, 1986; Monnier *et al.*, 2013; Rabbani and Thornalley, 2012c). Other important AGEs in vivo are: glyoxal-derived hydroimidazolone G-H1 and 3-DG-derived hydroimidazolone isomers 3DG-H, pyrraline; and the pentose-derived fluorophore, pentosidine—**Fig. 3**C–F. Pyrraline is an AGE formed at high temperatures of culinary processing and mostly originates from ingested food (Rabbani *et al.*, 2014a). AGE residues are released from proteins by cellular proteolysis. The AGE free adducts thereby formed are released into plasma and excreted in urine. MG-H1 and CML are the major quantitative glycation free adducts excreted in human urine. AGE free adducts were detected in plasma, urine, cerebrospinal fluid, synovial fluid and haemodialysis and peritoneal dialysate. Loss of renal clearance in diabetic and nondiabetic chronic kidney disease leads to accumulation of AGE free

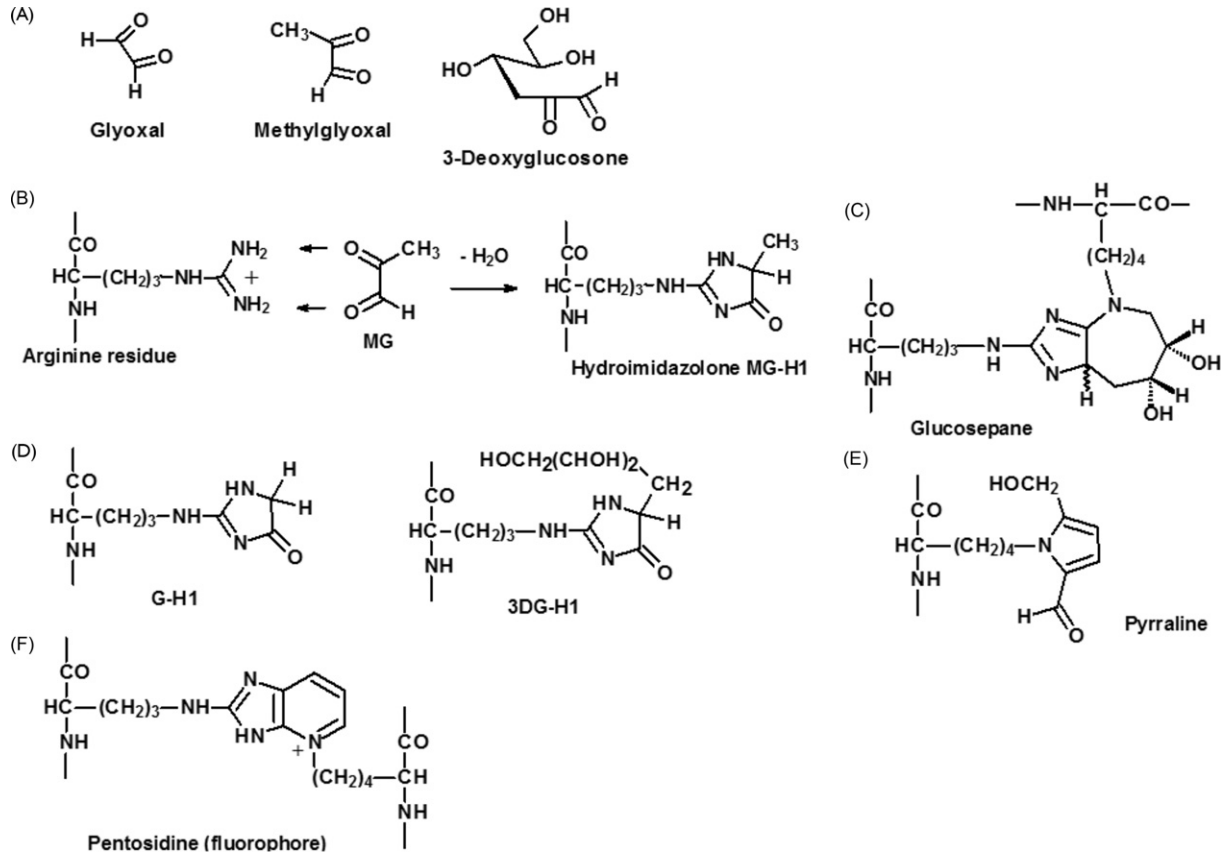

Fig. 2 *Glycation of proteins to form advanced glycation endproducts.* (A) Reactive α-oxoaldehydes in physiological glycation process. Molecular structures of AGEs. (B) Reaction of methylglyoxal with arginine residues to form hydroimidazolone N_δ-(5-hydro-5-methyl-4-imidazolon-2-yl) ornithine (MG-H1). Other AGEs: (C) Glucosepane; (D) Hydroimidazolones derived from glyoxal, G-H1, and 3-deoxyglucosone, 3DG-H1, formed with related structural isomers; (E) Pyrraline; and (F) Pentosidine. AGE adduct residues are shown with the peptide backbone –CO-CHR-NH- on the left. For the corresponding free adducts at physiological pH, the N-terminal amino group is protonated $-NH_3^+$ and the C-terminal carbonyl is a carboxylate $-CO_2^-$ moiety.

adducts in plasma. In patients with renal failure on peritoneal dialysis and hemodialysis, plasma MG-H1 free adduct increased 18- and 40-fold.

Glyoxal and MG are also important precursors of nucleotide AGEs. The quantitatively major nucleotide AGE is formed by MG —deoxyguanosine-derived imidazopurinone, 3-(2′-deoxyribosyl)-6,7-dihydro-6,7-dihydroxy-6/7-methylimidazo-[2,3-b]purine-9(8)one isomers (MGdG) (Thornalley *et al.*, 2010).

AGEs are quantified by stable isotopic dilution analysis liquid chromatography–tandem mass spectrometry (LC-MS/MS). There is limited correlation between amounts of different AGEs as they have different metabolic precursors, stabilities and in situ enzymatic activities preventing their formation. Estimates of individual AGEs are therefore required. AGE residues in protein and DNA are determined after prior exhaustive enzymatic digestion. AGE free adducts are determined directly in ultrafiltration of plasma, urine or other physiological fluids. Immunochemical techniques may be used for assay of AGEs. They perform best when corroborated by LC-MS/MS as interferences and lack of robust quantitation can give misleading estimates. Fluorescence of the trace AGE, pentosidine, in skin contributes to skin autofluorescence (SAF). The many other non-AGE fluorophores contributing to SAF and lack of responsiveness to major non-fluorescent AGEs make SAF an unreliable measure of AGEs (Rabbani *et al.*, 2014a; Thornalley and Rabbani, 2014; Thornalley *et al.*, 2010).

AGEs have different stabilities: some AGEs are highly stable (half-lives of years)—such as CML, whereas others have only moderate stability (half-lives of 2–3 weeks)—such as hydroimidazolones G-H1, MG-H1 and 3DG-H. There are at least four processes involved in the formation of AGEs in physiological systems: (i) monosaccharide autoxidation (autoxidative glycosylation)—the degradation of saccharide unattached to a protein, (ii) Schiff's base fragmentation, (iii) fructosamine degradation, and (iv) direct reaction of dicarbonyls formed from the degradation of glycolytic intermediates and lipid peroxidation with proteins (Rabbani and Thornalley, 2014; Thornalley *et al.*, 1999). Glycation is usually a minor posttranslational modification of protein and DNA. In proteins, the extent of glycation depends on concentration, reactivity and half-life of the protein and the concentration and reactivity of the glycating agent. The range of extent of glycation is typically 0.1%–1% of lysine and arginine

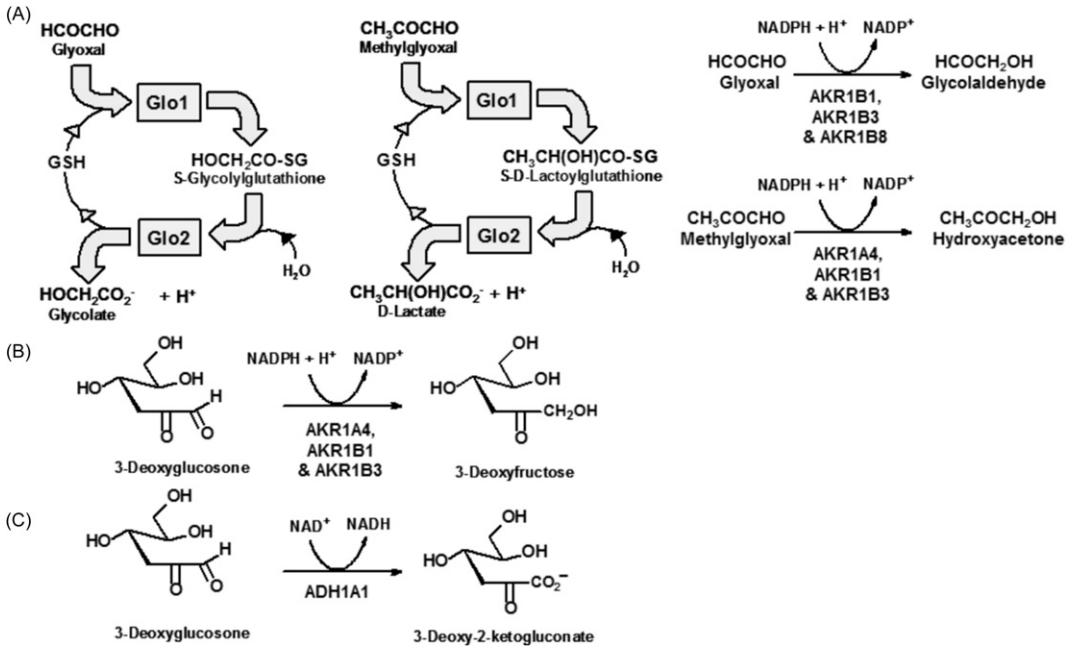

Fig. 3 *Metabolism of dicarbonyl metabolites—the enzymatic defense against glycation.* (A) Metabolism of glyoxal and methylglyoxal by the glyoxalase system and aldoketo reductases. (B) Metabolism of 3-deoxyglucosone by 3-DG reductase (AKRs 1A4, 1B1 and 1B3). (C) Metabolism of 3-deoxyglucosone by 3-DG dehydrogenase reductase (ADH 1A1).

residues in proteins and up to 1 in 10^5 nucleotides in DNA (Rabbani and Thornalley, 2012c; Thornalley *et al.*, 2010). For HSA, the concentration ranges (mol/mol albumin) of Schiff's base adduct, fructosamine and AGEs are c. 1%–5%, 6%–15% and 0.01%–7%.

Metabolism of dicarbonyls provides a physiological defense against AGE formation. Glyoxal and MG are detoxified to glycolate and D-lactate, respectively, by the glutathione-dependent glyoxalase system. When the glyoxalase system is impaired, AKR isozymes 1B1 (aldose reductase), 1B3 and 1B8 metabolize glyoxal to glycolaldehyde and AKR isozymes 1A4, 1B1 and 1B3 metabolize MG to mainly hydroxyacetone—**Fig. 3**A. The rate controlling step is catalyzed by Glo1 which has expression regulated by the transcription factor Nrf2. 3-DG is metabolized to 3-deoxyfructose by AKRs 1A4, 1B1 and 1B3 (3-DG reductase activity) and to 3-deoxy-2-ketogluconate by aldehyde dehydrogenase ADH1A1 (3-DG dehydrogenase activity)—**Fig. 3**B and C. All genes encoding these enzymes have expression regulated by transcription factor Nrf2. Additionally, there is a high cysteinyl thiol pool that binds dicarbonyls reversibly and thereby suppresses their irreversible reactions to form AGEs (Rabbani and Thornalley, 2012a).

Contribution of Food AGEs to Clinical AGE Exposure and Health Impairment

Thermally processed food is a rich source of AGEs which may be absorbed as free adducts after digestion of ingested protein. Dietary AGEs have poor bioavailability. There is no evidence that the AGE free adducts absorbed therefrom are incorporated into endogenous proteins. Rather, AGE free adducts have high renal clearances and are efficiently excreted in urine. So that unless renal function is impaired they are rapidly cleared and excreted (Agalou *et al.*, 2005; Rabbani and Thornalley, 2014). The proportions of urinary AGE free adducts sourced from food and endogenous glycation may be deduced by plotting urinary AGE free adduct excretion against the urinary excretion of pyrraline. Urinary excretion of AGE free adducts provides an estimate of total body AGE exposure and urinary exertion of pyrraline reflects absorption of AGEs from food. Correlation of urinary excretion of a particular AGE with urinary exertion of pyrraline reflects a significant contribution of the AGE from food. Linear regression of urinary AGE excretion on urinary exertion of pyrraline and extrapolation to zero pyrraline excretion gives an estimate of the flux of AGE formed endogenously in the body. AGE absorbed from food then equals the total urinary AGE flux minus this deduced endogenous AGE flux. This analysis was performed recently for MG-H1. In healthy overweight and obese subjects, the flux of endogenous formation of MG-H1 at baseline was c. 13 nmol/mg creatinine, representing 68% of total MG-H1 exposure; the mean contribution to total MG-H1 exposure from the diet was 32% but highly variable (Xue *et al.*, 2016). The diet is likely often a minor source of MG-H1 exposure.

Several clinical studies with interventions to decrease exposure to dietary AGEs for improved vascular health in chronic kidney disease have been performed (Harcourt *et al.*, 2011; Vlassara *et al.*, 2009; Yacoub *et al.*, 2017). The outcomes are difficult to interpret as unblinded study designs were used. These and other studies were evaluated by meta-analysis for overall assessment of evidence of health benefits (Kellow *et al.*, 2014). It was concluded that there is insufficient evidence, at present, to recommend dietary AGE restriction for health benefit (Kellow *et al.*, 2014). There is a need for long-term, high-quality randomized controlled

trials with large sample size and masking of the AGE intervention to provide more robust evidence on the health impact of dietary AGEs—also taking advantage of recent advances in improved quantitation of AGEs in food (Scheijen *et al.*, 2016).

Functional Consequences of Glycation

Glycation occurs inside and outside of cells. Glycation of basic phospholipids may induce changes in membrane structure and lipid peroxidation. Glycation of nucleotides in DNA normally induces DNA repair but may induce apoptosis or senescence if glycation is excessive. Glycation of proteins may also induce apoptosis by modification of mitochondrial proteins and activation of mitochondrial apoptotic pathway and glycation of extracellular proteins leading to cell detachment-stimulated apoptosis. Glycation of cellular and extracellular proteins produces loss of function or acquisition of new pathogenic function. These effects are countered by protein degradation and renewal. Glycation by MG to form MG-H1 is particularly damaging because: (i) loss of positive charge of arginine residues with MG-H1 formation produces loss of all electrostatic interactions involved in neighboring group and ligand binding interactions; (ii) arginine residues have the highest probability of any amino acid residue for location at functional sites of proteins; and (iii) MG-H1 is one of the most quantitatively important, spontaneous irreversible modifications of the proteome in health and disease (Rabbani and Thornalley, 2014). The extent of modification of proteins is only minor but increases in this low level of modification may have profound physiological effects. For example, detachment of vascular endothelial cells by glycation of collagen-IV of the extracellular matrix and atherogenic transformation of LDL by glycation of apolipoprotein B100 with MG—both contributory factors to increased cardiovascular disease, and MG modification of mitochondrial proteins linked to mitochondrial dysfunction and increased formation of reactive oxygen species (ROS) (Thornalley and Rabbani, 2010).

Protein Glycation and Risk of Developing Diabetic Complications

A1C is a risk factor for the development of chronic clinical complications as a surrogate indicator of hyperglycemia (Stratton *et al.*, 2000; The Diabetes *et al.*, 2000). Skin collagen content of stable AGEs such as CML, pentosidine, glucosepane and others are linked to risk of developing and microvascular complications of diabetes and their progression, probably as surrogate markers of long-term metabolic control (McCance *et al.*, 1993; Monnier *et al.*, 2013). In recent studies of AGEs and related analysis of skin collagen in patients with type 1 diabetes mellitus (T1DM), an analyte panel of glucosepane, MG-H1, CML, N_{ϵ}(1-carboxyethyl)lysine (CEL), glyoxal-derived hydroimidazolone (G-H1), pentosidine, furosine, collagen fluorescence, skin collagen acid solubility and pepsin digestibility was linked to risk of progression of diabetic microvascular complications. The FL-linked analyte, furosine, was a strong predictor—likley as a surrogate indicator of hyperglycemia (Genuth *et al.*, 2015). In contrast, CML residue content of plasma protein alone was not linked to the risk of developing diabetic nephropathy (Klein *et al.*, 2017). Plasma MG-H1 free adduct concentration was an independent risk predictor for progression of diabetic kidney disease (Beisswenger *et al.*, 2013).

Dicarbonyl stress and related arginine directed glycation appears to be a driver for development of vascular complication of diabetes. There was a 5–6-fold increase of MG concentration in blood samples of patients with T1DM and 3–4-fold increase of whole blood MG in patients with type 2 diabetes mellitus (T2DM). This was disproportionately high compared to increase in glucose and D-lactate concentration—both increased 2–3-fold (McLellan *et al.*, 1994). The disproportionate increase in MG concentration likely reflects decrease in Glo1 activity at peripheral tissue sites – including kidney, peripheral nerve, retina and vascular endothelial cells (Bierhaus *et al.*, 2012; Miller *et al.*, 2010; Yao and Brownlee, 2009). Decreased Glo1 activity may reflect decreased Glo1 expression in response to inflammatory and/or hypoxia signaling and increased proteolysis (Bierhaus *et al.*, 2012; Yao and Brownlee, 2009; Zhang *et al.*, 2012). Increased MG has emerged as a factor linked to the development of chronic microvascular complications of diabetes (nephropathy, retinopathy and neuropathy) (Fosmark *et al.*, 2006; Hammes *et al.*, 1999; Kilhovd *et al.*, 1999; McLellan *et al.*, 1994). Functional genomics studies with Glo1 deficient and Glo1 overexpressing transgenic mice support this (Berner *et al.*, 2012; Bierhaus *et al.*, 2012; Giacco *et al.*, 2014).

The contribution of dicarbonyl glycation to diabetic macrovascular disease (coronary artery disease, peripheral arterial disease and stroke) is less certain. MG modification of LDL induced atherogenic transformation to small, dense LDL and MG modification of HDL induced destabilization and increase plasma clearance (Rabbani and Thornalley, 2014; Rabbani *et al.*, 2014b). In a large genome-wide integrated transcriptomic study, Glo1 deficiency emerged as a previously unrecognized driver of coronary heart disease (Mäkinen *et al.*, 2014). Treatment of apolipoprotein E deficient mice with a cell permeable Glo1 inhibitor increased vascular inflammation and atherogenesis in normoglycemia similar in extent to that found in diabetic mice (Tikellis *et al.*, 2014). Dicarbonyl glycation, therefore, likely contributes to dyslipidemia risk factors of cardiovascular disease and vascular cell dysfunction driving vascular inflammation and atherogenesis which is exacerbated in the diabetic state.

Accumulation of AGE crosslinks in proteins have been proposed as a mechanism contributing to basement membrane thickening in diabetes through increased resistance to proteolysis. This may be an oversimplification, however, as there are non-sulfhydryl crosslink of the extracellular matrix of markedly higher quantitative content that AGEs—such as transglutaminase-formed $N\epsilon$-(γ-glutamyl)lysine and dual oxidase-formed dityrosine and metabolic dysfunction in diabetes produced increased extracellular matrix deposition.

Alleviation of the damaging effects of glycation may be achieved through improvement of glycemic control but this is likely insufficient alone. Meta-analysis indicated that clinically achievable glycemic control addresses only 22% of risk of diabetic nephropathy (Hemmingsen *et al.*, 2011). Scavengers of dicarbonyls have been proposed as therapeutic agents but the high reactivity of them required to compete effectively with tissue proteins is often associated with toxicity and instability. Some current treatments have secondary pharmacological activities that decrease dicarbonyl glycation; for example, metformin and angiotensin receptor blocker Irbesartan (Rabbani *et al.*, 2011, 2010). Increasing Glo1 expression and activity would likely be more effective. A strategy to produce this is to develop Glo1 inducers (Xue *et al.*, 2012)—reviewed in (Rabbani and Thornalley, 2018).

Dietary bioactive compounds were screened as activators of transcription factor Nrf2 and inducers of Glo1 expression via a functional antioxidant response element and the best inducer of Glo1 expression or "Glo1 inducer" found to be a combination of *trans*-resveratrol and hesperetin (tRES-HESP). In a double blind, randomized, placebo-controlled crossover study evaluation of tRES-HESP, expression and activity of Glo1 in peripheral blood mononuclear cells was increased, plasma MG decreased and total body MG-protein glycation decreased. There was related decreased fasting plasma glucose (FPG) and postprandial plasma glucose (PPG), increased insulin sensitivity, improved arterial dilatation and decreased vascular inflammation marker, soluble intracellular vascular cell adhesion molecule-1 (sICAM-1). There was also minor weight loss and improvement in renal function (Xue *et al.*, 2016). Clinical therapeutic response of the tRES-HESP combination was profoundly stronger than either compound alone. This is likely due to HESP improving bioavailability of tRES by inhibition of intestinal glucuronosyltransferases—reviewed in (Rabbani and Thornalley, 2018).

Comparison of the effect of tRES-HESP in overweight and obese subjects to that of metformin and Olristat on similar subjects groups in similar intervention trials suggested the effect of tRES-HESP on glycaemic control exceeds that of metformin and matches that of Olristat (Mancini and Halpern, 2008; Park *et al.*, 2009). Decrease in FPG in the normal range may help reduce the risk of developing T2DM (Tirosh *et al.*, 2005) and improvement in insulin resistance was comparable to that achieved with extreme weight loss with gastric band surgery in morbid obesity (Hanusch-Enserer *et al.*, 2004). tRES-HESP could be a suitable treatment for improved metabolic and vascular health in overweight and obese populations. Glo1 inducer development appears to be particularly appropriate and timely for treatment of high prevalence complications of obesity such as nonalcoholic fatty liver disease (NAFLD) and vascular complications of diabetes. Increased AGEs have been associated with the development of T1DM (Beyan *et al.*, 2012) and increased Glo1 protein was found to be protective of experimental chemically-induced pancreatic beta-cell toxicity (Kim *et al.*, 2013). The Glo1 inducer formulation may also be considered for prevention of T1DM, particularly as it is a synergistic binary combination of active agents involving tRES. tRES has previously been found to be effective in prevention of diabetes in experimental mouse model of non-obese type 1 diabetes, albeit at doses higher than tolerated clinically (Lee *et al.*, 2011).

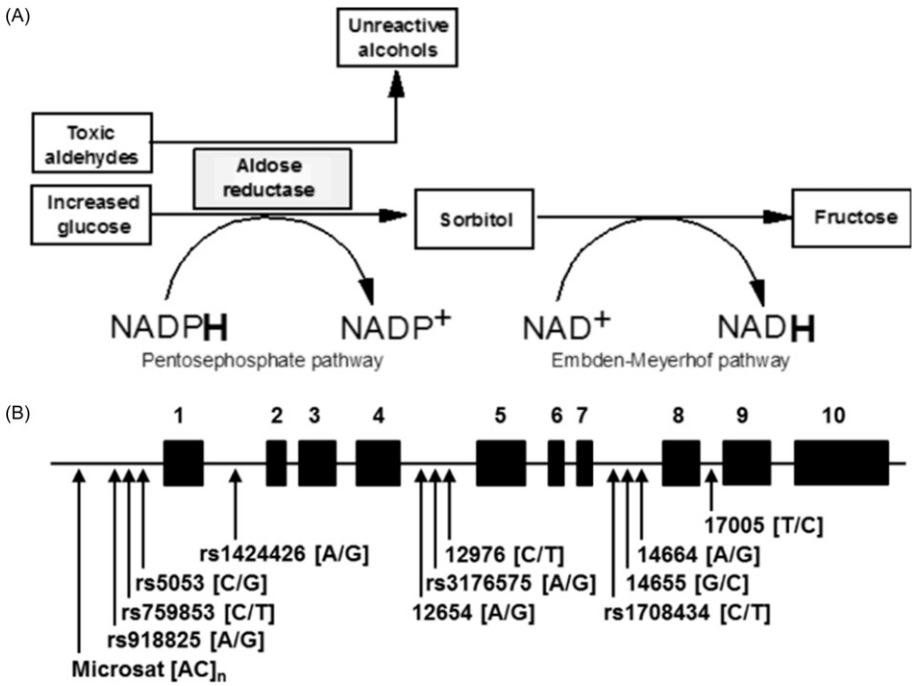

Fig. 4 *The polyol pathway.* (A) Metabolic pathway and cofactors. (B) AK1B1 Gene structure showing location of polymorphisms. The position of each variant within AKR1B1 is designated by an arrow. Exons are numbered and are represented by filled rectangles. Single nucleotide polymorphism (SNPs) are identified by the dbSNP identifier when available or by the nucleotide position within the aldose reductase genomic sequence (AF032455); the polymorphic dinucleotide repeat is designated "microsat." The locus size is approximately 17 kb (Wolford et al., 2006).

Polyol Pathway and Diabetic Complications

Aldose reductase (AR; AKR1B1) is the first enzyme in the polyol pathway. It catalyzes the NADPH-dependent reduction of glucose and many other carbonyl compounds to sorbitol and the corresponding alcohol derivatives—**Fig. 4**A. AR also catalyzes the formation of prostaglandin F2α from prostaglandin H2 and thereby influencing the production of prostaglandin E2 (PGE2) (Lacroix Pépin *et al.*, 2013) and catalyzes the reduction of MG to hydroxyacetone—although this is only a significant fate for MG metabolism in the renal medulla where expression of AR is high (Rabbani *et al.*, 2016). Indeed, AR has an extraordinarily high expression in the human renal medulla where it constitutes c. 2% total protein and a cellular concentration of c. 100 μM (Nishimura *et al.*, 1993). Its role therein is to reduce glucose to sorbitol and produce intracellular osmotic pressure to counter extracellular hypertonicity of increasing sodium chloride and urea concentrations produced during antidiuresis (Moriyama *et al.*, 1989). Sorbitol content of the renal medulla is relatedly very high—c. 100 mM, as expected for a role in osmoregulation (Grunewald *et al.*, 1995). In comparison, vascular endothelial cell content of AR is 0.08% total protein and sorbitol concentration is much lower, c. 0.6 mM, were there is limited effect on osmotic pressure of AR activity (Hawthorne *et al.*, 1989; Nakamura *et al.*, 2000).

AR has a low affinity (high K_M) for glucose. Hence, there is an increased flux of glucose metabolism via the polyol pathway in hyperglycemia. In the renal medulla of streptozotocin (STZ)-induced diabetic rats, sorbitol synthesis was increased and tissue content of sorbitol increased twofold (Willi and Kinne, 1989). In human red blood cells, glucose metabolism increases from 3% of total glucose metabolism in normoglycemia to 6% in moderate hyperglycemia (Morrison *et al.*, 1970). Red blood cell content of sorbitol in healthy subjects is c. 3 μM and increased threefold in patients with type 1 diabetes (Malone *et al.*, 1984). In vascular endothelial cells the flux of glucose metabolized by the polyol pathway, as judged by pentosephosphate pathway activity, was relatively low in normoglycemia and increased little in model hyperglycemia in vitro (Kashiwagi *et al.*, 1997) with an increase in sorbitol content to c. 1.1 mM (Hawthorne *et al.*, 1989). Estimates of sorbitol concentration in sural nerve of patients with diabetes were c. 0.1 mM (Greene *et al.*, 1999). Sorbitol was increased in retina of STZ-induced diabetic rats from c. 0.06 mM in healthy controls to c. 0.66 mM in diabetes (Poulsom *et al.*, 1983). This suggests that AR activity may not contribute significantly to osmotic pressure in tissues other than the renal medulla in diabetes. The effects of activation of the polyol pathway in diabetes have also been attributed to decreased Na^+K^+ ATPase activity, in situ inhibition of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) by change in NADH/NAD^+ ratio, in situ inhibition of glutathione reductase by depletion of NADPH—exacerbating intracellular oxidative stress. These effects have been linked to depletion of myo-inositol with decreased incorporation into cell phosphoinositides, chronic elevation of diacylglycerol and abnormal activation of protein kinase C (PKC) and decreased activity of NAD^+-dependent deacetylase sirtuin-1 and protein hyperacetylation (Vedantham *et al.*, 2014; Xia *et al.*, 1994). More recently, hyperglycemia-induced sorbitol accumulation in Schwann cells of peripheral nerve has been linked to their dedifferentiation to immature cells and peripheral nerve de-myelination (Hao *et al.*, 2015). This was prevented by treatment with an AR inhibitor (ARI).

Sorbitol produced in the first step of the polyol pathway is oxidized by NAD^+-dependent sorbitol dehydrogenase (SDH) to fructose in the second step. The complete traverse of the polyol pathway involves oxidation of NADPH to $NADP^+$ and reduction of NAD^+ to NADH. This represents a net hydride transfer from NADPH in the pentosephosphate pathway to NAD^+ in Embden-Meyerhof pathway and thereby a net reduction of NAD^+ to NADH in Embden-Meyerhof pathway and an increase in cytosolic NADH/NAD^+ ratio.

Mice with AR gene deletion had defective urine concentrating ability with a phenotype resembling nephrogenic diabetes insipidus (Ho *et al.*, 2000), reflecting the role of AR in osmoregulation and antidiuresis. Diabetes induced in homozygous AR knockout mice protected against decreased GSH content of sciatic nerve, decreased motor nerve conduction velocity, in contrast to wild-type mice and degeneration of retinal capillaries (Liu *et al.*, 2011; Tang *et al.*, 2013). AR deficiency prevented renal extracellular matrix accumulation and collagen IV overproduction, activation of renal cortical PKC, transforming growth factor-beta 1 (TGF-β1) and glomerular hypertrophy in diabetic mice and decreased urinary albumin excretion (Liu *et al.*, 2011). In contrast, AR deficiency increased development of atherosclerosis in diabetic apolipoprotein E deficient mice (Srivastava *et al.*, 2009)—exemplifying the complex involvement of AR in pathogenesis in diabetes.

The human AR gene—**Fig. 4**A,B, AKR1B1 (also known as ALR2), is located at chromosome 7q35. In meta-analysis, AKR1B1 polymorphisms were associated with diabetic nephropathy: the $Z-2$ allele was associated with increased risk whereas the $Z+2$ allele was associated with decreased risk of diabetic nephropathy. The T allele in SNP rs759853 was associated with increased risk of diabetic nephropathy. AKR1B1 polymorphisms were also associated with diabetic retinopathy: the $z-2$ microsatellite increased risk in type 1 and type 2 diabetes and $z+2$ conferred protection against diabetic retinopathy in type 2 diabetes. The T allele of the AKR1B1 promoter rs759853 variant was protective against diabetic retinopathy in type 1 diabetes (Abhary *et al.*, 2009; Mooyaart *et al.*, 2011).

Studies of the inhibition of the polyol pathway in vivo with specific inhibitors have given inconsistent results. Several clinical trials have been performed for treatment of diabetic neuropathy with negative outcomes. Recent meta-analysis of clinical trials of ARIs indicate there are beneficial effects in diabetic cardiovascular autonomic neuropathy (Hu *et al.*, 2014). A potential problem for ARIs is the adverse effect of decreasing the antidiuretic activity of AR in the kidney.

Hypertension and Diabetes☆

Atossas Niakan and William C Cushman, University of Tennessee Health Science Center, Memphis, TN, United States

Glossary

Diastolic blood pressure Pressure as measured during the rhythmic relaxation of the muscles of the heart chambers during the time they fill with blood.

Hyperglycemia An abnormally high concentration of sugar in the blood.

Nephropathy Any disease of the kidney.

Macrovascular disease Disease involving large blood vessels

Microvascular disease Disease involving small blood vessels.

Systolic blood pressure SBP Pressure as measured during contraction of the heart chambers.

Introduction

The management of the hypertension so frequently seen in diabetic patients has now become one of the most critical challenges of health care. However, numerous controversies over the appropriate way in which to treat hypertension in diabetic patients have arisen, including, the appropriate level of blood pressure at which antihypertensive therapy should be started, the blood pressure goals of such therapy, and the best choices of antihypertensive drugs. Here, we aim to review the evidence and make recommendations for management of hypertension in patients with type 2 diabetes mellitus.

Evidence for Intensive Treatment of Blood Pressure

Randomized controlled trials (RCTs) have provided conclusive evidence of the impressive benefits of reducing the blood pressure at least to below 150/85 mmHg (**Table 1**). In the diabetes subgroups of the systolic hypertension in the elderly program (SHEP, $n = 583$) and the systolic hypertension in Europe (Syst-Eur, $n = 492$) trials, both of which treated patients age ≥ 60 years with isolated systolic hypertension, treatment to a systolic blood pressure goal <150 mmHg with therapy based on the thiazide-type diuretic chlorthalidone or the dihydropyridine calcium channel blocker (CCB) nitrendipine, respectively, reduced major cardiovascular disease events by 34% and 62%, respectively (Curb *et al.*, 1996; Tuomilehto *et al.*, 1999). The mean achieved blood pressure in the active treatment arms of the diabetic subgroups in SHEP and SYS-EUR trial were 146/68 and 153/78, respectively.

In the United Kingdom Prospective Diabetes Study (UKPDS), control of blood pressure to a target $<150/85$ mmHg versus a target of $<180/105$ mmHg significantly reduced microvascular disease, stroke, heart failure, and deaths related to diabetes (UK Prospective Diabetes Study Group, 1998). The attained mean blood pressure was 144/82 mmHg in the "tight" control arm and 154/87 mmHg in the less tight control arm.

In a post hoc analysis of the hypertension optimal treatment (HOT) trial, 1501 diabetic hypertensives were randomly allocated to achieve diastolic levels of less than 90, 85, or 80 mmHg with therapy based on a CCB but often requiring addition of one or two other drugs. Those assigned to the 80-mmHg goal reached a mean level of 81 mmHg, only 4 mmHg lower than those assigned to the 90-mmHg goal. Despite this relatively small difference in achieved pressure, there was a very impressive reduction in all events. However, some guideline committees discount this analysis since it was not prespecified.

The hypertension component of the ABCD (appropriate blood pressure control in diabetes) trial, compared intensive control of blood pressure (diastolic blood pressure of 75 mmHg) with moderate control of blood pressure (target diastolic blood pressure of 80–89): achieved blood pressure was 132/78 mmHg and 138/86 mmHg, respectively.

While there was no reduction in the primary microvascular or secondary cardiovascular disease, the total mortality was significantly reduced (Schrier *et al.*, 1996).

In the action in diabetes and vascular disease: Preterax and diamicron modified-release controlled evaluation (ADVANCE) trial, treatment with an angiotensin converting enzyme (ACE) inhibitor and a thiazide-type diuretic in patients with type 2 diabetes reduced deaths from all causes significantly (Patel *et al.*, 2007). The ADVANCE trial had no specified blood pressure goals but the mean achieved systolic blood pressure in the more intensive arm was 134 mmHg.

The action to control cardiovascular disease in diabetes—blood pressure (ACCORD—BP) trial is the only randomized controlled trial that has examined the effect of a systolic blood pressure goal of lower than 140 mmHg on major cardiovascular disease

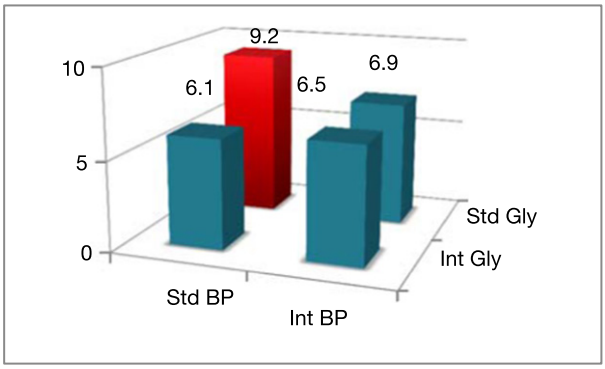

Fig. 1 ACCORD-BP: Primary 5 year CVD event rates by glycemia and BP randomized subgroups.

outcomes among diabetics. This trial compared intensive treatment (systolic blood pressure goal of <120 mmHg) with standard treatment (goal of <140 mmHg) in 4733 patients with type 2 diabetes with entry systolic blood pressure of 130–180 mmHg (The ACCORD Study Group, 2010). The 12% reduction in mortality or overall primary cardiovascular outcomes in the intensive treatment group compared with the standard goal group was not statistically significant. However, intensive treatment was associated with a significant reduction in the occurrence of stroke (risk reduction 41%; $P = .01$), which was a prespecified secondary outcome. In addition, in the standard glycemia subgroup (approximately ½ of the BP study population, the primary outcome was reduced by 26% with intensive treatment of blood pressure compared with standard blood pressure treatment (Margolis *et al.*, 2014). Standard glycemic/standard BP subgroup had significantly higher CVD event rate than other subgroups (**Fig. 1**).

In 2015, the findings from the systolic blood pressure intervention trial (SPRINT) brought the discussion of target blood pressure goals in diabetic patients to light again. SPRINT randomized 9361 persons with systolic BP >130 mmHg and increased CV risk, but without type 2 DM, to a systolic BP target <120 mmHg (intensive treatment) or a target of <140 mmHg (standard treatment). At 1 year, the mean systolic BP was 121.4 mmHg in the intensive treatment group and 136.2 mmHg in the standard-treatment group (The SPRINT Reseach Group, 2015). The study was stopped early after a median follow-up of 3.26 years due to a 25% lower rate of the primary composite outcome in the intensive-treatment group than in the standard-treatment group ($P < .001$). All-cause mortality was also lower by 27% in the intensive treatment group ($P = .003$). SPRINT findings support intensive BP lowering in nondiabetic patients with increased CV risk. Diabetic patients were not included in the SPRINT but are known to be at increased risk for CV events and one could speculate that SPRINT results could apply to diabetics. In fact, it was recently reported from SPRINT that the beneficial effects of intensive systolic blood pressure treatment were similar among those with prediabetes (fasting glucose ≥100 mg/dL) and fasting normoglycemia (Bress *et al.*, 2017).

Several reasons can explain the discrepancy of the findings of ACCORD and SPRINT (Margolis *et al.*, 2014). Participants in ACCORD were younger compared to SPRINT (mean age of 62 vs. 68), and had lower event rates than initially predicted. Participants in the BP intervention of ACCORD had healthier cardiovascular risk profile than expected because patients with dyslipidemia were assigned to the lipid arm and were excluded from the BP arm and those with chronic kidney disease (creatinine >1.5 mg/dL) were excluded. The complex factorial study design in ACCORD could have made it harder to detect a statistically

significant finding. Because event rates were 50% lower than was expected in the standard-treatment group, ACCORD—BP could be viewed as underpowered.

A large network meta-analyses of 42 randomized clinical trials, including 144,220 patients with multiple comorbidities including diabetes, compared multiple levels of achieved systolic blood pressure on the risk of CVD and all-cause mortality. The lowest risk of cardiovascular disease and mortality was present for randomized groups with a mean achieved SBP range of 120 to 124 mmHg (Bundy *et al.*, 2017). This group had a hazard ratio (HR) for major cardiovascular disease of 0.71 (95% CI, 0.60–0.83) compared with randomized groups with a mean achieved SBP of 130–134 mmHg. A sensitivity analysis was also conducted excluding SPRINT from the meta-analyses, HRs and 95% CIs were consistent with results from the main analyses for major CVD, CHD, and all-cause mortality, and most of the trials included significant numbers of participants with diabetes mellitus.

The totality of evidence suggests that a target of BP $<$130/80–85 mmHg is reasonable in most diabetic patients and it is possible that if diabetic patients were included in SPRINT, they could have similarly benefited from intensive systolic BP lowering to about 120 mmHg. Based on the currently available evidence, the 2017 Canadian Hypertension guidelines and a 2017 American Diabetes Association position paper have both recommended advising patients with diabetes (and high cardiovascular risk in the ADA statement) to be treated to attain a blood pressure of $<$130/80 mmHg (Leung *et al.*, 2016; American Diabetic Association, 2017).

Evidence That Antihypertensive Drugs Reduce Risk

There have been a number of major outcome trials demonstrating that diuretics, CCBs, angiotensin-converting enzyme inhibitors (ACEIs), and angiotensin II receptor blockers (ARBs) reduce cardiovascular morbidity and mortality or progression of renal damage in patients with diabetes mellitus. Therefore, the initial several drug classes for treatment for hypertension in diabetes should include these classes. For patients with albuminuria (urine albumin-to-creatinine ratio [UACR] $\geq$30 mg/g), and possibly patients with chronic kidney disease without albuminuria, initial treatment should include an ACEI or ARB in order to reduce the risk of progressive kidney disease. ACEIs and ARBs have not been shown to be superior in reducing cardiovascular events when compared with other antihypertensive agents, and thiazide-type diuretics and CCBs are superior to ACEIs and ARBs in reducing cardiovascular events in blacks with diabetes. β-blockers may be used for the treatment of coronary disease or heart failure in diabetes but have not been shown to reduce cardiovascular events more than these other agents in treatment of hypertension in the absence of these conditions.

Comparison of Major Drug Classes

The overall data from comparative trials of diabetic hypertensives provide no clear proof that one class of drug is better than another among diabetic without kidney disease. However, the current recommendations vary among different guidelines about the role of RAS blockade for treatment of hypertension among diabetics without involvement of kidneys.

A prospective meta-analysis by the Blood Pressure Lowering Treatment Trialists' Collaboration showed that major cardiovascular disease events were reduced to a similar extent in individuals with or without diabetes regardless of the drug class used to reduce blood pressure (Turnbull *et al.*, 2005). However, this meta-analysis lumped diuretics and β-blockers together and treated them as one class. However, these drug classes and their results in trials are quite different from each other.

The antihypertensive and lipid-lowering treatment to prevent heart attack trial (ALLHAT) studied various antihypertensive agents in a large number (13,101) of diabetic patients. The trial failed to show superiority with use of CCBs or ACEIs compared with a thiazide-type diuretic, when used as the first-step antihypertensive agent (Whelton *et al.*, 2005). A significantly higher incidence of heart failure was present among those assigned to amlodipine compared with chlorthalidone in the diabetic patients (RR, 1.39 [95% CI, 1.22–1.59]) (**Fig. 2**).

An overview of eight systematic reviews regarding choice of antihypertensive agents among diabetic patient with hypertension, failed to show any difference between ACEIs, ARBs, β-blockers, CCBs, and diuretics in preventing all-cause or cardiovascular mortality, combined cardiovascular disease, coronary heart disease, and end-stage renal disease (Brunström, *et al.*, 2017).

A meta-analysis of 19 randomized controlled trials (including 25,414 patients with diabetes and elevated blood pressure), studied use of RAS blockers versus other antihypertensive agents. It concluded that RAS blockers did not have any advantages compared with commonly used antihypertensive agents such as β-blockers, CCBs, and thiazide diuretics with respect to death, myocardial infarction, heart failure, stroke, or end stage renal disease (Bangalore *et al.*, 2016).

The use of β-blockers among diabetic patients as an initial antihypertensive agent have been discouraged by several current guidelines. This is supported by the findings from the diabetes subgroups of the LIFE (Losartan Intervention for Endpoint reduction in hypertension) and ASCOT—BPLA (Anglo-Scandinavian Cardiac Outcomes Trial—Blood Pressure Lowering Arm) trials. In the LIFE study, losartan significantly reduced cardiovascular disease mortality, total mortality, heart failure, and composite cardiovascular disease outcomes compared with the β-blocker atenolol among the diabetic subgroup (Lindholm *et al.*, 2002). Amlodipine improved total cardiovascular disease events and procedures, and fatal and nonfatal stroke, compared with atenolol among diabetics enrolled in ASCOT (Ostergren *et al.*, 2008).

All of the above findings are in support of the 2014 United States evidence-based guidelines from the panel members of the eighth Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure who also

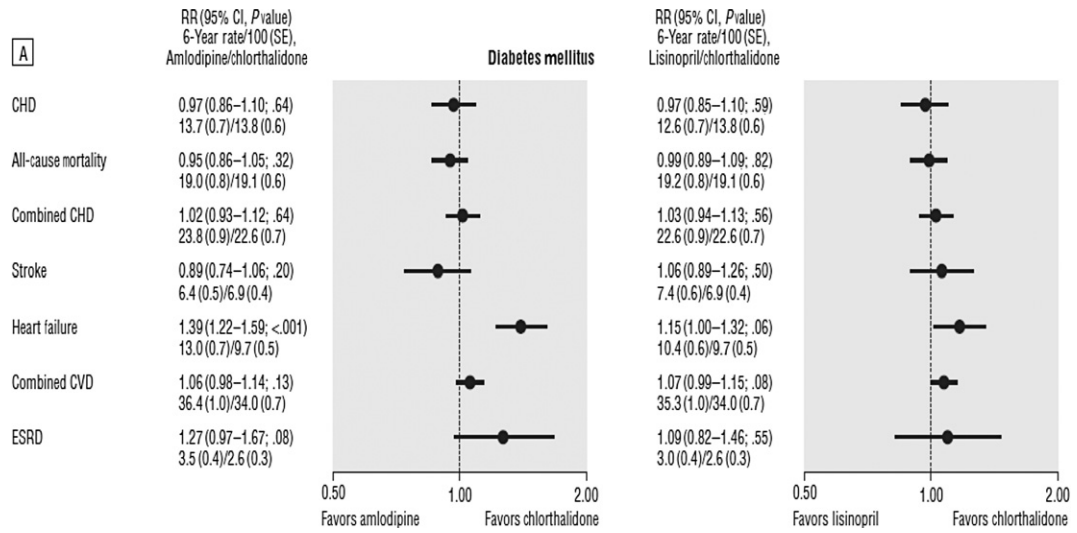

Fig. 2 Relative risks (RRs), 95% confidence intervals (CIs), *P* values, and 6-year rates per 100 and standard error (SE) for nondiuretic treatment compared with diuretic treatment for participants with diabetes mellitus at baseline, for coronary heart disease (CHD), all-cause mortality, combined CHD (includes CHD, coronary revascularization, or hospitalized angina), stroke, heart failure, combined cardiovascular disease (CVD) (includes combined CHD, stroke, other treated angina, heart failure, or peripheral arterial disease), and end-stage renal disease (ESRD) in the Antihypertensive and Lipid-Lowering to Prevent Heart Attack Trial (ALLHAT) Whelton, P.K., Barzilay, J., Cushman, W.C., Davis, B.R., Ilamathi, E., Kostis, J.B., Leenen, F.H., Louis, G.T., Margolis, K.L., Mathis, D.E. and Moloo, J. (2005). Clinical outcomes in antihypertensive treatment of type 2 diabetes, impaired fasting glucose concentration, and normoglycemia: Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT). *Archives of Internal Medicine* 165(12), 1401–1409.

recommends use of thiazide-type diuretics, ACEIs, ARBs, and CCBs as initial antihypertensive drug classes for patients with diabetes without proteinuria or microalbuminuria (James *et al.*, 2014).

It is known that presence of albuminuria or reduced eGFR is associated with significant risk of CVD among diabetic patients (Solini *et al.*, 2012). There is considerable evidence that RAS blockers are protective against one of the most common and serious complications seen in diabetic hypertensives: progressive renal damage leading to end stage renal disease. In the Irbesartan Type II Diabetic Nephropathy Trial (1715 patients with diabetic nephropathy) the RAS blocker irbesartan compared with the calcium channel blocker amlodipine was associated with a significant reduction in the risk of the primary composite end point (32.6% vs. 41.1%; $P = .006$) of a doubling of serum creatinine concentration, the development of end stage renal disease, or death from any cause. Benefits of angiotensin receptor blockers were also demonstrated in the Microalbuminuria, Cardiovascular, and Renal Outcomes substudy of the Heart Outcomes Prevention Evaluation study (MICRO-HOPE) and Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan study (RENAAL) (Bakris *et al.*, 2003) These studies demonstrated that RAS blockers when compared to placebo were associated with a reduction in doubling of serum creatinine concentration and in the rate of progression to end stage renal disease or death from any cause (Heart Outcomes Prevention Evaluation (HOPE) Study Investigators, 2000; Bakris *et al.*, 2003).

In a meta-analysis of trials that included patients with diabetes and kidney disease, end stage renal disease and a doubling of creatinine concentration was less likely and regression of albuminuria was more likely with ACE inhibitors or ARBs compared with placebo.

The Need for Multiple Drugs

To achieve the desired reduction in blood pressure to a level of 130/80 mmHg or lower, most diabetic hypertensives will require two, three, or four antihypertensive drugs. As noted in the position statement by American Diabetic Association (2017):

> Multiple-drug therapy is often required to achieve blood pressure targets, particularly in the setting of diabetic kidney disease. However, the use of both ACE inhibitors and ARBs in combination is not recommended given the lack of added ASCVD benefit and increased rate of adverse events namely, hyperkalemia, syncope, and acute kidney injury (71–73). Titration of and/or addition of further blood pressure medications should be made in a timely fashion to overcome clinical inertia in achieving blood pressure targets.

The burden of such multiple drugs, both financial and beyond, can be lessened by intensive attention to lifestyle modifications, including weight reduction, physical activity, and moderation of sodium, protein, and alcohol intake. It will helpful to attempt to simplify the regimen by using combination antihypertensive medications and once-daily long-acting medications as much as

possible. These maneuvers may also improve control of hyperglycemia and dyslipidemia, which also demand attention. Despite the need for such intensive therapy, the benefits may well exceed the miseries and costs of uncontrolled diabetes and hypertension.

Conclusion

The following guidelines seem to be appropriate for the management of hypertension in diabetic patients:

- The target of blood pressure reduction should be lower than 130/85 mmHg.
- The initial several drug classes for treatment of hypertension in diabetes should include classes with the best evidence for benefit in outcome trials: ACEIs, ARBs, thiazide-type diuretics, and CCBs.
- Multiple drugs will usually be needed to achieve the target.
- The choice of drugs should usually include an ACEI or an ARB (but not both) and a diuretic and/or a CCB. Other classes, including a β-blocker, or an α-blocker may be used.
- Attention should be given to lifestyle changes (e.g., weight reduction; regular exercise; moderation of sodium and alcohol) as well as control of hyperglycemia, dyslipidemia, and proteinuria.

As the population grows older and more obese, diabetes and hypertension will become increasingly common. It is hoped that such an approach can reduce their serious consequences.

T2D	Type 2 diabetes mellitus
TG	Triglyceride
VLDL	Very low-density lipoproteins

Introduction

Worldwide over 400 million people have diabetes, a chronic disease characterized by hyperglycemia and associated complications. Type 2 diabetes (T2D), the most common form, accounts for 90%–95% of cases. Atherosclerotic cardiovascular disease (CVD) is the leading cause of morbidity and mortality in T2D, where the risk of death from CVD is increased two- to threefold (Stamler *et al.*, 1993). Individuals with diabetes have a worse prognosis after an acute coronary event than those without diabetes, with a higher frequency of congestive heart failure and higher mortality rate (Gaede *et al.*, 2003; Gu *et al.*, 1998; Kannel and McGee, 1979). Individuals with T2D often have features of the metabolic syndrome, a clustering of risk factors that significantly increase CVD risk. Development of these features, including abnormal fasting glucose, lipid abnormalities and central adiposity, often predates the development of T2D (Adiels *et al.*, 2006a).

People with autoimmune or type 1 diabetes (T1D) also have a two- to eightfold increased risk of CVD and death (Harjutsalo *et al.*, 2011). Atherosclerotic CVD is more aggressive in individuals with T1D than in individuals without diabetes.

Hyperglycemia alone cannot account for the increased CVD risk in diabetes (Skyler *et al.*, 2009). It is well established that dyslipidemia is a major risk factor for CVD. Dyslipidemia is a characteristic feature of the metabolic syndrome and T2D; the presence of features of the metabolic syndrome is associated with significantly increased CVD risk (Dekker *et al.*, 2005; Malik *et al.*, 2004). In T1D, the dyslipidemia that occurs with untreated or poorly controlled T1D corrects with tight glycemic control. However, correction of insulin deficiency can bring out features of genetic dyslipidemias or the metabolic syndrome (Purnell *et al.*, 2013). In this article, we will review the pathophysiology of dyslipidemia in diabetes, including rarer causes, and discuss management strategies.

Description of Diabetic Dyslipidemia

Dyslipidemia in Type 2 Diabetes

Lipid abnormalities, which can be quantitative, qualitative, and kinetic, commonly occur in T2D even with good glycemic control (Verges, 2015). The hallmark of dyslipidemia in diabetes is high plasma triglycerides (TGs) and low high density lipoprotein cholesterol (HDL-C). Low-density lipoprotein cholesterol (LDL-C) concentrations are normal or only slightly elevated, but the LDL particles are characteristically small and dense with TG-enrichment (Verges, 2015). The decrease in HDL-C is associated with qualitatively altered HDL particles with TG-enrichment and decreased phospholipids and surface apoproteins such as apoE. Plasma apoA-I and apo-II levels are decreased (Syvanne *et al.*, 1995). Reduced HDL levels in individuals with T2D are manifest as decreased HDL_{2b} subspecies and increase in smaller and denser HDL_3 particles (Gordon *et al.*, 2013; Hopkins and Barter, 1986). ApoC-III levels are increased in insulin resistance and T2D (Brahimaj *et al.*, 2017; Juntti-Berggren and Berggren, 2017). Postprandial lipemia also is accentuated (Sondergaard *et al.*, 2017). Poor glycemic control can further increase TG levels, cause modest increases in LDL-C, and affect HDL functionality (Gomez Rosso *et al.*, 2017). It is important to note that similar lipid changes (especially elevated TGs and low HDL-C) also occur in the metabolic syndrome; these changes often are present years before development of overt diabetes (Adiels *et al.*, 2006a). Reduced adiponectin levels in T2D inversely correlate with plasma TGs and positively with HDL-C (Schulze *et al.*, 2004).

Dyslipidemia in Type 1 Diabetes

Dyslipidemia in T1D primarily occurs in the setting of dysglycemia. With diabetic ketoacidosis, absolute insulin deficiency results in hypertriglyceridemia (HTG) with low HDL-C and LDL-C levels (Verges, 2009), which improve with treatment. HTG with increased LDL-C levels are observed with suboptimal glycemic control (Marcovecchio *et al.*, 2009). Elevated apoB levels and increased small, dense LDL particles have been described in young adults with T1D, regardless of glycemic control (Guy *et al.*,

 doi:10.1016/B978-0-12-801238-3.65798-7

2009). In the presence of diabetic kidney disease (DKD), total cholesterol, TG and LDL-C are elevated, and HDL-C is decreased (Mattock *et al.*, 2001; Haaber *et al.*, 1993). Elevated LDL-C levels also are independently associated with progression of nephropathy in T1D (Thomas *et al.*, 2006).

Individuals with well-controlled T1D often have better lipid profiles than their counterparts without diabetes (Wadwa *et al.*, 2005), with average total and LDL cholesterol levels that are lower and HDL-C levels that are higher than individuals without diabetes (Guy *et al.*, 2009; Wadwa *et al.*, 2005; Eckel *et al.*, 1981). The increase in HDL-C levels may relate to the HDL_2 fraction and is associated with an increase in apoA-I (Eckel *et al.*, 1981; Kahri *et al.*, 1993; Winocour *et al.*, 1986).

Lipoprotein (a)

Lipoprotein (a) (Lp(a)) is an atherogenic lipoprotein, which is an independent risk factor for CVD (Bennet *et al.*, 2008; Kamstrup *et al.*, 2009). Lp(a) levels usually are within the normal range in T2D and are not affected by glycemic control. However, the presence of DKD is associated with an increase in Lp(a). High Lp(a) also is associated with development of retinopathy (Tu *et al.*, 2017). In small cohort studies, elevated Lp(a) was an independent cardiovascular risk factor in T2D (Lim *et al.*, 2016). Lp(a) levels are frequently elevated in T1D and improve with glycemic control (Haffner *et al.*, 1991; Purnell *et al.*, 1995). The development of microalbuminuria and the onset of DKD also are associated with an increase in Lp(a) levels in T1D (Groop *et al.*, 1994; Winocour *et al.*, 1991).

Prevalence of Dyslipidemia in Diabetes

The prevalence of dyslipidemia in T2D ranges between 70% and 80% (Doucet *et al.*, 2012) and is associated with increased CVD risk (Anon, 1998). Of patients with diabetes, 30%–40% have TG levels >200 mg/dL and 10% >400 mg/dL (Taskinen and Boren, 2015). In NHANES III, 62% of T2D subjects >50 years old had TG levels >150 mg/dL, and 60% had low HDL-C levels (Carroll *et al.*, 2012). In the United Kingdom Prospective Diabetes Study (UKPDS), baseline HDL-C levels were 9% lower in men with diabetes and 23% lower in women with diabetes compared with individuals without diabetes (Anon, 1998). TG levels were 50% higher and LDL-C values were similar in men and higher in women with T2D compared with their counterparts without diabetes; 38% of recruited subjects had both high TGs (>230 mg/dL) and low HDL-C in the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study (Keech *et al.*, 2005). Thus, despite treatment with statins, the high prevalence of dyslipidemia in T2D subjects leaves considerable residual risk. The prevalence of lipid disorders in well-controlled T1D is generally thought to be similar to that of the general population (Verges, 2009).

Pathophysiology of Dyslipidemia in Diabetes

Type 2 Diabetes

Type 2 diabetes is characterized by hyperinsulinemia, insulin resistance, and gradual pancreatic β-cell failure. Factors that contribute to the dyslipidemia in diabetes are complex.

Overproduction of TG-rich lipoproteins (TRLs)

In the fasted state, the liver constitutively synthesizes apoB-100, the primary structural apolipoprotein of very low-density lipoprotein (VLDL). Newly synthesized apoB-100 undergoes lipidation by microsomal transfer protein (MTP) to form pre-VLDL. Additional lipidation results in its further maturation of the particle, transport to the Golgi apparatus, and after more TGs are added, secretion as mature VLDL (Adiels *et al.*, 2006b). ApoB-100 synthesized in excess of TG available for VLDL secretion undergoes mis-folding and degradation (Olofsson *et al.*, 2012).

A key abnormality contributing to dyslipidemia in T2D is overproduction of VLDL. The rate of synthesis and secretion of VLDL is highly dependent on TG availability, which is abundant in diabetes. As a result, excess lipidation of apoB-100 leads to increased VLDL formation and secretion. In the absence of diabetes, insulin inhibits apoB-100 secretion by increasing intrahepatic apoB-100 degradation (Fisher, 2012). However, because of insulin resistance in T2D and the metabolic syndrome, the ability of insulin to inhibit apoB-100 secretion is blunted, resulting in overproduction of apoB-100 and VLDL (Taskinen and Boren, 2015). Peripheral insulin resistance also increases availability of circulating free fatty acids (FFAs), which are a substrate for TG synthesis, thus increasing TG availability.

Visceral obesity, commonly present in the metabolic syndrome and T2D, is accompanied by increased cytokine production by adipose tissue macrophages. Proinflammatory cytokines such as TNF-α and IL-1β stimulate lipolysis in adipocytes (Hardardottir *et al.*, 1992) and increase circulating FFA levels, providing additional substrate for hepatic TG synthesis (Grunfeld and Feingold, 1996). In the liver, these cytokines also can stimulate de novo fatty acid and TG synthesis (Grunfeld and Feingold, 1996).

Decreased catabolism of TRLs

While overproduction of TRLs is the major cause of HTG in T2D, reduced TG clearance also can contribute. The activity of lipoprotein lipase (LPL), the rate limiting enzyme in TG catabolism, is decreased in diabetes. Since insulin stimulates LPL activity,

abnormal insulin action in T2D decreases LPL activity (Taskinen *et al.*, 1982), thereby decreasing hydrolysis of the TGs in chylomicrons and VLDL. Patients with T2D also have increased levels of apoC-III (Hiukka *et al.*, 2005), an inhibitor of LPL. ApoC-III plays a critical role in the hepatic clearance of VLDL remnants (Chan *et al.*, 2008). Therefore, excess apoC-III may result in impaired removal of these particles and a prolonged residence time in the circulation, as shown by delayed catabolism of VLDL-TG and apoB in T2D subjects with increased plasma levels of apoC-III (Chan *et al.*, 2008).

Intestinal lipoprotein overproduction and delayed clearance of chylomicrons

Increased chylomicron production in T2D contributes to postprandial hyperlipidemia (Hogue *et al.*, 2007). Individuals with T2D have increased intestinal apoB-48 secretion and augmented intestinal expression of MTP. The normal acute suppression of postprandial chylomicron secretion by insulin also is reduced (Nogueira *et al.*, 2012). Chylomicron clearance is impaired (Adiels *et al.*, 2012) due to reduced LPL activity, and increased plasma levels of apoC-III.

Production of small dense LDL and HDL

The increase in TRLs affects other circulating lipoproteins. Cholesteryl ester transfer protein (CETP) mediates exchange of TGs from TRLs to LDL and HDL, leading to TG-enrichment of LDL and HDL. Hydrolysis of LDL and HDL-TG by hepatic lipase and LPL leads to the production of small dense LDL and HDL (Garvey *et al.*, 2003). Notably hepatic lipase activity is increased in patients with T2D (Laakso *et al.*, 1987). The atherogenicity of small, dense LDL particles has been attributed to their increased vulnerability to oxidative modification (Chait *et al.*, 1993; Tribble *et al.*, 2001), increased binding to vascular proteoglycans (Olin-Lewis *et al.*, 2002) and increased uptake by the arterial wall (Bjornheden *et al.*, 1996). Poor glycemic control in T2D enhances compositional changes in small, dense HDL, resulting in defective functionality of these HDL particles (Gomez Rosso *et al.*, 2017). Insulin stimulates apoA-I expression (Mooradian *et al.*, 2004). Therefore, a reduction in insulin actin due to insulin resistance or decreased insulin levels may decrease apoA-I expression. High glucose levels also can activate carbohydrate response element binding protein, a transcription factor that inhibits apoA-I expression (Murao *et al.*, 1998). Therefore, production of apoA-I also can be reduced in diabetes (Mooradian *et al.*, 2004).

Proinflammatory cytokines can affect HDL metabolism by decreasing apoA-I production and reverse cholesterol transport. HDL from people with T2D stimulate tumor necrosis factor-α (TNF-α) secretion by human peripheral blood mononuclear cells than HDL from control subjects (Sun *et al.*, 2016). This proinflammatory property of HDL predicted CAD in these patients. In addition, HDL particle number predicted CHD and CVD in patients with the metabolic syndrome and diabetes, whereas in the metabolic syndrome in the absence of diabetes, only LDL particle number positively associated with CVD (Tehrani *et al.*, 2016).

Type 1 Diabetes

Significant dyslipidemia in T1D usually occurs in the setting of poor glycemic control, nephropathy, central adiposity, or the coexistence of genetic forms of HTG. Since insulin stimulates LPL activity, severe insulin deficiency impairs TRL catabolism in diabetic ketoacidosis (Taskinen, 1987), in which there is a concomitant drop in LDL-C and HDL-C (Weidman *et al.*, 1982), changes that all reverse with insulin therapy (Verges, 2009). Moderate HTG due to increased VLDL production results from increased FFA availability associated with insulin deficiency (Nikkila and Kekki, 1973). LPL activity also can be impaired in T1D patients with poor or suboptimal glycemic control (Verges, 2009). In T1D patients optimally controlled with intensive insulin therapy, plasma TG and LDL-C are normal or slightly decreased (Verges, 2009).

Qualitative changes in lipoproteins also have been observed in individuals with T1D. VLDL can be enriched in esterified cholesterol at the expense of TGs, likely due to increased cholesteryl ester transfer between lipoproteins (Bagdade *et al.*, 1991a). LDL can be TG-enriched, leading to the formation of small, dense LDL particles despite normal LDL-C levels. HDL particles have been shown to have higher TG content, increased sphingomyelin, as well as glycation of apoA-I (Denimal *et al.*, 2015). Functional changes in HDL include reduction in the activity of the antioxidant enzyme paraoxonase (Karabina *et al.*, 2005), and increased susceptibility to oxidative stress (Ganjali *et al.*, 2017). Some of these compositional and functional changes in HDL are independent of glycemic control (Manjunatha *et al.*, 2016).

Role of Glycemic Control

Poor glycemic control can adversely affect lipid and lipoprotein metabolism in both T1D and T2D. In T2D, deterioration of glycemic control will exacerbate underlying dyslipidemia resulting in greater increases in plasma TG levels. This is due to decreased catabolism of TRLs as well as increased FFA flux to the liver, leading to increased VLDL synthesis. Improved glycemic control can lower plasma TG and increase HDL-C levels. However, subcutaneous insulin therapy does not appear to alter lipoprotein composition despite good glycemic control (Bagdade *et al.*, 1991b). Uncontrolled T1D results in HTG due to insulin deficiency and decreased LPL activity (see above).

Table 1 summarizes the changes in the various lipoprotein classes in both types of diabetes.

Diabetic Kidney Disease (DKD)

Renal complications of diabetes, including microalbuminuria, overt proteinuria, and nephrotic syndrome, manifests with HTG and low HDL-C. Plasma levels of apoB and apoC-III often are elevated (Thomas *et al.*, 2015). Hyperglycemia, hyperlipidemia, abdominal obesity, hypertension, and smoking are risk factors for microalbuminuria in patients with diabetes (Rutledge *et al.*, 2010). Dyslipidemia promotes progression of renal insufficiency through glomerular and tubulointerstitial injury with concomitant accelerated atherosclerosis (Shoji *et al.*, 2001). CVD risk factors such as elevated levels of circulating cell-adhesion molecules and systemic inflammatory markers are found in the early stages of both DKD and nondiabetic chronic kidney disease (Thomas *et al.*, 2015). Macroalbuminuria has been associated with an increase in oxidized LDL levels (Jandeleit-Dahm *et al.*, 1999), and HDL may lose antiinflammatory and antioxidant properties in DKD (Thomas *et al.*, 2015). HDL_3-C, sphingolipid, and TG-enrichment of HDL have been suggested as potential contributors to DKD (Thomas *et al.*, 2015).

Role of Genetics

Human genetic studies have attempted to identify variants that associate with lipid traits and CAD risk. Genome wide association studies (GWAS) have identified over 40 genetic variants associated with CHD, several of which also associate with T2D (Strawbridge *et al.*, 2011; Willer *et al.*, 2013). Single nucleotide polymorphisms significantly associated with CHD have been identified in patients with T2D (Qi *et al.*, 2012). Some genetic data link diabetes and CAD to dyslipidemia. A common genetic basis for regulation of glucose and lipid homeostasis has been reported (Albert *et al.*, 2014), as well as polygenic overlap between T1D, T2D, LDL, and CAD (LeBlanc *et al.*, 2016; Zhao *et al.*, 2017). Genetic loci exclusively associated with TG levels also have been associated with CAD risk, suggesting a causal role for TRLs in CVD (Do *et al.*, 2013). There also is evidence that genetic predisposition to low HDL-C or high TGs significantly increases T2D risk (Qi *et al.*, 2012). Data concerning the role of genetics in CVD in T1D is more limited. Associations of certain polymorphisms with CAD in T1D have been identified, possibly acting through TGs (Pettersson-Fernholm *et al.*, 2003, 2004). With advances in knowledge of the genetics of human lipid biology, important insights into mechanisms of CAD in diabetes can be expected.

Special Considerations

Genetic disorders of lipid metabolism

Genetic disorders of lipid metabolism can be present in individuals with diabetes. While the prevalence of these disorders in individuals with diabetes is unknown, underlying lipid disorders often compound CVD risk and are hence important to identify and treat. Genetic lipid disorders that can coexist in individuals with diabetes include disorders of cholesterol (familial hypercholesterolemia), accumulation of LDL and VLDL (familial combined hyperlipidemia), disorders of TG metabolism (e.g., familial HTG), and accumulation of remnants (remnant removal disease or dysbetalipoproteinemia). Familial hypercholesterolemia is characterized by mutations in the LDL receptor pathway and typically results in elevations of LDL-C only, unless features of the metabolic syndrome coexist. All of the other genetic disorders usually result in mild-to-moderate HTG. Importantly, coexistence of diabetes with these genetic disorders can lead to marked elevations of TG levels and the multifactorial chylomicronemia syndrome (MFCS). Very severe HTG in association with diabetes also can be seen in lipodystrophic syndromes.

Familial partial lipodystrophies (FPLD)

The lipodystrophies are a group of heterogeneous inherited or acquired disorders that are characterized by selective loss of body fat. Congenital forms that manifest at birth with generalized fat loss and profound metabolic dysfunction are beyond the scope of this discussion. In FPLD, where fat loss is localized to the extremities, HTG and diabetes with severe insulin resistance is common, the extent of fat loss being a major determinant of the severity of metabolic complications. The two most common forms of FPLD are Kobberling's and Dunnigan's lipodystrophy, which are genetically distinct. Both appear to have autosomal-dominant inheritance, with variable fat loss from extremities and truncal regions. Onset is typically around puberty or early adulthood (Lightbourne and Brown, 2017). Patients with the Kobberling variety lose subcutaneous fat on their limbs, with excessive fat accumulation in the dorso-cervical, supraclavicular and submental regions, sometimes leading to a Cushingoid appearance (Guillin-Amarelle *et al.*, 2016; Herbst *et al.*, 2003; Kobberling *et al.*, 1975). The Dunnigan variety involves fat loss from both the extremities and the trunk. HTG is common in both forms, potential mechanisms being decreased storage capacity of fat in adipose tissue, with increased hepatic VLDL synthesis and delayed clearance. Individuals with both types of FPLD can develop TG-induced pancreatitis, especially in the presence of marked insulin resistance and hyperglycemia.

Diabetes in adolescents and youths

Lipid abnormalities occur in youth with both T1D and T2D (Kershnar *et al.*, 2006). T2D in children and adolescents has increased in prevalence, especially in minority populations (Mayer-Davis *et al.*, 2017). Dyslipidemia in adolescent and youth with diabetes is similar to that seen in adults, with mild-to-moderate TG elevations and reduced HDL-C. Pathology and imaging studies have demonstrated progression of atherosclerotic lesions in children and adolescents with T1D (Dahl-Jorgensen *et al.*, 2005). Lipid levels in childhood are predictive of adult lipoprotein profiles in T1D (Guy *et al.*, 2009).

Few longitudinal studies exist of changes in lipids in youth with T1D. However, in a 7 year study of youth with T1D, progression of dyslipidemia occurred in ~25%, predictors of progression being waist to hip ratio and A1C burden over time, particularly in males (Shah *et al.*, 2017).

Management of Dyslipidemia in Diabetes

Brief Overview of Current Guidelines for Adults With Diabetes

Current guidelines from the American Diabetes Association (ADA) recommends measuring a lipid profile at the time of diagnosis of diabetes, at initial evaluation, or prior to starting therapy (American Diabetes Association, 2018a). In people under the age of 40, lipid testing every 5 years is recommended, with consideration for more frequent testing for those with longer duration of diabetes. Monitoring of the lipid profile is recommended 4–12 weeks after initiation of statin therapy, after any change in dosing, or as needed to assess for efficacy and adherence. Recommendations for lipid-lowering therapy in diabetes are similar to those by the American Heart Association/American College of Cardiology (Stone *et al.*, 2013). Statin treatment is recommended to reduce CVD risk in adults with T1D or T2D. High-intensity statins in addition to lifestyle therapy should be prescribed for individuals of all ages with diabetes and CVD, with a goal of LDL-C < 70 mg/dL. Moderate intensity statins are recommended for primary prevention in individuals aged 40–75 years without CVD. Clinical trial evidence is limited for individuals >75 years, but since CVD risk increases with age, therapy with moderate intensity statins may offer benefit. If LDL-C remains ≥70 mg/dL on maximally tolerated statin dose, additional LDL-lowering therapy (such as ezetimibe or a proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitor) may further reduce CVD risk. Guidelines from the Canadian Diabetes Association, albeit similar to the US guidelines, recommend statins for individuals younger than 40 with diabetes if they have microvascular complications, have had diabetes for more than 15 years, and for those younger than 30 years with other CVD risk factors such as hypertension or renal disease (Anderson *et al.*, 2016; Canadian Diabetes Association Clinical Practice Guidelines Expert Committee *et al.*, 2013). The National Lipid Association recommends goals for LDL-C < 100 mg/dL and non-HDL-C < 130 mg/dL, with lower targets in those at very high risk. The European Society of Cardiology and the European Association for the Study of Diabetes recommend LDL-C levels of <70 mg/dL, or a reduction of >50% from baseline LDL-C values if target cannot be reached in T1D and T2D at very high risk (known CVD, severe chronic kidney disease (CKD) with end-organ damage). The common feature of all guidelines is use of statins in all individuals older than 40 with diabetes, with more aggressive LDL-C lowering in those at very high risk. Non-HDL-C targets also are recommended in Canadian and European guidelines.

Lifestyle Intervention

Guidelines for the management of people with diabetes always include a section on nutrition therapy and physical activity. In addition, weight loss is recommended for the many overweight people with the metabolic syndrome and T2D. Weight loss results in a mild-to-moderate decrease in TG levels and a modest increase in HDL-C. In addition, small, dense LDL particles decrease (Purnell *et al.*, 2000). Short of surgical intervention, maintenance of weight loss has proved to be difficult, but can be aided by regular physical activity (Knowler *et al.*, 2002). Nonetheless, maintaining even modest amounts of weight loss can beneficially affect plasma lipids and lipoproteins (Knowler *et al.*, 2002; Tuomilehto *et al.*, 2001). Frequent moderate intensity aerobic exercise increases HDL-C, and leads to a small decrease in TGs in association with a decrease in intraabdominal fat (Leon and Sanchez, 2001; Ross *et al.*, 2000).

Nutrition therapy should be individualized for all patients with diabetes, since one size does not fit for all. Nutrition therapy in patients with T1D and those with T2D on a flexible insulin regimen typically involves carbohydrate counting to determine mealtime insulin dosing for postprandial glucose control. Some controversy still exists as to the best macronutrient composition for individuals with T2D. While the mainstay for glycemic control is carbohydrate restriction, replacement of carbohydrate with saturated fats can increase LDL-C levels (American Diabetes Association, 2018b), which increase the risk of developing CVD. Moreover, dyslipidemia in the metabolic syndrome and T2D is characterized by HTG, which can respond to both weight loss and carbohydrate restriction, including consumption of a low glycemic index diet with a high fiber content (Jung and Choi, 2017).

Effect of Glucose Lowering Agents on Lipids

Initiation of insulin treatment has long been known to reduce plasma TG levels in people with diabetes (Lewis *et al.*, 1972). As TG levels fall, HDL-C levels increase (Brunzell, 2007). Some studies have shown that insulin also lowers LDL-C levels (Chaudhuri *et al.*, 2012). Moreover, initiation of therapy in previously undiagnosed or untreated diabetes also can improve lipid and lipoprotein levels, independent of the modality of pharmacological therapy (Pfeifer *et al.*, 1983). How much of these effects are due to their effects on glycemic control versus specific effects of the drugs is difficult to ascertain, since several drugs used for the treatment of hyperglycemia may independently affect lipid and lipoprotein levels. These include metformin, the glucagon-like peptide 1 (GLP1)-receptor agonists, thiazolidinediones (TZDs), and the sodium-glucose cotransporter 2 (SGLT2) inhibitors, as well as insulin. Several studies have shown that metformin modestly lowers plasma TGs and increases HDL-C (Bolen *et al.*, 2007; Buse *et al.*, 2004; Stumvoll *et al.*, 1995), although some of this effect might be due to the modest weight loss commonly seen with its

use. Although metformin has been associated with some protection against CVD (Anon, 1998), including in patients with T1D (Livingstone *et al.*, 2017), this data is not robust. Fasting as well as postprandial TG levels are reduced and HDL-C levels modestly increased by GLP1 receptor analogs (Bandsma and Lewis, 2010; Chaudhuri and Dandona, 2011; Hermansen *et al.*, 2013), which also may in part relate to the weight loss commonly seen with this class of drugs. In addition, liraglutide led to a decrease in CVD outcomes in the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial (Marso *et al.*, 2016). Cardiovascular benefit also has been demonstrated with semaglutide (Marso *et al.*, 2016), but not with exenatide (Holman *et al.*, 2017). While TZDs also reduce plasma TG levels, LDL-C levels increase with the use of this class of drugs (Buse *et al.*, 2004; Chaudhuri and Dandona, 2011), accompanied by no change in apoB levels and by the presence of larger, more buoyant LDL particles (Freed *et al.*, 2002). One TZD, pioglitazone, improved CVD outcomes in the PROspective pioglitAzone Clinical Trial In macroVascular Events (PROactive) trial (Erdmann *et al.*, 2007), as well as reducing recurrent strokes in patients with metabolic syndrome (Kernan *et al.*, 2016). The effect of rosiglitazone on CVD outcomes is more controversial, with early studies suggesting that it actually increased CVD (Nissen and Wolski, 2007), and effect that was reversed with later trials and analyses (Home *et al.*, 2007; Stafylas *et al.*, 2009). The SGLT2 inhibitors adversely affect both LDL-C and apoB levels (Briand *et al.*, 2016; Fulcher *et al.*, 2016; Ptaszynska *et al.*, 2013; Zaccardi *et al.*, 2016); however, this effect is likely to be abrogated by the widespread use of statins in people with diabetes. Two SGLT2 inhibitors, empagliflozin and canagliflozin, have been shown to reduce both CVD events and deaths (Neal *et al.*, 2017; Zinman *et al.*, 2015) by mechanisms that are not well understood.

Although some studies have suggested mild beneficial changes in lipids and lipoproteins, sulfonylureas, dipeptidyl peptidase 4 inhibitors, meglitinides and alpha-glucosidase inhibitors (Buse *et al.*, 2004; Monami *et al.*, 2012) are generally considered lipid neutral (Chaudhuri and Dandona, 2011).

Effects of Bariatric Surgery on Lipids

The most commonly performed bariatric procedures are Roux-en Y gastric bypass and sleeve gastrectomy, both of which improve dyslipidemia on patients with and without diabetes, Although HDL-C levels tend to fall during the first 6 months of rapid postsurgical weight loss, both procedures result in a decrease in LDL-C, non-HDL-C, apoB and TG levels, and an eventual increase in HDL-C (Bays *et al.*, 2016). Lp(a) levels do not change (Woodard *et al.*, 2010).

Drugs for Lipid Lowering

Statins

Of the various therapies to prevent or treat CVD in diabetes, particularly T2D, the most successful to date has been statins, which inhibit cholesterol synthesis, thereby increasing the levels of hepatic LDL receptors and clearance of LDL from plasma. Statins reduce CVD events in diabetes, despite elevation of LDL-C not being characteristic of either T2D or the metabolic syndrome (see earlier). The first study to show a benefit of statin therapy on CVD endpoints specifically in subjects with T2D was the Collaborative Atorvastatin Diabetes Study (CARDS) (Colhoun *et al.*, 2004). These benefits have been confirmed and extended in subsequent studies, including meta-analyses that have included several thousand subjects with T2D. Meta-analyses show that statin-induced reduction of LDL-C by approximately 40 mg/dL was associated with an ~20% reduction in CVD events and an ~10% decrease in mortality (Cholesterol Treatment Trialists Collaborators *et al.*, 2008). Very limited clinical trial evidence exists for statins and CVD risk reduction in individuals with T1D. In the Heart Protection Study, which included 615 patients with T1D, statin therapy resulted in a proportionately similar (though not statistically significant) reduction in CVD risk as in T2D (Collins *et al.*, 2003). Similarly, meta-analysis also has shown a reduction in CVD events in mortality in subjects with T1D (Cholesterol Treatment Trialists Collaborators *et al.*, 2008). As a result, statin use has become the mainstay of CVD prevention, and are included in all guidelines for CVD prevention in diabetes (see earlier). There is less information on the role of statins in the metabolic syndrome without overt diabetes, although similar outcomes for CVD prevention have been observed as for diabetes (Matikainen and Taskinen, 2012).

A downside of statin use of is an increased risk of developing diabetes. It is estimated that there is an ~10% increased risk of developing diabetes for every 40 mg/dL reduction of LDL-C by statins, and that this risk is greatest in individuals at high risk of developing diabetes, including those with the metabolic syndrome (Preiss and Sattar, 2011). However, best estimates strongly suggest that the benefit of statin use on CVD prevention far outweighs the risk of developing diabetes, the biggest consequence of which is developing premature CVD (Preiss and Sattar, 2011). Hence all guidelines still advise that all patients with T2D and adult patients with T1D be treated with statins (see earlier), unless contraindicated for various reasons.

Fibrates

Fibrates are PPARα agonists, that are effective in lowering plasma TGs and modestly increase HDL-C levels. Fenofibrate also modestly reduces LDL-C. Since HTG and low levels of HDL-C are hallmarks of T2D and the metabolic syndrome, the use of TG-lowering drugs is logical. Despite fibrates having been around for several decades, their value in the prevention of CVD in diabetes remains uncertain. Early studies such as The Diabetes Atherosclerosis Intervention Study (DAIS), in which progression of angiographically assessed CAD in T2D was reduced with fenofibrate use (Anon, 2001), gave confidence that fibrates might also reduce CVD endpoints in diabetes. Moreover, post hoc analysis of several earlier trials (The Helsinki Heart study, the Veterans

Affairs HDL Intervention Trial and the Bezafibrate Infarction Prevention study) all found that the reduction in CAD events was confined to patients with high TG and low HDL-C levels (Bezafibrate Infarction Prevention Study, 2000; Koskinen *et al.*, 1992). In the FIELD study, the greatest benefit of fenofibrate treatment also was in patients with the combination of elevated TGs and low HDL-C, with 27% relative reduction in CVD events (Keech *et al.*, 2005). Nonetheless, the Action to Control Cardiovascular Risk in Diabetes (ACCORD)-LIPID trial (ACCORD Study Group *et al.*, 2010), included diabetic subjects that were not hypertriglyceridemic. Perhaps not surprisingly there was no CVD benefit of fenofibrate in the entire cohort, but those diabetic subjects with baseline HTG once again demonstrated reduced CVD events. Although no fibrate studies to date has focused solely on subjects with HTG, evidence from post hoc analysis of these various clinical trials suggest that they might well be of use, either alone or in combination with a statin if used in the appropriate patient. Prominent, an ongoing clinical trial that is testing a novel selective peroxisome proliferator-activated receptor α modulator with unique PPARα activity and selectivity in individuals with HTG and diabetes (Camejo, 2017) might for once and for all provide a definitive answer to whether the addition of a fibrate to a statin will further reduce CVD risk in people with diabetes.

Ezetimibe

The cholesterol absorption inhibitor, ezetimibe, also lowers LDL-C, although to a lesser extent than statins. It often is used as monotherapy in individual who are statin intolerant, as well as in combination with statins in those unable to reach LDL goals on statins alone. Little data exists as to the value of ezetimibe in persons with diabetes. However, in the Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) secondary prevention study, in which statin plus ezetimibe had a beneficial effect on CVD outcomes compared with statin alone, the strongest benefit of ezetimibe addition was in subjects with diabetes (Cannon *et al.*, 2015; Giugliano *et al.*, 2017). Thus, ezetimibe is being increasingly used in statin-intolerant patients with diabetes, or as an adjunct to statin therapy.

Bile Acid Sequestrants

This class of drugs works by binding bile acids in the intestine, thereby interrupting the enterohepatic circulation of bile acids. As a result, hepatic LDL receptors are induced and plasma LDL levels fall, although not nearly as markedly as with statins, averaging around 15% (Hou and Goldberg, 2009; Out *et al.*, 2012). Although these agents have been around for many years and were the first to demonstrate a beneficial effect on clinical outcomes (Anon, 1984), it was only more recently appreciated that they also were able to modestly improve glycemic control and to lower HbA1C levels by about 0.5% (Brunetti and DeSantis, 2015). The newest agent in this class is colesevelam, with which compliance is much improved compared to the older bile acid sequestrants. Use of bile acid sequestrants, either as monotherapy in statin-intolerant subject, or in combination with a statin, is somewhat limited since they all raise plasma TGs (Denke and Grundy, 1988).

Proprotein convertase subtilisin/kexin type 9 (PCSK9) antibodies

These injectable drugs have been available since late 2015 and are indicated in most countries for individuals with familial hypercholesterolemia or with established CVD unable to achieve target LDL-C levels with other lipid-lowering therapies. These antibodies trap PCSK9 in plasma, thereby preventing PCSK-9 from binding to LDL receptors at the hepatocyte surface. As a result, LDL receptors are targeted for recycling to the cell surface rather than for lysosomal degradation. PCSK9 antibodies lower LDL-C levels well beyond that achievable with statins with or without ezetimibe (Farnier *et al.*, 2016; Sabatine *et al.*, 2017a, 2015). There is little data on their use in people with diabetes, although the first clinical trial to show benefit of these inhibitors, the Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk (FOURIER) trial (Sabatine *et al.*, 2017b), did include some patient with diabetes, who appeared to benefit in a similar to those without diabetes. Interestingly, that trial did not show an increase in diabetes associated with the use of a PCSK9 antibody.

Niacin

Niacin, which has been in use for many years, reduces plasma TGs in addition to lowering LDL-C and apoB, and increases HDL-C. Thus niacin seems ideal for treating the dyslipidemia of diabetes. However, it also increases insulin resistance, thus limiting its use in people with diabetes. Studies in the prestatin era showed a beneficial effect of niacin in reducing both CVD events and mortality in hypercholesterolemic subjects (Canner *et al.*, 1986). However, negative outcomes in two recent clinical trials in which niacin, when added to statin therapy in nondiabetic subjects failed to show a beneficial effect on CVD endpoint (HPS2-THRIVE Collaborative Group *et al.*, 2014; AIM-HIGH Investigators, 2011), has dampened enthusiasm for its use, especially in diabetic dyslipidemia, where it increases insulin resistance and worsens glycemic control.

Omega 3-fatty acids

Omega-3 fatty acids lower plasma TG levels. Although one clinical trial showed a reduction in the cumulative incidence of major coronary events in a subgroup of subjects with HTG and low HDL-C (Saito *et al.*, 2008), benefits of omega-3 fatty acids appears to relate mainly to a reduction in sudden death (Rice *et al.*, 2016). Most meta-analyses show little if any beneficial effect on CVD events, which may be a result of inadequate doses of omega-3 fatty acids being used (Rice *et al.*, 2016). Several CVD outcomes trials with omega-3 fatty acids are in progress.

Management in Special Situations

Multifactorial chylomicronemia syndrome (MFCS) and familial partial lipodystrophy (FPLD)

Most, if not all, patients with MFCS have a genetic form of HTG coexisting with one or more secondary forms of HTG (Chait and Brunzell, 1983). TG levels can increase markedly with suboptimal glycemic control. Following correction of treatable secondary forms of HTG in the MFCS, TG levels usually decrease to the moderately elevated levels seen in their affected relatives (Chait and Brunzell, 1983). Individuals with FPLD present with severe insulin resistance and difficult to control diabetes and marked HTG (Herbst *et al.*, 2003). Recurrent pancreatitis can occur (Herbst *et al.*, 2003) and may lead to exocrine pancreatic insufficiency.

In both MCFS and FPLD, the primary goal of therapy is to lower TGs sufficiently to prevent pancreatitis. From a practical standpoint, it is best to maintain levels <1000 mg/dL, ideally lower if possible. This requires reversal of any secondary cause of HTG, including aggressive glycemic control. Acute pancreatitis is managed similar to non-TG-induced pancreatitis, other than for avoidance of TG emulsions for parenteral feeding. TGs fall rapidly with cessation of oral intake and intravenous hydration. Once stable, fibrate therapy is indicated to prevent recurrent pancreatitis.

Diabetic kidney disease (DKD)

While LDL-C is an established CVD risk factor in the general population, its prognostic value appears to be less in those with CKD due to DKD or other causes (Tonelli *et al.*, 2013), despite the magnitude of LDL-C reduction with statin therapy in CKD and end-stage renal disease (ESRD) being similar to that seen in individuals with preserved kidney function. However, CVD events and mortality were reduced with statins and statins/ezetimibe in a study with mild-to-moderate CKD (Sarnak *et al.*, 2015).

ESRD is associated with very high risk for CVD events. Randomized clinical trials of lipid therapies have not consistently shown a reduction in CVD mortality or survival benefit in this population. Moreover, intensive lipid-lowering to decrease cardiovascular risk in these very ill patients may not be practical (Palmer *et al.*, 2013). There are no clear recommendations for lipid lowering therapy in ESRD and should be individualized based on clinical judgment.

Management of adolescent and youth with diabetes

In children and adolescents with T1D, the ADA recommends a screening nonfasting lipid profile at the age of 10 years. Data from the SEARCH for Diabetes in Youth (SEARCH) study show that improved glucose control over a 2-year period improved the lipid profile; however, improved glycemic control alone will not normalize lipids in dyslipidemic youth with T1D (Guy *et al.*, 2009). Assessment of other risk factors including smoking, obesity, physical activity, age-appropriate blood pressure, and family history of CVD should be routinely sought (Springer *et al.*, 2013). Lifestyle management should be initiated to improve lipid levels (Kavey *et al.*, 2006). Statins should be considered after the age of 10 for LDL-C $>$ 160 mg/dL after lifestyle intervention, or for LDL-C $>$ 130 mg/dL with one or more additional CVD risk factors (American Diabetes Association, 2018c). The goal of LDL-lowering in childhood and adolescence is to reduce LDL-C to below the 95th percentile or <130 mg/dL (American Diabetes Association, 2018c).

A fasting lipid panel and risk factor assessment is recommended at the time of diagnosis of T2D in youth, since comorbidities often already exist (American Diabetes Association, 2018c; Nadeau *et al.*, 2016). The coexistence of obesity with the polycystic ovarian syndrome can contribute to dyslipidemia. Treatment recommendations are similar to youth with T1D. Lifestyle modification is an essential part of management of these patients. As in adults, weight loss results in TG reduction. Reduction of simple carbohydrate intake with an increase in complex carbohydrates and an increase in physical activity are important in management of dyslipidemia in these young patients. Recommendations for statin therapy is similar for youth with T1D.

Conclusions

The constellation of lipid and lipoprotein abnormalities that comprise diabetic dyslipidemia differs between T1D and T2D. Dyslipidemia in T1D often disappears with good glycemic control, unless concomitant features of the metabolic syndrome, nephropathy or a genetic lipid disorder is present. Dyslipidemia in T2D resembles that seen in the metabolic syndrome, which often precedes the onset of hyperglycemia. Treatment of diabetic dyslipidemia is a mainstay of preventing the onset or recurrence of CVD, the risk of which is increased in both types of diabetes. Current data indicates that statins confer the most benefit, despite elevations of LDL-C not being a characteristic hallmark of diabetic dyslipidemia. While HTG is a major feature of diabetic dyslipidemia, uncertainty still exists as to whether lowering of the TRLs with fibrates or other means will reduce the incidence of CVD. Severe HTG can occur in diabetes, especially in the presence of a concomitant genetic form of hypertriglyceridemia or familial forms of partial lipodystrophy. When TGs are markedly elevated, the risk of pancreatitis is increased, in addition to the risk of CVD.

Ocular Manifestations Associated With Diabetes☆

S Lauhon, MS Stem, and PE Fort, University of Michigan, Ann Arbor, MI, United States

Introduction

Diabetes mellitus (DM) has deleterious effects on every organ system in the body, and the eye is no exception. DM impacts every ocular structure, from the cornea to the optic nerve. However, no part of the eye suffers more greatly from the effects of DM than the retina. Diabetic retinopathy (DR) continues to be the primary cause of vision loss and blindness among working age people in the United States. Vision loss due to DR can occur as a result of many mechanisms, such as retinal detachment, macular ischemia, vitreous hemorrhage, and macular edema. This chapter describes the current classification and treatment of DR, in addition to other adverse sequelae such as neurotrophic keratitis, neovascular glaucoma, and cataract, that may arise as a result of DM.

Diabetic Retinopathy

DR affects roughly a third of people with diabetes above 40 years old, and the prevalence increases with disease duration (Zhang *et al.*, 2010). The Diabetes Control and Complication Trial (DCCT) provided definitive evidence that intensive glycemic control reduces the likelihood of developing vision-threatening complications from type 1 DM (The Diabetes Control and Complications Trial Research Group, 1993), and the United Kingdom Prospective Diabetes Study (UKPDS) provided similar evidence for those with type 2 DM (UK Prospective Diabetes Study (UKPDS) Group, 1998). In addition to sustained hyperglycemia, uncontrolled hypertension and pregnancy are among the main risk factors for DR progression.

DR has classically been characterized as a microvascular complication of DM due to the histological and clinically evident effects that DM has on the retinal vasculature. For example, DM leads to loss of pericytes, the modified smooth muscle cells that surround capillary walls, early in the course of the disease. Loss of pericytes is associated with the formation of microaneurysms, which are focal dilations in capillaries. Prolonged hyperglycemia is also associated with "capillary dropout" in the diabetic retina, which can lead to retinal ischemia. The early effects of ischemia, or decreased blood flow, manifest in the retina as hemorrhages or cotton wool spots (CWS), which are focal infarctions taking place mostly in the retinal nerve fiber layer. Progressive retinal ischemia contributes to the vision-threatening complications of DR such as proliferative diabetic retinopathy (PDR) and diabetic macular edema (DME).

Traditionally, DR is clinically classified as either non-proliferative or proliferative, referring to the absence or presence of new blood vessels in the retina, respectively. Non-proliferative diabetic retinopathy (NPDR) exists along a spectrum ranging from mild to very severe disease. Microaneurysms are the only retinal finding in mild NPDR, whereas severe NPDR is characterized by extensive hemorrhages, venous beading, or intraretinal microvascular abnormalities (IRMA), which may represent dilated pre-existing capillary networks.

About 50% of patients with severe or very severe NPDR will develop PDR within one year (Royle *et al.*, 2015). The hallmark of PDR is retinal neovascularization. With prolonged exposure to the diabetic milieu, oxygen deprivation of the retinal tissue results in the release of angiogenic growth factors, such as vascular endothelial growth factor (VEGF) (Aiello *et al.*, 1994). Molecules like VEGF promote the development of new blood vessels within the retina. However, the newly formed blood vessels are fragile and ineffective in restoring retinal perfusion. The vessels are prone to bleeding and fibrosis, which can result in the vision-threatening complications of DR such as vitreous hemorrhage and tractional retinal detachment.

Another vision-threatening complication of DR is DME, which is characterized by accumulation of fluid and lipids within the neuroretina, thought to mostly originate from the retinal capillaries. As with PDR, molecules such as VEGF may disrupt endothelial cell tight junctions, which increases capillary permeability and results in leakage of substances from the intravascular compartment into the retinal tissue. There are two patterns of DME: diffuse and focal. Diffuse DME involves widespread and poorly defined leakage in the macula, while focal macular edema is typically characterized by a "circinate ring" of exudates around a leaky microaneurysm.

Eye-specific treatments for DR are aimed at halting the progression of PDR or reducing macular swelling in DME. Pan retinal photocoagulation (PRP) has been the mainstay of treatment for PDR for decades (The Diabetic Retinopathy Study Research Group, 1981). Typical PRP involves the use of an argon laser to destroy the peripheral outer retina — photoreceptors and RPE — thus sacrificing peripheral vision in an attempt to save central vision or macular function. The exact mechanism through which PRP promotes regression of new blood vessels in PDR is unclear, though one hypothesis is that destruction of the peripheral outer retina decreases the oxygen demand and overall metabolic needs of the retina as a whole, thus reducing the liberation of pro-

☆*Change History:* April 2016. S Lauhon, MS Stem, and PE Fort participated in updating the chapter. The whole chapter was rewritten to integrate the evolution of knowledge over the different complications and their treatment.

angiogenic factors and the stimulus for neovascularization. A current exciting new treatment for PDR that is being actively studied is the injection of anti-VEGF agents directly into the eye (Writing Committee for the Diabetic Retinopathy Clinical Research Network *et al.*, 2015).

While anti-VEGF treatments are currently under investigation for the treatment of PDR, they have become the gold standard for the treatment of DME. Before the development of anti-VEGF medications such as bevacizumab, ranibizumab, and alfibercept, the treatment for DME consisted mainly of either focal or grid laser onto the retina. This was moderately effective in preventing severe vision loss in patients with DME (Early Treatment Diabetic Retinopathy Study research group, 1985). Anti-VEGF therapy revolutionized the treatment of DME because such treatment can prevent subsequent vision loss, or in some cases even reverse it (Diabetic Retinopathy Clinical Research Network *et al.*, 2015). Nevertheless, anti-VEGF therapy is only effective in ~50% of patients with DME (Nguyen *et al.*, 2012) and requires frequent injections (as many as one per month) in order to prevent vision loss. Intravitreal delivery of steroids is another treatment option for DME patients, especially in those non-responsive to anti-VEGF therapy. The anti-inflammatory and antiangiogenic properties of steroids have been shown to stabilize the blood-retinal barrier and reduce intraocular inflammation (Sarao *et al.*, 2014). However, like anti-VEGF agents, corticosteroids are only effective in a subset of patients and can lead to negative side effects such as glaucoma and cataract. Thus, newer and more sustainable treatments for DME are still needed.

Neurotrophic Keratitis

Trigeminal nerve damage caused by DM results in the breakdown of corneal epithelial cells and reduced corneal healing and sensitivity (Lockwood *et al.*, 2006). If left untreated, this degenerative disease, known as neurotrophic keratitis (NK), can lead to corneal ulceration, infection, and perforation. NK is commonly classified by three progressive stages (Bonini *et al.*, 2003). Stage 1 includes corneal epithelial changes, such as punctate epithelial erosions or epithelial irregularities. Stage 2 consists of a persistent epithelial defect that is usually oval in shape and surrounded by an area of loose epithelium that can spontaneously detach. Stromal melting, corneal ulcer, and potential perforation characterize stage 3. Early diagnosis is essential for the treatment of NK, as progression of the disease can lead to blindness. Current treatments aim to halt the progression of corneal damage and differ according to the stage of the disease. In mild cases of NK, the application of preservative-free artificial tears can help to preserve the corneal surface, thus preventing epithelial breakdown. In severe cases, surgical methods such as amniotic membrane grafting may be used to prevent corneal ulceration and perforation.

Neovascular Glaucoma

Progressive retinal ischemia in patients with DM causes an increase in the synthesis and release of VEGF in the retina, which can diffuse into the vitreous and aqueous humor. It has been suggested that this spread of VEGF can trigger abnormal blood vessel growth on the iris, just as it can promote abnormal vascular growth in the retina. When fibrovascular proliferation on the iris spreads to the trabecular meshwork, it can result in a severe rise in intraocular pressure known as neovascular glaucoma (NVG). Normally, aqueous humor is produced by the ciliary body and drains through the trabecular meshwork, which is located near the junction of the iris, cornea, ciliary body, and scleral spur in the "angle" of the eye. In patients, with NVG, the rate of aqueous production exceeds the capacity of the trabecular meshwork to drain fluid. The sustained increase in intraocular pressure can result in irreversible vision loss as a result of damage to the optic nerve. Treatment options for patients with NVG are similar to those of patients with PDR and are aimed at reducing the stimulus for VEGF production by sacrificing the peripheral retina. While PRP remains the primary therapeutic option, anti-VEGF agents can also be used to treat patients with NVG. However, despite these treatments, patients with NVG often require adjunct medical therapy to lower intraocular pressure and in many cases surgical intervention with glaucoma drainage devices is also necessary to restore normal intraocular pressure.

Cataract and Lens Changes

A cataract is defined as a clouding or whitening of the lens inside the eye and is a natural consequence of aging. However, there is an increased prevalence of nuclear, cortical, and especially posterior subcapsular cataract in patients with DM. Furthermore, cataract occurs earlier and progresses more rapidly in diabetic individuals. Currently, cataract removal with surgery is the only available method to restore vision in patients with severe cataracts. However, cataract surgery in patients with DR may promote progression of retinopathy, and thus the risks and benefits of cataract surgery must be carefully considered prior to proceeding with cataract removal.

Diabetes can produce transient refractive changes and blurred vision in individuals due to the effects of hyper or hypoglycemia on lens hydration and refractive index. Severe hyperglycemia can lead to myopic or hyperopic shifts in a patient's refraction, but these effects are typically transient and reverse upon restoration of normoglycemia.

Conclusion

Diabetes has devastating effects on ocular structure and function, but these effects can be mitigated with intense glycemic control and regulation of blood pressure. However, even patients with DM and superb metabolic control can develop ocular complications from DM such as DR, NK, NVG, and cataract. Eye-specific treatments for DR are aimed at reducing the stimulus for neovascularization or capillary leakage and include PRP, focal laser, steroids or anti-VEGF therapy. As in other parts of the body, DM seems to exert its deleterious effects on the eye through a combination of dysregulated glucose metabolism, alteration of trophic factor signaling, and ischemia. Preventive, eye-specific treatments for diabetic eye disease are needed to help reduce the burden of patients with vision-threatening complications of DM.

Kidney Disease in Diabetes☆

Stephanie Toth-Manikowski and Mohamed G Atta, Johns Hopkins University, Baltimore, MD, United States

Driven by the obesity epidemic, the prevalence of diabetes mellitus (DM) has become a worldwide epidemic that continues to escalate. Its health sequela that comprises micro- and macrovascular complications is undeniably pressuring all health care systems. Apart from its associated risk with coronary heart disease, stroke, and visual impairment, DM is the leading cause of end stage kidney disease in Western countries. Renal involvement in DM is manifested in a variety of ways that can be collectively called diabetic kidney disease (DKD). These syndromes include diabetic nephropathy (DN), ischemic nephropathy, cholesterol embolic disease, and renal interstitial fibrosis. In DN, microalbuminuria (urine albumin 30–300 mg per 24 h) was once considered to define early or incipient nephropathy despite not always being a predictive marker of the disease or its progression. In patients with DM, microalbuminuria predicts progression in only 25%–40% and even in those with proven renal injury, many have diagnoses other than DN. Regression of microalbuminuria has been recognized in patients with either type 1 or type 2 DM though appears to be irreversible in African Americans. More importantly, only 45% of patients with an estimated glomerular filtration rate (eGFR) <60 mL/min and DM have microalbuminuria. Consequently, the presence or absence of microalbuminuria in patients with DM should not be solely used as a prerequisite for the diagnosis or exclusion of DN.

Similar histological and clinical courses in all diabetic individuals suggest that the pathogenesis of DN is similar in patients with both types and is closely related to longstanding metabolic and hemodynamic derangements. However, the fact that DN develops in only a subset of diabetic patients implies that other modulating factors such as inflammatory (infectious and non-infectious), environmental, and/or genetic exposures may also be involved in determining disease onset and severity. To date, glycemic control, blood pressure control, lipid control, and renin–angiotensin–aldosterone system (RAAS) inhibition remain the mainstays of therapy in patients with DKD.

Histological Changes

All patients with diabetes mellitus develop some histological changes within the kidney. Kidney hypertrophy is usually the earliest structural change in DKD although this is not usually associated with any specific findings on light microscopy. The first changes seen on light microscopy are cellular enlargement and an increased production of extracellular matrix (ECM), the latter resulting in mesangial expansion. Areas of severe mesangial expansion occur in some patients and result in nodular glomerulosclerosis classically known as Kimmelstiel-Wilson nodules. Glomerular vessels develop intimal hyaline thickening resulting in arteriolar hyalinosis, efferent arteriolar narrowing leading to glomerular hyperfiltration. Other ultrastructural changes seen on electron microscopy include a thickening of the glomerular basement membrane and podocyte hypertrophy. Podocytes later become effaced, leading to functional changes such as albumin excretion. With time, continued mesangial expansion results in external compression of the glomerular capillaries resulting in reduced blood flow to the kidney and ultimately a decline in glomerular filtration rate.

Clinical Course

DN is clinically characterized by glomerular hyperfiltration with increased filtration fraction in 50% of patients with type 2 DM. This is followed by a reduction in glomerular filtration rate (GFR) with or without albuminuria, ultimately leading to end stage kidney disease. In patients who develop macroalbuminuria (urinary albumin excretion >300 mg/day), progression of disease is likely and higher quantities of urinary albumin excretion correlate with the decline in glomerular filtration rate. Hence, treatment often focuses on reducing albuminuria to slow progression of DN.

Pathogenesis

The development of DN occurs as a consequence of multiple factors and pathways. The hemodynamic pathway is attributing to RAAS and endothelin-1 (ET-1) activation which occurs in the metabolic milieu of diabetes. Both increased angiotensin II levels and ET-1 are key mediators of efferent arteriole vasoconstriction resulting in glomerular hyperfiltration. With time, this causes

Diabetic kidney disease: Pathophysiology and therapeutic targets. *Journal of Diabetes Research* 697010. Epub 2015 Apr 30.

endothelial dysfunction, inflammation, and fibrosis within the glomerulus ultimately leading to worsening albuminuria and progression of DN. RAAS activation is also involved in the pathogenesis of mesangial cell hypertrophy and ECM expansion.

The metabolic pathway (Fig. 1) of DN is driven by the consequences of longstanding hyperglycemia. In a non-diabetic kidney, normoglycemia predominates and glucose is normally metabolized via glycolysis. However, in patients with diabetes, a hyperglycemic state predominates leading to the activation of excess superoxide generation. The latter inhibits the enzyme glyceraldehyde-3-phosphate dehydrogenase (GADPH) which is paramount to allowing glycolysis to occur in a normal manner. When glycolysis is inhibited, glucose is metabolized into precursors that are not normally present in the bloodstream such as: fructose, glucosamine-6-phosphate, advanced glycation end products (AGEs), and protein kinase C (PKC). These precursors activate a

cascade of events in the diabetic glomerulus such as ECM expansion and production of reactive oxygen species, cytokines, and growth factors. There is also upregulation of transforming growth factor-β (TGF-β), collagen, laminin, and fibronectin which in turn lead to tubular hypertrophy, glomerular hypertrophy, and ultimately glomerular sclerosis.

The inflammatory pathway (Fig. 1) is a distinct pathway that supports the notion that DN does not occur solely as a result of perturbed hemodynamics and hyperglycemia. It proposes that patients with DM have a chronically activated low-grade inflammatory state with subsequent increased expression of NF-κB and other inflammatory cytokines such as interleukins 1, 6, and 18 (IL-1, IL-6, IL-18, respectively) as well as tumor necrosis factor-α (TNF-α). Together, these inflammatory cytokines paly key role in the development of mesangial hypertrophy, glomerular hypercellularity, GBM thickening, albuminuria, and overt proteinuria.

Lastly, there are additional or "alternate" pathways, although perhaps not as clearly delineated, that have also been suggested to have a role in the pathogenesis of DN. For example, patients with diabetes are believed to have alterations in evolutionary protective mechanisms that are otherwise well conserved in a normoglycemic phenotype. Autophagy is an example of a highly conserved protective mechanism that usually allow cells to degrade cytotoxic proteins whenever a cell is experiencing stress. Podocytes are cells that are particularly sensitive to hyperglycemic conditions and defective autophagy ultimately results in podocyte injury within the kidney. Another highly conserved evolutionary mechanism is the sodium-glucose transporter 2 (SGLT2), a transporter in the renal proximal tubule responsible for $>90\%$ of glucose reabsorption in the proximal tubules. In normoglycemic conditions, this transporter helps conserve energy which benefits both the body and brain. In hyperglycemic conditions, SGLT2 counterproductively absorbs excess glucose which contributes further to a hyperglycemic state.

Finally, genetic susceptibility appears to play a key role in both development and progression of DN as suggested by cross-sectional studies demonstrating a concordance for DN in both type 1 and 2 diabetic sibling pairs.

Treatment

Despite multiple advances in drug therapy, the mainstay of DKD management remains glycemic control, blood pressure control, lipid control, and RAAS inhibition. This strategy is centered on targeting aspects of the metabolic and hemodynamic pathways. The diabetes control and complications trial (DCCT) demonstrated a reduction in micro- and macroalbuminuria in patients with type 1 diabetes that were randomized to intensive glucose control. Long-term follow-up was notable for a reduction in the rate of decline in GFR. The United Kingdom prospective diabetes study (UKPDS) demonstrated a reduction in microvascular complications in patients with type 2 diabetes randomized to intensive glycemic control. Long-term follow-up of this study was notable for a decrease in diabetes-related death, which included death from macrovascular complications and renal disease in the group randomized to intensive glycemic control. Similarly, RAAS inhibition with angiotensin converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) have consistently demonstrated a reduction in albuminuria and progression to DN and ESRD. Their benefit is largely attributed to reduced vasoconstriction of the efferent arteriole which in turn reduces glomerular hyperfiltration. The addition of a nonsteroidal mineralocorticoid receptor antagonist (MRA) was recently shown to augment the effects of an ACEI or ARB when used together in patients with type 2 DM and DN. Finerenone is a more selective MRA than its predecessors, spironolactone and eplerenone, and was found to reduce albuminuria in a dose-dependent fashion without incurring any adverse events such as hyperkalemia or worsened kidney function. Its efficacy and safety on cardiovascular morbidity are being tested in the FIGARO-DKD phase III multicenter trial. Other therapeutic investigative options that target the hemodynamic pathway include ET-1 antagonists that are developed to counteract the glomerular hyperfiltration that occurs as a result of efferent arteriolar vasoconstriction. The combination of the ET-1 antagonist, atrasentan, with a RAAS inhibitor demonstrated a dose-dependent decrease in albuminuria and is currently in the final stages of clinical assessment.

Because the metabolic pathway plays such an important role in the pathogenesis of DN, multiple therapeutic options have been developed to target various aspects of this pathway. For example, data are now emerging on the favorable renal outcome in patients with DKD with the use of the sodium-glucose co-transporter 2 (SGLT2) inhibitors; empagliflozin, canagliflozin, dapagliflozin, and ipragliflozin, ertugliflozin, and luseogliflozin (the latter three agents have not been approved for use in the United States). They work by decreasing the amount of glucose that is reabsorbed from the renal proximal tubules. The most impressive evidence to date in support of SGLT2 inhibitors for DN comes from the EMPA-REG OUTCOME trial, a study that randomized patients with type 2 diabetes and an eGFR ≥ 30 mL/min to receive either empagliflozin (at an oral dose of 10 mg or 25 mg daily) or placebo in addition to standard care. In addition to a lower risk for composite cardiovascular outcome, those receiving empagliflozin were less likely to experience worsening of their DN (as defined by progression of macroalbuminuria), doubling of their creatinine, and were less likely to be initiated on renal replacement therapy. A study of canagliflozin (at an oral dose of 100 or 300 mg daily) compared to glimepiride at a dose of 6–8 mg demonstrated a significant reduction in the rate of eGFR decline compared to glimepiride. Additionally, macroalbuminuric participants receiving canagliflozin had a more pronounced decrease in urinary albumin-to-creatinine ratio compared to those on glimepiride alone. The latter study did not evaluate harder clinical endpoints such as doubling of serum creatinine or time to renal replacement therapy. A pooled analysis of 11 phase 3 clinical trials of dapagliflozin demonstrated that while the effect of HbA1c decline decreases with lower levels of eGFR, placebo-adjusted reductions in urinary albumin-to-creatinine ratio were actually largest in the lowest eGFR subgroup. The final results of the CANVAS and DECLARE-TIMI-58 trials, the two clinical trials studying canagliflozin and dapagliflozin, respectively, are still pending. Of note, while all SGLT2 inhibitors carry an FDA warning about the increase in risk for severe urinary tract infections and

Table 1 Effects of empagliflozin, canagliflozin, dapagliflozin, and ipragliflozin on renal-relevant endpoints

Drug name	*Dose*	*Comparator*	*Study characteristics*	*Summary of renal-relevant endpoints*
Empagliflozin	10 or 25 mg daily	Placebo	• Double blind, randomized controlled trial • $N = 7020$	• Empagliflozin was associated with a decreased risk of incident or worsening nephropathy; HR 0.61, 95%CI (0.53–0.70) • Progression to macroalbuminuria occurred in 11.2% of empagliflozin group and 16.2% in placebo group, a significant relative risk reduction of 38%; HR 0.61, 95% CI (0.54–0.72) • Doubling of serum creatinine level occurred in 1.5% of empagliflozin group and 2.6% in placebo group, a significant relative risk reduction of 44%; HR 0.56, 95% CI (0.39–0.79) • Initiation of RRT occurred in 0.3% of empagliflozin group and 0.6% in placebo group, a significant relative risk reduction of 55%; HR 0.45, 95% CI (0.21–0.97) • Doubling of serum creatinine, initiation of RRT, or death from renal disease occurred in 1.7% of empagliflozin group and 3.1% in placebo group; HR 0.54, 95% CI (0.40–0.75)
Canagliflozin	100 or 300 mg daily	Glimepiride	• Double blind, randomized controlled trial • $N = 1450$	• Annual decline in eGFR was 3.3 mL/min with glimepiride, 0.5 mL/min with canagliflozin 100 mg (compared to glimepiride, $P < 0.001$), and 0.9 mL/min with canagliflozin 300 mg (compared to glimepiride, $P = 0.002$) • Relative to glimepiride, canagliflozin 300 mg decreased UACR by 11.2%, 95% CI (3.6–18.3) • Among patients with UACR $\geq$30 mg/g, canagliflozin 100 and 300 mg decreased UACR by 31.7% and 59.3%, respectively, when compared to glimepiride; 95% CI (8.6–48.9) and (31.9–62.2), respectively
Dapagliflozin	10 mg daily	Placebo	• Pooled analysis of 11 phase 3 clinical trials • $N = 4404$	• Among patients with UACR >30 mg/g, after 24 weeks of dapagliflozin therapy, UACR was decreased by 16.1% (95% CI: -32.3, 3.8), 23.3% (95% CI: -35.5, -8.7), and 38.3% (95% CI: -54.5, -16.6) in participants with eGFR of $\geq$90 mL/min, $\geq$60- < 90 mL/min, $\geq$45- < 60 mL/min, respectively
Ipragliflozin[a,b]	50 mg daily	None	• Multicenter, open-label study • $N = 50$	• After 24 weeks of ipragliflozin therapy, median UACR decreased from 15.5 to 12.9 mg/g Cr ($P = 0.007$). In subgroup analyses, the significant drop in UACR was only noted in those with eGFR $\geq$90 mL/min ($n = 20$)

[a]This drug is not yet approved by the FDA for use in the United States.

[b]Phase 4 study of ipragliflozin and its effects on UACR, efficacy and safety in patients with type 2 diabetes is currently underway.

RCT, randomized controlled trial; *RRT*, renal replacement therapy; *UACR*, urine albumin-to-creatinine ratio.

Note: Ertugliflozin, luseogliflozin, and tofogliflozin have not yet undergone studies to evaluate effects on renal-relevant endpoints and were not been included in this table for this reason.

ketoacidosis and have not been approved for use in patients with type 1 diabetes, canagliflozin carries a drug-specific FDA warning for increased risk of leg and foot amputations. The effects of gliflozins on renal-relevant endpoints are summarized in **Table 1**.

Aldose reductase inhibitors such as epalrestat and tolrestat were first developed to decrease conversion of glucose to sorbitol and fructose. Tolrestat was later removed from the market when it was found to have an association with hepatic necrosis. Azaserine and rhein were both developed to inhibit an enzyme which would otherwise lead to increased transcription of TNF-α and TGF-β1. While neither of these have yet been tested in humans, in vivo studies have shown promise. AGEs are another product of the metabolic pathway that when unhindered, lead to ECM expansion, increased reactive oxygen species (ROS), cytokine production, and eventually DKD progression. Drugs such as benfotiamine, aminoguanidine, pyridoxamine have all attempted to diminish AGE production. While a large trial evaluating aminoguanidine was stopped due to lack of efficacy and safety concerns, pyridoxamine is currently undergoing a phase 3 study to evaluate its effect on time to ESRD in patients with DN. There are also multiple therapeutic agents that target the downstream products of AGEs. These include nicorandil, bardoxolone, sulodexide, pirfenidone, sevelamer, cilostazol, tranilast, and FG-3019 and they target downstream products such as connective tissue growth factor (CTGF), ROS, and TGF-β1. Of these agents, nicorandil has shown promise in diabetic mouse models whereas pirfenidone,

sevelamer, cilostazol, tranilast, and FG-3019 have all shown promise in patients with DN. The latter two agents are currently undergoing testing in patients with DN. Lastly, ruboxistaurin was developed as a protein kinase C-β inhibitor, one of the final endpoints in the metabolic pathway. Although this agent was sufficiently promising to initiate a phase 3 trial, it was halted for business considerations.

Treatment options have also targeted the inflammatory markers and cytokines that are prevalent as part of the inflammatory pathway. These drugs include NF-κB inhibitors such as thiazolidinediones and 1, 25-dihydroxyvitamin D3 and JAK1/STAT pathway inhibitors such as baricitinib. The latter is currently undergoing a phase 2 study in patients with DN whereas thiazolidinediones are undergoing a phase 4 study to evaluate the long-term effects of these agents on patients with DM type 2 and DN. Apoptosis signal-regulating kinase 1 (ASK1) mediates the downstream inflammatory signals of ROS. Despite early stage potential of AKS1 inhibition on this pathway, it failed in phase II clinical trial to demonstrate clinical benefit in in patients with DN. Existing or novel agents that have been developed to target the more ubiquitous inflammatory pathway include mycophenolate mofetil, drugs derived from turmeric, and TNF-α inhibitors such as etanercept, infliximab, pentoxifylline, and selective CCR2 inhibitors (CCX140-B). While some of these agents have far-reaching effects in the body which unfortunately limit their use solely for DN, pentoxifylline, CCX140-B, silymarin, and curcumin (the latter two being derived from turmeric) have all shown promise in patients with DN. Conversely, cytokines that favorably modulate inflammation such as IL-17A have been shown to treat, reverse, and even prevent established nephropathy in diabetic mouse models and may become a therapeutic option beyond animal models.

In the end, it is conceivable that management of DN will require first a good and reproducible marker, other than microalbuminuria, that accurately predicts disease onset and progression; and second a multi-targeted approach that works in concert with currently existing therapeutic options in order to modify the diverse pathways involved in the pathogenesis of the disease. Key to success of these new approaches is not only to prove their efficacy in halting or reversing progression of DN but also avoidance of their potentially off-target effects.

Diabetic Nerve Disease, Neuropathy☆

Jean-Marie Ekoe, University of Montreal, Montreal, QC, Canada

Glossary

Antiarrhythmic A drug that restores normal heartbeat regularity.
Arrhythmia An irregularity of the heartbeat.
Axon A nerve cell process responsible for conducting electrochemical impulses.
Glycation The addition of sugars to other molecules.
Hyperglycemia Elevated blood glucose levels.
Hypoxia Decreased levels of oxygen in air, blood, or tissue.
Ischemia Reduced blood flow.
Polyol pathway Polyhydroxy alcohol, specifically the metabolites and enzymes that create sugar alcohols and inositols.
Proprioception Information concerning movement and position of body parts.

Distal Symmetric Sensorimotor Polyneuropathy

Distal symmetric sensorimotor polyneuropathy (DPN) first appears as a sensory disorder of the feet, reflecting distal axonal damage. As the disease progresses, loss of sensation ascends, and by the time DPN reaches midcalf, many patients notice a sensory loss in their hands. This slow progression results in the classical "stocking-glove" sensory loss. Vibration and proprioception are transmitted along large myelinated fibers, whereas small myelinated and unmyelinated nerve fibers transmit information concerning pain, light touch, and temperature. Patients with DPN have symptoms of decreased vibration and light touch, altered temperature sensation, and poor pain perception. This indicates damage to or loss of all three fiber types. Patients may have "positive" symptoms and complain of pain, paresthesias, and/or dysesthesias. More often, patients demonstrate "negative" symptoms, with sensory loss only identifiable following an examination.

Weakness of the toes and ankles is a late manifestation of DPN. Sensory loss combined with weakness predisposes the foot to ulcer formation. Ulceration is classified into two categories: acute and chronic. Patients with insensate feet are vulnerable to acute foot ulcers caused by improper shoeware. Chronic ulceration is likely to have many causes, including autonomic neuropathy and compromised vascular supply.

Estimates of the prevalence of DPN vary greatly according to the diagnostic criteria and population studied. Large epidemiological studies have shown that DNP will develop within 10 years of the onset of diabetes in 40%–50% of both types of diabetes. Up to 50% of DPN may be asymptomatic.

Pathogenesis of DPN

Despite intense research, the exact pathogenesis of DPN remains unknown. The Diabetes Control and Complications Trial (DCCT) proved that hyperglycemia is essential for the development of DPN. Commonly proposed theories for DPN include alterations in the polyol pathway, vascular insufficiency, abnormal glycation of proteins and lipids, increased oxidative stress, altered nitric oxide synthesis, impaired axonal transport, and reduced neurotrophism. Classically, these theories are categorized as metabolic or vascular. It is likely that these are related and overlapping factors and all contribute to the loss of peripheral nerve function and subsequent symptoms of DPN.

The metabolic theory is based on the conversion of excess glucose to sorbitol by aldose reductase as part of the polyol pathway. Elevated sorbitol results in reciprocal decreases of myoinositol and taurine. Depletion of these metabolites becomes rate limiting for essential intracellular metabolism. The vascular theory was once considered separate from the metabolic theory. It states that reduced nerve blood flow results in hypoxia/ischemia and causes the development of DPN. It is now clear that the metabolic and vascular theories are linked on many levels. Glucose flux through the polyol pathway causes the depletion of NADPH and NAD^+. Without sufficient NADPH, cells cannot regenerate the glutathionine required to neutralize reactive oxygen species. Consequently, the peripheral nerve sustains oxidative damage that decreases endoneurial blood flow and promotes ischemia. The activity of the potent vasodilator, nitric oxide (NO), is also tightly linked to NADPH. NO, synthesized by NO synthase, is a NADPH-dependent reaction. Therefore, depletion of NADPH limits NO synthesis and in turn causes vasoconstriction and ischemia, which contribute to nerve conduction slowing.

Diagnosis and Treatment

Three treatment strategies are clinically available. Of most importance is the early diagnosis of DPN. Early diagnosis allows for the implementation of the second strategy: good glycemic control and foot care. The third approach is focused on the treatment of painful DPN and is added to good glycemic control and foot care.

The early diagnosis of DPN is imperative. It makes early intervention possible, thereby significantly decreasing patient morbidity. It is important that other causes of neuropathy are excluded prior to DPN being related to diabetes. This is especially important if there are unusual features of the neuropathy, such as rapid progression, marked asymmetry, or more motor than sensory deficits.

In 1988, the San Antonio Consensus Panel recommended five quantifiable measures for the accurate diagnosis of DPN: a symptom questionnaire, a standardized clinical examination, quantitative sensory testing, nerve conduction studies, and autonomic function testing. Patients are classified as having stage I (no symptoms) or stage II (symptoms) neuropathy. Each stage is further divided into grades from A to C depending on the number of positive test results and the severity of clinical impairment. These criteria are being used to study the Rochester Diabetic Cohort. Modified criteria have been implemented in several clinical trials, including the DCCT.

Simpler screening instruments for DPN are also available. These instruments were developed because patient and physician resources are frequently limited, making completion of the San Antonio criteria difficult. In the United Kingdom, DPN is diagnosed if patients present with mild signs and moderate symptoms or moderate signs alone, in the absence of symptoms. The Michigan Neuropathy Screening Instrument includes inspecting the feet for dry skin, callus, fissure, or ulceration; assessment of vibratory sensation in the great toes; and testing for ankle reflexes. A score of >2 indicates neuropathy with a high sensitivity (80%) and specificity (95%). Because of its simplicity, the Michigan Neuropathy Screening Instrument is also highly reproducible. Another simple method for screening patients for the presence of DPN is the use of a 10-g nylon monofilament. The filament is pressed against the sole of the foot until the filament buckles, indicating a known force has been applied. If a patient is unable to perceive the filament, he or she is at increased risk for complications of DPN.

Glycemic Control and Foot Care

The DCCT clearly demonstrates that improved glycemic control decreases the frequency of DPN in patients with type I diabetes mellitus. Glycemic control requires thorough patient education. Patients are instructed on the importance of diet and regular glucose monitoring. This is achieved with a team consisting of the patient, a diabetes nurse educator, a dietician, and a physician.

Good foot care is also important. Patients are instructed to inspect their feet every night for evidence of dry skin, cracking, or fissuring of the skin. The importance of shoeware is also well documented. Shoes must cushion the points of contact between the foot and the shoe and must accommodate any inherent or acquired foot deformities. For patients with mild neuropathy, cushioned socks and high-quality athletic shoes with room for the forefoot and toes are helpful. In severe cases, patients may require customized inserts or molded shoes.

Acute and Chronic Painful DPN

Multiple treatments are available for the management of neuropathic pain. It has been shown that few people have complete relief of painful symptoms with any treatment and that a 30%–50% reduction in baseline pain is considered to be a clinically meaningful response. The lack of comparative studies makes it difficult to recommend which oral medication should be used first line. Opioids have shown good efficacy for neuropathic pain but they are not recommended due to the high risk of dependency, tolerance, and dose escalation.

A stepwise treatment protocol is used for patients with painful DPN. Nonsteroidal anti-inflammatory drugs provide relief in many patients with chronic painful DPN. In a double-blind, placebo-controlled trial, both ibuprofen (600 mg four times per day) and sulindac (200 mg two times per day) effectively decreased pain associated with DPN. However, this class of drugs cannot be used in patients with renal impairment.

Anticonvulsants (gabapentin, pregabalin) and antidepressants are most commonly used as first-line therapy.

The tricyclic antidepressants are the best studied class of drugs for the treatment of painful DPN. In double-blind, placebo-controlled trials, amytriptyline, nortriptyline, and imipramine were each effective in the treatment of painful DPN. Duloxetine and venlafaxine are newer antidepressants that may also be useful for the treatment of painful neuropathy. If a patient continues to experience disabling pain, a second drug, *pregabalin* or *gabapentin*, is added to the therapeutic regimen. Patients may also be started on gabapentin as a first-line therapy, with a tricyclic added if a second medication is needed. Carbamazepine is also a good drug to add to either a tricyclic antidepressant or a serotonin uptake inhibitor. Double-blind, placebo-controlled trials have found that it provides symptomatic relief to a large percentage of afflicted patients.

For patients who are on two medications and still experiencing significant discomfort, capsaicin cream may be used. Capsaicin cream is a topical therapy that inhibits the uptake of substance P at sensory endings. Patients are instructed to apply capsaicin cream (0.075%) four times per day, the regimen that was successful in a double-blind, placebo-controlled trial. Topical nitrate sprays are another therapeutic option.

If these therapeutic strategies fail, the second drug is discontinued and a new drug is instituted. The first choice is the cardiac antiarrhythmic drug mexiletine, which is effective in patients who otherwise are refractory to treatment. The antiepileptic topiramate can also be used in refractory patients. If a patient remains resistant to these treatment strategies, he or she should be referred to a comprehensive pain clinic. Here, patients frequently receive local nerve blocks, a transcutaneous electrical nerve stimulation (TENS) unit, or, in certain cases, acupuncture. Unfortunately, the prognosis for good pain relief in patients who require a pain clinic referral is low.

In summary, either pregabalin or duloxetine are recommended today as initial pharmacologic treatments for neuropathic pain in diabetes. They have received regulatory approval by the US Food and Drug Administration (FDA), Health Canada, and the European Medicines Agency (EMA) for the treatment of neuropathic pain in diabetes.

Conclusion

A systematic, stepwise approach to patients with DPN ensures optimal patient care and decreases the risks for short- and long-term disability (American Diabetes Association, 2018). Future therapies hold promise, particularly those targeted toward ameliorating the metabolic and vascular abnormalities that develop in the peripheral nervous system as a result of continued hyperglycemia.

Glossary

Autonomic nervous system The portion of the nervous system that regulates individual organ function and homeostasis not under voluntary control. The autonomic nervous system is also responsible for conveying visceral sensation. The autonomic nervous system is typically divided into two divisions, the parasympathetic system and the sympathetic system, based on anatomical and functional differences.

Diabetic neuropathy A demonstrable disorder, either clinically evident or subclinical, that occurs in the setting of diabetes mellitus without other causes of peripheral neuropathy. The neuropathic disorder associated with diabetes includes manifestations in the somatic and/or autonomic parts of the peripheral nervous system.

Parasympathetic nervous system The portion of the autonomic nervous system concerned with the conservation and restoration of energy. It causes a reduction in heart rate and blood pressure, facilitates the digestion and absorption of nutrients, and facilitates the excretion of waste products from the body.

Sympathetic nervous system The portion of the autonomic nervous system that enables the body to be prepared for fear, flight, or fight. Sympathetic responses include increases in heart rate, blood pressure, and cardiac output and the diversion of blood flow from the skin and splanchnic vessels to those vessels supplying the skeletal muscle.

Introduction

Individuals are not aware of their autonomic nervous system when it functions normally; only when there is dysfunction can the manifestations be diverse and devastating. Diabetes mellitus can cause dysfunction of any or every part of the autonomic nervous system, leading to a wide range of disorders. If an individual knows the autonomic nervous system and its disorders, he or she will know the whole of medicine. The organ systems that most often exhibit prominent clinical autonomic signs and symptoms in diabetes include the ocular pupil, sweat glands, genitourinary system, gastrointestinal tract system, adrenal medullary system, and cardiovascular system. Clinical symptoms of autonomic neuropathy generally do not occur until long after the onset of diabetes. Subclinical autonomic dysfunction can, however, occur within 1 year of diagnosis in type 2 diabetes patients and within 2 years in type 1 diabetes patients. In fact, impaired autonomic function may be associated with early glucose dysmetabolism (impaired glucose tolerance and impaired fasting glucose) and be involved in the pathogenic pathway leading to the development of diabetes.

Epidemiology of Diabetic Autonomic Neuropathy

The reported prevalence of diabetic autonomic neuropathy varies, with community-based studies finding lower rates than clinic-based and hospital-based studies, in which the prevalence may be as high as 90%. The variance among prevalence studies also reflects the type and number of tests performed and the presence or absence of signs and symptoms of autonomic neuropathy. Another important factor that accounts for the marked variability in reported prevalence rates is the lack of a standard accepted definition of diabetic autonomic neuropathy. Ziegler found that 25.3% of patients with type 1 diabetes and 34.3% of patients with type 2 diabetes had abnormal findings in more than two of six autonomic function tests.

Pathogenesis of Diabetic Autonomic Neuropathy

Hypotheses concerning the multiple etiologies of diabetic autonomic neuropathy include a metabolic insult to nerve fibers, neurovascular insufficiency, autoimmune damage, and neurohormonal growth factor deficiency. The most important clinical factors include poor glycemic control, diabetes duration, age, female sex, and higher body mass index (BMI). Several different

☆*Change History:* December 2014. AI Vinik, T Erbas, M-L Névoret, and C Casellini introduced small edits in the text of the article including citations, added the sections "Applications" and "References", and Tables.

 doi:10.1016/B978-0-12-801238-3.03845-9

pathogenic processes have been described. Hyperglycemic activation of the polyol pathway leading to the accumulation of sorbitol and potential changes in the NAD:NADH ratio may cause direct neuronal damage and/or decreased nerve blood flow. Activation of protein kinase C induces vasoconstriction and reduces neuronal blood flow. Increased oxidative stress, with increased free radical production, causes vascular endothelium damage and reduces nitric oxide bioavailability. Alternatively, excess nitric oxide production may result in the formation of peroxynitrite and damage to the endothelium and neurons, a process referred to as nitrosative stress. In a subpopulation of individuals with neuropathy, immune system mechanisms may also be involved. Reduction in neurotrophic growth factors, deficiency of essential fatty acids, and formation of advanced glycation end products (AGEs) also result in reduced endoneural blood flow and nerve hypoxia with altered nerve function. The result of this multifactorial process may be the activation of poly(ADP) ribosylation depletion of ATP, resulting in cell necrosis and the activation of genes involved in neuronal damage.

Clinical Manifestations of Diabetic Autonomic Neuropathy

The metabolic disorders of diabetes lead to diffuse and widespread damage of nerves and small vessels. Clinical manifestations of autonomic dysfunction frequently occur concurrently but in inconsistent patterns (Table 1). Diabetic autonomic neuropathy is typically assessed by focusing on symptoms or dysfunction attributable to a specific organ system. Cardiac autonomic neuropathy is the most prominent focus because of the life-threatening consequences of this complication and the availability of direct tests of cardiovascular autonomic function. However, neuropathies involving other organ systems should also be considered in the optimal care of patients with diabetes.

Cardiac Autonomic Neuropathy

Cardiac autonomic neuropathy results from damage to the autonomic nerve fibers that innervate the heart and blood vessels and results in abnormalities in heart-rate control and vascular dynamics. The 5-year mortality rate from this serious complication is five times higher for individuals with cardiac autonomic neuropathy than for individuals without cardiovascular autonomic involvement. Autonomic dysfunction can impair exercise tolerance. The severity of cardiac autonomic neuropathy has been shown to correlate inversely with an increase in heart rate at any time during exercise and with the maximal increase in heart rate. Cardiac autonomic neuropathy also leads to a reduced cardiac ejection fraction, systolic dysfunction, and decreased diastolic filling. In fact,

Table 1 Clinical Manifestations of Autonomic Neuropathy

Cardiovascular
Resting tachycardia
Exercise intolerance
Orthostatic hypotension, orthostatic tachycardia and orthostatic bradycardia
Silent myocardial ischemia
Sudden death

Diarrhea
Fecal incontinence
Genitourinary
Neurogenic bladder
Erectile dysfunction
Retrograde ejaculation
Female sexual dysfunction (loss of vaginal lubrication)
Metabolic
Hypoglycemia unawareness
Hypoglycemia-associated autonomic failure
Sudomotor
Anhidrosis
Heat intolerance and hyperhidrosis
Gustatory sweating
Dry skin
Pupillary
Argyll-Robertson pupil
Decreased diameter of dark-adapted pupil
Failure of pupillary constriction with light exposure

diastolic dysfunction is considered the earliest manifestation of diabetic cardiomyopathy. There is a consistent association between cardiac autonomic neuropathy and the presence of silent myocardial ischemia (MI). The perception of angina is severely impaired in diabetic patients, allowing these individuals to exercise longer after the onset of MI with dire consequences. Chest pain in any location in a patient with diabetes should be considered to be of myocardial origin until proven otherwise; however, of equal importance, unexplained fatigue, confusion, tiredness, edema, hemoptysis, nausea and vomiting, diaphoresis, arrhythmias, cough, or dyspnea should alert the clinician to the possibility of silent MI. Mortality rates after a MI are also higher for diabetic patients than for nondiabetic patients, and higher still if autonomic dysfunction is present. This may be due to regional differences in autonomic nerve damage within the heart, increasing the tendency for the development of ventricular arrhythmia and cardiovascular events after infarction. Cardiac failure is also more frequent following a MI in patients with autonomic neuropathy.

Orthostatic hypotension, another sign of autonomic neuropathy, is a fall in systolic blood pressure of greater than 30 mm Hg on standing. It is aggravated by peripheral vascular pooling of blood such as occurs with hot baths or drugs used to treat hypertension. Patients with orthostatic hypotension typically present with lightheadedness and presyncopal symptoms. Symptoms such as dizziness, weakness, fatigue, visual blurring, and neck pain also may be due to orthostatic hypotension. It is now recognized that a similar syndrome can occur with orthostatic tachycardia and/or bradycardia without a drop in blood pressure simply because there is a reduction in cardiac output.

Gastrointestinal Autonomic Neuropathy

Gastrointestinal symptoms are relatively common among patients with diabetes and often reflect diabetic gastrointestinal autonomic neuropathy. Esophageal dysfunction results at least in part from vagal neuropathy; symptoms include heartburn and dysphagia for solids. Gastroparesis in diabetes is usually clinically silent and may be the most important cause of "brittle diabetes." Severe diabetic gastroparesis is one of the most debilitating of all diabetic gastrointestinal complications. Via the use of radioisotopic techniques that quantify gastric emptying, it appears that 30–50% of patients with longstanding diabetes have delayed gastric emptying. Major clinical features of this disorder are early satiety, anorexia, nausea, vomiting, epigastric discomfort, and bloating. Episodes of nausea or vomiting may last for days to months or occur in cycles. Even with mild symptoms, gastroparesis interferes with nutrient delivery to the small bowel and therefore disrupts the relationship between glucose absorption and exogenous insulin administration. These changes may result in wide swings in glucose levels, unexpected episodes of postprandial hypoglycemia and apparent brittle diabetes. Gastroparesis should therefore always be suspected in patients with erratic glucose control. Diarrhea is evident in 20% of diabetic patients, particularly those with known diabetic autonomic neuropathy. Diarrhea is typically intermittent, but bowel movements may occur 20 or more times per day with urgency, and the stools are often watery. Constipation is the most common gastrointestinal complication, affecting nearly 25% of diabetic patients. Individuals with constipation may have less than three bowel movements per week and these may alternate with diarrhea. Fecal incontinence due to poor sphincter tone is common in individuals with diabetes and may be associated with severe paroxysmal diarrhea or constitute an independent disorder of anorectal dysfunction.

Genitourinary Autonomic Neuropathy

Neurogenic bladder

The earliest bladder dysfunction is a sensory abnormality that results in impaired bladder sensation, an elevated threshold for initiating the micturition reflex, and an asymptomatic increase in bladder capacity with urinary retention. Overflow incontinence occurs because of denervation of the external and internal sphincters. Individuals with bladder dysfunction are predisposed to the development of urinary tract infections, including pyelonephritis, which may accelerate or exacerbate renal failure.

Erectile dysfunction

Erectile dysfunction is the most common form of organic sexual dysfunction in males with diabetes, with an incidence estimated to be between 35% and 75%. It is defined as the consistent inability to attain and maintain an erection adequate for sexual intercourse. Erectile dysfunction may be the presenting symptom of diabetes and more than 50% of men with diabetes notice the onset of erectile dysfunction within 10 years of onset of the diabetes. Erectile dysfunction is a marker for the presence and development of generalized vascular disease and for premature demise from a myocardial infarct. Penile failure may portend an upcoming and possibly preventable, cardiovascular event. Erectile dysfunction should alert physicians to perform cardiovascular evaluations for these patients. Retrograde ejaculation into the bladder also occurs in diabetic males.

Hypoglycemia Unawareness

The counterregulatory hormone responses and awareness of hypoglycemia are reduced in patients with diabetes mellitus. Unawareness of hypoglycemia and unresponsiveness to it are serious problems that hamper the patient's ability to manage his or her diabetes. In most diabetic patients, catecholamine release, triggered by low glucose levels, produces noticeable symptoms, such as tremulousness and cold sweat, that alert the patients to eat and take other measures to prevent coma. Diabetic autonomic neuropathy impairs catecholamine release and prevents the warning signs of hypoglycemia, leaving the patient unaware of it. The

related problem of hypoglycemic unresponsiveness occurs when impaired autonomic responses derange glucose counter-regulation during fasting or periods of increased insulin activity. In healthy people and in patients with early stage diabetes, these autonomic responses result in the release of glucagon and epinephrine for short-term glucose counterregulation and the release of growth hormone and cortisol for long-term regulation. Failure in glucose counter-regulation can be confirmed by the absence of glucagon and epinephrine response to hypoglycemia induced by administration of a controlled dose of insulin. The glucagon response becomes impaired after 1–5 years of type 1 diabetes. After 15–30 years, the glucagon response is almost undetectable, and it is absent in patients with autonomic neuropathy. The difficulty is in distinguishing the loss of counterregulation due to autonomic neuropathy from that due to the dampening effects of intensive glycemic control and recurrent hypoglycemia, called "hypoglycemia-associated autonomic failure."

Neurovascular Disturbances

Skin blood flow is important in maintaining nutrition, maintaining regional and whole body temperature, and healing skin trauma. The apical (glabrous) skin is present in the palmar surface of the hand, the plantar surface of the foot, and the face. It contains a large number of arteriovenous anastomoses or shunts and functions in thermoregulation. In contrast, nonapical (hairy) skin is present over most of the body surface. There are relatively few arteriovenous shunt vessels and blood flow is primarily nutritive in function. Microvascular skin flow is under the control of the autonomic nervous system and is regulated by both the central and peripheral components. In diabetes, the rhythmic contraction of arterioles and small arteries is disordered. Microvascular blood flow can be accurately measured noninvasively using laser Doppler flowmetry. Defective blood flow in the small capillary circulation is found with decreased responsiveness to mental arithmetic, cold pressor, handgrip, and heating. The defect is associated with a reduction in the amplitude of vasomotion and resembles premature aging. There are differences in the glabrous and hairy skin circulations. In hairy skin, a functional defect is found before the development of neuropathy; it occurs in family members and it may precede the development of diabetes. The clinical impact is dry skin, loss of sweating, and the development of fissures and cracks that are portals of entry for microorganisms leading to infectious ulcers and ultimately gangrene. The effect of autonomic neuropathy on the risk of developing a foot ulcer is independent of other measures of sensory neuropathy. Autonomic neuropathy may also lead to hyperperfusion of bone with increased osteoclastic activity, resulting in reduced bone density. Thus, a hot foot should alert the physician to impending Charcot's neuroarthropathy.

Diagnostic Tests of Diabetic Autonomic Neuropathy

Assessing Cardiovascular Autonomic Function

Tests of cardiovascular reflexes are sensitive, reproducible, simple, and noninvasive; they allow extensive evaluation of diabetic cardiovascular autonomic neuropathy and are regarded as the gold standard for clinical autonomic testing. These include measurements of the resting heart rate, beat-to-beat heart rate variation, blood pressure response to the Valsalva maneuver, changes in heart rate and systolic blood pressure in response to sustained exercise, and the QT interval. An increased resting heart rate and loss of heart rate variation in response to deep breathing are primary indicators of parasympathetic dysfunction. Tests for sympathetic dysfunction include measurements of changes in heart rate and blood pressure in response to standing, exercise, and handgrip. Heart rate variability (HRV) can be evaluated in the time and frequency domain derived from ECG recordings, ideally under paced breathing. Reduced HRV is the earliest clinical indicator of cardiac autonomic neuropathy and a strong independent predictor of mortality after acute myocardial infarction. A 24 h recording of HRV can reveal abnormal circadian rhythms regulated by sympathovagal activity. In vagal dysfunction, the high-frequency (HF) component of HRV is reduced; in sympathetic dysfunction, the low-frequency (LF) and very low-frequency components are reduced. Furthermore, in advanced cardiac autonomic neuropathy, all three components are reduced, as is the LF:HF ratio, which represents sympathovagal balance. Recently it has been recognized that the frequency of oscillations may yield important objective measures even with normal traditional changes in HRV. A reduction in the total spectral power and/or a reduction in the root mean square of the difference of successive RR intervals (rmsSD) is a measure of both sympathetic and parasympathetic activity while the standard deviation of normal RR intervals (SDNN) reflects predominantly parasympathetic nervous system function.

Both time and frequency analyses of HRV should be assessed during deep breathing, the Valsalva maneuver, and standing. They may be used to diagnose the cause, for example, of gastroparesis or erectile dysfunction, to give an incentive for intensive glycemic control, to quantitate the risk of macrovascular events and guide the use of a more conservative approach to medical management, and to monitor the response to therapy. Abnormalities in two or more of these tests suggest a diagnosis of autonomic neuropathy. Sympathetic/parasympathetic imbalance may produce significant symptoms and even herald the development of autonomic neuropathy and its consequences. The sympathetic innervation of the heart can also be visualized and quantified by single-photon emission computed tomography with metaiodobenzylguanidine in a research setting.

Thermoregulatory control of sweating occurs via sympathetic C fibers of the autonomic nervous system. Sweating disturbances are prevalent very early in diabetes and its precursors. Quantification of sweating using a sudomotor function test may be useful as an index of diagnosis of somatic and, probably, autonomic dysfunction.

The American Diabetes Association (ADA) and the American Association of Clinical Endocrinologists now recommend that patients with type 1 diabetes be screened for signs and symptoms of cardiac autonomic neuropathy 5 years after diagnosis and yearly thereafter and that patients with type 2 diabetes be tested at diagnosis and yearly thereafter.

Assessing Gastrointestinal Autonomic Function

The finding of retained food in the stomach after an 8–12 h fast in the absence of obstruction is diagnostic of gastroparesis. Basic diagnostic tests include upper gastrointestinal (GI) endoscopy or barium series to rule out structural or mucosal abnormalities of the GI tract. Gastric emptying can be visualized by scintigraphic imaging after the patient consumes radionuclide-labeled food, but the scintigraphic results do not always correlate with the severity of the symptoms. The blood glucose should be normal at the time of testing because hyperglycemia decreases gastric motility. Gastroduodenal manometry may be helpful in patients with symptoms but apparently normal emptying because it can help identify pylorospasm or incoordinate gastric and duodenal motility. Tachygastria and bradygastria, abnormal frequencies and propagation of gastric myoelectric activity, result in abnormalities in gastric emptying and can produce symptoms traditionally associated with gastroparesis.

Before attributing constipation to diabetic autonomic neuropathy, the clinician should rule out other causes of constipation such as hypothyroidism, side effects of drugs such as amitriptyline or calcium channel blockers, and colonic carcinoma. All patients should have a careful digital rectal examination and women should have a bimanual pelvic examination. Three stool specimens should be tested for occult blood. Anorectal manometry may be used to assess the rectal anal inhibitory reflex, which can distinguish rectosigmoid dysfunction and outlet-obstructive symptoms from colonic hypomotility.

Assessing Genitourinary Autonomic Function

A thorough workup for erectile dysfunction in men should include a medical and sexual history, physical and psychological evaluations, blood tests for testosterone, prolactin, and thyroid hormones, a test for nocturnal erections, tests to assess penile, pelvic, and spinal nerve functions, and tests to assess penile blood supply and blood pressure. Physical examination must include an evaluation of the autonomic nervous system, vascular supply, and hypothalamic–pituitary–gonadal axis. Autonomic neuropathy that causes erectile dysfunction is usually accompanied by loss of the HRV, ankle jerk reflex, and absent or reduced vibration sense over the large toes. To determine the integrity of sacral parasympathetic divisions, the physician should assess perianal sensation, sphincter tone, and the bulbocavernous reflex. Stenosis of the internal pudental artery is another potential cause of impotence. A penile/brachial index of less than 0.7 indicates diminished blood supply. A venous leak manifests as unresponsiveness to vasodilators and must be evaluated by penile Doppler sonography. In simple terms, unresponsiveness to intracavernosal injection of a direct vasodilator means arterial or venous insufficiency and requires inflatable devices, prostheses, or vascular reconstruction. A response to the vasodilator indicates autonomic insufficiency or a psychogenic cause that can be further defined using the HRV.

Treatment of Autonomic Neuropathy

Intensive glycemic control is critical to prevent the onset of diabetic autonomic neuropathy and slow its progression. The Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) provided extensive clinical evidence that good metabolic control reduces diabetic complications. Specifically, DCCT/EDIC showed that intensive glycemic control reduced cardiovascular autonomic neuropathy by 45% in individuals with type 1 diabetes, and the incidence and prevalence of CAN remained lower in the former intensively treated group despite similar levels of glycemic control at 13–14 years of follow-up. The Steno Memorial Study emphasized a multifactorial approach including blood pressure, lipid, and glucose control and the use of vitamins and antioxidants and the researchers were able to reduce the likelihood of development of autonomic neuropathy by 68%. Early identification of cardiac autonomic neuropathy permits the timely initiation of therapy with the antioxidant α-lipoic acid, which appears to slow or reverse the progression of neuropathies in some studies. The use of cardioselective (e.g., atenolol) or lipophilic (e.g., propranolol) beta-blockers may also modulate the effects of autonomic dysfunction (**Table 2**). By opposing the sympathetic stimulus, they may restore the

Table 2 Diagnosis and management of autonomic dysfunction

Symptoms	*Assessment modalities*	*Management*
Resting tachycardia, exercise intolerance, early fatigue and weakness with exercise	HRV, respiratory HRV, MUGA thallium scan, 1231 MIBG scan	Graded supervised exercise, beta blockers, ACE-inhibitors
Postural hypotension, lightheadedness, weakness, fatigue, syncope, tachycardia/ bradycardia Hyperhidrosis	HRV, blood pressure measurement lying and standing Sympathetic/ parasympathetic balance	Mechanical measures, clonidine, midodrine, octreotide, erythropoietin, pyridostigmine Clonidine, amitryptyline, trihexphenidyle, propantheline, or scopolamine, botox, glycopyrrolate

ACE, angiotensin–converting enzyme; HRV, heart rate variability, MIBG, metaiodobenzylguanidine; MUGA, multi-gated acquisition.
Reproduced from vinik *et al.*[66].

parasympathetic–sympathetic balance. Studies using graded exercise, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, C-peptide, digoxin, and verapamil as a means to improve HRV have resulted in suggestive results in small populations in research studies. Cardiovascular evaluation should include macrovascular risk factors and their elimination.

Orthostasis is best treated by avoiding precipitating factors such as hot baths and drugs that accentuate the fall in blood pressure. Patients should stand slowly and useful drugs include clonidine, midodrine, and somatostatin. The use of fludrosterone and the liberalization of salt intake usually result in weight gain, edema and inadequate control of the orthostatic symptoms. Northera (droxidopa), a dopamine agonist, has just received approval by the FDA for the treatment of neurogenic orthostatic hypotension.

Neurovascular dysfunction requires the use of emollient creams, scrupulous attention to foot care, vasodilators, bisphosphonates and TNF-α antagonists for impending Charcot's neuroarthropathy.

Treatment of gastroparesis should stress improvement of glycemic control and correction of other metabolic abnormalities. It also includes dietary modification, gastric suction, and prokinetic agents such as metoclopramide, domperidone, erythromycin, Amitiza (lubiprostone) and Linzess (linaclotide). In some severe cases, jejunostomy may be needed to provide for nutrient intake and to allow the stomach to rest until such time that it recovers its function.

The severe and intermittent nature of diabetic diarrhea makes treatment difficult. Because afferent denervation may contribute to the problem, a bowel program that includes restriction of soluble fiber and regular effort to move the bowels is indicated. In addition, trials of lactose restriction or of a gluten-free diet, cholestyramine, clonidine, somatostatin analogue, pancreatic enzyme supplements, and antibiotics, such as metronidazole, may be indicated. Treatment of constipation should begin with an emphasis on good bowel habits, including regular exercise and maintenance of adequate hydration and fiber consumption. Sorbitol and lactulose may be helpful.

A grossly overdistended bladder should be drained by catheter to improve contractility and the patient should be instructed to void by the clock rather than waiting for the sensation of bladder distension. Cholinergic agents or clean intermittent self-catheterization may also be used to facilitate emptying.

Treatment of erectile dysfunction may include withdrawal from offending medications coupled with psychological counseling, medical treatment, or surgery. Medical treatment may include the 5′-phosphodiesterase inhibitors, such as sildenafil, tandalophil, or vardenofil. A lower dosage is needed for individuals with renal failure or liver dysfunction. It may, however, take several doses to achieve an effect in patients with diabetes. These drugs should not be taken by individuals with unstable ischemic heart disease or those using nitroglycerin or other nitrate-containing medications. Alternative treatments include suction devices with or without a constriction ring, injections of vasodilators into the corpus cavernosum, and ultimately prostheses.

Prospects for the Future

With improved understanding of the pathogenesis of autonomic neuropathy, agents that have the potential for treating the underlying biologic defect rather than purely symptomatic therapy are being investigated. The situation is much less gloomy than the 1994 Lancet editorial that stated, “all we can do is make the diagnosis and commiserate with the patient.”

Glossary

Amputation Removal of an anatomic segment of the lower extremity, most often below the knee.
Diabetic foot Foot problems related to the metabolic and physiologic complications of diabetes mellitus.
Foot ulcer Full-thickness ulceration of the skin, usually at a site of high pressure in an insensate foot.
Neuropathy Damage to the sensory, motor, or autonomic pathways of the peripheral nerves of the foot.

Because of the metabolic and physiological complications of their disease, diabetic patients are prone to various foot disorders that cause substantial morbidity, the most dreaded of which is amputation.

Introduction

Foot lesions are a common, complex, and costly problem among patients with diabetes mellitus. Caring for diabetes-related foot wounds is often looked on as a thankless task, where much effort yields few rewards. However, increasing research in recent years has resulted in a better understanding of the pathophysiology and proper management of this problem. Diabetes-related peripheral neuropathy of the foot has emerged as the key factor leading to skin ulceration and its attendant complications. Pain insensitivity and motor-neuropathy-induced deformities are the principal disorders leading to skin ulceration. Other factors (e.g., autonomic nerve dysfunction, immunologic deficiencies, and metabolic perturbations) also contribute to the problem. Gaining more complete knowledge of the causes of these problems is a first step to reducing their consequences, but it will take a coordinated effort by interested providers or multidisciplinary teams to properly apply this knowledge. Data from the United States Department of Veterans Affairs Health System show that amputation rates are falling in all classes of patients *except* those with diabetes, emphasizing the need to improve efforts in this arena.

Epidemiology of Diabetic Foot Lesions

Incidence and Prevalence of Ulcers

Approximately 5%–10% of diabetic persons have had or currently have a foot ulceration. Foot problems are the major cause of hospitalization in patients with diabetes-related complications. One longitudinal study found that the incidence of ulceration over a 4-year period was 9.5%, with the risk increasing with the duration of diabetes. A study of mostly type 1 diabetic patients under age 50 in Sweden found that the prevalence of active ulcers was 2%, whereas 10% had a past history of ulceration. In an American investigation of a large health maintenance organization diabetic population, the cumulative incidence of ulceration was 5.8% over 3 years. In this study, 15% of patients with an ulcer required amputation.

Amputation Related to Foot Ulcers

Lower limb amputation can be life-saving in some patients and may improve the quality of life for those with recalcitrant or recurring foot ulcers. Improvements in prosthetic devices have enabled patients who require an amputation to enjoy a reasonable quality of life. In most instances, however, amputation is an outcome to be avoided. Diabetes is the commonest cause of nontraumatic lower limb amputation in the developed world. Persons with diabetes are at 15 to 46 times greater risk for lower extremity amputation than persons without diabetes. Foot wounds are the proximate cause of 90% of these nontraumatic amputations. In addition to the physical and emotional problems they cause, amputations have been associated with an increased mortality in the subsequent 3 years. By 2025, there will be more than 300 million persons with diabetes worldwide, emphasizing the urgency of this problem.

 doi:10.1016/B978-0-12-801238-3.03824-1

Financial Cost

As with the clinical morbidity, the financial cost of treating diabetic foot ulcers is substantial. One database of approximately 7 million patients followed over a 2-year period revealed that the total direct cost for treated diabetic foot ulcers was $16 million or an average of $4595 per ulcer episode. Another study identified attributable costs for a 40- to 65-year-old male with a new foot ulcer as $27,987 for the 2 years after its occurrence. Studies of diabetes-related lower extremity amputation in Europe and the United States over the past decade have reported direct related costs ranging from $20,000 to $27,000. Indirect costs, such as loss of productivity and long-term care at skilled facilities or by family members, may double the total cost to society. The recent National Diabetes Statistics Report (2017) about the estimates of diabetes and its burden in the United States shows striking figures. Diabetes foot complications cost more than the five deadly forms of cancer. A total amount of 245 billion dollars has been spent in 2012 for diabetes including 15 billion dollars for diabetic foot health. An amputation cost on average over 70,000 dollars.

Pathways to Ulceration and Amputation

Risk Factors for Foot Problems

Many factors, especially poor foot care and inappropriate footwear, increase the risk of foot ulceration. Most studies have shown that foot lesions generally arise from a combination of three factors. Peripheral neuropathy (the insensate foot) is the most important and can be identified by the patient's inability to feel 10 g of pressure applied with a Semmes-Weinstein monofilament. Loss of sensation to the 10 g Semmes-Weinstein monofilament is a significant and independent predictor of future foot ulcer and lower-extremity amputation. The other two factors are foot deformity, largely related to motor neuropathy, and repetitive moderate pressure or stress. In a case-control model assessing 225 diabetic patients, Lavery and coworkers noted that the presence of neuropathy alone increased the risk of ulceration 1.7-fold, neuropathy and deformity increased the risk 12.1-fold, and neuropathy, deformity, and a history of previous ulcer or amputation increased the risk of developing another ulcer approximately 36-fold. The major precipitating cause of foot amputation is an ulceration that fails to heal. An additional contributing factor is the presence of arterial vasculopathy, most frequently involving the infrageniculate blood vessels. Accelerated atherosclerosis associated with diabetes can lead to critical foot ischemia that impairs wound healing and infection resolution.

The Role of Infection

All open wounds are colonized by microorganisms, but when the lesion is complicated by clinical signs and symptoms of infection (which occurs in perhaps half the cases), the likelihood of a poor outcome greatly increases. Diabetic foot ulcers with concomitant infection and ischemia are up to 90 times more likely to result in a high-level amputation than wounds without those two additional risk factors. Infection is usually caused by aerobic gram-positive cocci, particularly staphylococci; chronic wounds, especially those previously treated with antibiotics, may become infected with aerobic gram-negative rods and anaerobes. Deep infections, which often involve the underlying bone, can be both limb- and life-threatening. Diagnosing bone infection can be difficult and may require imaging procedures (preferably magnetic resonance studies) or bone biopsy.

Treating Foot Wounds

Once an ulcer develops, it is critical to get it healed as quickly as possible. This requires attention to local, systemic, and social or psychological issues. The wound must be carefully assessed for neurologic, vascular, and infectious complications. Some patients will need to be hospitalized, whereas others can be safely treated at home. Several wounds classifications have been developed to provide objective assessment of foot ulcer severity. The simple Wagner classification is commonly used: Wagner Grade 0, skin intact; Grade 1, superficial ulcer; Grade 2, ulcer extending to tendon, capsule or bone; Grade 3, deep ulcer with osteomyelitis or abcess; Grade 4, gangrene of toes or forefoot; Grade 5, gangrene of midfoot or hindfoot. The University of Texas Diabetic Wound Classification System has been validated as a predictor of serious outcomes in people with diabetes who have foot ulcers. Almost all wounds will require some debridement of necrotic material and callus; some may require further surgical intervention (e.g., incision and drainage, or bone resection). Infected wounds should be cultured (preferably by sending a sample of tissue, not a swab) and empiric antibiotic therapy should carefully be selected. If the limb is ischemic, a vascular evaluation may be needed. Appropriate dressings must be selected, based on the type of wound, and the patient or caregiver must be instructed on how to properly change them. Limb edema and dry skin should be treated. Any systemic metabolic problems (e.g., poor glycemic control, malnutrition) should be addressed. The patient should never walk out of the office in the same shoe that caused an ulceration; proper footwear and methods or devices to offload the involved site are crucial to healing the wound. Foot lesions present the provider with a teachable moment to instruct the patient on the causes of foot problems and how they may be prevented.

How Ulcers and Amputations Can Be Prevented

Intervention at any point in the critical pathway to ulceration may prevent the serious foot complications of diabetes. For instance, reducing foot pressure points with appropriate footwear or orthoses and modulating activity should help avoid ulceration. Treating infected wounds with appropriate (and not excessive) antimicrobial therapy should prevent deeper infections. Improving blood flow (e.g., with a distal bypass procedure) to a critically ischemic wound should lessen the likelihood of amputation. Other key preventative factors include the following: regular foot inspection by the patient and health care providers; for patients with risk factors for foot ulcerations, regular foot examination and care by primary care and podiatric providers; wearing appropriate shoe gear; and, in some instances, undergoing judicious surgical interventions to reduce deformity may be helpful. Lower extremity ulcerations and amputations in persons with diabetes take a terrible toll on the individual and on the world's health care systems, but the good news is that they are almost entirely preventable with appropriate care and education.

Cardiovascular Burden of Diabetes

Diabetes mellitus (DM), a chronic metabolic condition characterized by hyperglycemia, represent a major risk factors for microvascular and macrovascular diseases (Goldenberg and Punthakee, 2013). Cardiovascular disease (CVD) is the most prevalent cause of morbidity and mortality in diabetic populations. Approximately 75% of patients with type 2 DM (T2DM) will die from CVD (Leiter and Fitchett, 2006; Klein and Gheorghiade, 2004; Emerging Risk Factors Collaboration *et al.*, 2011). The United Kingdom Prospective DM Study (UKPDS) showed a progressive increase in risk for nonfatal and fatal myocardial infarction, nonfatal and fatal stroke, amputation from peripheral vascular disease, and heart failure (HF) with increasing hemoglobin A1c (A1C) levels (Stratton *et al.*, 2000b). Atherosclerotic CVD remains the principal cause of disability and death among patients with DM. Type 2 DM is associated with a two- to fourfold increased risk for coronary artery disease (CAD) and a fourfold increase in mortality especially in women (Emerging Risk Factors Collaboration *et al.*, 2011; Abi Khalil *et al.*, 2012; Lloyd-Jones *et al.*, 2006). Diabetes mellitus poses the greatest life-time risk of any traditional cardiovascular (CV) risk factor for the development of CAD (Lloyd-Jones *et al.*, 2006). Myocardial infarction occurs 15 years earlier in patients with DM, with greater severity, and with more diffuse distribution than in those without (Booth *et al.*, 2006). Type 1 DM (T1DM) also markedly increases the risk of premature CVD; in patients aged <40 years the risk of CAD was >10-fold higher than that of the general population (Dorman *et al.*, 1984; Retnakaran and Zinman, 2008).

Although the relationship between A1C levels and microvascular outcomes is much stronger than that observed with risk of myocardial infarction (Stratton *et al.*, 2000b), close to 50% of patients with CAD have co-existing DM; CAD is frequently observed in patients at the time of diagnosis of T2DM, and even at the time of presentation of CVD, many with DM are undiagnosed (Hu *et al.*, 2002; Standl, 2015; Bartnik *et al.*, 2004; Gholap *et al.*, 2012). In CAD patients without known DM, a considerable proportion have evidence of either impaired glucose tolerance (IGT) or impaired fasting glucose (IFG) or undiagnosed DM with the latter affecting 14%–22% of them (Bartnik *et al.*, 2004). Both undiagnosed T2DM and other disorders of glucose metabolism are risk factors for CVD. Diabetes mellitus is also a major risk factor for HF (Schocken *et al.*, 2008) and is found in 24%–40% of patients with HF (Dei Cas *et al.*, 2015). The presence of HF in DM patients is associated with a 3 year mortality of 40%, which is 10 times higher than individuals with DM and no HF (Cubbon *et al.*, 2013) (**Table 1**).

Mechanisms of Increased Cardiovascular Risk and Mortality in Diabetes

Both T1DM and T2DM increase the risk of CVD and associated mortality, largely because of increased atherosclerosis. Patients with DM have greater atherosclerotic plaque burden, higher atheroma volume, and smaller coronary artery lumen diameter than persons without DM (Nicholls *et al.*, 2008). Multiple cellular and molecular pathophysiologic factors participate in the diabetic atherosclerosis burden (Ross, 1993; Tabas *et al.*, 2015) (**Fig. 1**). Pathophysiology of CVD in DM is complex and is affected by the type of diabetes (T1DM and T2DM). Type 1 DM, generally of young onset, reflects largely a hyperglycemia-driven disease caused by insulin deficiency, whereas in T2DM, generally of adult onset, reflects a hyperglycemia-driven disease that is modified by

Table 1 Cardiovascular burden of diabetes

- Patients with diabetes mellitus have a reduced life expectancy largely secondary to CVD
- Diabetes mellitus increases risk of CVD two- to fourfold and mortality fourfold especially in women
- Diabetes mellitus poses the greatest life-time risk of any traditional CV risk factor and enlarge impact of other CV risk factors
- Diabetes mellitus increases the morbidity and mortality of all CVD including HF
- Diabetes mellitus is common in patients with CVD and is frequently undiagnosed even at the time of presentation of CVD

CVD, Cardiovascular disease; CV, Cardiovascular; HF, Heart failure.

☆*Change History*: March 2018. ME Piché and P Poirier updated all sections in this chapter.

This article is an update of Helaine E. Resnick and Barbara V. Howard, Cardiovascular Disease in Diabetes, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 476–479.

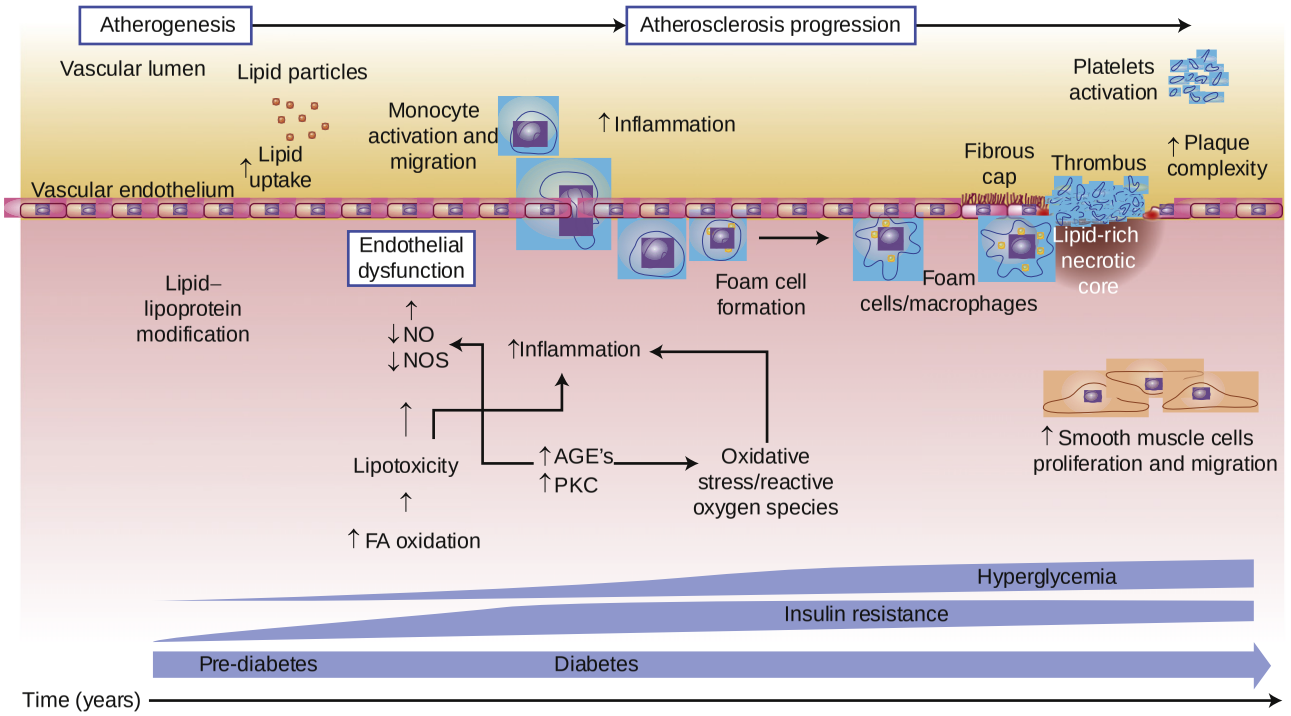

Fig. 1 Atherosclerosis development and progression in diabetes mellitus. Insulin resistance is present before the onset of prediabetes or diabetes mellitus, and increases progressively over time, whereas hyperglycemia develops in prediabetes and worsens with development of diabetes mellitus. Insulin resistance with impairment of insulin signaling and hyperglycemia contribute both to multiple processes of atherosclerosis. NO, Nitric oxide; NOS, Nitric oxide synthase; FA, Fatty acids; AGE, Advanced glycation end-product; PKC, Protein kinase C.

multiple other mechanisms including insulin resistance, abnormal fatty acid metabolism and CV co-morbidities leading to accelerated atherosclerosis (Armstrong *et al.*, 2013; Bornfeldt and Tabas, 2011; Ferreiro and Angiolillo, 2011; Catrina, 2014; Fiorentino *et al.*, 2013; Kayama *et al.*, 2015; Kozakova and Palombo, 2016; Laakso and Kuusisto, 2014; Loader *et al.*, 2015; Mapanga and Essop, 2016; Tkac, 2013; Zeadin *et al.*, 2013).

Hyperglycemia

Abundant epidemiological data support the association between hyperglycemia and increased CV risk (Gerstein *et al.*, 2005; Stratton *et al.*, 2000a). There is strong evidence demonstrating greater risk for CAD with increasing dysglycemia (Emerging Risk Factors Collaboration *et al.*, 2010, 2011; Coutinho *et al.*, 1999) with an estimated 11%–16% increase in CV events for every 1% increase in A1C (Stratton *et al.*, 2000b; Rodriguez *et al.*, 1999). In vitro studies and in vivo models in which hyperglycemia is induced in the absence of elevated lipids are consistent with a direct effect of hyperglycemia on endothelial dysfunction (Perkins *et al.*, 2015; Ceriello *et al.*, 2002), atherosclerotic lesion severity and complexity (Suzuki *et al.*, 2001) and plaque burden (Bornfeldt, 2014) (**Fig. 1**).

Hypoglycemia

Hypoglycemia, a consequence of therapy, also has deleterious CV effects mediated by multiple mechanisms (Dandona *et al.*, 2010; Bedenis *et al.*, 2014; Ziegler *et al.*, 2008; Stahn *et al.*, 2014; Sommerfield *et al.*, 2007; Odeh *et al.*, 1990; Desouza *et al.*, 2010; Chow and Heller, 2012; Sanon *et al.*, 2014; Yang *et al.*, 2016). Risk factors for hypoglycemia include age, cognitive impairment, use of insulin or insulin-secretagogues, renal impairment, presence of diabetic neuropathy and prior episodes of hypoglycemia (Canadian Diabetes Association Clinical Practice Guidelines Expert Committee *et al.*, 2015). A higher annual rate of severe hypoglycemia in the Action to Control Cardiovascular Risk in Diabetes (ACCORD), Action in Diabetes and Vascular Disease (ADVANCE) and Veterans Affairs Diabetes Trial (VADT) in the intensive vs. the standard treatment groups was reported (Bonds *et al.*, 2010; Advance Collaborative Group *et al.*, 2008; Duckworth *et al.*, 2009a) and was associated with >4-fold higher CV mortality in VADT and a >2.8% mortality rate per year in ACCORD. While specific mechanisms mediating adverse CV effects are unique to either hyperglycemia or hypoglycemia, there are both many similarities. They both impair endothelial function, augment thrombotic and platelet aggregation, compromise cardiac function and disrupt the renin-angiotensin-aldosterone and autonomic nervous systems. Thus, from a CV perspective, it should be emphasized to avoid acute hyper- and hypoglycemia on chronic vascular insults and this principle should be reflected in therapeutic choices (Goto *et al.*, 2013).

Insulin Resistance

Insulin resistance plays an important role in the pathophysiology of DM and CVD, and both genetic and environmental factors facilitate its development. Insulin resistance is a characteristic feature of T2DM but is also a consistent finding in patients with T1DM (Yki-Jarvinen and Koivisto, 1986; Cleland *et al.*, 2013). Epidemiological evidence strongly associates insulin resistance with CV risk in humans (Rodriguez *et al.*, 1999; Howard *et al.*, 1996; Ferrannini *et al.*, 2007; Wilson *et al.*, 1998). Insulin resistance is a general term meaning that insulin does not exert its normal effects in insulin-sensitive target tissues, such as skeletal muscle, adipose tissue, liver, heart and pancreas, the major target tissues for insulin action in glucose metabolism. Insulin resistance, measured using the clamp technique, is associated with asymptomatic atherosclerosis (Laakso *et al.*, 1991) and CAD (Bressler *et al.*, 1996) in individuals without DM. Fasting insulin levels, a marker of insulin resistance, have also been associated with CV events in nondiabetic individuals, independent of other risk factors (Laakso, 2001, 1996). Insulin resistance can promote atherogenesis and plaque progression via multiple mechanisms, including changes in insulin signaling pathways (Bornfeldt and Tabas, 2011), and through their effects on CV risk factors. Impairment of insulin signaling at multiple points in the insulin signaling pathway in endothelial cells (Muniyappa *et al.*, 2007; Potenza *et al.*, 2009), vascular smooth muscle cells (Wang *et al.*, 2004; Suzuki *et al.*, 2001), and macrophages (Bornfeldt, 2014) promotes development and progression of atherosclerosis, as does the pro-inflammatory state induced in insulin resistance (**Fig. 1**). Insulin resistance alone or combined with hyperglycemia promotes adverse changes in CV risk factors, including pro-atherogenic dyslipidemia and blood pressure elevation (Ferrannini *et al.*, 2007; Golden *et al.*, 2002; Eckel *et al.*, 2005), which contribute to the development, progression, and complexity of atherosclerosis.

Cardiovascular Risk Factors in Diabetes

CV risk factors such as obesity, hypertension and dyslipidemia are common in patients with T2DM, placing them at increased risk for the development of early CVD (**Table 2**). These result in metabolic changes which, coupled with a sedentary lifestyle and smoking, enhance the deleterious effects of hyperglycemia and accelerate atherosclerotic disease in the vasculature (**Fig. 2**). In the United Kingdom Prospective Diabetes Study (UKPDS), the major risk factors for myocardial infarction (MI) in patients with T2DM were high LDL cholesterol levels, low HDL cholesterol, elevated diastolic blood pressure, smoking, and A1C levels (Turner

et al., 1998). These factors were similar to findings from a 7-year follow-up study of 1059 patients with T2DM in Finland (Lehto *et al.*, 1997), and suggest that traditional CV risk factors are major predictors of CV events in patients with T2DM (**Table 3**).

DM and dyslipidemia commonly occur together, with lipid abnormalities affecting 60%–70% of T2DM (Parhofer, 2015), and hyperglycemia accelerates atheroma formation in the setting of diabetic dyslipidemia (Renard *et al.*, 2004). LDL cholesterol

- Higher concentrations of apolipoprotein B-containing particles

HDL, High-density lipoprotein; LDL, Low-density lipoprotein.

particles are more atherogenic in DM even in the absence of overt increased LDL concentrations (Carmena *et al.*, 2004), with small dense particles that are particularly prone to modification and oxidation (Rabbani *et al.*, 2011). Diabetic dyslipidemia is also characterized by elevated triglycerides, low HDL cholesterol, and higher concentrations of apolipoprotein B-containing particles (Taskinen, 2003; Kannel, 1985) (**Table 4**). Lipid changes are observe in insulin resistant individuals with normal glucose tolerance and in those with metabolic syndrome years before clinical diagnosis of T2DM (Lorenzo *et al.*, 2013), suggesting either co-associations of independent disorders or a pathophysiologic role for insulin resistance, rather than hyperglycemia, in the development of DM dyslipidemia. About two-thirds of patients with T2DM have elevated blood pressure (Ferrannini and Cushman, 2012). In addition to sympathetic nervous system overactivity, the effects of insulin resistance on the nitric oxide pathway, smooth muscle growth, sodium and fluid retention, and the effect of hyperglycemia on the renin–angiotensin–aldosterone system are plausible mechanisms that increase blood pressure in patients with T2DM (Ferrannini and Cushman, 2012). Obesity is a typical CV risk factor in individuals with T2DM. The effects of weight gain (define as a change in body mass index (BMI)) over the 6.5-year follow-up period on CV risk factors was investigated in 1168 participants in the Diabetes Control and Complications Trial (DCCT) (Purnell *et al.*, 2013). Excess weight gain (an increase in BMI of ≥ 4.39 kg/m^2 vs. a BMI increase < 4.39 kg/m^2) was associated with sustained increases in central obesity, insulin dose, dyslipidemia and systolic and diastolic blood pressure, as well as more extensive atherosclerosis (evaluated by carotid intima–media thickness) (Purnell *et al.*, 2013).

Targeting individual CV risk factors reduces CV risk in DM, but addressing multiple risk factors simultaneously may synergistically reduce CV event risk even further. This hypothesis is supported by the Steno-2 study, in which participant with T2DM and albuminuria were randomized to intensive vs. conventional control of glycemia, blood pressure, and lipids, and followed for a mean of 7.8 years (Gaede *et al.*, 2003). The trial showed a statistically and clinically significant 53% reduction for the primary composite CV event end point. CV risk differences between intensive and conventional therapy separated after 1 year. The number needed-to-treat was 5 over 7.8 years to achieve this magnitude of CV risk reduction. The long-term 21 year follow-up data from the Steno-2 study have demonstrated the sustainability of intensified multifactorial intervention strategy in T2DM and microalbuminuria, in terms of gained years of life and years free from incident CVD over conventional DM treatment (Gaede *et al.*, 2016). Metabolic changes specific to DM very likely contribute to the excess risk of CVD in patients with T2DM. A secondary analysis of the Bypass Angioplasty Revascularization Investigation in Type 2 Diabetes (BARI-2D) trial evaluating multiple interventions also supports concurrent risk factor control lowers total mortality and the composite of death, MI, and stroke in patients with T2DM and established coronary heart disease (Bittner *et al.*, 2015). While achievement of multiple treatment goals in DM care has improved over time, currently only 14.3% of US adults with T2DM are at recommended goals for A1C, blood pressure, and LDL cholesterol (Ali *et al.*, 2013).

Diabetes and Heart Failure

Risk for HF in DM increases 2.4-fold in men and fivefold in women in comparison with those without DM (Kannel and McGee, 1979). Conversely, DM is an important predictor of HF, independent of concomitant hypertension or CAD. Heart failure is the second most common manifestation of CVD after peripheral artery disease, as demonstrate in the largest cohort study of almost

1.9 million patients with T2DM followed for a median of 5.5 years (Shah *et al.*, 2015). Multiple factors, including age, ischemic heart disease, and peripheral artery disease, as well as DM-specific risk factors, such as poor glycemic control (higher A1C) and insulin resistance, have been associated with HF in patients with DM (Nichols *et al.*, 2001; Iribarren *et al.*, 2001). The pathogenesis of HF in DM is complex and multifactorial (**Fig. 3**). Although hyperglycemia and insulin resistance are the main physiological disturbances in DM, multiple mechanisms, such as derangements in cellular metabolism, function and structure, autonomic neuropathy, and neurohormonal dysregulation are believed to play a role in the associated HF (Chong *et al.*, 2017; Levelt *et al.*, 2016). Accelerated atherosclerosis of DM may be diffuse and severe. Consequently, ischemic cardiomyopathy is a major cause of HF in the DM population. Even in the absence of CAD, microvascular disease, characterized by arterial thickening and fibrosis, as well as endothelial and vasomotor dysfunction, can increase risk of HF in DM. Hypertension is another common comorbid condition in DM, causing left ventricular hypertrophy and contributing to the development of HF (Adler *et al.*, 2000). Furthermore, although DM is now accepted as an independent cause of HF, severity of DM-related cardiac abnormalities may be amplified by comorbid conditions which impact the CV system, ultimately increasing the risk for HF.

Assessment of Cardiovascular Risk in Diabetes

Compared to subjects without DM, patients with T1DM and T2DM (especially women) are at higher risk of developing CVD, at an earlier age. Furthermore, people with DM have a high prevalence of silent myocardial ischemia, and almost one-third of MI occur without recognized or typical symptoms (silent MI) (Cohn *et al.*, 2003). Silent ischemia is most likely to occur in individuals with DM who are older (mean age 65 years), and is more frequent in those with DM who also have microalbuminuria (Rutter *et al.*, 1999). People with DM and silent ischemia have an annual event rate for CAD of 6.2% (50% of events were new-onset angina and 50% were cardiac death or MI) (Rutter *et al.*, 2002). The 2013 Joint European Society guidelines on CVD prevention recommended that patients with DM, and at least one other CV risk factor or target organ damage, should be considered to be at very high risk and all other patients with DM to be at high risk (Authors/Task Force *et al.*, 2013).

The goals of screening for CVD in DM are to improve quality of life and life expectancy by preventing CV events and HF through early detection of significant CAD. There is some evidence that early screening and intervention in people with T2DM and with silent ischemia is beneficial and may improve long-term survival (Inoguchi *et al.*, 2000; Sorajja *et al.*, 2005). In the absence of data to the contrary, one approach to identifying CVD in peoples with T1DM is to apply the same CV risk assessment and diagnostic strategies used in T2DM or in the general population (Greenland *et al.*, 2010). Identification of asymptomatic CAD may allow the opportunity for more aggressive lifestyle or pharmacological interventions to prevent clinical events or, when disease is advanced, the pursuit of cardiac revascularization.

The most predictive clinical observation for CAD in patients with DM is a history of chest pain or discomfort, but these features will be absent in a significant number (20%–50%) of patients with DM (Zellweger *et al.*, 2004; Wackers *et al.*, 2004). Clinical

findings, such as resting electrocardiogram (ECG) abnormalities or multiple risk factors for atherosclerosis, may also suggest the presence of CAD. Successful CV risk prevention depends on a comprehensive detection and management of all modifiable CV risk factors. This includes evaluation of CV risk factors (e.g., lifestyle habits including smoking, hypertension and dyslipidemia), microvascular and macrovascular diseases, cardiac co-morbidities (e.g., HF and arrhythmias) and inducible myocardial ischemia by means of exercise testing, or cardiac imaging.

Cardiovascular Screening Tests

Although it is important to individualize clinical decision making, widespread screening for silent CAD in DM cannot be recommended at this time (Upchurch and Barrett, 2012). Screening for silent myocardial ischemia may be considered in selected high risk patient with DM (**Fig. 4**).

Resting Electrocardiogram

The presence of CV risk factors and resting ECG abnormalities identify patients with DM at increased risk of important CAD burden. Several prior studies have demonstrated that baseline ECG abnormalities are common in asymptomatic patients with DM and no history of CAD. In the UKPDS, 1 in 6 patients with newly diagnosed T2DM had evidence of silent myocardial ischemia on baseline ECG (Davis *et al.*, 2013). An ECG with ST-T abnormalities at rest has been shown to be most predictive for silent ischemia and was the only significant predictor of silent ischemia in women (Milan Study on Atherosclerosis and Diabetes (MiSAD) Group, 1997). The relevance of ST-T abnormalities as a predictive factor for silent ischemia emphasizes the importance of recording a resting ECG in most individuals with T2DM. An abnormal resting ECG may indicate the need for further investigations and result in the earlier detection and treatment/revascularization of CAD.

Exercise Stress Testing

Exercise stress testing is useful in patients at high risk of CAD for the assessment of prognosis and the identification of individuals who may benefit from coronary artery revascularization to improve long-term survival. An abnormal exercise

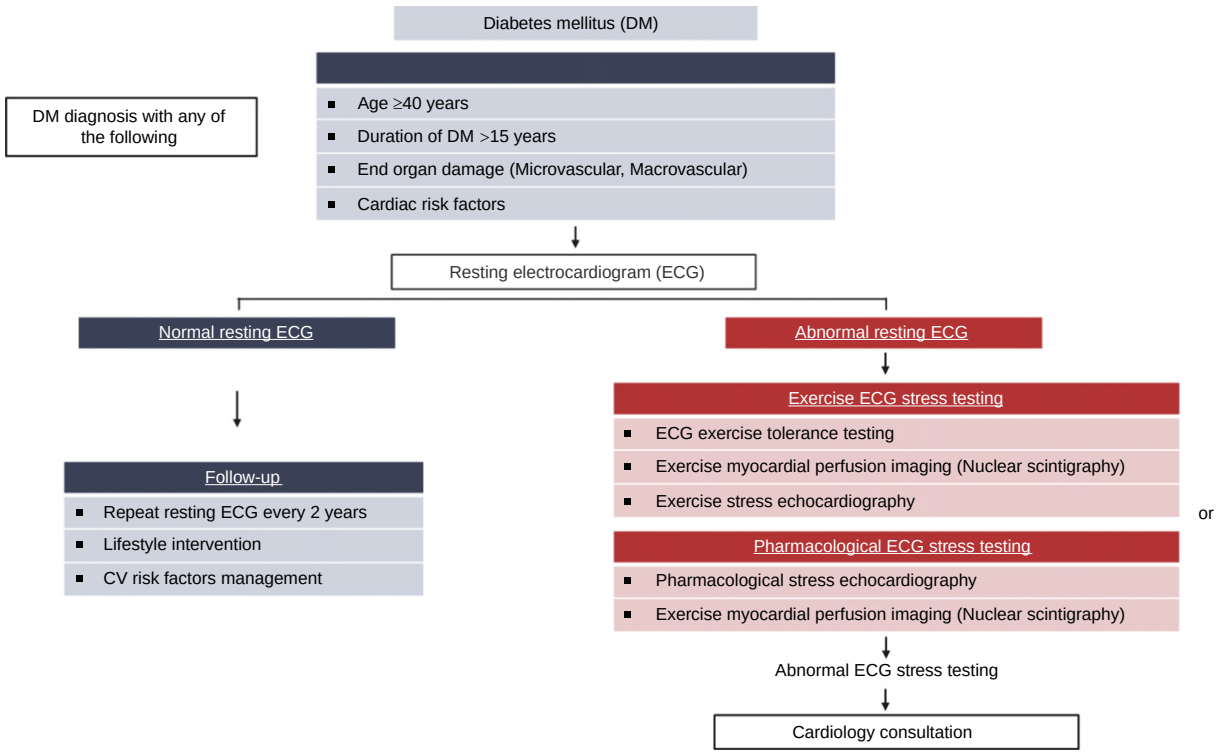

Fig. 4 Investigational algorithm and cardiovascular disease management in diabetes. DM, Diabetes mellitus; ECG, Electrocardiogram; CV, Cardiovascular.

ECG is associated with an annual CAD event rate of 2.1%, compared with 0.97% in subjects with normal exercise ECG (Faglia *et al.*, 2005). Myocardial ischemia (whether silent or symptomatic) detected during exercise stress testing in individuals with DM is associated with poorer long-term survival compared to individuals without DM (Inoguchi *et al.*, 2000). The strongest and most consistent prognostic marker identified during exercise ECG stress testing is the person's maximum exercise capacity (Zellweger *et al.*, 2004). Although exercise capacity is decreased in individuals with DM (Poirier *et al.*, 2000), it is still of prognostic importance.

The choice of initial stress test should be based on evaluation of the resting ECG, the individual's ability to exercise, and local expertise and technology. Screening tests include ECG exercise tolerance testing, exercise (or pharmacological) myocardial perfusion imaging (nuclear scintigraphy), and exercise (or pharmacological) stress echocardiography. The ankle-brachial index and coronary artery calcium scoring by computed tomography (CT) are used to detect evidence of atherosclerosis, although these methods cannot assess for active or inducible ischemia. Emerging techniques include CT angiography, cardiac magnetic resonance imaging, and cardiac positron emission tomography, but none have had wide spread application in asymptomatic patients. The utility of these newer CAD diagnostic modalities, is currently unknown in terms of guiding management decisions in patients with DM. The reliability of exercise testing, stress echocardiography, or myocardial scintigraphy is of a particular concern in the detection of ischemia in DM. Confounders are a high threshold for pain due to autonomic dysfunction, the multivessel nature of CAD, baseline ECG abnormalities, co-existence of peripheral artery disease and use of multiple medications.

Exercise capacity is frequently impaired in people with DM due to the high prevalence of obesity, sedentary lifestyle, peripheral neuropathy (both sensory and motor), and vascular disease in this population. Individuals who cannot adequately exercise on a stress test have a poorer prognosis than those who can, regardless of the reason for this incapacity (Zellweger *et al.*, 2004). Perfusion imaging also provides important prognostic information. Myocardial perfusion imaging has similar predictive value for cardiac death and nonfatal MI in individuals with DM as in those without DM (Shaw and Iskandrian, 2004). For those unable to perform an exercise ECG stress test, pharmacologic stress imaging, using dipyridamole, adenosine, or dobutamine testing, is required. Stress echocardiography and stress nuclear imaging have similar values for cardiac events in the general population (Schinkel *et al.*, 2004), but no comparative data are available for patients with DM.

Future large, randomized trials are needed to determine whether screening for subclinical CAD, particularly with newer modalities that may improve detection of functional CAD, can reduce CV event rates in patients with DM. Such studies would need to be adequately powered to assess the potential of additive impact of screening results and subsequent interventions on actual patient outcomes.

Establishing a Diagnosis of Diabetes in Cardiovascular Disease

Screening for DM using a fasting blood glucose and/or A1C is recommended every 3 years in individuals $\geq$40 years of age or at high risk for developing DM based on a DM risk score (Ekoe *et al.*, 2013; Robinson *et al.*, 2011; Abbasi *et al.*, 2012; Lindstrom and Tuomilehto, 2003). More frequent and/or earlier testing should be considered in those at very high risk or in people with additional risk factors for DM, including the presence of coronary, cerebrovascular and peripheral vascular disease (Robinson *et al.*, 2011; Ekoe *et al.*, 2013; Gyberg *et al.*, 2015). A 75 g Oral Glucose Tolerance Test (OGTT) should be strongly considered in patients with impaired fasting glucose or with A1C in the prediabetes range. Diagnosis in patients with CVD is especially important. A cross sectional survey of 4004 patients with stable CAD demonstrated that 29% had undetected DM and screening with an OGTT detected 96% of cases, while combining the fasting plasma glucose and A1C test identified 81% (Gyberg *et al.*, 2015; Norhammar *et al.*, 2002).

Fasting plasma glucose can be transiently elevated in acute coronary syndrome (ACS) and is unreliable for establishing a diagnosis in the first 2 days of an ACS (Hage *et al.*, 2010). While impaired glucose tolerance (IGT) is the predominant glucose abnormality in ACS (Bartnik *et al.*, 2004), an OGTT is rarely performed in that setting and may also be unreliable if done within 4–5 days of the event (Hage *et al.*, 2010). An in-hospital A1C test has been proposed as a practical method for screening patients with ACS. Those with A1C $\geq$6.5% should undergo a confirmatory measurement 4–8 weeks post-discharge, and those with A1C between 6.0% and 6.4% should have an OGTT 6–8 weeks post discharge (Gholap *et al.*, 2012).

Cardiovascular Risk Reduction in Diabetes

Targeting individual CV risk factors reduces CVD risk in DM, but addressing multiple risk factors concurrently may synergistically reduce CV event risk even further (**Table 5**). DM therapies should otherwise be selected on an individual basis, with special caution used when treating older patients or specific population. CV protective measures in patients with DM include health behavior interventions (diet, weight modification, increased physical activity, smoking cessation) and pharmacological therapies [anti-platelet agents, statins, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), blood glucose and blood pressure control]. A systematic approach to all CV protective measures has been proven to reduce the risk of CV events (Gaede *et al.*, 2008; Anselmino *et al.*, 2008).

Table 5 Cardiovascular risk reduction in diabetes

- Glucose control alone has not been clearly shown to reduce CV risk in diabetes mellitus
- Multiple risk factors contribute to CV risk in T1DM and T2DM
- Addressing multiple risk factors simultaneously may synergistically reduce CV event risk
- Effective CV risk management in diabetes mellitus requires lifestyle intervention, management of glucose control and CV risk factors

CV, Cardiovascular; T1DM, Type 1 diabetes mellitus; T2DM, Type 2 diabetes mellitus.

Lifestyle Management

A joint scientific statement from the ADA and EASD advocates lifestyle management (including healthy eating, physical activity and cessation of smoking) as a first measure for the prevention and/or management of T2DM, with targets of weight loss and reduction of CV risk (Inzucchi *et al.*, 2012). An intensive program including counseling about medical nutrition therapy, physical activity, and behavior changes, with ongoing support and frequent follow-up are needed for long term lifestyle management of body weight, CV risk factors and glycemia itself in DM. Weight loss, a healthy eating pattern, and increasing physical activity are also effective for reducing CV risk factors in individuals without DM. Lifestyle interventions should be recommended in all patients with DM, patients at risk for CVD, and patients with known CVD. The Look AHEAD trial is a large multicentre randomized clinical trial on the effects of long-term lifestyle intervention-associated weight loss on glycemia and prevention of CVD events in T2DM. One year results in the intensive lifestyle intervention group have showed an average 8.6% weight loss, a significant reduction in A1C, an improvement in fitness and a reduction in several CVD risk factors, benefits that were sustained after 4 years (Pi-Sunyer *et al.*, 2007; Look and Wing, 2010). Despite greater weight loss, reduction in A1C, and improvements in fitness and CV risk factors in the intervention group, there was no difference in the incident of CV events.

Weight Loss Bariatric Surgery

Most individuals with T2DM are obese, and weight control has been considered a central component of lifestyle intervention. Weight reduction or at least stabilization in overweight or moderately obese patients will still be an important component in a lifestyle programme and may have pleiotropic effects. In severely obese individuals, bariatric surgery causes long-term weight loss and reduces the rate of incident T2DM and mortality (Sjöström *et al.*, 2004). Bariatric surgery induces remission or improvement in T2DM in 40%–85% of patients (Sjöström *et al.*, 2004; Puzziferri *et al.*, 2014). It is not known whether the remission in T2DM seen after bariatric surgery will lead to a reduction in CV events.

Glucose Control

Myocardial infarction and stroke accounts for up to 80% of mortality in T2DM (Morrish *et al.*, 2001). Medications taken to manage hyperglycemia must not adversely impact CV risk factors or increase CVD, and ideally would reduce CV risk. However, many of the medications available to treat hyperglycemia in DM have no effect on CV risk or may have a theoretical concern for exacerbating CV risk factors or CVD itself. Although lowering glucose concentrations will ameliorate immediate symptoms of hyperglycemia (polyuria, polydipsia, and weight loss) and longer term microvascular complications of DM (Ross, 1993; UK Prospective Diabetes Study (UKPDS) Group, 1998a,b), there is less evidence for targeting A1C to lower CV risk (Nathan *et al.*, 2005; Holman *et al.*, 2008a). The reasons, of which there are several, include the presence of multiple co-morbidities in long-standing T2DM and the complex risk phenotype generated in the presence of insulin resistance.

Intensive glycemic control reduces relative risk of nonfatal myocardial infarction and coronary heart disease events by about 15%, although there is no effect of intensive glycemic control on all-cause mortality in meta-analysis of the multiple randomized clinical trials targeting different intensity of glycemic control (Ray *et al.*, 2009). Most studies are of relatively short duration, and long-term follow-up of both the Diabetes Control and Complications Trial (DCCT) (Nathan *et al.*, 2005) and United Kingdom Prospective Diabetes Study (UKPDS) (Holman *et al.*, 2008a) show reduced risk for CV events emerge over time in those with recently diagnosed T1DM and T2DM, respectively, who were previously randomized to intensive glycemic control. However, these effects take years to manifest and few studies extend observations over the extended time frame which may be necessary to provide benefit of glucose lowering per se.

Glucose Targets

An A1C target of 7.0% to reduce microvascular disease is a generally accepted level (The Diabetes Control and Complications Trial Research Group, 1993; Holman *et al.*, 2008a). The evidence for an A1C target in relation to macrovascular risk is less compelling, in part due to the complexities surrounding the chronic, progressive nature of DM and the effects of "metabolic memory."

Consensus indicates that an A1C of ≤7% should be targeted, this can be achieved through balanced assessment of efficacy, risk of hypoglycemia, effect on body weight, and costs of available glucose-lowering agents and their combination (Inzucchi *et al.*, 2015). Ideally, tight control should be instigated early in the course of the disorder in younger patients and without attendant co-morbidities. Fasting plasma glucose should be 7.2 mmol/L (120 mg/dL) and post-prandial 9–10 mmol/L (160–180 mg/dL) on an individualized basis (Inzucchi *et al.*, 2015). Successful glucose lowering therapy is assisted by self-monitoring of blood glucose, most notably in patients with insulin-treated DM.

This "universal" glycemic target (A1C value ≤7%), however, has been challenged by the results of subsequent intervention trials (Gerstein *et al.*, 2008; Advance Collaborative Group *et al.*, 2008; Duckworth *et al.*, 2009b). Given the critical analysis of the results of these trials, the American Diabetes Association (ADA) and the American Heart Association suggested that an individualized A1C target should be identified based on the duration of DM, life expectancy, presence and severity of DM complications, and propensity for hypoglycemia (Skyler *et al.*, 2009). This suggestion has been endorsed by several international guidelines. Although the concept of treatment individualization is appealing, how to pursue it in the clinical setting remains highly debated. On the basis of the patient's individual phenotypic and genetic profiles, precision medicine aims at predicting which patient is more likely to benefit and which one is more likely to experience side effects in response to therapeutic modalities (Lyssenko *et al.*, 2016). These advances open attractive opportunity to determine the utility of phenotypic and genetic profiles to predict treatment response. However, interpretation is not always clear and translation into clinical guidance remain uncertain and insufficiently investigated.

More stringent targets (e.g., A1C 6.0%–6.5%) might be considered in selected patients with short disease duration, long life expectancy and no significant CVD, if it can be achieved without hypoglycemia or other adverse effects. As discussed above, the accumulated results from T2DM CV trials suggest that not everyone benefits from aggressive glucose management. It follows that it is important to individualize treatment targets guidelines support the concept of targeting A1C and individualization of A1C goals in order to minimize microvascular and macrovascular complications (Imran *et al.*, 2013, American Diabetes Association, 2016, The Diabetes Control and Complications Trial Research Group, 1993, UK Prospective Diabetes Study (UKPDS) Group, 1998b, Advance Collaborative Group *et al.*, 2008). For the vast majority, the A1C goal is 7% or less (Imran *et al.*, 2013). In T2DM, this has been shown to reduce microvascular complications, and over time, macrovascular complications when implemented early in the disease course (UK Prospective Diabetes Study (UKPDS) Group, 1998b, Holman *et al.*, 2008b). For those who have had longer duration of T2DM, intensive glycemic control also reduces microvascular complications (Advance Collaborative Group *et al.*, 2008; Ismail-Beigi *et al.*, 2010) and the risk of nonfatal MI (Control Group *et al.*, 2009). However, mortality was slightly increased when targeting an aggressive A1C of 6% or less in high risk patients (Action to Control Cardiovascular Risk in Diabetes Study Group *et al.*, 2008; Duckworth *et al.*, 2009a). Therefore, for some patients a higher A1C target is more appropriate. This issue is particularly important in patients with existing CVD (Imran *et al.*, 2013).

Patients with a shorter life expectancy may not live long enough to procure the benefits of tight glycemic control and the frail patient will be at higher risk of hypoglycemia, less tolerant of many side effects and prone to the drawbacks of polypharmacy. In addition, some patients may be at very high risk of ischemic events secondary to the negative impact of hypoglycemia. Therefore, in these scenarios, a target A1C of 7.1%–8.5% is reasonable. However, a CV patient who does not have these limitations would still benefit from an A1C target of ≤7% (Advance Collaborative Group *et al.*, 2008; Ismail-Beigi *et al.*, 2010; Control Group *et al.*, 2009; Action to Control Cardiovascular Risk in Diabetes Study Group *et al.*, 2008; Duckworth *et al.*, 2009a; Hayward *et al.*, 2015).

Glucose Lowering Agents

In T1DM, the pharmacologic therapy is insulin due to complete insulin deficiency, and insulin is also used in the metabolically compromised patient with T2DM requiring urgent therapy. In stable T2DM, there are a number of noninsulin options that counteract the diverse mechanisms contributing to hyperglycemia (Harper *et al.*, 2013, 2015; Liu *et al.*, 2012) (**Fig. 5**).

Multiple factors must be considered in the selection of diabetes medications for patients with CVD. The strong data supporting the effect of glucose-lowering to reduce microvascular disease which has a direct impact on CV risk and eventual long-term reduction in CVD over 20 years (from the UKPDS follow-up study) must be balanced against potential acute effects of hypoglycemic episodes, increased risk of HF (thiazolidinediones and potentially some DPP-4 inhibitors) and weight gain (sulfonylureas, insulin), other side effects, and cost. Excluding contraindications, metformin is the traditional first choice followed by add-on agents selected on the basis of key patient characteristics and preferences despite low evidence for CV protection (Harper *et al.*, 2015), among which documentation of CV safety (or superiority) and a low risk of hypoglycemia should be weighted. To date, there are no convincing data to suggest that any single type of antihyperglycemic therapy in T2DM has a CV advantage over another other than perhaps metformin (Joffe *et al.*, 2010). There are limited data on the comparative effectiveness of the many other effective antihyperglycemic drugs; most studies are of short duration and focus on glycemic lowering and side effects rather than CV outcomes.

A number of new approaches for glucose lowering are under development and may provide agents with dual benefit for DM and the diabetic heart. Additionally, drugs that are developed for CV risk reduction may also lower glycemia. In the meantime, CV outcome trials will provide useful information on CV safety of use of DM drugs in patients with established heart disease or at high risk for CV events and additional exposure information that may reveal previously unrecognized positive or negative effects. These trials may help to better address the question of the impact of specific glucose-lowering drugs and pharmacologic class agents on the diabetic heart.

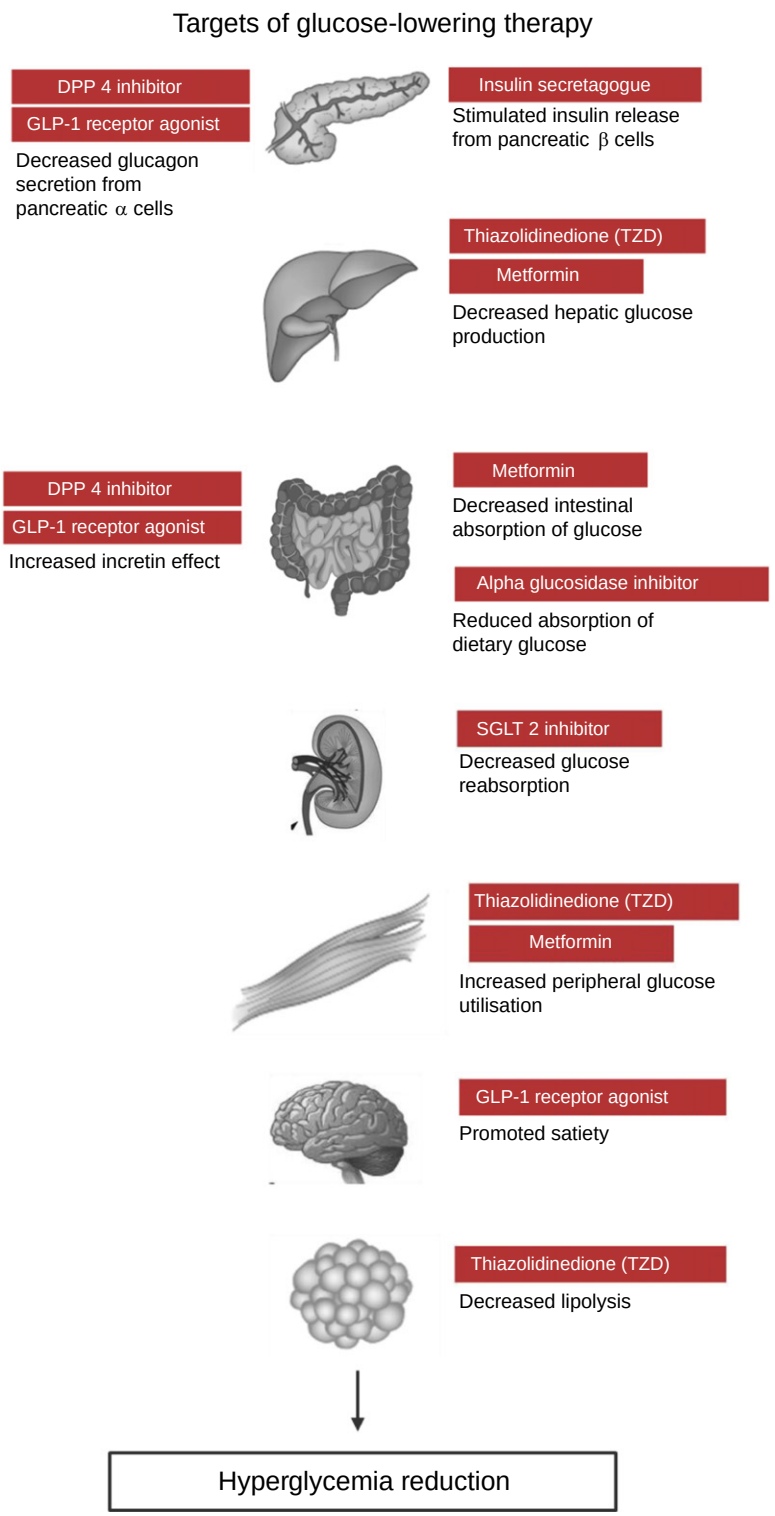

Fig. 5 Mechanism of action of antihyperglycemic medication classes. DPP-4, Dipeptidyl peptidase 4; GLP-1, Glucagon-like peptide 1; SGLT2, Sodium-glucose cotransporter 2.

CV Safety of Glucose Lowering Agents

CV safety has been demonstrated for insulin glargine (Origin Trial Investigators *et al.*, 2012; Marso *et al.*, 2017), thiazolidinediones (TZDs) (rosiglitazone, Home *et al.*, 2009), pioglitazone (Dormandy *et al.*, 2005; Kernan *et al.*, 2016), DPP-4 inhibitors (alogliptin,

White *et al.*, 2013), saxagliptin (Scirica *et al.*, 2013), sitaglipitin (Green *et al.*, 2015) and GLP-1 receptor agonists (lixisenatide, Pfeffer *et al.*, 2015). There was an unexpected finding of increased hospitalization for HF noted with saxagliptin that was not seen with the other CV trials of DPP-4 inhibitors and the explanation remains elusive (Scirica *et al.*, 2013). Moreover, based on diverse and large registries of clinical use, the class as a whole appears to be quite safe regarding HF (Filion *et al.*, 2016). The SGLT2 inhibitor CV outcome trial using empagliflozin (Zinman *et al.*, 2015; Neal *et al.*, 2017) demonstrated superiority with reduction in CV death, hospitalization for HF and all-cause mortality compared to placebo (Zinman *et al.*, 2015). Mechanisms of benefit remains speculative (DeFronzo, 2016; Kalra, 2015) but the Canadian Diabetes Association clinical practice guidelines committee has recommended the use of an SGLT2 inhibitor with proven CV benefit, in patients with T2DM and clinical CVD on top of existing antihyperglycemic therapy (Harper *et al.*, 2015; Goldenberg *et al.*, 2016). Also, the recently published results from the Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial and the Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes (SUSTAIN-6) show not only CV safety but also CV superiority (Marso *et al.*, 2013, 2016).

Special Circumstances

Several complicated circumstances will often require a multidisciplinary team approach to ensure optimal management that can be enhanced (Leiter and Fitchett, 2006; Tardif *et al.*, 2013). These include management of women with CVD and DM in the peripregnancy period, hyperglycemia management in the setting of ACS, and management during CV procedures such as diagnostic catheterization or cardiac surgery including coronary artery bypass grafting.

The Peripregnancy Period

In addition to macrosomia, observational studies show an increased risk of congenital heart disease and other DM-related embryopathies that increase directly with elevations in A1C. Therefore, glucose control must be optimized before conception so that it is optimal in the first 12 weeks of pregnancy. All potentially teratogenic CV medications (e.g. ACE inhibitors, statins) should be avoided (American Diabetes Association, 2015) as should antihyperglycemic agents (DPP-4 inhibitors, TZDs, GLP-1 RAs, SGLT-2 inhibitors, alpha-glucosidase inhibitors) for which safety during pregnancy has not been established. Additionally, patients planning to conceive should have any indicated investigations completed well in advance. Because most women of conceiving age who have DM have T1DM, the management is generally performed in high risk pregnancy clinics and the focus is on insulin optimization. In the minority of women with T2DM who are not post-menopausal, metformin and sulfonylureas have been shown to be safe in terms of birth defects, but may not provide as good glycemic control and have been associated with higher perinatal mortality perhaps because of that. This is why insulin is always the therapy of choice. If warranted, lipid management with resins can be considered and BP control can be achieved with methyldopa, diltiazem, labetolol, clonidine, or prazosin. If angina is present, beta-blockers can be used cautiously.

Management of Patients With Diabetes Mellitus and/or Hyperglycemia During ACS

Approximately 15%–35% of patients admitted with an ACS have known DM; an additional 15%–25% have dysglycemia (Tardif *et al.*, 2013; Deedwania *et al.*, 2008). Elevated plasma glucose during an ACS is associated with a more serious prognosis in patients with DM than without, including a >2-fold increased incidence of short- and long-term recurrent ischemic events, HF, cardiogenic shock, and death (Klein and Gheorghiade, 2004; Tardif *et al.*, 2013; Deedwania *et al.*, 2008). The worse outcome in ACS in DM patients is independent of other known prognostic risk factors (Leiter and Fitchett, 2006; Klein and Gheorghiade, 2004; Deedwania *et al.*, 2008). Hyperglycemia may relate to previously undetected glucose perturbations, but also to stress-induced catecholamine release increasing free fatty acid concentrations, decreased insulin production and increasing insulin resistance and glycogenolysis (Opie, 2008), with a negative impact on cardiac metabolism and function.

The possible benefits of glucose management have been studied in ACS in randomized controlled trials Diabetes and Insulin–Glucose Infusion in Acute Myocardial Infarction (DIGAMI) 1 and 2 and Hyperglycemia: Intensive Insulin Infusion in Infarction (HI-5). The Diabetes Mellitus, Insulin-Glucose infusion in Acute Myocardial Infarction (DIGAMI 1) trial (Malmberg *et al.*, 1995, 1996) randomized patients with an acute MI and a mean glucose of 15.6 mmol/L and A1C 8.1% at entry to treatment with IV insulin followed by 3 months of intensive insulin therapy or standard treatment. Intensive treatment had a significantly lower 1 (8.6% vs. 18%) and 3 (33% vs. 44%) year mortality (Malmberg *et al.*, 1999; Amsterdam *et al.*, 2014). But these results were not confirmed in the subsequent DIGAMI 2 (Malmberg *et al.*, 2005) which compared 3 methods of achieving glucose control: IV insulin infusion followed by long-term subcutaneous insulin, IV insulin then standard treatment and a third group treated by local standards. The overall mortality was 18.4% and there was no difference among groups. The most plausible reason for this discrepancy is that, in DIGAMI 1, admission A1C decreased more (1.5%), from a higher level (9.1%), compared with 0.5% from 8.3% in DIGAMI 2. In addition, the use of beta-blockers, statins and revascularization was more extensive in DIGAMI 2. The difference in glucose levels between the control and insulin groups in the HI-5 study was small and there was no reduction in

mortality among patients treated with insulin (Cheung *et al.*, 2006). Pooled data from the three studies confirmed that insulin–glucose infusion did not reduce mortality in the absence of glucose control in patients with ACS and DM (Zhao *et al.*, 2010). Finally, the BIOMarker Study to Identify the Acute Risk of a Coronary Syndrome-2 (BIOMArCS-2) trial (de Mulder *et al.*, 2013) compared very tight control (target 4.7–6.1 mmol/L) with standard management in patients with ACS. Glucose levels were lower in the intensive arm but averaged <10 mmol/L in both groups. There was no difference in the primary endpoint of infarct size but the intensively treated group had more hypoglycemia and a higher incidence of death or a second infarction before discharge. In summary, regarding patients with ACS, the evidence supports avoidance of hypoglycemia and achieving glucose levels <10 mmol/L during admission. This is more important than the agents used to achieve this level of glucose control. Longer term A1C goals should adhere to the principles already outlined for patients with CVD.

Management of Patients With Diabetes During Cardiac Procedures

Although hypoglycemic medications may influence the safety of coronary angiography, as well as early and late outcomes of revascularization with percutaneous coronary intervention or coronary artery bypass grafting, few trials have addressed interactions with myocardial revascularization in DM.

Percutaneous Coronary Intervention

Metformin is the most commonly used oral antihyperglycemic medication; concerns about metformin-associated lactic acidosis have previously led to the practice of metformin discontinuation prior to diagnostic coronary angiography and percutaneous coronary intervention (Baerlocher *et al.*, 2013; Benko *et al.*, 2007). However, more recent randomized trials and observational studies have not identified cases of nonfatal or fatal lactic acidosis (Maznyczka *et al.*, 2012; Goergen *et al.*, 2010). Most guidelines have now relaxed their recommendations around the holding of metformin, ranging from 24 to 48 h prior to the day of the procedure if renal dysfunction is present, to no stopping at all (Benko *et al.*, 2007; Miller and Richman, 2016). And when stopped, metformin is generally restarted ≥ 48 h after contrast administration if renal function has not deteriorated (Baerlocher *et al.*, 2013, Benko *et al.*, 2007). Rather than stopping metformin treatment in all patients, a reasonable approach is to carefully monitor renal function after the procedure and to withhold metformin for 48 h if it deteriorates and until renal function has resumed its previous level. Observational data reported concern over the use of sulphonylureas in patients treated with primary percutaneous coronary intervention for ACS: this has not been confirmed by a post hoc analysis of the DIGAMI 2 trial, although the number of patients undergoing primary percutaneous coronary intervention in this trial was low (5%) (Mellbin *et al.*, 2008). Arrhythmias and ischemic complications were reported less frequent in patients receiving gliclazide/glimepiride (Zeller *et al.*, 2010). Thiazolidinediones might be associated with lower re-stenosis rates after percutaneous coronary intervention with bare metal stents (Takagi *et al.*, 2009), but carry an increased risk of HF. No trial has demonstrated that the administration of insulin or insulin infusion improves percutaneous coronary intervention outcome after STEMI.

Cardiac Surgery

Diabetes mellitus is also common in patients undergoing cardiac surgery and is associated with increased rates of early and late mortality as well as renal failure, deep sternal infections and stroke (Herlitz *et al.*, 1996). In surgical studies, a dose-response relationship has been reported with each 1.1 mmol/L increase in glucose >5.5 mmol/L associated with a 34% increased risk of complications (Gandhi *et al.*, 2007). The Portland Diabetic Project demonstrated that using IV insulin infusions rather than subcutaneous sliding scale resulted in decreased mortality, reduced infections and shorter hospital stay (Furnary *et al.*, 1999). Lazar *et al.* in a randomized trial found that maintaining glucose levels in the 6.7–9.9 mmol/L range resulted in fewer infections and in-hospital cardiac complications as well as less recurrent ischemia and a significantly higher 5-year survival (Lazar *et al.*, 2004). However, studies have also shown that extremely tight glucose control is not beneficial in cardiac surgery patients (Lazar *et al.*, 2011; Umpierrez *et al.*, 2015). The current consensus is that moderate glucose control, generally assumed to mean target glucose levels in the 7.8–10 mmol/L range, provides the best outcomes.

Conclusions

The long-term treatment of DM is challenging because of diverse goals: to address metabolic derangements and to reduce risks for both microvascular and macrovascular adverse outcomes. Diabetes mellitus clearly exacerbates mechanisms of atherosclerosis and HF. Unfortunately, these mechanisms are not adequately fully modulated or addressed by focusing solely on optimal glycemic control. Aggressive global management of CV risk factors, along with glycemic management, provides substantial improvements in CV outcomes.

Treatment: Alpha Glucosidase Inhibitors

Markolf Hanefeld, Technical University Dresden, Dresden, Germany
Gabriele Mertes*, Mülheim, Germany

Carbohydrate Digestion and Glucosidases

Carbohydrate intake from whole grains, vegetables, fruits, bread, rice, and legumes is an essential part of nutrition therapy in diabetes and should provide 40%–50% of the patient's daily energy consumption in diabetes therapy (American Diabetes Association, 2016). Carbohydrates are digested by enzymes of the brush border of the small intestine with alpha glucosidases playing a key role for the release of monosaccharides which are then absorbed by complex cellular transport mechanisms. Thus, alpha glucosidase enzyme activity regulates availability of glucose for intestinal absorption as well as speed and extent of postprandial hyperglycemia (Puls, 1996). Alpha glucosidase inhibitors (AGIs) reversibly reduce or abolish the hydrolytic activity of alpha glucosidases. These inhibitors were developed in the 1980s when the importance of postprandial hyperglycemia for better diabetes control and cardiovascular risk, respectively, was realized. Postprandial hyperglycemia accounts for about 70% of the daily blood glucose load. Using continuous glucose measurement (CGMS) of diurnal glucose profiles, it could be shown that the relative contribution of postprandial hyperglycemia to HbA1c in patients with type 2 diabetes is high and varies depending on the quality of diabetes control between 30% and up to 70% in well controlled individuals (Monnier *et al.*, 2003). CGMS measurements furthermore revealed that uncontrolled postprandial hyperglycemia is a strong predictor of chronic progression of diabetes (Monnier *et al.*, 2007). Moreover, postprandial hyperglycemia was identified as an independent risk factor of cardiovascular diseases in individuals with prediabetes and early diabetes (Hanefeld *et al.*, 1996; Temelkova-Kurktschiev *et al.*, 2000; Qiao *et al.*, 2002). The disappointing cardiovascular outcome results of the University Group Diabetes Program (UGDP) evaluating efficacy of intensified glucose control with biguanide (phenoformin), sulfonylurea (tolbutamide), and insulin in type 2 diabetes (Goldner *et al.*, 1971) were another reason for the development of an alternative therapeutic approach. Thus, from the viewpoint of the pathophysiology of glucose homeostasis and with a key role of postprandial hyperglycemia for diabetes control, AGIs were the first oral antidiabetic drugs to act via a therapeutic modification of carbohydrate digestion and gastrointestinal transport on nutrients with pleiotropic effects on insulin resistance and the metabolic syndrome.

Clinical Pharmacology of Alpha Glucosidase Inhibitors

Fig. 1 shows the molecular structures of the three AGIs in therapeutic use: acarbose, miglitol, and voglibose, while **Figs. 2** and **3** show their mechanism of action.

Acarbose was the first AGI with now >25 years in clinical use, and has the most data on mode of action, therapeutic benefits, and cardiovascular outcome trials. It is a pseudo tetrasaccharide and has a 10^4–10^5 higher affinity to alpha glucosidases of the brush border than oligosaccharides. Acarbose is derived from bacterial cultures of *Actinoplanes utahensis*, thus representing a highly purified, standardized natural product. It is a potent reversible inhibitor of glucoamylase, sucrose, maltase, and isomaltase with moderate effect on amylase. Under adequate dosing it delays carbohydrate digestion to lower parts of the small intestine but causes no malabsorption (Truscheit *et al.*, 1988). After administration as a tablet with the first bite of a meal, acarbose is rapidly bound to the microvilli of the brush border with the consequence of an antihyperglycemic effect and reduced postprandial glucose excursion resulting in lower demand on insulin secretion. It is excreted to >95% as degradation products, ~51% of these via the feces and 30%–40% renally (**Table 1**). Only <2% are absorbed as unchanged drug and excreted renally (no systemic metabolization). Voglibose is also a nonsystemic AGI and is mainly used in Japan. After oral administration, it is nearly completely excreted unchanged in the feces (Maeshiba *et al.*, 1991) (**Table 1**).

Miglitol by contrast is synthesized by biotechnological and chemical procedures. >70% is absorbed after oral administration; >95% of the absorbed compound is excreted unchanged by the kidneys (**Table 1**). Miglitol and voglibose have no effect on amylase but specifically act on disaccharides.

Effects on Hormonal Regulation and the Metabolic Syndrome

AGIs primarily act on postprandial hyperglycemia by an antihyperglycemic effect. They exert no direct effects on insulin secretion. Data of clinical investigations show a ~30% lower postprandial insulin excursion (Hanefeld *et al.*, 1991). However, due to the subsequently lower glucotoxicity, insulin resistance is improved. In a placebo-controlled, hyperglycemic

(http://www.tandfonline.com).

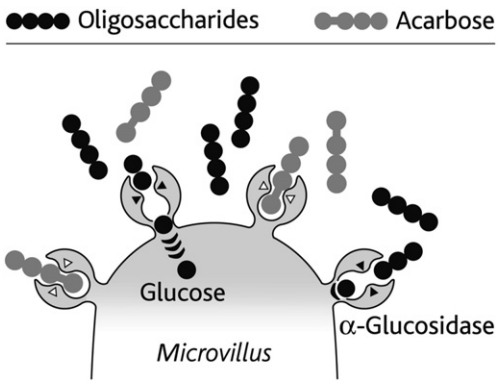

Fig. 2 Mechanism of action of acarbose: competitive inhibition of intestinal enzymatic hydrolysis of oligosaccharides. Adapted from Bischoff, H. (1991). Effect of acarbose on diabetic late complications and risk factors—New animal experimental results. *Aktuelle Endokrinologie und Stoffwechsel* 12, 25 – 32 with permission from Thieme Publishers.

CLAMP study, acarbose intake significantly improved insulin resistance in elderly patients but had no effect on insulin secretion after one treatment year (Meneilly *et al.*, 2000). The same effect was observed in subjects with impaired glucose tolerance (IGT) (Chiasson *et al.*, 1996).

Since more complex carbohydrates reach the lower parts of the small intestine, the release of glucagon like peptide 1 (GLP_1) is induced (Qualmann *et al.*, 1995; Enc *et al.*, 2001; Zheng *et al.*, 2013). GLP_1 increase was associated with enhanced nitric oxide synthase activity (Zheng *et al.*, 2013). Gastric emptying is delayed, and glucagon release reduced. The unique postprandial antihyperglycemic mechanism leads to several pleiotropic effects associated with downregulation of insulin resistance (Chiasson *et al.*, 1996; Meneilly *et al.*, 2000); Delgado *et al.*, 2002), protection (also of ß-cells) from oxidative stress (Ceriello *et al.*, 1996; Meneilly *et al.*, 2000; Hanefeld *et al.*, 2004a; Wang *et al.*, 2011; Sun *et al.*, 2016), decrease of low grade inflammation (Wang *et al.*, 2003; Li *et al.*, 2016), downregulation of proinflammatory transcription factor NFκB (Rudofski *et al.*, 2004), reduction of post-prandial leucocyte increase (Hanefeld *et al.*, 2009a), and improvement of prodiabetic microbioma (Weaver *et al.*, 1997; Yin *et al.*, 2014; Su *et al.*, 2015; Zhang *et al.*, 2017) (**Table 2**). A reduction in hypertriglyceridemia, in particular postprandial, was observed (Kado *et al.*, 1998; Ogawa *et al.*, 2004). Acarbose also modulated vasoregulatory peptide levels in type 2 diabetic patients (Rudovich *et al.*, 2016).

Acarbose extended lifespan in mice, preferentially in male animals (Harrison *et al.*, 2014). AGIs can reduce bodyweight by 1–3 kg or help maintain weight if combined with insulinotropic antidiabetic drugs (van de Laar *et al.*, 2005; Schnell *et al.*, 2016; Nakhaee and Sanjari, 2013). The beneficial effect on body weight appears to be more pronounced in Asian than

Table 1 Pharmacokinetic properties of alpha glucosidase inhibitors in therapeutic use

Properties	*Acarbose*	*Miglitol*	*Voglibose*
Global launch	1990	1996	1994
Doses			
Initial	25 mg t.i.d., orally at the start of each meal	25 mg t.i.d., orally at the start of each meal	0.2 mg t.i.d., orally before/with each meal
Maintenance	25 → 50 mg t.i.d. after 4–8 weeks intervals 50 → 100 mg t.i.d.	25 → 50 mg t.i.d. after 4–8 weeks intervals 50 → 100 mg t.i.d.	May be increased up to 0.3 mg t.i.d.
Maximum	Up to 100 mg t.i.d.	100 mg t.i.d.	Not mentioned
Extent of absorption	Poorly absorbed (<2% as unchanged drug), bioavailability is low	25 mg completely absorbed; 100 mg 50%–70% absorption	Poorly absorbed (<6%); absorption is dose dependent
Distribution	Extracellular fluid	Extracellular fluid	Lumen of gastrointestinal tract
Metabolism	Gastrointestinal tract principally by intestinal bacteria, also by digestive enzymes	None, metabolites not detected in plasma, urine/feces	Intestinal enzymes and microbial flora
Excretion			
Fecal	51%	—	98%
Renal	34% (metabolites)	>95%	5%
Plasma elimination half-life	2 h	2 h	Not available
Therapeutic indications	Adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus Adjunct to diet and insulin in type 1 diabetes mellitus Prevention of onset of type 2 diabetes mellitus in individuals with impaired glucose tolerance in combination with diet and exercise	Adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus	Adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus

Western patients and more marked than under gliptins or metformin (He *et al.*, 2014). Furthermore, it has beneficial effects on major components of the metabolic syndrome as shown in the Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM) (Chiasson, *et al.*, 2003) (**Table 2**). Vice versa, in subjects with IGT and the metabolic syndrome, the number needed to treat to prevent one case of newly diagnosed diabetes was 5.8 versus 16.5 in IGT subjects without the metabolic syndrome (Hanefeld *et al.*, 2009b).

Table 2 Pleiotropic effects of alpha glucosidase inhibitors on cardiovascular risk factors and traits of the metabolic syndrome

Factor	*Effect*
Body weight	1–3 kg ↓ (neutral in combinations)
Blood pressure	Newly diagnosed hypertension in impaired glucose tolerance ↓ Clinical hypertension in overt diabetes ↓
Lipids	Triglycerides (postprandial) ↓ Free fatty acids ↓
Biomarkers of inflammation	Nuclear factor kappa B ↓ High sensitive C-reactive protein ↓ Leucocytes (postprandial) ↓
Endothelium	Flow mediated vasodilation ↑ Nitric oxide synthase activity ↑
Blood coagulation	Plasminogen activator inhibitor ↓ Prothrombin fragments 1 + 2 ↓ Di-dimers ↓
Microbiota	Improved Lactobacillus ↑

Therapeutic Indications and Clinical Use

AGIs are used in patients with type 2 diabetes as monotherapy (first line) or in combination with all other antidiabetic drugs. Because of their special antihyperglycemic mode of action, they can be well combined with all hypoglycemic substances. Acarbose is also used for the treatment of excessive postprandial hyperglycemia and rapid fluctuations in type 1 diabetes. It has complex beneficial effects in elderly patients with type 2 diabetes. As the efficacy of acarbose has been documented in a huge number of clinical studies and has evidence from cardiovascular outcome trials, the focus in this article will be on this drug. A systematic Cochrane review of double-blind, controlled clinical studies found a placebo-subtracted mean HbA1c decrease of 0.8% in type 2 diabetes patients treated with acarbose (van de Laar *et al.*, 2005). In comparative studies, acarbose shows the same effect on HbA1c as other established oral antidiabetic drugs (Joshi *et al.*, 2015). Several double-blind, controlled studies reveal a comparable efficacy of acarbose with the first-line drug metformin. Acarbose is also recommended as first-line drug in China (Yang *et al.*, 2001). It should be emphasized again that by contrast to other antidiabetic drugs, the efficacy is mainly due to better postprandial glucose control.

Under acarbose, efficacy depends on the composition of diet and carbohydrate intake. In a comparative trial of Western versus Asian food, acarbose showed larger HbA1c reductions with Chinese food (by 1.54% vs. 0.52% with Western food) (Zhu *et al.*, 2013). Studies in Chinese patients often observe higher HbA1c reductions (He *et al.*, 2014; Hu *et al.*, 2015) than Western studies (which were primarily enclosed in the Cochrane analysis). Long-term observations show a sustained effect on type 2 diabetes control under real world conditions (Mertes, 2001; Li *et al.*, 2011). In a recent review of efficacy of diabetes treatment in Eastern populations, acarbose was equipotent with metformin in the reduction of HbA1c (Gu *et al.*, 2015).

To ensure maximum efficacy, AGIs must be taken directly with the first bite of a meal or during meals. A study with acarbose showed a 50% reduction in efficacy when taken 15 min before a meal (Rosak *et al.*, 1995).

AGIs for IGT Treatment and Diabetes Prevention

With a global tsunami of newly diagnosed type 2 diabetes primary prevention by treatment of IGT is of the utmost importance. Worldwide prevalence of IGT was estimated at 318 million adults aged 20–79 years (6.7% of adults) in 2015 (IDF Diabetes Atlas, 2015). Numbers are high for Asian populations; a 2013 survey found that more than one-third of Chinese adults suffer from prediabetes (Wang *et al.*, 2017). Furthermore, IGT is a significant coronary risk factor (Qiao *et al.*, 2003; Grundy, 2012). Acarbose is the only oral antidiabetic drug besides metformin that is approved in 84 countries for the treatment of prediabetes. In the STOP-NIDDM trial, acarbose reduced incidence in people with IGT by 25% and was associated with a significant conversion to normal glucose tolerance (Chiasson *et al.*, 2002). Recently published data of the Acarbose Cardiovascular Evaluation (ACE) study in patients with coronary heart disease and IGT has shown a decrease in the incidence of newly diagnosed diabetes by 18% after 5 years follow up (Holman *et al.*, 2017). In a 4-arm prospective controlled trial in Chinese IGT subjects comparing regular life style advice, intensified diet and exercise education, metformin and acarbose, a significant reduction of the incidence of newly diagnosed diabetes could be achieved with pharmacological intervention (Yang *et al.*, 2001). Acarbose was numerically more effective than metformin. Furthermore, a 3-year placebo-controlled study with voglibose in high-risk Japanese IGT subjects revealed a 40% reduction of diabetes incidence (Kawamori *et al.*, 2009).

Cardiovascular Results and Possible Pleiotropic Effects on Comorbidities

Pathophysiological studies with acarbose reveal its potential for beneficial effects on cardiovascular diseases. Besides advantageous effects on inflammation and oxidative stress, several acarbose studies and one miglitol study found an improvement in endothelial function (Wascher, *et al.*, 2005; Shimabukuro *et al.*, 2006; Pistrosch *et al.*, 2009; Kato *et al.*, 2010; Kitano *et al.*, 2013). Several studies showed a reduced progression in intima media thickness (Hanefeld *et al.*, 2004a; Yamasaki *et al.*, 2005; Geng *et al.*, 2011; Patel *et al.*, 2013).

In IGT subjects, the STOP-NIDDM trial investigated the efficacy of acarbose on cardiovascular events over 3 years as secondary objective (Chiasson, *et al.*, 2003). The incidence of myocardial infarction and cardiovascular events was significantly reduced. Accordingly, a meta-analysis of seven double-blind, controlled trials in patients with type 2 diabetes calculated a 64% risk reduction of myocardial infarction and 35% risk reduction of any cardiovascular event in the acarbose treatment group (Hanefeld, *et al.*, 2004b).

The large cardiovascular outcome ACE trial including patients with preexisting coronary heart disease and IGT over 6 years in China ended with a neutral result regarding cardiovascular diseases and mortality (Holman *et al.*, 2017). Although the incidence of newly diagnosed diabetes was significantly reduced in this study, no significant beneficial effects on cardiovascular events were observed in the sensitivity analysis. The different outcome regarding cardiovascular events in the STOP-NIDDM and the ACE trial might be explained by the differences between the trials in acarbose dosing regimen, study population characteristics, and cardiovascular therapy. Patients in the ACE trial received a lower acarbose dose (50 mg t.i.d. vs. 100 mg t.i.d. in the STOP-NIDDM trial), were older (median 64.3 years vs. 54.5 years) and of a different ethnicity (Chinese vs. Caucasian), and all presented with established coronary heart disease (inclusion criterion vs. low cardiovascular risk in the STOP-NIDDM trial). Recommended secondary cardiovascular prevention measures had to be consistent with internationally accepted treatment guidelines and were more aggressive than treatment in the 1990s when the STOP-NIDDM trial was carried out.

It must be emphasized that acarbose is at least safe for individuals with preexisting cardiovascular disease. No conclusive data are available on the effect of AGIs on microvascular disease.

As acarbose acts in the intestine, its relationship with intestinal diseases has been discussed since its approval for type 2 diabetes. Patients with type 2 diabetes and the metabolic syndrome exhibit an increased risk of cancer with colon cancer as a leading cause of death from neoplasia. A nationwide prospective register with newly diagnosed type 2 diabetes in Taiwan has revealed that patients treated with acarbose as first-line drug had a significantly (27%) lower dose-dependent incidence of colon cancer versus standard therapy including metformin and other antidiabetics (Tseng *et al.*, 2015). This finding might theoretically be a consequence of the beneficial effects of acarbose on the microbiota and the intestinal environment.

Favorable effects on microbiota and improvement in hepatic encephalopathy were found in a randomized controlled trial of acarbose in patients with liver cirrhosis (Gentile *et al.*, 2005). Similar to positive results in a mouse model (Nozaki *et al.*, 2009), a combination of acarbose and ezetimibe was reported to have therapeutic effects on the development of nonalcoholic fatty liver in a preliminary study (Rudovich *et al.*, 2010). The sample size was, however, very small.

Safety, Adverse Effects, and Contraindications

The side effect profile is similar for all AGIs. Based on >25 years of therapeutic use, a large number of controlled clinical trials, follow up and postmarketing studies, AGIs do not show any signs of toxicity or possible relationships with subsequent comorbidities. Consistently, no serious or fatal systemic complications related to acarbose have been reported so far. Monotherapy was not associated with clinical hypoglycemia. Hypoglycemia in combination therapy with hypoglycemic agents is a rare event. If it occurs, it must be treated with glucose, not with starch or table sugar. Transient gastrointestinal symptoms are the main adverse effects under AGI therapy, because meteorism, flatulence, soft stool, and diarrhea may occur at the beginning of treatment. The reported incidences vary dramatically between $<10\%$ and up to 50% depending on the study site and the geographic areas with their different dietary habits (Rosak and Mertes, 2012). The lowest rates are reported in Asian trials. These initial side effects can be minimized by a diet of complex carbohydrates prior to therapy avoiding table sugar or fructose and sorbitol and by appropriate application: start low, go slow. Slow titration from low to medium dose, depending on the individual patient's tolerability, is recommended.

A recent reappraisal of the clinical drug–drug interaction potential of AGIs did not find a meaningful influence on absorption and bioavailability of many co-administered medications (Dash *et al.*, 2018). Labeled contraindications are related to conditions that might deteriorate as a result of possibly increased gas formation in the intestine as pregnancy, lactation, inflammatory bowel disease, and partial intestinal obstruction. Due to lack of experience AGIs should also not be used in patients younger than 18 years, in pregnant women, and in cases of renal insufficiency.

Glossary

Basal insulin Insulin that controls blood glucose in the fasting state.
Beta cells Insulin-producing cells located in the islets of Langerhans of the endocrine pancreas.
Bolus insulin Insulin administered to cover requirements for meals or used on occasional basis to correct high glucose levels.
Carbohydrate counting Meal planning method where the patients need to estimate the carbohydrate content of their meals and match their insulin bolus accordingly. See also insulin-to-carbohydrate ratio.
Continuous subcutaneous insulin infusion Insulin infusion through the subcutaneous depot via an infusion device, also called insulin pump.
Continuous glucose monitoring system Device measuring glucose levels in the subcutaneous interstitial fluid every 1–5 min via a small subcutaneous probe.
Glycated hemoglobin (HbA1c) A biomarker of glucose control which represents the average glycemia over the past 2–3 months.
Gestational diabetes Diabetes that develops during pregnancy and which in most cases resolve after delivery.
Glucometer Device that measures capillary blood glucose.
Hyperglycemia High blood glucose, possibly accompanied with symptoms (e.g., thirst, headache). Generally defined as blood glucose >10.0 mmol/L.
Hypoglycemia Low blood glucose, typically accompanied with symptoms (e.g., trembling, sweating, hunger). Generally defined as blood glucose <4.0 mmol/L.
Hypoglycemia unawareness A condition where hypoglycemia symptoms recognition is attenuated or absent.
Insulin pump A device that infuses insulin through the subcutaneous depot, also called continuous subcutaneous insulin infusion.
Insulin-to-carbohydrate ratio A method to determine how much insulin is needed proportionally to the carbohydrate content of the meal, generally expressed in units of insulin per 10 g of carbohydrates. See also carbohydrate counting.
Ketosis Excess formation of ketones in the blood seen in cases of hyperglycemia in the context of low insulin levels and metabolism predominantly based on lipid substrates.
Self-monitoring of blood glucose Measurement of blood glucose with glucometers.

Introduction

The two most common types of diabetes are distinguished by their main pathophysiology. Type 1 diabetes (T1DM) is characterized by an autoimmune destruction of the endocrine beta cells of the pancreas resulting in complete insulin deficiency (Acharjee *et al.*, 2013). It thus necessitates life-long insulin replacement from the time of diagnosis, which can occur at any age starting in childhood. Type 2 diabetes (T2DM) is approximately 10 times more frequent, it occurs mainly in adulthood and is due, in its early stages, to a state of insulin resistance coupled with relative insulin deficiency (Fonseca, 2009). T2DM is treated with a large array of oral or injectable hypoglycemic agents; however, insulin deficiency worsens over the years requiring insulin replacement for many patients at some point in the course of their disease. Both types of diabetes (T1DM and T2DM) face a rising prevalence. An optimal control of blood glucose levels is essential to prevent diabetes-related microvascular complications (retinopathy, nephropathy, and neuropathy) and, on the long-term, also possibly contribute to macrovascular risk reduction (coronary artery disease, strokes, etc.) (Diabetes Control and Complications Trial Research Group *et al.*, 1993; Nathan *et al.*, 2005).

Insulin replacement in diabetes is achieved with subcutaneous injections using multiple daily injections (MDI) or continuous subcutaneous insulin infusion (CSII) systems also called insulin pumps (CADTH, 2015; Gururaj Setty *et al.*, 2016). The main goal of CSII is to provide a more flexible insulin delivery. To mimic insulin action in subjects without diabetes, exogenous human insulins or analogs are designed as long or rapid release formulations from the subcutaneous depot; long release insulins are used to replace daily basal insulin needs while rapid acting boluses cover prandial insulin requirements (**Fig. 1**) (Gururaj Setty *et al.*, 2016). Only rapid acting insulins are used in pumps because of their continuous infusion mode of action.

Despite significant improvements in insulin formulations, delivery systems and treatment modalities, many insulin-dependent patients do not reach the recommended glycemic target (represented by a glycated hemoglobin [HbA1C] level that is $<6.5\%$ or $<7\%$, depending on various diabetes associations recommendations as well as patient's age and conditions) (Miller *et al.*, 2015; Hayward *et al.*, 2015). Intensifying insulin replacement to decrease hyperglycemia events is often challenged by an increased risk of iatrogenic hypoglycemia complicating diabetes management. Moreover, increased physical activity, illnesses, missed meals or

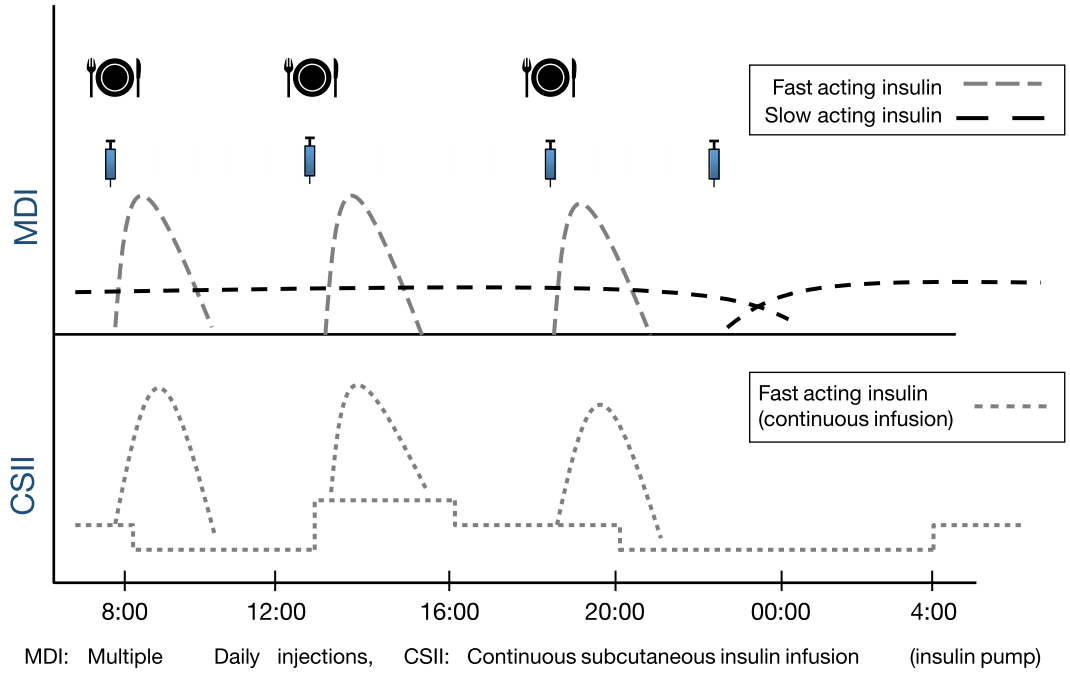

Fig. 1 Comparison of insulin use in multiple daily injection (MDI) regimens and in continuous subcutaneous insulin infusion (CSII) systems.

erroneous carbohydrate counting, stress, low reproducibility in insulin absorption, infrequent blood glucose level monitoring via capillary testing (glucometers), etc., adds-up and can lead to unpredictable changes in daily glucose levels.

Mimicking hormonal secretion by a normal pancreas with a technology that dynamically controls insulin infusion in a timely manner according to changing glucose levels has haunted researchers in the diabetes field for ages. In the years 2000s, continuous glucose monitoring systems (CGMS) have been implemented paving the way to further technological advances (Klonoff, 2005). CGMS measures glucose levels in the interstitial fluid every 5–15 min via a small subcutaneous probe providing an indirect measurement of blood glucose levels in the surrounding capillaries (Klonoff, 2005). With CGMS and better performing insulin pumps, the development of the external artificial pancreas, also called closed-loop automated insulin delivery system (CLS), was made possible (Thabit and Hovorka, 2016a). An artificial pancreas consists of three components that communicate remotely including a CGMS, a hormone infusion pump and a dosing algorithm implanted in an external device (e.g., smart phone) or in the pump (Thabit and Hovorka, 2016a). The CGMS sends its glucose readings in real-time to the dosing algorithm that commands dynamic changes in hormonal infusion closing the loop of glucose control (**Fig. 2**) (Thabit and Hovorka, 2016a). The number of studies on the artificial pancreas has grown exponentially in the past years leading to the commercialization of the first system in the United States in 2017 (Voelker, 2016).

This article aims to explore the use of technology in diabetes management focusing on the uses, benefits and limitations of the insulin pumps, CGMS and artificial pancreas systems. We are also addressing challenges that need to be overcome in the future with these technologies.

Insulin Pumps (CSII)

Description

Since the first therapeutic use of insulin in 1921, an important shift towards the use of technology has been observed starting in the 1970s with the introduction of the insulin pumps (CSII). The first pumps were not very popular at the time, mainly because of their inconvenient size and multiple technical issues (Lenhard and Reeves, 2001). The new-generation pumps are smaller and come in two main designs: most available pumps have the reservoir connecting via a tubule to the subcutaneous catheter that infuses insulin; other systems called patch or tubeless pumps are directly attached to the skin with an underneath subcutaneous catheter (**Fig. 3**) (Thabit and Hovorka, 2016b). Based on the typical variation of insulin requirements across the day, patients can program their pump to deliver various basal rates and boluses of insulin. The pump is also used to administer meal boluses according to individualized insulin-to-carbohydrate ratios. The programming of pumps has become more sophisticated over the years. For example, nowadays insulin pumps offer several delivery profile selections (e.g., for days with and without physical activity), an estimation of the insulin on board (estimation of insulin already injected but not yet absorbed) and integrated meal as well as hyperglycemia correcting bolus calculator (Thabit and Hovorka, 2016b). Insulin pumps are mostly used by patients with T1DM and very few with T2DM. Rates of use in T1DM

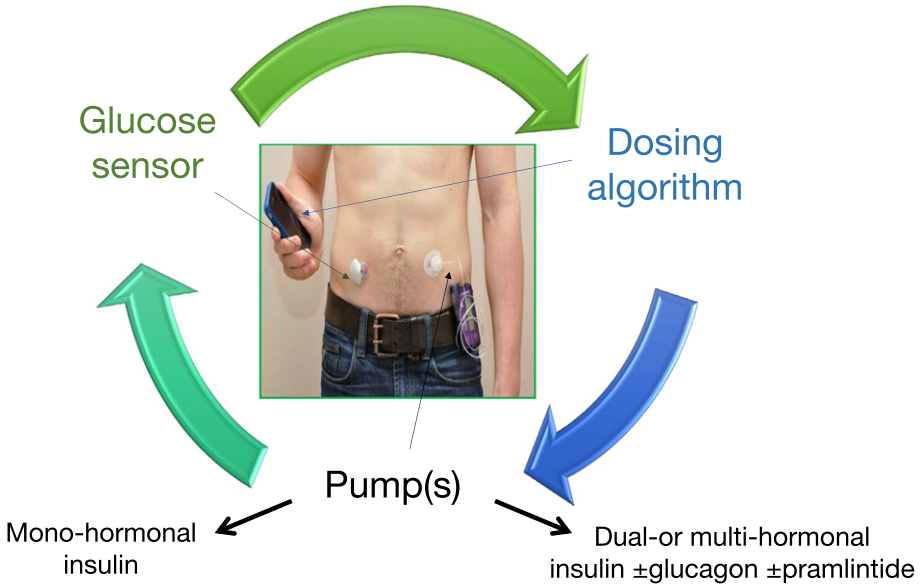

Fig. 2 Artificial pancreas or closed-loop insulin infusion system (CLS) components.

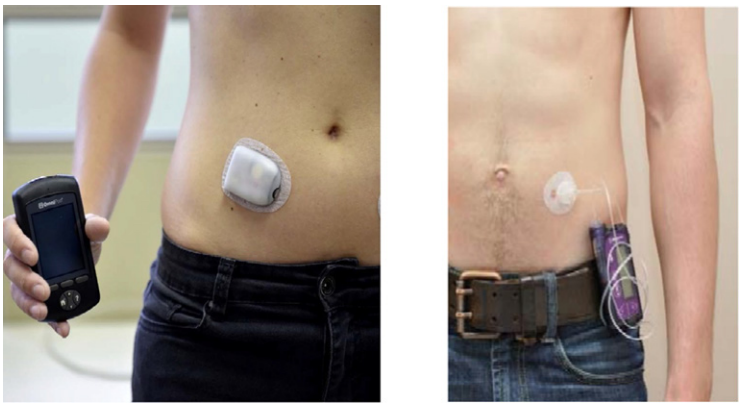

Fig. 3 Examples of the two main insulin pump designs available on the market.

vary widely across different countries (e.g., 20%–25% in the United States and Norway and 6% in the United Kingdom) (Thabit and Hovorka, 2016b). According to the T1DM exchange registry in the United States, the rate of CSII use varies also by age (up to 50% in children and adolescents) and ethnicity (22.1% in minorities vs. 34.55% in nonminorities) (Miller *et al.*, 2015). CSII use rates can also be influenced by other factors such as diabetes duration, therapeutic objectives, general health, interest and motivation as well as reimbursement policy (e.g., private insurance or public drug coverage).

Clinical Benefits

The clinical efficacy of CSII has long been established while its superiority (lower HbA1c with less hypoglycemia) in comparison to MDI has been proven in most patient populations; however, some authors and healthcare authorities challenge the magnitude of the cost required to achieve such benefits (Lenhard and Reeves, 2001). A Cochrane systematic review and a recent meta-analysis in adult patients with T1DM revealed a decrease in HbA1C of 0.3% with CSII as opposed to MDI (Misso *et al.*, 2010; Yeh *et al.*, 2012). The incidence of severe hypoglycemia (requiring third-party assistance) is also decreased with CSII versus MDI especially for patients who are at increased risk for hypoglycemia (hypoglycemia unaware; low perception of hypoglycemia symptoms) (Misso *et al.*, 2010; Pickup and Sutton, 2008). The comparative evidence is less clear and harder to interpret in the case of mild and moderate hypoglycemia due to discrepancies in reporting and defining thresholds for these episodes. In the pediatric population, the evidence comes mostly from registries and prospective cohorts suggesting a better glycemic control with CSII. In the T1DM Registry, CSII users had lower mean HbA1c and were more likely to achieve levels lower than 7.5% while the difference was not significant in a European registry with younger participants (Maahs *et al.*, 2014). In a large population based case-control European

cohort, children using CSII maintained average HbA1c values that are 0.6% lower than in MDI users and had a decrease in the incidence of severe hypoglycemia over a mean follow-up of 7 years (Johnson *et al.*, 2013). In general, positive effects on quality of life and personal satisfaction, partly due to the greater treatment flexibility, were reported with CSII use across all age groups (Life EQSG–EoQo, Costs in Diabetes Type 1, *et al.*, 2008; Muller-Godeffroy *et al.*, 2009; Linkeschova *et al.*, 2002).

Few patients with advanced T2DM who are treated with basal-bolus insulin regimens use pumps. However, the number of users is expected to rise as more trials show a better glycemic outcome with CSII therapy. Patients with poorly controlled diabetes on MDI are the ones to benefit the most from shifting to CSII. In the OpT2mise trial undertaken in patients with poorly controlled T2DM despite using MDI, patients who switched to CSII required less total insulin doses and had a 0.7% additional HbA1c reduction, in comparison with patients kept on MDI, without increasing their risk of hypoglycemia (Reznik *et al.*, 2014). In a recent meta-analysis, a 26% reduction of insulin requirements without weight change and a reduction in HbA1c by 0.4% were observed in patients with T2DM after shifting to CSII therapy (Pickup *et al.*, 2017).

In the specific case of pregnant women with preexisting diabetes or with gestational diabetes, the current evidence does not support CSII treatment over MDI. The available trials are small and do not always assess similar outcomes according to the latest Cochrane review including only five trials (total of 154 pregnancies) that are adequate for analysis (Farrar *et al.*, 2007). No clear differences between CSII and MDI could be detected for some of the reported primary outcomes including caesarian section risk, large-for-gestational-age birth and perinatal mortality nor for secondary outcomes such as maternal weight gain, 24-h mean blood glucose, mean maternal HbA1c and maternal hypoglycemia or hyperglycemia (Farrar *et al.*, 2007). Larger trials with adequate reporting of outcomes are still needed to compare CSII with MDI for pregnant women.

CSII Related Adverse Events

The use of CSII is associated with a number of adverse events despite the progress in this technology and can be categorized into perfusion site or catheter problems, cutaneous reactions, metabolic adverse events, and pump software problems. These adverse events are common and can occur in 40% of users per year but they necessitate hospital admissions only in very rare cases (Ross *et al.*, 2015). The most serious adverse events are related to metabolic control, particularly diabetic ketoacidosis that can result from perfusion site/catheter failure and prolonged insulin infusion interruption (Ross *et al.*, 2015). In a recent online survey including adult patients and examining their perceptions about CSII use, the majority of participants perceived it positively, reporting improvements in glucose control without compromising their quality of life. However, technical issues related to perfusion site, catheter and cutaneous problems were quite common with only 3% of patients reporting no problems of any kind in the past year of use (Nadine Taleb *et al.*, 2017a). Other major issues with CSII are the need to carry the pump at all times as well as associated costs (significantly higher than MDI) leading to limited access and coverage in a lot of countries.

Glucose Sensors, Sensor-Augmented and Threshold-Suspend Pump Therapy

Glucose Sensors

Glucose concentration monitoring is an essential part of diabetes management, especially for T1DM. Self-monitoring of blood glucose (SMBG) with capillary glucometers is cumbersome and is usually limited to few measurements per day. On the other hand, continuous glucose monitoring (CGMS) allows 24-h glucose profiling in real-time with glycemic trends to foresee hyper or hypoglycemic episodes to which, in most of the cases, the patient can also be alerted by preset sensor alarms (Klonoff, 2005). CGMS includes a subcutaneous probe connected to the outer scan by a transmitter that sends glucose measurements to the pump or to a separate receiver or, for a new type of sensors, it requires a scanning with a dedicated receiver (**Fig. 4**).

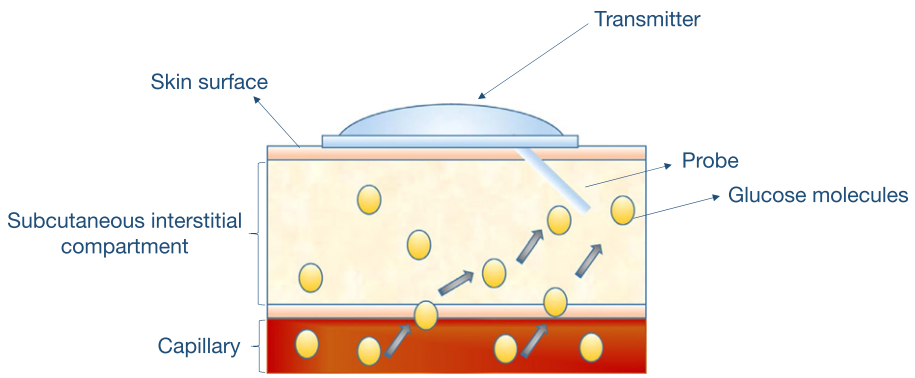

Fig. 4 Schematisation of the subcutaneous probe and the transmitter which are two main components of the continuous glucose monitoring system (CGMS).

Most CGMS still require at least two calibrations per day with capillary glucose levels obtained from a glucometer but some of the newer generations do not need calibration anymore (Bailey *et al.*, 2015). Interstitial glucose is an estimation of capillary glucose and not a direct measure. A certain delay is expected to equilibrate glucose between the interstitial and capillary compartments especially when blood glucose is rapidly changing such as during meals or physical activity; for example, the sensor may lag behind resulting in an underestimation of the rising postprandial blood glucose or, on the opposite, may result in a more problematic situation with an overestimation of the blood glucose while it's declining during exercise (Taleb *et al.*, 2016a). Accuracy and performance of new-generation CGMS have improved significantly with a margin of error in comparison to blood glucose that decreased from $\pm 20\%$ with the first generation to $\pm 10\%$ with the third ones (Rodbard, 2016). Due to these improvements, United States health authorities have recently approved one CGMS for making diabetes treatment decisions without the need for confirmation of sensor readings using a capillary blood glucose measurement (Shapiro, 2017). Clinical data supports the importance of CGMS in improving glucose control. A study conducted by the Juvenile Diabetes Research Foundation (JDRF) showed a reduction in HbA1c with regular use of CGMS in children and adolescents. This was similarly confirmed in adults with T1DM or T2DM (Rodbard, 2016; Ehrhardt *et al.*, 2011; Garg *et al.*, 2009). A recent meta-analysis of 11 randomized controlled trials similarly found a decrease in HbA1c (-0.3%) for patients with T1DM using CGMS and a decrease in time spent in hypoglycemia that did not, however, reach statistical significance. These benefits are observed in patients with insulin pumps as well as those treated with multiple daily injections (Garg *et al.*, 2011); yet, less than 10% of patients with T1DM use CGMS on a regular basis, with a particularly low use of the devices in the pediatric population (Wong *et al.*, 2014). This is mainly related to cost and low public or private coverage, but also to possible difficulties for some patients with the use of technology, the amount of data it generates and the need to have an additional device attached to the body.

Sensor-Augmented, Suspend and Predictive Suspend Pump Therapy

The development of CGMS allowed the progression of CSII into sensor-augmented pump (SAP) therapy. SAP potentiates insulin therapy with real-time glucose levels to help patients in adjusting pump's insulin infusion accordingly (Bergenstal *et al.*, 2013; Ly *et al.*, 2012). Improvement in glucose control, in comparison with MDI, have been observed in most studies including a meta-analysis of four randomized controlled trial (HbA1C decreased by an average of 0.7% with SAP) (Yeh *et al.*, 2012). Improvement in HbA1c and a decrease in hypoglycemia were also seen with SAP in comparison with conventional CSII (Soupal *et al.*, 2016).

Recently, two new systems, suspend and predictive-suspend, have evolved adding advanced features to SAP with the objective of reducing hypoglycemia. In the suspend pump system (also referred to as threshold-suspend), low glucose sensor values can trigger an automatic transient (up to 2 h) insulin infusion suspension. Suspend systems have shown the ability to reduce the frequency and duration of nonsevere hypoglycemic episodes by one third without increasing the risk of ketosis or worsening HbA1c levels (Bergenstal *et al.*, 2013; Ly *et al.*, 2012). Further progress has been achieved with the predictive—suspend systems which predict the risk of reaching the defined hypoglycemia threshold and allow an earlier insulin suspension. A trial addressing the risk of severe hypoglycemia has shown that such insulin suspension systems can probably eliminate this major acute complication (Ly *et al.*, 2012).

External Artificial Pancreas or Closed-Loop System (CLS)

Definition and Components

The artificial pancreas (AP) or closed-loop automated insulin delivery system (CLS) brought the combination of CGMS and pump therapy a step further with automation of hormone delivery to improve glucose control and reduce the burden of self-management. It is one of the most promising therapies for T1DM. In this system, insulin only (single-hormone artificial pancreas) or insulin and a second drug, typically glucagon (dual-hormone artificial pancreas), infusion rates are regulated in a dynamic fashion based on algorithm-generated recommendations which rely on continuous glucose monitoring systems readings. In dual-hormone artificial pancreas, glucagon is administered as intermittent mini-boluses to further prevent and treat hypoglycemia in a preemptive way and/or to allow more aggressive insulin therapy without increasing hypoglycemic risk. The *JDRF* recently published a pathway towards fully automated artificial pancreas starting from currently available systems and the future steps that need to be achieved (Kowalski, 2015) (**Fig. 5**).

A key step in recent years was the ability to move to outpatient studies with automated glucose control. Kovatchev *et al.* conducted, in 2014, the first automated single-hormone artificial pancreas study using the DiAs platform (Kovatchev *et al.*, 2014) and since then, many research groups have developed and studied automated systems (Bally *et al.*, 2017; El-Khatib *et al.*, 2017; Russell *et al.*, 2014; Garg *et al.*, 2017; Grosman *et al.*, 2016). The first hybrid artificial pancreas (MiniMed 670G; Medtronic) has been introduced to the United States market in April 2017. This system is called hybrid because it still requires interventions to be applied to the artificial pancreas system by the patient in order to announce and to initiate required adjustments during exercise (e.g., suspension or reduction of insulin infusion) and during meals (e.g., bolus based on carbohydrate counting).

In an artificial pancreas, the key addition to the pump and CGMS is the predictive dosing algorithm used with the system. The general goal of the algorithm is to maintain glucose levels within a predefined target range minimizing hypo and hyperglycemia episodes. Two control models, frequently used in the current artificial pancreas studies, are the Proportional-Integral-Derivative

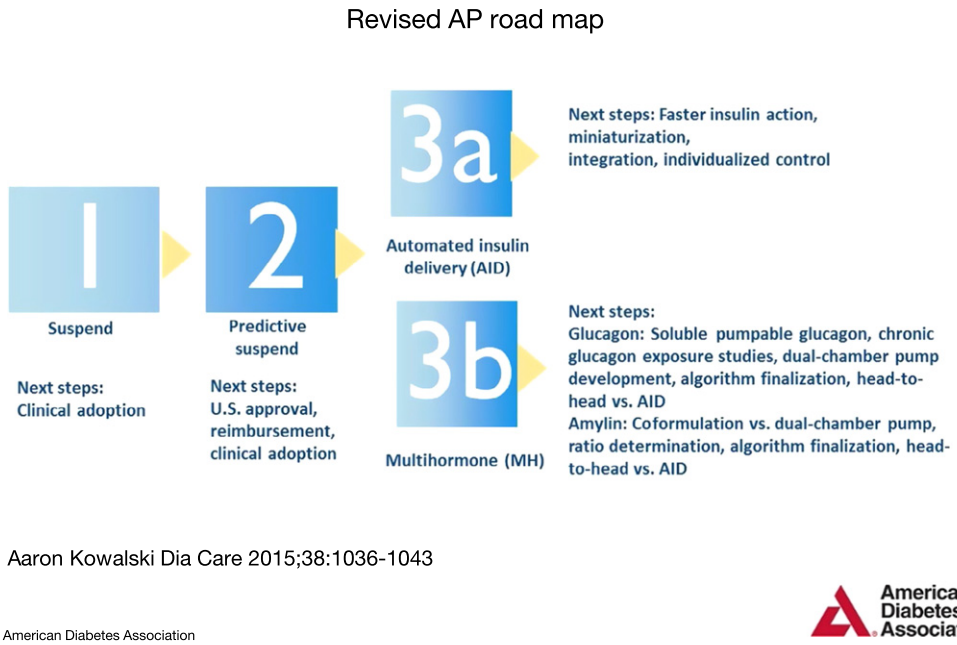

Fig. 5 Revised artificial pancreas road-map from the JDRF. From Kowalski, A. (2015). Pathway to artificial pancreas systems revisited: Moving downstream. *Diabetes Care* **38**(*6*), 1036–1043.

(PID) and the Model Predictive Control (MPC). The PID model is a reactive strategy that takes into account the actual glycemia and the baseline glucose level (proportional component), the area under the curve between measured and desired target glucose level (integral component) and rate of change of glucose levels (derivative component) (Thabit and Hovorka, 2016a). Adaptations to this model have been proposed to reduce the risk of early postprandial hypoglycemia but resulted in higher mean glucose levels (Gondhalekar *et al.*, 2013; Palerm, 2011). MPC has been favored by most research groups over the past few years. This model integrates subcutaneous insulin and interstitial glucose kinetics through compartments to calculate insulin dosing. MPC allows adjustments in response to meals and manual insulin boluses or corrections by adding a meal compartment (Thabit and Hovorka, 2016a). A compartment for glucagon kinetics is also incorporated in dual-hormone artificial pancreas systems. Importantly, MPC is based on repeated optimisation steps at finite times. Cobelli *et al.* compare the strategies of MPC to those applied in a chess game (Cobelli *et al.*, 2014). Previous glucose levels constitute the history of the game and are used to plan several moves-ahead (insulin infusion rates) but only the first move is applied (ex. insulin infusion rate over the next 10 min) followed by a re-evaluation of the adversary response (new glucose data) to re-plan the subsequent moves-ahead and so on, repeatedly. This strategy can thus adjust for unexpected events such as new information entered into the meal compartment. Some controllers include the fuzzy logic approach in their models (Haidar *et al.*, 2014; Mauseth *et al.*, 2013) which relies on estimated rather than accurate values and thus allows integrating the empirical knowledge of glucose control. Several algorithms also have safety checks in their models to limit the maximum rate of insulin infusion or to suspend it in the case of rapidly decreasing glucose levels (Thabit and Hovorka, 2016a).

Clinical Studies and Benefits

The artificial pancreas could help reduce the burden associated with day-to-day self-management while improving glucose control (Thabit and Hovorka, 2016a). Its efficacy over conventional insulin pump therapy for glycemic control in patients with T1DM was demonstrated in several studies (Thabit and Hovorka, 2016a; Hovorka, 2011; Haidar *et al.*, 2013). The main benefits associated with the artificial pancreas are: improved glucose time in target range and reduced time in hypoglycemia. Both benefits being more pronounced at night-time than during daytime (Phillip *et al.*, 2013; Haidar *et al.*, 2015a, Del Favero *et al.*, 2015; Nimri *et al.*, 2014; Kropff *et al.*, 2015; Russell *et al.*, 2014; Wolpert *et al.*, 2016).

Studies comparing the artificial pancreas to conventional pump therapy have shown improvements from 10% to 15% of the time spent in target glucose range. The largest outpatient study so far included 33 adults and 25 children, and lasted 12 weeks. In this study, Thabit *et al.* (AP@home Consortium) compared the suspend-threshold pump system to an automated single-hormone artificial pancreas over a 12-week period in children and adults with T1DM (Thabit *et al.*, 2015a). Children were using the system overnight only while adults were using it all day and night. Time in target range was significantly improved by 11% in adults and 9% in children using the artificial pancreas while reducing mean glycemia (− 0.8 mmol/L), HbA1c (− 0.4%) and time spent in hypoglycemia (Thabit *et al.*, 2015a). More recently, with the 12-week use of the MiniMed 670G (Medtronic, first hybrid artificial pancreas system on the market), a 7% improvement of time in target range was observed in adolescents, and a 5% improvement

was observed in adults, to note that this study is a safety nonrandomized trial (Garg *et al.*, 2017). Improvements in time in target range vary based on study length, type of artificial pancreas used (single or dual-hormone), time of its use (night only or all day) and treatment comparators (conventional insulin pump or sensor-augmented pump therapy) (Weisman *et al.*, 2017). A meta-analysis showed that, overall, the artificial pancreas improves time in target range by 12.59% [9.02%–16.16%] (equivalent to 172 min/day) compared to conventional treatment, and that dual-hormone systems are associated with a greater improvement (19.52%, 281 min/day) compared to single-hormone systems (11.06%, 159 min/day) (Weisman *et al.*, 2017). The different artificial pancreas systems have been particularly efficient at night. A combined analysis of the studies conducted by the Cambridge research team showed that the single-hormone artificial pancreas, as compared to conventional pump therapy, was associated with an 18.5% increased time in target range and a 0.9% lower time spent in hypoglycemia (Thabit *et al.*, 2015b). A 2-month study with a single-hormone system worn only at night showed the same benefits along with a reduced glycated hemoglobin (Kropff *et al.*, 2015).

An important reduction of the time spent in hypoglycemia, in the order of four to eight times, has also been observed with the artificial pancreas in comparison to conventional pump therapy depending on study conditions (Nimri *et al.*, 2014; Russell *et al.*, 2016; Kovatchev *et al.*, 2017; Haidar *et al.*, 2015b). This reduction is one of the most consistent benefits of artificial pancreas systems and it has been particularly important at night. According to the latest meta-analysis, time spent in hypoglycemia (glucose <3.9 mmol/L) was reduced by an average of 35 min per day overall with the artificial pancreas (27 min with single-hormone systems and 54 min in dual-hormone systems) (Weisman *et al.*, 2017).

No significant safety issues have emerged from the longest available trials (3 months) with single-hormone artificial pancreas systems (Thabit *et al.*, 2015a; Bergenstal *et al.*, 2016). For example, in the longest outpatient trial that was conducted over 3 months, loss of connectivity between the algorithm and the pump occurred in two instances and once the artificial pancreas system was not turned on by mistake. In the case of loss of connectivity, the pump operates with a preset insulin infusion as a safety measure (Thabit *et al.*, 2015a).

Multihormonal Approach With the Artificial Pancreas

Achieving fully automated glucose control with a single-hormone approach may prove to be impractical especially that diabetes is not limited to insulin deficiency but involves other hormonal defects as well. Thus, the multihormonal approach with artificial pancreas systems is of significant interest. The hormone most used is glucagon through dual-hormone studies; glucagon addition mainly aims to reduce the risk of hypoglycemia but it could also allow more aggressive insulin infusion aiming for lower mean blood glucose without increasing hypoglycemic risk (Thabit *et al.*, 2015a). The Bionic Pancreas group (Boston) examined the efficacy of the dual-hormone artificial pancreas in several automated outpatient studies (El-Khatib *et al.*, 2017; Russell *et al.*, 2014, 2016). Their longest study to date extended over 11 days and showed, in adults, reduced means of glycemia (-1.1 mmol/L) and time spent in hypoglycemia (-1.3%) compared to conventional or sensor augmented pump therapies (El-Khatib *et al.*, 2017). In children (6—11 years old), the dual-hormone artificial pancreas was also associated with a lower mean glycemia compared with conventional therapy (7.6 vs. 9.3 mmol/L) while reducing hypoglycemia frequency (Russell *et al.*, 2016). The CLASS (Closed Loop Assessment Study) Program (Montreal) is the first to have developed in parallel single- and dual-hormone systems, allowing a direct comparison between the two strategies in different contexts (Haidar *et al.*, 2013, 2015a,b, 2016; Gingras *et al.*, 2016a; Taleb *et al.*, 2016b). As observed in previous studies, the dual-hormone artificial pancreas improved time in target range while reducing time spent in hypoglycemia compared to conventional therapy as well as to single-hormone artificial pancreas (Haidar *et al.*, 2013); the difference being more pronounced at night than for the entire day (Haidar *et al.*, 2015b, 2017). The longest published face to face comparison of single and dual-hormone artificial pancreas systems (60 h) demonstrated benefit for dual-hormone over single-home artificial pancreas for glucose time below 3.5 mmol/L while both systems were superior to sensor augmented pump therapy for all hyperglycemic thresholds (Haidar *et al.*, 2017).

The addition of pramlintide to the artificial pancreas has recently been suggested and is currently being investigated to further improve glucose control (Weinzimer *et al.*, 2012; Sherr *et al.*, 2016). Pramlintide is a stable analog of amylin, another defective hormone in diabetes, and is known to reduce postmeal glycemic excursion mainly by slowing gastric emptying and suppressing glucagon release (Hay *et al.*, 2015). Meal pramlintide injections in the context of artificial pancreas have been associated with improved postprandial blood glucose excursions in the small studies conducted to date (Weinzimer *et al.*, 2012;Edelman *et al.*, 2006). The use of pramlintide in an infusion pump in the artificial pancreas, before meals or as a continuous infusion with insulin, is being proposed and tested by some research groups. Short-term studies have also explored the addition of other adjunct therapies such as incretins (DPP4 inhibitors and GLP-1 analogs) (Renukuntla *et al.*, 2014; Underland *et al.*, 2017).

Awaiting further studies, it is expected that multihormone artificial pancreas systems would be beneficial for certain patients or in certain situations such as in patients failing to achieve optimal glucose control with single-hormone systems, those with impaired awareness of hypoglycemia or with brittle diabetes, or during exercise (Taleb *et al.*, 2016b). Adding other hormones to the artificial pancreas imposes increased complexity (additional material, pumps, reservoirs, tubules, and catheters) and costs. Another challenge is to prove the safety of such chronic daily use of additional hormones or their analogs. The safety of chronic glucagon use has not yet been established and considering the multiple systemic effects of glucagon, its long-term chronic use has to be monitored (Taleb *et al.*, 2016c). No side effects have been reported in most dual-hormone systems, but an increased nausea perception was observed with the longest study of 11 days (El-Khatib *et al.*, 2017). Finding a stable glucagon formulation that

withstands the fibrillation and degradation in an infusion pump is also a pressing need. The currently used formulation of the hypoglycemia emergency kits require reconstitution and immediate use. Available evidence support possible use in pumps for up to 24-h thus requiring daily change with freshly reconstituted glucagon (Taleb *et al.*, 2017). Thus, despite its potential benefits (lower hypoglycemic risk, lower mean glucose, better postprandial glucose control), multihormone artificial pancreas systems still have a lot of challenges to overcome and warrant further clinical testing to confirm their feasibility before appearing on the market.

Artificial Pancreas Strategies in Challenging Conditions and Use in Specific Patient Populations

Besides the multiple benefits associated with artificial pancreas use, some challenges remain to be tackled such as optimal strategies for glucose control during and postmeals, and exercise. Its potential use and efficacy for specific patient populations also needs to be studied such as in children, pregnant women, and patients with T2DM.

Meal strategies with the artificial pancreas

Controlling postprandial glucose excursions is identified as a key component to achieve recommended HbA1c targets (Ceriello *et al.*, 2004; Canadian Diabetes Association Clinical Practice Guidelines Expert Committee, 2013) and meal carbohydrate content is the main determinant of this excursion (Scavone *et al.*, 2010; Rabasa-Lhoret *et al.*, 1999). Consequently, in intensive insulin therapy, prandial insulin dosage depends on the carbohydrate content of each ingested meal (carbohydrate counting) (Canadian Diabetes Association Clinical Practice Guidelines Expert Committee, 2013). Precision of carbohydrate counting is associated with better glycemic control (Mehta *et al.*, 2009) but it remains a challenging task for patients (Fortin *et al.*, 2017), with an average error in carbohydrate counting of approximately 20% (Brazeau *et al.*, 2013). Any technology or strategy that would alleviate the burden of carbohydrate counting could not only improve overall glycemic control but patients' quality of life as well. Several strategies have been proposed to control postmeal glucose excursions with the artificial pancreas: (1) a fully automated artificial pancreas (no meal announcement); (2) hybrid artificial pancreas with a meal bolus announcement implemented by the patient based on the carbohydrate content of the meal; (3) hybrid artificial pancreas with a meal announcement strategy that is completely or partially independent of the carbohydrate meal content (simplified meal bolus) (Gingras *et al.*, 2018).

Fully automated artificial pancreas (no meal insulin bolus)

A fully automated artificial pancreas is entirely reactive to real-time glucose values and no meal information is manually announced to the algorithm. While it offers the advantage of relieving the patient from frequent interventions, such as carbohydrate counting; it should not be at the expense of good glucose control. Few groups are investigating the potential of a fully automated artificial pancreas in patients with T1DM (Steil *et al.*, 2006; Ruiz *et al.*, 2012; El-Khatib *et al.*, 2010; Blauw *et al.*, 2016), but these groups have, so far, all faced significant postprandial hyperglycemic excursions and late postprandial hypoglycemia (Gingras *et al.*, 2018). Some meal detection algorithms (Dassau *et al.*, 2008) or the addition of pramlintide (Weinzimer *et al.*, 2012) could potentially improve the performance of the fully automated system, but the strategies have not yet been tested in large randomized controlled studies.

Hybrid artificial pancreas (accompanied with input from patients for meal bolus based on carbohydrate content of meals)

Hybrid artificial pancreas, or artificial pancreas with carbohydrate-matched meal bolus that is manually fed to the algorithm has been well studied (Hovorka, 2006; Clarke *et al.*, 2009). These studies typically demonstrate that hybrid systems, as compared to CSII, increase overall time in target range, reduces time in hypoglycemia, and improves glucose control overnight. However, even if preprandial glucose values are improved, postprandial glucose control remains suboptimal. Glucose levels are kept in-target for 70%–75% of the time with hybrid artificial pancreas with the remaining time spent outside target mostly due to postmeal hyperglycemia (Thabit and Hovorka, 2016a). Limitations of a hybrid system include the cumbersome carbohydrate counting and a potential increased risk of late postprandial hypoglycemia (Steil *et al.*, 2006). A partial prandial bolus could thus be interesting but the optimal strategy remains to be determined. Administration of a prandial bolus equivalent to 30%–50% of a carbohydrate-matched bolus with the rest of insulin being administered based on early postprandial glucose profile has been associated with an improved postprandial glucose profile compared to the fully-automated system; yet, this strategy still requires carbohydrate counting (Weinzimer *et al.*, 2008).

Hybrid artificial pancreas (accompanied with simplified patient input for meal bolus)

Additional strategies have been tested to reduce or avoid the need for carbohydrate counting. In a pilot project, a prandial bolus based on body weight (0.047 U of insulin per kg) was compared with a carbohydrate-matched bolus within the context of dual-hormone artificial pancreas. The simplified approach resulted in more prolonged glycemic excursion (Haidar *et al.*, 2014). The efficacy of a meal bolus based on semiquantitative carbohydrate content assessment: patient's current insulin-to-carbohydrate ratio and meal category (e.g., snack, regular meal, large meal or very large meal) has also been investigated (Gingras *et al.*, 2016a). This strategy was compared to carbohydrate-matched boluses in the context of single and dual-hormone artificial pancreas demonstrating its ability to achieve similar glucose control (Gingras *et al.*, 2016a,b). Adaptive meal-priming boluses have been developed and used in a first study by El-Khatib *et al.* (2014). With this strategy, patients have to select a meal (breakfast, lunch or dinner), and then select a meal size: typical, more than usual, less than typical or a small bite, eliminating the need for exact carbohydrate

counting. Outpatient studies have demonstrated the merits of this approach to improve glucose control in both adults and children (Russell *et al.*, 2016; El-Khatib *et al.*, 2014). Other teams using a similar approach based on semiquantitative carbohydrate meal content rather than precise carbohydrate counting have shown comparable results (Gingras *et al.*, 2016a,b, 2018). However, the simpler meal classification, the way to educate patients, risk associated with meal misclassification, impact of other macronutrients, possible risk of hypo and hyperglycemia, etc., still need to be explored in larger groups of patients with less controlled conditions.

In the current context, informing the algorithm of a pending meal consumption is probably a needed compromise so that the system is prepared to manage rapid prandial changes in blood glucose. Simplified meal priming approaches still require some carbohydrate content or meal size assessment, but are simpler and more convenient to patients than exact carbohydrate counting.

Postprandial glucose control in the context of the artificial pancreas is mainly challenged by CGMS lag time in the context of rapidly varying blood glucose, current pharmacokinetic profiles (delayed action, variability, etc.) of subcutaneously injected insulin, the impact of other nutrients (lipids, proteins, etc.) and the inter and intra-individual variability in insulin sensitivity (Gingras *et al.*, 2018). Some advances could compensate or resolve some of these issues, including: faster acting insulins such as the faster Aspart (FiAsp) in which modified excipients allow faster absorption which improves postprandial glucose profile (Russell-Jones *et al.*, 2017; Fath *et al.*, 2017; Heise *et al.*, 2016), intraperitoneal insulin infusion allowing a more physiologic hepatic action (Renard, 2008), and the use of other adjunctive therapies alongside advanced algorithms such as pramlintide, glucagon-like peptide-1 (GLP-1) analogs and sodium-glucose co-transporter-2 inhibitors (SGLT2-i).

Artificial pancreas strategies with exercise

Despite the established beneficial health effects of exercise, the majority of patients with T1DM lead a sedentary lifestyle (Brazeau *et al.*, 2012; Chimen *et al.*, 2012). This is partly due to the loss of metabolic control and the increased risk of hypoglycemia during and up to 18 h postexercise (Riddell and Sigal, 2013; Brazeau *et al.*, 2008). While in healthy subjects a suppression of insulin secretion and an increase of counter-regulatory hormones (catecholamines, glucagon, etc.) occurs in a timely manner in response to increased uptake of glucose by muscles during exercise, patients with T1DM are challenged by the inability to adjust absorption of previously injected insulin and defective counter-regulatory hormones increasing their risk of hypoglycemia with most types of exercise (Riddell and Sigal, 2013; Colberg *et al.*, 2015; Richter and Hargreaves, 2013). Several strategies have been studied to manage glucose during exercise such as the addition of snacks and/or reduction of basal or insulin boluses, but none of these strategies allow a reasonable hypoglycemia prevention and all require significant anticipation (Taleb and Rabasa-Lhoret, 2016). The first artificial pancreas trials included exercise sessions but were not specifically designed or powered to examine its efficacy with exercise. Analysis of recent studies that specifically address exercise is also limited by the large variability in terms of type, duration, and intensity of exercise as well as snack consumption and time to preceding meals (Taleb *et al.*, 2016b; Breton *et al.*, 2017; Jayawardene *et al.*, 2017). Artificial pancreas control during exercise has shown potential for better glucose control than strategies applied with conventional therapy (Breton *et al.*, 2017; Dovc *et al.*, 2017; Huyett *et al.*, 2017). For example, glucose control was improved with artificial pancreas compared to sensor augmented pump during high intensity prolonged exercise (skiing) in adolescents mainly with improved time in target that was particularly observed late at night (Riddell *et al.*, 2015). Nevertheless, important challenges still need to be overcome with artificial pancreas systems during exercise. This is due to the sharp changes in glucose levels and subsequent delays in glucose sensing which impedes insulin infusion adjustment by the algorithm in a timely manner. Several strategies with the artificial pancreas are being tested such as manual entry of pending exercise to the algorithm (ahead or at its start) or exercise detection by heart rate monitors, accelerometers or other sensors (Taleb *et al.*, 2016b; DeBoer *et al.*, 2016; Jacobs *et al.*, 2015). Another promising strategy is the addition of glucagon in dual-hormone systems; in comparison to single-hormone artificial pancreas the number of exercise-induced hypoglycemic events was significantly reduced (3 vs. 15 episodes out of 34 interventions) with glucagon addition during continuous and interval exercise sessions lasting 60 min (Taleb *et al.*, 2016b). Therefore, the artificial pancreas has a good potential to improve glucose control with physical activity but larger studies are still needed to determine the best strategies that allow a maximum benefit of this technology during exercise.

Particularities of the artificial pancreas in children

The use of the artificial pancreas in children is more recent; yet, studies have shown that its use in children and adolescents is feasible and improves glucose control, especially at night (Weinzimer *et al.*, 2008; Elleri *et al.*, 2013). Many studies have investigated overnight glycemic control in children and these studies showed a substantial reduction of hypoglycemia frequency and duration (Haidar *et al.*, 2015a; Elleri *et al.*, 2014; Hovorka *et al.*, 2014). Fewer studies have investigated the benefits of the artificial pancreas during the day, but a recent study with children aged 5–8 years showed a reduced mean glycemia without increasing time in hypoglycemia using a single-hormone system compared to pump therapy over a 68-h period (DeBoer *et al.*, 2017). Young children are more vulnerable to hypoglycemia and this subgroup of patients presents specific challenges such as unpredictable appetite and food intake and variable physical activity patterns, and thus, the artificial pancreas could be particularly beneficial to address these challenges.

Artificial pancreas in pregnant women with diabetes

Diabetes in pregnancy could be related to a preexisting diagnosis of T1DM or T2DM or could be diagnosed during pregnancy, also called gestational diabetes (Berger *et al.*, 2016). A tight glucose control is required throughout gestation to reduce the multiple

diabetes-related complications for the fetus (macrosomia, neonatal hypoglycemia, respiratory difficulties, etc.) and the mother (infections, preeclampsia, preterm delivery, C-section, etc.) (Berger *et al.*, 2016). Insulin is the mainstay treatment for diabetes in pregnancy through basal-bolus insulin regimen or insulin pumps. The first artificial pancreas study in pregnancy undertaken with a single-hormone system in 12 women with preexisting T1DM showed that thigh glucose control was feasible and safe (less time spent in hypoglycemia) (Murphy *et al.*, 2011). A more recent study compared overnight artificial pancreas control with sensor augmented pumps over a 4-week period in 16 women showing a 15.2% increase in time in target with the artificial pancreas without differences in hypoglycemia (Stewart *et al.*, 2016). The same women were then continued on artificial pancreas control during day and night for up to 14.6 weeks (including hospitalization, labor and delivery); glucose was in target for 68.7% of the time with a mean value of 7 mmol/L (Stewart *et al.*, 2016). The artificial pancreas in pregnancy seems to be safe and promising, thus larger studies are expected in the future.

Artificial pancreas in type 2 diabetes

Many patients with T2DM progress over the years to a state of insulin requirement on top of their insulin resistance (Fonseca, 2009). The use of basal insulin therapy and then intensive basal-bolus insulin regimen are thus needed for a large proportion of patients over the course of their disease. But even under insulin therapy, only one third of these patients reach glycemic targets. It is therefore proposed that the artificial pancreas could potentially improve glucose management in T2DM. So far, only two published studies have tested single-hormone artificial pancreas in T2DM. In the first trial, patients who were treated with oral hypoglycemic agents had 20% improvement in time spent in target glucose levels when the artificial pancreas was used over 24 h in a controlled laboratory setting (Kumareswaran *et al.*, 2014). The second trial was conducted in patients admitted to the emergency ward who were treated with insulin to control their glucose levels; time in target was increased from 38% to 60% with artificial pancreas therapy during their hospital stay (Thabit *et al.*, 2017). An ongoing randomized cross-over study is currently comparing artificial pancreas with MDI over 24-h in patients with T2DM on basal-bolus insulin regimen in a controlled laboratory setting (NCT02490085). Preliminary results showed more time spent within target glucose levels with artificial pancreas (+ 10%) which was particularly significant in the overnight period (+ 28%) without increasing hypoglycemic risk (Nadine Taleb *et al.*, 2017b). Clinical testing of the artificial pancreas is thus warranted in a broader population of patients with T2DM through larger and longer trials including outpatient settings.

Patients' Expectations and Perceptions With Artificial Pancreas Use

Most importantly, for an optimal use of the artificial pancreas, patients' expectations and perceptions need to be considered and prioritized. A study in parents of children with T1DM showed they were interested in the use of the artificial pancreas for nocturnal glycemic control and that they would trust such a system for their children (Elleri *et al.*, 2010). Similarly, a high interest in artificial pancreas use has been observed in adults (van Bon *et al.*, 2011). What patients expect from this technology is an improvement in glucose control with a system that is easy to use and that is reliable (Gonder-Frederick *et al.*, 2011). Recently, a focus group study following artificial pancreas use showed that patients did perceive benefits including improved glycemic control, long-term reduced risk of complications, improved quality of life and a reduced diabetes-associated psychological burden (Iturralde *et al.*, 2017). However, tasks that required their intervention (boluses, calibrations, etc.), technical issues with wearing the system, and a perception of elevated hyperglycemia frequency were reported as negative aspects of this technology (Iturralde *et al.*, 2017). Artificial pancreas development and implementation need to account for patients' experiences and in some cases, some unrealistic expectations must be realigned.

Conclusion

Significant technological advances to manage diabetes have marked the last two decades and continue to move at a fast pace. Insulin pumps are offering a more flexible insulin delivery than multiple daily injections and can be an option for insulin-treated patients. Glucose sensors have taken glucose monitoring to a high level of detailed profiling. Combining these two technologies in sensor augmented pump therapy is currently the gold standard for intensive insulin therapy allowing the lowest achievable HbA1c concurrently to a reduced hypoglycemic risk. Despite the advantages of these advanced features, many barriers still need to be faced to make these costly therapies accessible to patients. Other unmet needs include the way to select patients that would most-benefit from incorporating technology in their treatment as well as optimal educational strategies allowing patients to take advantage of all the features of various devices.

These technologies also allowed the development of the artificial pancreas that has proved its efficacy in further improving blood glucose control and reducing hypoglycemic risk. Several challenges still need to be tackled with the artificial pancreas and larger and longer trials are needed. The addition of other hormones (glucagon and pramlintide) offers an interesting perspective (e.g., achieving fully automated glucose control) but still requires additional work specially to demonstrate incremental benefit and safety. Due to its increased complexity and cost, this multihormonal approach might be only justified in specific patients or conditions. However, on the long-term, a multihormonal approach is viewed as the way to reach fully automated glucose control. The first hybrid system has already been approved in the United States and other systems such as the iLet (Beta Bionics) and

Diabeloop (in France) will reach the market in the coming 2–3 years. The artificial pancreas is considered by most experts as the most promising therapy to revolutionize diabetes management making it safer and simpler.

Acknowledgments

This work was supported by funds from Canadian Diabetes Association and NIH grant number 1DP3DK106930-01 held by R R-L, and Canadian Institutes of Health Research scholarship held by NT and Fonds de Recherche Santé Québec scholarship held by VG.

Disclosure Statements: NT and VG have no conflicts of interests to declare. RRL has the following to declare: Research grants from Astra-Zeneca, E Lilly, Merck, NIH, Novo-Nordisk, Sanofi-Aventis; Consulting/advisory pannel with Abbott, Amgen, Astra-Zeneca, Boehringer, Carlina Technology, Eli Lilly, Janssen, Medtronic, Merck, Neomed, Novo-Nordisk, Roche, Sanofi-Aventis; Honoraria for conferences received from Abbott, Astra-Zeneca, Boehringer, E Lilly, Janssen, Medtronic, Merck, Novo-Nordisk, Sanofi-Aventis; consumable gift (in Kind) from Abbott, Animas, Medtronic, Roche; unrestricted grants for clinical and educational activities from Eli Lilly, Lifescan, Medtronic, Merck, Novo Nordisk, Sanofi; patent for T2DM risk biomarkers, catheter life & artificial pancreas; Purchase fees related to artificial pancreas from Eli Lilly.

MSC Mesenchymal stem cells
T1DM Type 1 diabetes mellitus
Tregs T regulatory cells

Glossary

Type 1 diabetes Type 1 diabetes is a chronic autoimmune disorder that attacks beta cells within islets of Langerhans in the pancreas. Insulin injections are life-sustaining but imperfect, with imprecise glycemia, risk of hypoglycemia and accelerated secondary diabetic complications.

Islet cell transplant Islet cell transplant is the clinical application of isolating islets from a donor pancreas with intraportal transplantation into patients with unstable type 1 diabetes. Once transplanted, endogenous regulated insulin secretion is restored to variable degrees dependent upon engrafted islet mass.

Introduction

Diabetes currently affects over 382 million people throughout the world and is expected to rise to 592 million by 2035 (Guariguata *et al.*, 2014). Type 1 Diabetes Mellitus (T1DM) is treated with exogenous insulin. This is typically given in multiple boluses by subcutaneous injection of short and long-acting forms. Tight glycemic control mitigates secondary complications and end-organ failure, but increases the risk of severe and recurrent hypoglycemic reactions. Continuous glucose monitoring systems (CGMs) may improve monitoring and control, and closed loop technology that infuses insulin and/or glucagon in response to glycemic thresholds may further optimize control. These systems are bulky however, must be worn externally, and often still fail to provide perfect glycemic control.

T1DM is an autoimmune disease with complex genetic and environmental overlay. Controlling autoimmunity in new onset diabetes remains challenging due to the complexity of the multicomponent and heterogeneous immunologic response. The potential to intervene and potentially reverse beta (β) cell destruction after clinical diagnosis of diabetes could be accomplished by identifying potential risk markers and quantified risk projection (Skyler and Ricordi, 2011; Skyler *et al.*, 2008). Intensive pilot trials conducted through TrialNET have demonstrated sustained honeymoon periods but do not routinely restore normoglycemia. One exceptional clinical trial (NCT00315133) conducted in Brazil by Voltarelli *et al.* attempted to immune reset newly diagnosed T1DM patients. The trial utilized peripheral blood autologous bone marrow-derived hematopoietic stem cells after myeloablative conditioning with cyclophosphamide and rescue with granulocyte-colony stimulating factor. Approximately two to 3 weeks post myeloablative conditioning, autologous stem cells were thawed and administered intravenously. The majority of subjects (20 of 23) demonstrated reversal of diabetes for sustained periods. However the immune reset caused dysregulation of T and B cell responses, subjects frequently developed cyclophosphamide-related oligospermia and other adverse endocrine dysfunctions, polyendocrine syndrome and side effects such as pneumonia and rashs (Malmegrim *et al.*, 2017; Couri *et al.*, 2009; Voltarelli *et al.*, 2007). The future direction to prevent or decrease the progression of T1DM needs to evaluate the memory T and B cell subsets in an effort to abolish recurrent autoimmune destruction.

An alternate means to restore euglycemia in patients suffering from T1D is to replace β cell mass through transplantation of a whole pancreas or an islet transplant. Whole pancreas transplantation is an invasive surgical procedure that carries risk of complications and potential death, but is currently the most reliable means to restore insulin independence with glycemic reserve. Islets of Langerhans are clusters of cells composed of four main cellular components: glucagon-producing α cells, insulin-producing β cells, somatostatin-producing δ cells, and pancreatic polypeptide-producing cells (Halban, 2004). Islets range in size from <50 to ~800 μm of diameter, and only constitute $\sim1\%$–2% of the total pancreatic tissue (Bonner-Weir *et al.*, 1993; Halban, 2004; Vanikar *et al.*, 2016). As highly vascularized cells, islets rely on complex cell–cell interactions between different cell subsets in order to maintain glucose homeostasis. Islet transplantation (IT) is generally considered a safer approach as it does not require invasive surgery, and only the islets contained in the pancreas are transplanted without the challenges associated with exocrine drainage. Islet cells are obtained from deceased organ donor pancreatectomy, ABO compatible with the recipient, and infused into the recipient portal vein under the cover of anticoagulation, antiinflammatory medications and inductive and maintenance immunosuppression. While insulin independence is often achieved at early time points, maintaining a completely insulin free state is challenging due to early and late islet cell loss. Islet loss may occur due to an instant blood-mediated inflammatory reaction (IBMIR) triggered by tissue factor expressed on the islet surface, inflammation, alloimmune rejection, recurrence of autoimmunity, or toxicity to β cells from immunosuppressive medications. To alleviate islet cell loss, alternative transplantation sites, stem cell-derived cellular products, cotransplantation with alternative cells or immune protective agents are the focus of active study. **Table 1**

Table 1 Comparison of islet versus whole pancreas transplantation

	Islet	*Pancreas*
Reduce or eliminate hypoglycemia	Yes	Yes
Insulin independence	Yes—but often transient	Yes—more durable reserve than islet
Improves glycemia and HbA_{1c}	Yes	Yes
Improves diabetic-related complication	Not Known	Improved
Procedural risks	Minor	Major
Number of procedure	Multiple infusions	One transplant

Both islet and pancreas transplantation can render insulin independence and normoglycemia. Pancreas transplantation is associated with multiple risks, including graft thrombosis, hemorrhage, pancreatitis, wound infection, etc. Whereas islet transplantation has minimal procedural risks such as posttransplant lymphoma, thrombosis posttransplant.

compares the relative benefits and disadvantages of islet over whole pancreas transplantation. While islet transplantation (IT) is safer than pancreas transplantation, it is associated with lower insulin reserve and lower rates of sustained insulin independence over time. Both require potent immunosuppression to sustain allograft function.

Pancreas Transplantation

Whole pancreas transplantation is an alternative procedure that can restore normoglycemia for patients without β cell function. The first pancreas transplant was carried out at the University of Minnesota by Kelly and Lillehei in 1966 (Kelly *et al.*, 1967). The rationale for the transplant was to prevent the recurrence of diabetic nephropathy in the previous transplanted kidney. Early outcomes were dismal, due to the need for high dose corticosteroid therapy. Introduction of more potent immunosuppressive agents such as cyclosporine and tacrolimus, and more potent inductive T-cell depletion therapies improved short and long-term outcomes of this surgical therapy in diabetes. By 1980, first and third year patient survival was 91% and 72%, respectively and pancreas graft survival was 84% and 62%, respectively (Gruessner and Sutherland, 1996). Currently, the International Pancreas Transplant Registry (IPTR) reports >42,000 pancreas transplants have been performed worldwide (>27,000 in the US and >15,000 elsewhere). Pancreas transplantation can be subcategorized as pancreas after kidney transplantation (PAK), islet after kidney transplantation (IAK) or simultaneous islet-kidney transplantation (SIK). The patient survival postpancreas-transplant can be as high as 95%, with up to 90% graft survival postprocedure (Sutherland *et al.*, 2001). Whole pancreas transplantation is a high-risk procedure that is currently the most reliable means to restore and maintain insulin independence.

Islet Transplantation

History

The earliest evidence of IT can be traced back to 1893 when Watson Williams and Harsant subcutaneously implanted fragments of sheep pancreases into a 13-year-old boy (Williams, 1894). The patient died within 3 days of the procedure, with the xenograft cells being rapidly rejected. Paul Lacy was the first to demonstrate in 1972 that chemically diabetic rats could be cured with islet transplantation (Ballinger and Lacy, 1972). In 1980, Najarian and colleagues from Minnesota performed a successful islet autotransplant, whereby the patient's own islets were transplanted into the portal vein in the setting of chronic pancreatitis (Najarian *et al.*, 1980). Ricordi developed a unique chamber and semiautomated method in 1988 to digest the human pancreas and liberate islets that could then be purified and transplanted (Ricordi *et al.*, 1989). The ability to obtain large quantities of islets was important for the clinical application of IT in 1990 when the first case of transient insulin independence was achieved post IT by Scharp *et al.* (1990). Almost 300 clinical attempts at islet allotransplantation were carried out in patients with T1DM between 1980 and 1999, but fewer than 8% resulted in anything more than transient insulin independence. In 2000, Shapiro and colleagues developed the Edmonton Protocol, the results of which transformed the field. The Edmonton Protocol was groundbreaking through use of: (i) a corticosteroid-free immunosuppressive protocol using the combination of potent drugs sirolimus and tacrolimus, combined with an anti-CD25 antibody to protect against rejection and recurrent autoimmunity; and (ii) augmenting the islet mass (>13,000 islet equivalents (IE) kg^{-1} recipient body weight) through transplantation of islets prepared from two or more fresh donor pancreatic islet preparations (Shapiro *et al.*, 2000). As a consequence of this refined approach, seven consecutive patients receiving an islet transplant achieved insulin independence up to 1 year posttransplant, a feat unprecedented at the time. Since the inception of the Edmonton Protocol, approximately 300 patients have received islet transplants at the University of Alberta with one-year insulin independence rates achieved in 80% of transplant recipients. The success of the Edmonton Protocol rejuvenated global interest in clinical islet transplantation, with numerous programs developed globally. Since 2000, >1000 patients have been transplanted using recent variants of the Edmonton Protocol in almost 50 centers worldwide (2015). At the University of Alberta, insulin independence is maintained in approximately 25% of patients at 5 years' post-transplant. Perhaps more importantly, these rates double to 50% in such patients receiving newer immunosuppression and

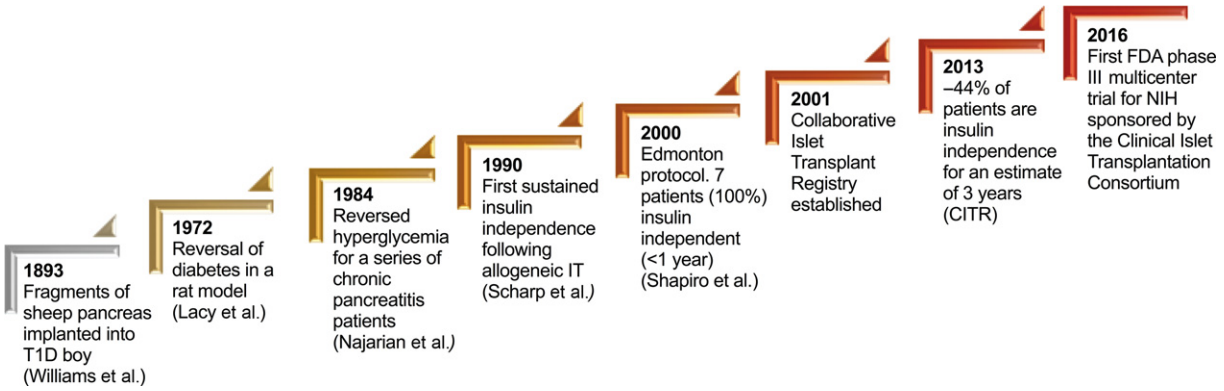

Fig. 1 Islet cell transplantation timeline chart. Throughout the past few decades, islet cell transplantation has evolved into a feasible clinical treatment for patients with brittle diabetes.

antiinflammatory induction protocols. The discrepancy between the prevalence of maintained C-peptide secretion relative to long-term insulin independence rates remains elusive, although it is accepted that multiple culprits may be responsible for hindering graft function and survival over time. To achieve insulin independence, most patients require two islet transplant procedures, and in some cases, three infusions. The achievement of insulin independence after single-donor islet infusion has occurred in few transplant centers globally, with the most success reported from the University of Minnesota (Hering *et al.*, 2004, 2005). At the University of Minnesota, they investigated donor characteristics of young donors (<50 years) with a high BMI (>27 kg m^{-2}) can achieve insulin independence via a single donor (Shapiro *et al.*, 2006). Moving forward, the field of IT has nonetheless continued to grow from an experimental procedure into a well-tolerated and effective clinical procedure. According to the Collaborative Islet Transplant Registry (CITR), over 1584 IT infusions in 819 recipients have been performed from 1999 to 2013, and currently 27 active registered centers are open (Collaborative Islet Transplant Registry, 2016). IT has drastically improved over the past few decades due to technology, improved islet quality and redefined immunosuppression regimens (**Fig. 1**). However, IT has yet to be a feasible clinical procedure for all spectrums of diabetes, and a breakthrough in the IT community is bound to emerge.

Islet Isolation, Purification and Culture

The islet cell isolation and transplant procedure can be foreseen as harmful to the islets, because it strips the islets from their native vascularization and environment. The automated method is part of the 5–7 h multistep process that carefully isolates, purifies and processes donor pancreatic tissue into singular clusters of islet cells (**Fig. 2**). The process commences with pancreas procurement from a deceased donor. The donor characteristics are important for acquiring an optimal islet cell yield. Characteristics such as age (between 20 and 50 years), BMI (>30 kg m^{-2}) and normalized HbA_{1c} levels are critical (Shapiro *et al.*, 2017). The donor pancreas is "cleaned," by the removal of the spleen, duodenum, surrounding fat, lymph nodes and vessels. Intravenous catheters are inserted into the main pancreatic ducts, and the pancreas is perfused with cooled collagenase and serine–protease inhibitor that serves to initiate enzymatic digestion. Once distended, the pancreas is cut into several small pieces and placed into the Ricordi chamber. The Ricordi® chamber is contains a superior and an inferior component that is seperated by a 700 μm filter. Within the chamber are stainless steel balls and is filled with digestion solution. The chamber is agitated to mechanically disrupts the tissue, and a peristaltic pump connected to the system creates a flow throughout the closed circuit. The digestion is terminated when most of the islets are free from the surrounding exocrine tissue by the addition of cold media (10°C). It is important to note, the time of terminating the digestion is critical because over digestion can lead to a decrease in islet cell yield and compromised function. The islets undergo a purification step, where a COBE 2991 cell processor utilizes a continuous density gradient of Biochrom Ficoll that separates the islets and acinar tissue. At the end of this step, the islets are collected and counted based on their morphology by dithizone (DTZ) staining. DTZ bonds to the zinc in the insulin granules and gives a visual red appearance to the islets, differentiating islets from exocrine tissue. The islets undergo a regimen of safety testing that analyzes the cells' viability, purity, insulin content, cell numbers and insulin secretory response. Once analyzed, the final enriched islet cell product must have the adequate islet purity ($>50\%$), dose (>5000 IEQ kg^{-1}), and have a volume less than 5cm^3 in size, in order to be safely infused into the recipient by a intraportal infusion (Kawahara *et al.*, 2011). Depending on the center preference, the purified islet cells can be infused within a few hours after the end of the isolation or cultured at 20°C or 37°C for a period up to 72 h (Yamamoto *et al.*, 2009). The culture period can be foreseen as beneficial for the islets because it may help reduce the immunogenicity of the islets and allow time for the recipient to commence immunosuppressive treatment, but despite considerable research efforts aimed to delineate optimal culture conditions, protocols have yet to be standardized (Ichii *et al.*, 2007).

Islet Transplant Procedure

Clinical islet transplantation is routinely carried out by intrahepatic infusion via the portal vein. The portal vein is located by interventional radiology that uses ultrasonographic and fluoroscopic guidance to make the hepatic infusion. The advent of the

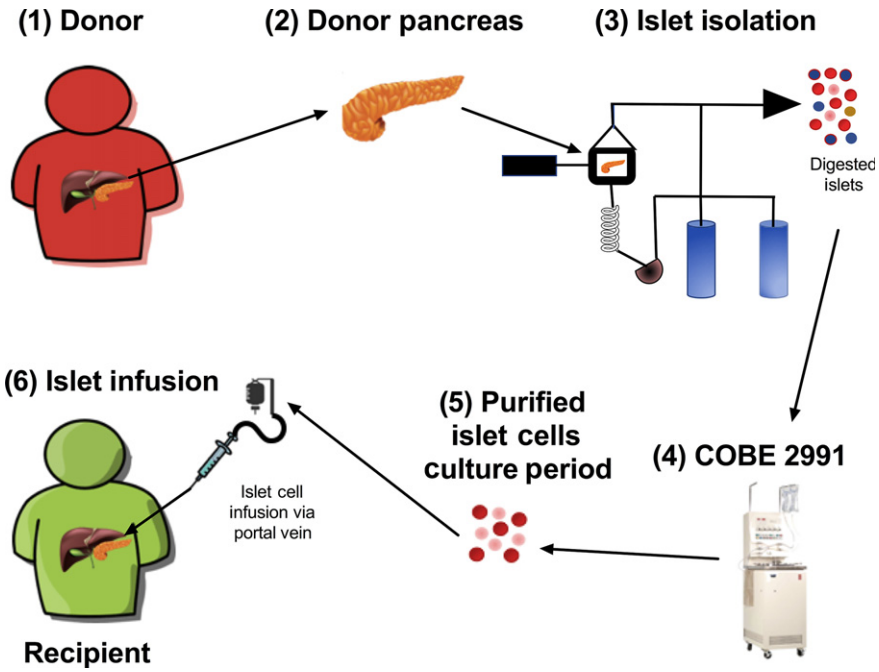

Fig. 2 Islet cell procedure. (1) A deceased human donor pancreas is isolated. (2) The pancreas is "cleaned" from surrounding tissue and is perfused with collagenase enzyme. (3) The schematic of digestion through the Ricordi chamber. (4) COBE 2991 cell purifies the islets utilizing a continuous Biochrom osmotic gradients. (5) After purification, viability and other islet assessments, the islets are cultured for a period up to 72 h. (6) The highly purified human islets are infused into the portal vein of a recipient with type 1 diabetes.

percutaneous method has made the procedure relatively noninvasive because it does not require general anesthesia or surgical incision. During the procedure, a potential complication is the risk of thrombosis and bleeding; however, sealing the catheter upon abstraction with a thrombostatic paste and administering heparin reduces the potential of thrombosis and hemorrhage (Kawahara *et al.*, 2011). Throughout the 15 to 60-min procedure, the portal pressure is well documented to be below 20 mmHg and the patient status is monitored. Even with minimal complications, the intrahepatic site may not be an optimal environment for islet engraftment. It is estimated that 50%–70% of islets are acutely destroyed following an intrahepatic infusion (Shapiro *et al.*, 2001). Alternative implantation sites have been explored in the clinical setting like the bone marrow (Maffi *et al.*, 2013), striated muscle (Christoffersson *et al.*, 2010), and omentum (Baidal *et al.*, 2017), but no site has yet to provide regulated glycemic control as efficiently as the intrahepatic infusion.

Islet Engraftment

Subsequent to organ retrieval, islet isolation and culture, the islet engraftment as a result of transplantation may present with some obstacles that may impede successful outcomes. To survive and function posttransplantation, islets must adequately engraft by developing new capillaries and vessels with the native islet vasculature. The engraftment process initiates 1–3 days posttransplant, whereby the new network develops from the recipient's blood vessels in concert with the remnants of the donor islet endothelium (Emamaullee and Shapiro, 2007). During this time, islets are subjected to considerable environmental stresses within the first days of transplant that can contribute to a reduction in the original islet mass by 50%–70% (Emamaullee and Shapiro, 2007; Merani *et al.*, 2008; Wang *et al.*, 2011).

The IBMIR reaction accounts for considerable islet loss in the acute transplant period. Extensive work by Korsgren *et al.* have elucidated that IBMIR is initiated upon infusion of islets into the portal vasculature (Ozmen *et al.*, 2002). IBMIR negatively influences islet engraftment through a cascade initiated by the expression of tissue factor, resulting in platelet adherence, activation, clot formation and lymphocyte recruitment (Plesner and Verchere, 2011; Emamaullee and Shapiro, 2006). These results suggest that despite being the current best clinical site for islet transplantation, the portal vein still has substantial limitations that need to be further optimized if long term outcomes of islet transplantation are to continue to improve.

Immunosuppression for Islet Transplantation—Risks and Side Effects

Islet transplant recipients require chronic maintenance immunosuppression to prevent graft rejection and to mitigate risk of recurrence of diabetic autoimmunity. The most potent antirejection treatments (tacrolimus and cyclosporine calcineurin inhibitors (CNI) have direct toxicity to beta cells (Nir *et al.*, 2007; Chand *et al.*, 2001; Ekberg *et al.*, 2009). Further, they inhibit insulin section

of the human islets (Rangel, 2014). Alternative CNI-free immunosuppression regimens have been investigated for IT, but no protocol has yet to provide significant evidence that avails long-term islet survival and renal protection (Posselt *et al.*, 2010). Notably, Efalizumab (Turgeon *et al.*, 2010) and Belatacept (Vincenti *et al.*, 2010) demonstrated the ability to become insulin independent for sustained periods without CNIs. Although a CNI-free regimen is desirable for islet engraftment, all medications that suppress the immune surveillance system pose increased risk of both cancer and infections for recipients (Penn, 2000). Immunological tolerance seeks to induce a stable, nonresponsive state to an islet or other organ allograft without need for chronic immunosuppression, and remains a much sought after goal in IT (Shapiro *et al.*, 2016). Moving forward, the use of encapsulation devices or therapeutic agents could potentially facilitate this, but are inherently challenged due to failure of engraftment and low cell survival, mainly due to lack of early rapid neovascularization.

Potential Islet Engraftment Improvements

Cotransplantation with mesenchymal stem cells

Mesenchymal stem cells (MSCs) are nonhematopoietic precursor cells that can differentiate into mesoderm lineages: adipocytes, osteocytes, chondrocytes, and myocytes (Brusko, 2009; Majumdar *et al.*, 2000). MSCs can be isolated from a multiple tissues sources such as amniotic fluid (Loukogeorgakis and De Coppi, 2016), skeletal muscle (Williams *et al.*, 1999), adipose tissue (Mahmoudifar and Doran, 2015), or umbilical cord (Lazarus *et al.*, 2005). Currently, inefficient evidence of MCSs' ability to differentiate into insulin producing cells is available, but the utilization of cotransplanting islets with MSCs can support islet engraftment (English and Wood, 2013).

The employment of MSCs in the IT field is an exciting endeavor because MSCs' can ameliorate islet engraftment by their secretion of trophic factors and assist the immune regulation (Zhang *et al.*, 2004b). Trophic factors secreted by MSCs include vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), Angiopoetin-1 (Ang-1), and transforming growth factor-β (TGF-β) have been shown to enhance islet engraftment (Kinnaird *et al.*, 2004; Liu and Han, 2008). In doing so, the trophic factors assist in the reduction of the migration and proliferation of immune cells, and promote vascularization in the islet engraftment (Sordi *et al.*, 2005; Caplan and Dennis, 2006; Chen *et al.*, 2008a). Carrying over, MSCs have demonstrated its ability to downregulate the immune response by interfering with different pathways of the immune response, via direct and indirect cell-to-cell interactions in both in vitro and in vivo (Vija *et al.*, 2009) (Le Blanc *et al.*, 2003; Liu and Han, 2008; Ramasamy *et al.*, 2007). MSCs can suppress T and B cell proliferation, interfere with dendritic cell maturation, modulate natural killer cells cytotoxicity, and decrease immunoglobulin production to a certain extent that promotes islet cell engraftment survival (Healy *et al.*, 2015; Kim *et al.*, 2011; English, 2016). Evidently, the cotransplantation of human islets with MSCs has the potential to help islet engraftment in the clinical setting (Yeung *et al.*, 2012).

T regulatory cells infusion

T regulatory cells (Tregs) are immune subpopulations of lymphocytes that can promote the tolerance of foreign particles and maintain immune homeostasis (Krzystyniak *et al.*, 2014). Regarding T1DM, Bluestone and colleagues demonstrated the ability to isolate and expand Tregs into newly diagnosed T1DM patients in an effort to repair or replace the native Tregs from autoimmune β cell destruction. (Gitelman and Bluestone, 2016; Bluestone *et al.*, 2015). Specifically for IT, Tregs cotransplanted with islets have been shown to help prevent autoimmunity and rejection of the islet engraftment (Marek *et al.*, 2011; Wu *et al.*, 2013). In the animal model, a localized cotransplantation with Tregs and islets within a kidney graft can significantly protract islet function and survival (Krzystyniak *et al.*, 2014). In the clinical setting, a ratio of 5:1, Tregs ($\sim 53 \times 10^9$ Tregs) to islets, can potentially induce the immunological tolerance during an IT (Tang and Bluestone, 2013). Tregs capability to regulate both the alloresponse and the autoimmunity make it an exciting addition in the employment of IT.

The Subcutaneous Space as an Alternative to Portal Vein Infusion

Intraportal islet infusion currently serves as the site of transplantation in the clinical realm. As previously noted, percutaneous infusion of islets into the portal vein has demonstrated the ability to regulate glycemic control in patients with brittle diabetes (Rajab, 2010). While the procedure itself is minimally invasive, it is not void of procedural risks and complications, including bleeding to portal vein thrombosis (Barshes *et al.*, 2005). Moreover, the initiation of inflammatory cascades through platelet activation and coagulation can confer significant islet loss. These events have propagated considerable experimental and clinical interest in identifying an alternative anatomical site for clinical islet transplantation. It is proposed that the ideal site for islet transplantation and subsequent engraftment should be in close proximity to vascular networks that supply physiologically sufficient oxygen and nutrients, as well as provide ample space to accommodate the necessary transplant volume. Furthermore, a site that can be easily monitored and is retrievable is also desirable, particularly if insulin-producing stem cells are to be transferred into clinical practice (Veriter *et al.*, 2013).

The translation of alternative transplant sites from experimental models to clinical practice has been met with considerable limitations. For example, the kidney capsule has demonstrated the ability accommodate a smaller islet mass capable of restoring euglycemia in rodent models, however when translated to humans, this site is clinically unfeasible, namely in that a greater transplant mass is required to restore glycemia in contrast to portal vein infusion. The subcapsular space is also considerably much more invasive and as such would present as less ideal from this perspective (Jindal *et al.*, 1998). Numerous additional transplant

sites have been explored experimentally, including the spleen, muscle and immune privileged sites, however, these sites have not conferred significant benefit. Within recent years, the subcutaneous space has garnered significant attention as an ideal site for islet transplantation for multiple reasons, including the ability to accommodate large transplant volumes, is easily accessible, and retrievable, if required. A primary limitation to the subcutaneous space is that it presents with poor blood supply, relative to the portal site, of which could compromise islet viability in the acute transplant period. As such, the utility of subcutaneous devices to promote neovascularization prior to islet infusion have been explored, and in some cases have been met with limited clinical success (Gala-Lopez *et al.*, 2016). Pepper *et al.* explores an effective means to exploit the foreign-body response, by creating a vascularized network in the subcutaneous space by the temporary transplantation of a medically approved vascular access catheter up to 4 weeks postimplantation. Removal of the catheter extinguishes the foreign body response, and the resulting void space is capable of accommodating the survival of human islets as well insulin-producing stem cells (Pepper *et al.*, 2015; Pepper *et al.*, 2017). This modified approach eliminates the need for long-term implantation of a subcutaneous device, while sufficiently correcting hyperglycemia in rodent models. Strategies aimed to utilize the subcutaneous space as an alternative site for islet engraftment holds significant promise for current and future clinical applications.

Alternative Cellular Sources to Ameliorate T1DM

Xenotransplantation

Since numerous islet infusions are often required to correct the consequences associated with T1DM, the identification of a xenogeneic supply of islets is an attractive alternative option to circumvent the need for human donor pancreases. This approach could provide an unlimited source of tissue to treat as many diabetic patients as required. One such xenogeneic option is the pig, a widely available source capable of producing insulin that is functional in humans. In 1994, Groth and colleagues presented the first clinical case where fetal porcine islet cell clusters transplanted under the renal capsule of a T1DM patient. This case demonstrated that these clusters were capable of surviving in patients as evidenced by sustained release of porcine C-peptide for many months, though unable to restore euglycemia and insulin-independence (Groth *et al.*, 1994).

Despite limited clinical success within the last decade, preclinical porcine islet xenotransplantation continues to garner enthusiasm. Of note, considerable progress using porcine tissue has been made in nonhuman primate models that utilize genetic donor manipulation and immunosuppressive protocols (Cardona *et al.*, 2006; Hering and Walawalkar, 2009; Hering *et al.*, 2006; van der Windt *et al.*, 2009; van der Windt *et al.*, 2012). For example, in immunosuppressed diabetic nonhuman primate studies where wild-type or genetically engineered porcine islets have been transplanted, the achievement of normoglycemia has been observed for more than 1 year posttransplant (Ekser *et al.*, 2016; Park *et al.*, 2015). Indeed, considerable efforts are currently being undertaken to establish highly monitored clean pig colonies to eliminate the potential for the transmission of zoonotic infections or endogenous retroviruses (Bottino and Trucco, 2015; Fishman and Patience, 2004; van der Windt *et al.*, 2012).

Efforts to transplant encapsulated neonatal porcine islets in nonimmunosuppressed diabetic patients are currently underway in New Zealand. Results from this clinical trial revealed only modest clinical outcomes, as a marginal reduction in hypoglycemic unawareness was reported (Matsumoto *et al.*, 2014). A second nationally regulated clinical trial in Argentina demonstrated improvements in HbA_{1c} with reduced hypoglycemic unawareness events up to 2 years posttransplant, though again only marginal reduction in insulin dose was observed (Matsumoto *et al.*, 2016). No risk of porcine endogenous retroviruses (PERV) was observed (Ekser *et al.*, 2016; Matsumoto *et al.*, 2016; Morozov *et al.*, 2017). Furthermore, the utilization of CRISPR-Cas9 can inactivate 62 copies of the PERV *pol* gene in a porcine kidney cell line and results in a >1000-fold reduction in PERV transmission to human cells (Yang *et al.*, 2015). Recently, PERV-inactivated pigs were successfully generated by Nui and colleagues and sheds light on the safety concern of the clinical application of porcine-to-human xenotransplantation (Niu *et al.*, 2017) Indeed, the results from this clinical trial made inroads in clinical islet xenotransplantation, however, further refinements to porcine islet xenotransplantation are necessary to advance large-scale clinical trials (van der Windt *et al.*, 2012).

Progress in gene therapy

Gene therapy is being explored both locally within transplanted islets to make them more robust, or systemically to transmute the native liver hepatocytes to secrete insulin. The possibility of genetically modifying islets to obviate immune rejection is an attractive approach, but current adenoviral vector strategies carry potential risk, and typically only affect the mantle islet cells and fail to reach the core. Application of adeno-associated viral vectors, herpes simplex viruses, retroviral vectors and other associated vectors have shown promise in rodent models (Wang *et al.*, 2011). To improve islet function, several factors must be considered, but decreasing the period to revascularization is beneficial for islet engraftment. To improve vascularization, an adenoviral transduced with VEGF-A has exhibited superior microvascular density and long-term survival in a mouse model (Zhang *et al.*, 2004a; Yancopoulos *et al.*, 2000). Likewise, Olerud and colleauges revealed that the utilization of a Thrombospondin 1 (TSP-1) knockout mouse model by RNA silencing can improve islet vascularizing (Olerud *et al.*, 2008). To help alleviate the occurrence of apoptosis prior to and postisolation can be foreseen by three different mechanisms; blocking the inducer, modulation of key proteins, and inhibiting effector caspases (Wang *et al.*, 2011). Key inhibitors for apoptosis proteins (IAPs), such as X-linked IAP has demonstrated its ability to restrain apoptotic cell death (Hui *et al.*, 2005).

Recent advances in genetic engineering and immunobiology have opened up the possibility of abrogating immune rejection through genome editing. An alternative approach to restore endogenous insulin production may be facilitated by viral vectors with transcriptional factors specific to β cell development, but transduced within non-β cells. Target transcriptional factors include

PDX1, NeuroD1, Neurog3, Nkx2.2, and Mafa. The ability to transfect alternative cell sources has been demonstrated in pancreatic exocrine cells (Li *et al.*, 2014), keratinocytes (Mauda-Havakuk *et al.*, 2011), adipose-derived stem cells (Lin *et al.*, 2009), and hepatocytes. Hepatocyte transduction represents a strong possibility as hepatocyte development shares similar embryological pathway development with the pancreas. The liver and pancreas both arise from the foregut endoderm with similar time in embryonic development and have similar glucose-sensing mechanism, such as glucokinase (GK) and glucose transporters 2 (Glut2) (Burcelin *et al.*, 2000). Diabetes has been reversed successfully in both rodent and large animal models using viral transfection (Dong *et al.*, 2001; Auricchio *et al.*, 2002; Calne, 2005; Alam and Sollinger, 2002; Chen *et al.*, 2008b; Gan *et al.*, 2016; Fodor *et al.*, 2007). Notable investigations from Calne *et al.* evaluate adeno-viruses, such as single stranded serotype 8 pseudotyped adeno-associated virus (ssAAV2/8) vectors, that encode human proinsulin in hepatocytes and demonstrate the ability to secrete human C-peptide and both improve and maintain euglycemia in an animal model (Gan *et al.*, 2016). These advances will escalate rapidly if a regulated glucose-sensitive insulin promotor and on/off control mechanisms could be built into the constructs.

An alternative approach is the application of a lentiviral transduction of the insulin gene into MSCs, such as primary canine MSCs, that demonstrate the ability to secreting insulin immediately and long term in vitro (Gautam *et al.*, 2016). Auto-transplantation could alleviate the necessity for immunosuppressive drugs since the cellular source is derived from the transplanted host, but factors such as unregulated insulin gene expression, surgical removal for biopsies, autoimmune destruction and possible teratoma limits its applicability, as do the possibility of autoimmune destruction from recurrent T1DM (Lee *et al.*, 2012). The ability to improve and utilize gene therapy may have important implications for the progression of diabetes management, but the lack of investigation to date may deprive its clinical potential.

Stem cell transplantation

Inroads in developmental biology and regenerative medicine have significantly contributed to research efforts currently underway to identify suitable islet precursor cells. Given that donor criteria, pancreas digestion and islet isolation can all contribute to compromised islet engraftment outcomes, the identification precursors with the potential to differentiate into an unlimited source of insulin-producing β-cells is an attractive approach to negate the need for pancreas donors. History has proven, however, that such a feat has been challenging to achieve; the ability to produce such cells capable of secreting insulin in a physiologically responsive manner whilst proliferating in a controlled manner (Bonner-Weir and Weir, 2005; Otonkoski *et al.*, 2005).

Considerable efforts have been undertaken to establish a renewable source of insulin-producing cells. For example, some approaches have been undertaken to exploit the pancreas's native ability to reestablish its β-cell population in response to injury by utilizing various transcription factors (Bouwens *et al.*, 2013; Zhou *et al.*, 2008). Others have sought to utilize cells derived from the hematopoietic lineage, including bone marrow-derived cells, as well as umbilical cord blood, as precursors to insulin-producing cells. Umbilical cord blood as a precursor is advantageous in that it can be easily obtained and would avoid some of the ethical implications associated with the use of stem cells. However, some animal studies utilizing hematopoietic lineages as a means to augment endogenous β-cell levels were inconclusive (Ianus *et al.*, 2003; Suri *et al.*, 2006). However, in a clinical study conducted by Haller and colleagues whereby newly diagnosed patients receiving autologous umbilical cord blood revealed lower HbA_{1c} and reduced insulin requirements (Haller *et al.*, 2008). Moreover, a study by Couri *et al.* revealed that newly diagnosed patients with T1DM infused with hematopoietic stem cells achieved insulin independence and exhibited elevated C-peptide levels (Couri *et al.*, 2009).

The self-renewing capacity and pluripotent properties of embryonic stem cells (ESCs) have warranted considerable research attention in recent years. Strategies to differentiate ESCs into insulin-producing cells have been underway since the early 2000s, and while initially promising, were met by impediments including low numbers of insulin-positive cells and a lack of glucose sensitivity (Assady *et al.*, 2001; Hori *et al.*, 2002; Lumelsky *et al.*, 2001; Soria *et al.*, 2000). Pivotal work in 2004 and 2006 laid the foundation to the development of effective strategies to differentiate human ESCs into pancreatic endoderm cells (PEC), containing both insulin and C-peptide (D'Amour *et al.*, 2006; Kubo *et al.*, 2004). Subsequent improvements resulted in the development of glucose-sensitive cells capable of restoring euglycemia in diabetic rodent models (Kroon *et al.*, 2008). Novel approaches have also been undertaken to differentiate human ESCs into pancreatic progenitor cells in vitro with final stages of differentiation into glucose-responsive, insulin-producing β cells in vivo (Bruin *et al.*, 2013; D'Amour *et al.*, 2006; Kelly *et al.*, 2011; Kroon *et al.*, 2008; Rezania *et al.*, 2012; Schulz *et al.*, 2012). Strategies to consistently produce PEC in sufficient quantities for clinical trials have also been developed (Schulz, 2015) with the capacity to restore normoglycemia (Pagliuca *et al.*, 2014; Rezania *et al.*, 2014).

Many of these seminal studies were paramount in the establishment of a US Food and Drug Administration- and Health Canada-approved, first-in-human pilot phase 1/2 clinical trial to be conducted by ViaCyte Inc., a commercial leader in regenerative medicine technologies. Approved in 2014, this trial sought to test the VC-01 combination product, which combines CyT49 hESC-derived PEC contained within an immune-protective, macroencapsulated device transplanted subcutaneously in a small cohort of patients with T1DM (NCT02239354). The results of this pilot study lead to further approval of a safety and tolerability study of Viacyte's PEC-Direct VC-02 combination product in patients with T1DM (NCT03162926). Further studies utilizing pancreatic progenitor cells transplanted into extrahepatic, subcutaneous devices will undoubtedly require further optimization and refinements to improve engraftment, oxygen delivery and metabolic exchange.

The prospect of establishing a limitless supply of glucose-responsive, insulin-producing cells as means for β-cell replacement therapy is undeniably attractive. Concerns pertaining to the risk of teratogenicity, as well as ethical and religious considerations over the use of ESCs warrant notable caution to proceed (Liu *et al.*, 2013; Werbowetski-Ogilvie *et al.*, 2009; Vanikar *et al.*, 2016). However, if such a product can be ethically derived from a donated, discarded human embryonic blastocyst from an in vitro

fertilization clinic, then the possibility to transition islet transplantation as a therapy for a select population of patients suffering from T1DM, to a β-cell replacement therapy for all.

Concluding Remarks

The main goal of IT is to stabilize glycemic control in patients at high risk of severe, recurrent hypoglycemia, that cannot be stabilized by other more standard means. Insulin independence is a desirable by-product of that process, but is currently often not sustainable long-term. IT has been shown to improve quality of life, and markedly reduce risk of hypoglycemia. Remarkable progress has occurred in this field, as documented in the recent reports of the Collaborative Islet Transplant Registry (CITR). Today, IT is an advantageous clinical procedure for patients with brittle T1DM and is covered by public or private health care services in countries like Canada, Australia, the UK, Switzerland, Italy, France, and other parts of Europe (Shapiro *et al.*, 2017). Recently, the NIH funded phase III multicenter trial in North America has confirmed IT as a safe and effective method that lead to the FDA approval for USA. Compared to whole pancreas transplantation, IT is a safer procedure to render insulin independence and glycemic control. Optimistically, IT has the future potential to serve as a feasible procedure for all patients with diabetes.

Hypoglycemic State, Nondiabetic☆

Pierre J Lefèbvre and André J Scheen, University of Liège, Liège, Belgium

Glossary

C peptide The peptide connecting the A and B chains of insulin in the proinsulin molecule; measured in the plasma C peptide is an index of endogenous insulin secretion.

Counterregulatory hormones Hormones released in response to hypoglycemia and contributing to raise blood glucose levels.

Factitious hypoglycemia Clandestine self-administration of insulin, a situation more frequently encountered in the relatives of diabetic patients, in the medical or paramedical profession, and sometimes in diabetic patients themselves.

Insulin The hormone released from the B cells of the islets of Langerhans; diabetes caused by lack of insulin; hypoglycemia caused by excess insulin.

Insulinoma Tumor developed from the B cells of the islets of Langerhans.

Islets of Langerhans Small group of endocrine cells making clusters (islets) in the pancreatic gland; represent about 1% of the mass of the pancreas.

Neuroglycopenia Neurological signs and symptoms associated with hypoglycemia.

Nesidioblastosis Neoformation of islets of Langerhans from pancreatic duct epithelium.

Introduction

Under physiological conditions, blood glucose is maintained within a given range, "normoglycemia," by remarkable regulatory mechanisms. In 30 healthy volunteers, ages 25 to 55 years, who were investigated by Marks, capillary blood glucose levels were determined 17 or 18 times a day during ordinary everyday life. The mean of all 498 blood samples was 4.2 $\pm$ 0.8 mmol/L. The lowest mean blood glucose of the day was 3.9 $\pm$ 0.6 mmol/L and was in samples collected at 17:00 h. The highest level was found in samples collected at 14:00 h and averaged only 4.9 $\pm$ 1.0 mmol/L. Blood glucose values of 3.0 mmol/L or less were recorded in 24 samples from 10 participants. In 14 samples (2.8%) collected in five participants, the concentration was 2.8 mmol/L (50 mg/dL) or less. Fully 95% of all blood glucose values were more than 3 mmol/L (54 mg/dL). These figures were recently confirmed by 24-h ambulant continuous glucose monitoring in young and middle-age individuals from the general population by Wijsman et al. In young individuals, minimum blood glucose was 3.45 mmol/L (95% C.I.: 3.10–3.70) and in middle-age individuals 3.59 mmol/L (95% C.I.: 3.40–3.78).

Hypoglycemia occurs when the blood glucose level is lower than the lowest limit of normal fluctuations (i.e., 2.8–3.0 mmol/L or 50–54 mg/dL). Such values have been confirmed in numerous experiments performed in healthy volunteers where mild hypoglycemia was induced using an insulin infusion. The threshold for symptoms in five different studies was precisely 3 mmol/L; the symptoms included weakness, difficulty in thinking and concentrating, diaphoresis, palpitations, and tremor. Neurophysiological testing, including reaction times, suggested a threshold between 2.2 and 3.5 mmol/L. Objective electrophysiological testing showed alterations between 2.4 and 3.0 mmol/L, with the exception of one study in which a response was already seen at 4 mmol/L. The remarkable study of Mitrakou and colleagues permitted identification of the various thresholds in the same 10 healthy volunteers submitted to progressively increasing insulin infusion rates. Activation of counterregulatory hormones (glucagon, epinephrine, norepinephrine, and growth hormone) began at arterialized venous plasma glucose levels of about 3.7 mmol/L. Autonomic symptoms (anxiety, palpitations, sweating, irritability, and tremor) began at 3.2 mmol/L, which was significantly lower. Neuroglycopenic symptoms (hunger, dizziness, tingling, blurred vision, difficulty in thinking, and faintness) and deterioration in cognitive function tests began at 2.8 and 2.7 mmol/L, respectively. There is a precise hierarchy of hormonal responses that remarkably maximizes the opportunity to avoid hypoglycemia. As depicted above, blood glucose values similar to those giving autonomic symptoms (3.2 mmol/L) and symptoms of neuroglycopenia or impairment of cognitive function (2.5–3.0 mmol/L) are sometimes observed in everyday life conditions in some individuals.

Various Forms of Nondiabetic Hypoglycemia, Diagnosis, and Treatment

There are two principal forms of hypoglycemia: (1) exogenous hypoglycemia attributable to the administration (injection or ingestion) of a hypoglycemic compound and (2) endogenous hypoglycemia.

This article is an update of Pierre J. Lefèbvre, André J. Scheen, Hypoglycemic State, Non-Diabetic, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 641-644.

 doi:10.1016/B978-0-12-801238-3.95801-X

Exogenous Hypoglycemia

Insulin is by far the most frequent cause of hypoglycemia. In nondiabetic as well as diabetic patients, insulin has been used for homicidal or suicidal purposes. Severe unexplained hypoglycemia in a nondiabetic individual should always raise the possibility of an exogenous insulin administration, either suicidal or criminal. Such cases are encountered more frequently in the medical milieu or in the families or neighborhoods of diabetic patients. Inadvertent insulin administration to a hospitalized nondiabetic patient has also been reported. Diagnosis of these conditions is often difficult. It requires the simultaneous demonstration of hypoglycemia, high plasma circulating insulin levels, and undetectable plasma C-peptide concentrations. In psychiatric patients, purposely induced insulin shock therapy sometimes leads to prolonged hypoglycemia and irreversible brain damage. Factitious hypoglycemia due to clandestine self-administration of insulin must always be considered in the differential diagnosis of hypoglycemia; again, this situation is encountered more frequently in the relatives of diabetic patients, in the medical or paramedical profession, or in diabetic patients themselves. Similarly, oral antidiabetic agents, mainly sulfonylureas, can be involved in the pathogenesis of hypoglycemia in nondiabetic individuals: inadvertent administration, accidental ingestion (mainly in children), suicide attempt, and clandestine ingestion (a variety of factitious hypoglycemia). Alcohol ingestion may lead to hypoglycemia if it occurs in fasting conditions while accidental intake of alcohol in children can also induce severe hypoglycemia. Sometimes, alcohol favors the "reactive hypoglycemia" following sugar ingestion (see below). Numerous other agents or drugs may induce hypoglycemia. In a systematic review of the literature, Murad et al. found 448 eligible studies that described 2696 cases of hypoglycemia associated with 164 different drugs. The quality of evidence supporting associations between drugs and hypoglycemia was mostly very low due to methodological limitations and imprecision. The most commonly reported hypoglycemia-associated drugs include salicylates, quinine, β-receptor blocking agents, pentamidine, mebendazole, isoproterenol, disopyramide, tranylcypramine, haloperidol, clofibrate, and, particularly, angiotensin-converting enzyme inhibitors (see **Table 1** for the most probable underlying mechanisms). Also note that all drugs that interfere with the metabolism of sulfonylureas could also induce hypoglycemia (not considered in the present section).

Endogenous Hypoglycemia

Endogenous hypoglycemia may be organic or functional.

Organic hypoglycemia

Insulinomas

Insulinomas are uncommon neoplasms, most often benign, that derive from the B-cells of the islets of Langerhans of the pancreas. An insulinoma should be suspected in any patient presenting with the triad described by Whipple: symptoms precipitated by fasting or exercise, proven hypoglycemia associated with symptoms, and relief of symptoms by glucose. The demonstration of endogenous plasma insulin (and C-peptide) levels inappropriate to the prevailing blood glucose level is the cornerstone of the diagnosis. Evidence of high circulating levels of proinsulin is confirmatory. Simultaneous determination of blood glucose and plasma insulin (and C-peptide) levels after an overnight fast and, mainly, during a 24- to 48-h fast is probably the best procedure to demonstrate relative hyperinsulinism. Before concluding on the presence of an insulinoma in case of low blood glucose associated with high plasma and C-peptide levels, factitious intake of sulfonylurea should be excluded with a sulfonylurea screen to avoid inappropriate imaging procedures and surgery. When one is convinced of the diagnosis, one attempts to localize the tumor before sending the patient to surgery. Preoperative localization procedures include tomodensitometry, conventional ultrasonography, selective arteriography, magnetic resonance imaging, ^{18}F-FDOPA PET/CT imaging, and (the most useful) endoscopic transduodenal ultrasonography. Surgical removal of the tumor is the first and obvious choice of treatment. It must always be accompanied by intraoperative ultrasensitive pancreas echotomography, particularly because there may be more than one tumor. In recent years, endoscopic ultrasound-guided ethanol ablation of insulinomas has emerged as a new therapeutic

Table 1 Most commonly cited drugs to be associated with hypoglycemia (outside antidiabetic agents) and most probable underlying mechanism

Drugs	*Increased insulin secretion*	*Increased insulin sensitivity*	*Miscellaneous effects*
Antibacterial sulfonamides	*		
Quinine/quinidine	*		
Pentamidine	*		
Disopyramide	*		
Fluoroquinolones (mainly gatifloxacin)	*		
Salicylates	*	*	
Beta-blockers (mainly nonselective)		*	
Angiotensin converting enzyme inhibitors		*	
Monoamine oxidase inhibitors		*	
Indomethacin			*

option, especially for elderly patients and candidates unfit for surgery, but the long-term effects of this procedure still need to be validated.

Medical management, mainly using diazoxide or somatostatin analogs, is reserved for patients who do not accept surgery or in whom major contraindications for the operation exist. Streptozotocin, in association with fluorouracil or doxorubicin, was considered to be the most effective antitumor agent for treating the rare metastatic malignant insulinomas, possibly after surgical reduction of the tumor mass and/or removal of liver metastasis. Other more modern therapeutic options may include targeted medical therapies using either mTOR inhibitors (everolimus) or small molecule inhibitors of the tyrosine kinase activity (sunitinib) (see review in Kinova, 2015).

Extrapancreatic neoplasms

Extrapancreatic neoplasms secreting insulin-like growth factor-2 (IGF-2), or a large form of it known as "big IGF-2," are usually large tumors present as masses in the mediastinum or the retroperitoneal space. They often have a mesenchymal origin but can originate from the liver, gastrointestinal tract, or pancreas or can be associated with lymphomas and leukemias. In these patients, hypoglycemia coexists with low or undetectable insulin and C-peptide levels, whereas high circulating levels of IGF-2 and related peptides are found, hence the recent proposal to label these neoplasms "IFG-2-omas." When feasible, surgery is the treatment of choice. When hypoglycemia persists after surgical interventions have reached their limits, several modalities have been employed and include glucocorticoids at increasing doses, and, experimentally antibodies against IGF-2 and specific IGF-2 antagonists (review in Dynkevich *et al.*).

Neonatal and infancy hypoglycemia

Numerous inborn errors of metabolism can induce hypoglycemia in neonates and young infants. They include hereditary fructose intolerance, fructose-1, 6-diphosphatase deficiency, phosphoenolpyruvate carboxykinase deficiency, some cases of galactosemia, and some of the 11 varieties of glycogen storage disease. Nesidioblastosis, now called "persistent hyperinsulinemic hypoglycemia of infancy" (PHHI), is a rare disease leading to persistent hypoglycemia of infancy. It is basically histologically characterized by the budding off from duct epithelium of endocrine cells and by the presence of microadenomas in the pancreas. The onset of symptoms of beta cell hyperplasia may occur during the first days of life but most commonly within the first 6 months. A few cases beginning with symptoms beyond 1 year of age have been reported. The group of Saudubray in Paris reported the features of 52 neonates with hyperinsulinism. Of these, 30 had diffuse B-cell hyperfunction and 22 had focal adenomatous islet cell hyperplasia. Among the latter, the lesions were in the head of the pancreas in nine, in the isthmus in three, in the body in eight, and in the tail in two neonates. Partial pancreatectomy has been successful in curing 19 of the 22 neonates in whom this procedure has been proposed. Recent studies have shown that congenital hyperinsulinism with focal or diffuse nesidioblastosis can be associated with several mutations affecting the beta cell such as the genes encoding for the sulfonylurea receptor, the glucokinase enzyme, the intramitochondrial enzyme glutamate dehydrogenase, the hepatocyte nuclear factor 4α (HNF-4α)… (see Review in Arya *et al.*). Medical treatment includes frequent feeding, diazoxide, and octreotide. Near-total pancreatectomy is often required.

Other causes of hypoglycemia during infancy (more functional in nature) include erythroblastosis fetalis, infants of diabetic mothers, leucine-induced hypoglycemia, ketotic or ketogenic hypoglycemia, maple sugar urine disease, and adrenal hyporesponsiveness.

Functional hypoglycemia

Alimentary hypoglycemia

Alimentary hypoglycemia can occur 1 to 2 h after a carbohydrate-rich meal in individuals who have had a gastrectomy or who, for other reasons, have rapid gastric emptying. It is believed that the rapid dumping of carbohydrates in the upper small intestine elicits an excessive insulin release mediated by both the release of intestinal gut factors (e.g., GLP-1, GIP) and a rapid rise in blood glucose. The treatment is identical to that of spontaneous reactive hypoglycemia.

Hypoglycemia complicating bariatric surgery

Consequent to the current obesity epidemics, bariatric surgery is worldwide performed with ever increasing frequency. Severe late postprandial hypoglycemia has been described in some patients after Roux-en-Y gastric bypass or duodenal switch. Continuous blood glucose monitoring in patients having undergone these procedures has shown frequent, but mainly, unnoticed, hypoglycemic episodes (Abrahamsson *et al.*). In a minority of patients (around 1%), hypoglycemia is severe. In some patients, postbariatric surgery hypoglycemia is associated with nesidioblastosis or even insulinoma. Better understanding of the mechanisms involved would make it possible to identify preoperatively those patients at greater risk of this complication. The recent study of Craig et al. has identified a critical role for GLP-1 in postbariatric hypoglycemia. In that study, GLP-1 receptor blockade with Exendin (9–39) prevented hypoglycemia in 100% of individuals studied, normalized β-cell function and reversed neuroglycopenic symptoms. Competitive antagonism at the GLP-1 receptor merits consideration as a therapeutic strategy in severe postbariatric surgery.

Spontaneous reactive hypoglycemia

Spontaneous reactive hypoglycemia is a poorly defined entity. The term is usually applied to a syndrome with the following features: (1) symptoms that resemble those seen in insulin-induced hypoglycemia (e.g., diaphoresis, tachycardia, tremulousness,

headache) but that often are accompanied by other symptoms less typical of hypoglycemia (e.g., fatigue, drowsiness, feelings of incipient syncope, depersonalization, irritability, lack of motivation); (2) symptoms that may be episodic, sometimes aggravated by carbohydrate-rich meals; and (3) plasma glucose concentrations that drop to 45 mg/dL (2.5 mmol/L) or less at one or more of the half-hourly samples taken in a 5- to 6-h glucose tolerance test. Abnormal insulin secretory patterns have been reported in some of these patients.

This entity has had a widespread vogue, particularly in the United States, over the past 40 years but has been said to be diagnosed more rarely elsewhere in the world. The American Diabetes Association and the Endocrine Society issued a joint statement to the effect that this entity is probably overdiagnosed. Indeed, the very existence of this condition has been called into question following several studies demonstrating that 25%–30% of apparently healthy individuals without any hypoglycemic symptoms may exhibit low plasma glucose values on being given a glucose load. Furthermore, the similarity of the symptoms to those of hyperventilation, and indeed to those of other functional syndromes, emphasizes the need to reevaluate the whole matter of so-called functional or reactive hypoglycemia. The question of cause and effect has not been settled. It would be reasonable at the current time to restrict the diagnosis of reactive hypoglycemia to individuals in whom hypoglycemic blood glucose levels are demonstrated in samples taken after the sort of meals that are said to induce their symptoms. Continuous blood glucose monitoring for a few days with precise recording of the allegated symptoms may be necessary. Furthermore, and as has been discussed by Lefèbvre, some patients have adrenergic responses after a meal or during oral glucose tolerance test without hypoglycemia. Such "adrenergic hormone postprandial syndrome" probably results from an altered glycemic threshold (a higher glucose level) for generating an adrenergic response. This results in confusion. A critical analysis of the reactive hypoglycemia syndrome can be found in the proceedings of an international symposium held in Rome in September 1986.

Diet is the first treatment of alimentary and reactive hypoglycemia. Simple sugars should be omitted and replaced by complex carbohydrates. If symptoms persist, small but frequent high-protein, low-carbohydrate meals should be tried. The pharmacological treatment of choice is α-glucosidase inhibitors such as acarbose and miglitol.

Alcohol-promoted reactive hypoglycemia

Alcohol-promoted reactive hypoglycemia can occur when insulinotropic sugars (e.g., glucose, saccharose) are ingested together with alcohol (e.g., beer, gin and tonic, rum and cola, whisky and ginger ale). Such mixtures should be avoided in susceptible individuals.

Other causes of functional hypoglycemia

Other causes of functional hypoglycemia include discontinuation of total parenteral nutrition, an endocrine deficiency state (glucocorticoid, growth hormone, or glucagon deficiency), severe liver disease, profound malnutrition, prolonged muscular exercise, the autoimmune insulin syndrome (where hypoglycemia is considered to be the consequence of inappropriate release of insulin from insulin–antibody complexes), and the rare syndrome of antibodies directed against the insulin receptor (where hypoglycemia is attributed to an insulinomimetic action of the antibody).

Conclusion

Hypoglycemia in nondiabetic individuals is not a rare condition. It is diagnosed when the blood glucose level is lower than the lowest limit of normal, that is, lower than about 3 mmol/L (or 54 mg/dL), a value also corresponding to the threshold for symptoms in various experimental studies performed in healthy volunteers in whom mild hypoglycemia was induced using graded insulin infusion. Hypoglycemia can result from the administration (injection or ingestion) of a hypoglycemic compound (e.g., insulin, oral antidiabetic agents, alcohol, various drugs). It can also be endogenous in nature. Organic endogenous hypoglycemia can be due to an insulin-producing tumor (insulinoma) or an extrapancreatic neoplasm. In neonates and young infants, hypoglycemia results mainly from various inborn errors of metabolism or of nesidioblastosis, now known as the syndrome of persistent hyperinsulinemic hypoglycemia of infancy, a condition in which several mutations in genes affecting the B-cell of the islets of Langerhans have been described. Functional hypoglycemia is called alimentary if it is due to gastrectomy or a too rapid gastric emptying or as a result of bariatric surgery. It is recognized as spontaneous reactive hypoglycemia if it occurs without any identified cause. Caution must be exerted in the diagnosis of this type of hypoglycemia. However, the diagnosis of reactive hypoglycemia can be made on the basis of a careful clinical and biochemical strategy. In such a case, simple therapeutic measures can be applied and the patient's quality of life can potentially be markedly improved.

Classification of Hyperlipidemias and Dyslipidemias

Jesús E Millán Núñez-Cortes, Gregorio Marañon University General Hospital, Madrid, Spain and Complutense University of Madrid, Madrid, Spain
Joaquín J Millán Pérez, Complutense University of Madrid, Madrid, Spain

Dyslipidemias are the main disorders of lipid metabolism and are typified by quantitative or qualitative changes in plasma lipoproteins. On the one hand, quantitative alterations are referred to increases or decreases in lipoproteins plasma concentrations (hyperlipidemias or hypolipidemias respectively). On the other hand, qualitative changes, which sometimes occur in isolation but are mainly associated with quantitative disorders, affect the composition of plasma lipoproteins as a consequence of modifications in their metabolisms (Ramasamy, 2016).

In most cases, both hyperlipidemias and hypolipidemias or qualitative changes in the composition of lipoproteins can be studied considering that the lipoproteins mainly affected contain cholesterol or triglycerides. As a consequence, cholesterol and triglycerides are the main biological markers of dyslipidemia and the frequent starting point for their studies.

The enormous importance of dyslipidemias with changes in the plasma concentrations of cholesterol and/or triglycerides is due to its potential association with cardiovascular diseases. In fact, it is considered that without the causal role of cholesterol it would be difficult to understand the vascular systemic affectation, origin of cardiovascular diseases, as the main cause of morbidity and mortality in our environment (Catapano *et al.*, 2016; Chapman *et al.*, 2011). Although the role of triglycerides has less impact on cardiovascular diseases, its role as an independent risk factor is out of doubt.

Furthermore, the study and analysis of the different lipoprotein fractions allows us to offer a clinical panorama that facilitates us the diagnosis and treatment of dyslipidemias. While chylomicrons (QL), very low-density lipoproteins (VLDL) and intermediate density lipoproteins (IDL) are families of lipoproteins rich in triglycerides, low-density lipoproteins (LDL) are rich in cholesterol.

In this way, the dyslipidemias most frequently associated with cardiovascular diseases are characterized by any of the following features:

- increase of cholesterol-rich LDL or its small and dense LDL particles phenotype;
- increase of triglycerides-rich VLDL;
- combined increase of LDL and VLDL (mixed dyslipidemia);
- decrease of apoAI-rich high density lipoproteins (HDL), responsible for the reverse cholesterol transport; and
- increase of apoB-rich lipoproteins (LDL, VLDL and remnant lipoproteins or IDL).

Classification of Dyslipidemias

Considering the combination between cholesterol and triglycerides plasma concentrations and different involved lipoproteins, the alterations in lipid metabolism has classified since almost 50 years ago (classification of phenotypes by Frederickson in 1970) as follows:

Lipoprotein increase	*Fundamental increase*	*Phenotype*
QL	Triglycerides	I
LDL	Cholesterol	IIA
LDL & VLDL	Cholesterol & Triglycerides	IIB
IDL	Triglycerides	III
VLDL	Triglycerides	IV
QL and VLDL	Triglycerides	V

QL, Chylomicrons; *LDL*, low density lipoproteins; *VLDL*, very low density lipoproteins; *IDL*, intermediate density lipoproteins.

However, a very accurate classification to assess an initial diagnostic with clear repercussions in the treatment is to combine the main affected fraction (cholesterol and/or triglycerides) with the origin of the alteration (primary or secondary).

Thus, the main primary hyperlipidemias to consider are the following:

1. Hypercholesterolemias
   a. Monogenic familial hypercholesterolemia
      i. Autosomal dominant
         1. Homozygous
         2. Heterozygous
      ii. Autosomal recessive

   b. Polygenic familial hypercholesterolemia
   c. Hyperlipoproteinemia (a)
   d. Hyperalphalipoproteinemia
   e. Sitosterolemia
   f. Cholesterol-7-alpha-hydroxylase deficiency
2. Hypertriglyceridemia
   a. Primary hypertriglyceridemia due to lipoprotein lipase (LPL), apoCII, apoAV, glycosylphosphatidylinositol-anchored high density lipoprotein-binding protein 1 (GPIHBP1) and lipase maturation factor (LMF1) genetic mutations.
3. Mixed hyperlipidemia
   a. Combined familial hyperlipidemia
   b. Familial dysbetalipoproteinemia
   c. Lysosomal acid lipase deficiency

In respect to secondary hyperlipemias, the main types are:

1. Hypercholesterolemias
   a. Hypothyroidism
   b. Nephrotic syndrome
   c. Cholestasis
   d. Drugs (cyclosporine, progestins, anti-HIV protease inhibitors, corticosteroids, thiazides)
   e. Acute intermittent porphyria
2. Hypertriglyceridemia
   a. Diabetes mellitus
   b. Obesity
   c. Metabolic syndrome
   d. Alcohol
   e. Chronic kidney disease
   f. Drugs (corticosteroids, beta-blockers, estrogens, thiazides, tamoxifen, antipsychotics, cyclophosphamide)
   g. Glycogenosis
   h. Lipodystrophies
   i. AIDS and treatment with antiretrovirals
   j. Cushing syndrome
   k. Pregnancy
   l. Acute hepatitis
   m. Connective tissue diseases (systemic lupus erythematosus)
   n. Stress, sepsis

Finally, we have to contemplate the small group of dyslipidemias clinically characterized by a decrease of cholesterol or triglycerides levels. These hypolipidemias are usually caused by specific mutations:

1. Hypocholesterolemias
   a. ApoCII deficiency
   b. ApoAI deficiency (hypoalphalipoproteinemia)
   c. Lecithin-cholesterol-acyl-transferase deficiency (LCAT)
   d. Lipoprotein lipase deficiency
   e. Glucocerebrosidase deficiency
   f. Tangier's disease
2. Hypotriglyceridemias
   a. ApoCIII deficiency
   b. Disfunction in lipoprotein lipase activity due to ANGPTL 3 and 4 genetic mutations

Most Common Primary Dyslipidemias

Familial Autosomal Dominant Hypercholesterolemia

As a consequence of its autosomal dominant hereditary pattern, it is transmitted to 50% of the offspring. The two clinical forms, homozygous and heterozygous, are composed by marked increases in total cholesterol and LDL cholesterol (LDL-C). Specifically, the homozygous form, which occurs in 1/300,000–600,000 individuals according to different populations, presents LDL-C ranges between 500 and 1000 mg/dL; whereas the heterozygous form, whose prevalence is 1/250–500 individuals, shows LDL-C figures between 190 and 500 mg/dL. In primary care, the clinical history may help us to detect first degree relatives with very high LDL-C levels. Moreover, familial hypercholesterolemia stigmas can be found in a clinical examination, being very characteristical their

clinical signs (tuberous and tendinous xanthomas in Achilles tendon, elbows, interphalangeal joints and knees; as well as corneal arcus at early ages) (Hopkins *et al.*, 2011; Civeira, 2004).

The incidence of cardiovascular disease, mainly coronary heart disease either in the affections or in first-degree relatives, is very high at an early age because the early deposition of cholesterol in the vascular tree. This can be recognized in a rigorous analysis of the family tree (Wiegman, 2015).

The cause of the disease is placed in a gene mutation, having detected in more than 90% of cases this alteration in the gene that codes for the LDL receptor located on chromosome 19, which means that its number and/or activity is greatly diminished and consequently the patient has an inability for plasma clearance of LDL particles (Hobbs, 1992; Goldstein, 2001; Rader *et al.*, 2003). While heterozygous cases may have a 50% clearance reduction, homozygous forms can express frequently less than 20% and even to very small activities (1%–2%) (Defesche, 2000; Raal and Santos, 2012).

Other less frequent cases are due to mutations in the apolipoprotein B or the PCSK9 (proprotein-convertase subtilisin-kexin type 9) genes (Innerarity *et al.*, 1987; Myant, 1993; Boren *et al.*, 2001; Abifadel *et al.*, 2003; Maxwell *et al.*, 2005). In the first case, the LDL particle cannot bind to the receptor even if it is undamaged. In the second, the PCSK9 activity, which intervens in the recycling of this LDL receptor, conditions its increased catabolism (Cohen *et al.*, 2006).

In all cases, the final result is the same. The LDL plasma concentration triking increase promotes the consequent rise of LDL vascular depositions, triggering the high incidence of cardiovascular diseases.

Autosomal Recessive Familial Hypercholesterolemia

Very infrequent recessive form of monogenic familial hypercholesterolemia (1/5 million inhabitants). It is due to a gene mutation that encodes the protein that facilitates the LDL receptor internalization after having bounded to the LDL particle (Soutar and Naoumova, 2004).

Polygenic Hypercholesterolemia

It is the most common primary hypercholesterolemia and shows moderately or frankly high levels of total cholesterol (not usually exceeding 300 mg/dL) or LDL (frequently less than 190 mg/dL).

It is a typical case of interaction between genetic factors and environmental factors, mainly those related to lifestyle. There are combined hypocatabolism elements (genetic) with an increase in cholesterol intake or synthesis (environmental).

Hyperlipoproteinemia (a)

The particular lipoprotein (a) has a specific apoprotein, apo (a), which, like LDL particles, is attached to apoB. This apo (a) molecule bears a strong resemblance to the plasminogen molecule, being able to compete for plasminogen activation and to cause hypofibrinolysis.

It is an inherited independent risk factor in a codominant manner, having been described up to different 30 isoforms, and it is associated with a high incidence of cardiovascular disease (Nordestgaard *et al.*, 2010).

Hyperalphalipoproteinemia

There is a mutation in the gene for the cholesterol ester transfer protein (CETP) or an increase in the synthesis of apoAI, the HDL fundamental apoprotein, causes an HDL cholesterol growth in plasma. In both cases, there is an evident rise in the HDL synthesis and its concentration, which reaches 100–200 mg/dL with regular levels in the LDL and VLDL fractions.

Although the cardiovascular risk in these patients is diminished, there is a controversy about the true protective role of very high HDL levels because, more than the quantity, it is basic to ensure a quality molecule in order to allow an adequate cholesterol reverse transport.

Sitosterolemia

It coexits an excessive intestinal absorption of cholesterol and plant sterols (sitosterol and campesterol), and a decrease in bile secretion. These cholesterol and sterol accumulations in different tissues motivate remarkable deposits, clinically represented by stigmas (tendon and corneal arc xantomas). Patients consequently have an increasing incidence of early cardiovascular disease (Escola Gil *et al.*, 2014).

The cause are located in genetical mutations of membrane transporters in the intestinal cells, whose modification produces an increasing cholesterol absorption, and in the hepatocytes, which entails a decreasing export to the biliary secretion. Nevertheless, the expression of the LDL receptor is secondarily modified.

Deficit of Cholesterol-7-Alpha-Hydroxylase

It is transmitted by an autosomal codominant manner, causing a reduction in the bile acids synthesis in the liver from cholesterol. As a consequence, there is an increase in the cholesterol hepatic deposits, the LDL receptor expression is frankly diminished and the LDL particles plasma clearance is finally reduced. According to this background, these patients logically present a higher cardiovascular risk and a higher incidence of cholelithiasis.

Primary Hypertriglyceridemia

The incidence of monogenic primary hypertriglyceridemia is approximately 1/1,000,000 individuals, manifesting triglyceride levels above 880 mg/dL (Chait *et al.*, 2000; Hegele *et al.*, 2014). The most severe hypertriglyceridemias are related to a pancreatitis elevated risk, while the more moderate hypertriglyceridemias (150–880 mg/dL) are accompanied by an increased cardiovascular risk (Valdivielso *et al.*, 2014) There are homozygous and heterozygous forms of different genetical alterations that determine diverse deficiencies in the triglycerides-rich lipoproteins metabolism (Lewis *et al.*, 2015).

Lipoprotein lipase (LPL) deficiency causes a hyperchylomicronemia, being affected the enzyme function of hydrolyzing the triglycerides in chylomicrons and VLDL; so that the organism disposes free fatty acids as an energy source. It is the most frequent cause of primary hypertriglyceridemia (Martin Campos *et al.*, 2014, Brahm and Hegele, 2015). There are discovered more than 100 mutations and, due to the severe hypertriglyceridemia, abdominal pain and pancreatitis episodes are very frequent. In the heterozygous forms, in which LPL activity is reduced approximately by half, moderate or even severe hypertriglyceridemia are developed when external factors coexist (alcohol, obesity, diabetes, high-fat diet) (Wang and Eckel, 2009).

ApoCII deficiency causes a partial or almost complete LPL activity decrease, bearing in mind it is its natural activator. Patients present severe hyperchylomicronemia and hypertriglyceridemia with pancreatitis and eruptive xanthomas episodes.

ApoAV deficiency is associated with IV and V hyperlipidemias phenotypes. The apoAV gene is linked to apoAI, apoAIV and apoCIII, a genes cluster with decisive influence on the triglycerides metabolism.

Glycosylphosphatidylinositol-anchored high density lipoprotein–binding protein 1 (GPIHBP1) deficiency causes a LPL transport protein defect towards the endothelial cell surface in the capillarie lights, difficulting its action on lipoproteins rich in triglycerides (Fong *et al.*, 2016, Ariza *et al.*, 2016). The homozygous forms present severe hyperchylomicronemia and hypertriglyceridemia, and pancreatitis and deposit stigmata episodes (lipemia retinalis and eruptive xanthomas), whereas the heterozygous forms may not show clinical manifestations.

Hepatic triglyceride lipase deficiency. Hepatic lipase (HL) is an important enzyme in the metabolism of triglyceride-rich lipoproteins and high density lipoproteins (Kobayashi *et al.*, 2015). Complete HL deficiency is a rare genetic disorder, inherited as an autosomal recessive or codominant trait. The absence of HL leads to pathologic levels of circulating lipoproteins and an increased risk of cardiovascular risk. HL deficiency is characterized by increased levels of triglycerides and cholesterol in the blood; and affected people may also have increased levels of HDL (Hegele *et al.*, 1993; Connely and Hegele, 1998).

Lipase maturation factor 1 (LMF1) deficiency, which is due to diverse mutations, affects the LPL activity being it an essential enzyme for its maturation.

Combined Family Hyperlipidemia

In this case, both different genes (polygenic primary hyperlipidemia) and environmental factors take part in its physiopathology. It is one of the most frequent hyperlipidemias, having a very variable phenotype and predominating hypercholesterolemia, hypertriglyceridemia or both (Brouwers *et al.*, 2012).

There is an increase in the lipoproteins rich in apoB and rich in triglycerides (VLDL) synthesis (Castro Cabezas *et al.*, 1993). These VLDL have a reducing plasma clearance motivated by a LPL decreasing activity. Its cardiovascular risk is very high because the apoB is characteristically increased, so that the LDL particles rate is boosted although its small size (small and dense LDL).

Familial Dysbetalipoproteinemia

It is consequence of an apoE genotype alteration, which has three possible isoforms (apoE2, apoE3 and apoE4) (Utermann *et al.*, 1975; Hopkins *et al.*, 2014). The specific apoE2/E2 modificated genotype shows a lower affinity for the LDL receptor to remaining particles, representing an infrequent 1% of apoE2 homozygous forms. As a result, VLDL and intermediate density lipoproteins (IDL) levels in plasma are very high, provoking that their cholesterol and triglycerides elevated concentrations are accompanied by an extraordinary elevation of cardiovascular risk (Marais *et al.*, 2014).

Lysosomal Acid Lipase (LAL) Deficiency

Not only is this enzyme responsible for hydrolyzing triglycerides to generate free fatty acids, but it does also for the colesterol esters in order to release cholesterol. Thanks to both constituent elements, fatty acids and cholesterol, the body manages to store energy and synthesize diverse structural (membranes) and functional (hormones and steroids) elements (Reiner *et al.*, 2014).

A LAL enzyme deficiency causes triglycerides and cholesterol esters lysosomal deposits (Fouchier and Defesche, 2013). As a result, the LDL receptors synthesis is upwardly regulated (up-regulation) and the colesterol intracellular deposits exponentially and perpetually increase.

The LAL gene mutations are autosomal recessive manner transmitted and its prevalence is low (1/200,000–300,000 individuals).

Most Frequent Secondary Dyslipidemias

Hypothyroidism

The hypercholesterolemia and hypothyroidism association is widely admitted. The mechanisms through which dyslipidemia can develop in the hypothyroidism are diverse (Shin and Osborne, 2003; Pearce, 2012):

- Thyroid hormone induces the cholesterol intracellular synthesis (by expression of the HMGCoAR enzyme), so in its absence the cholesterol hepatic synthesis is reduced.
- The LDL receptors expression is increased by thyroid hormone. Consequently, a low hormone level decreases the LDL plasmatic clearance.
- In hypothyroidism, there is a greater cholesterol intestinal absorption because the thyroid hormone modulates the intestinal expression of the protein Niemann-Pick C1-like 1.
- In these patients, the concentration and plasma activity of the cholesterol ester transfer protein are reduced.
- Hepatic lipase concentration and plasma activity are also dropped.
- Cholesterol reverse transport is declined due to a low ATP binding cassette A1 (ABCA1) activity.
- Lipoprotein lipase activity is diminished in hypothyroidism.
- Hepatic synthesis of bile acids from cholesterol is lessened.

Dyslipidemia associated with hypothyroidism is consistently global, affecting all lipoprotein families and having to highlight:

- Hypercholesterolemia with LDL-C increase.
- Hypertriglyceridemia with lipoproteins rich in apoB increase.
- Cholesterol efflux reduction due to dysfunctional HDL-C.

From the practical view and the high prevalence, it is always necessary to rule out hypothyroidism as secondary cause in the diagnosis of hypercholesterolemia. In addition, the previous correction of the thyroid disorder, regardless of the possible statin uses to reduce the cholesterol plasma concentrations, it will always be necessary.

Nephrotic Syndrome

Even though there is a global dyslipidemia, the most characteristic alteration is a total cholesterol and LDL-C increase. This is presented mainly for the increased hepatic synthesis and decreased plasma clearance confluence (Vaziri, 2003). Some of the involved mechanisms in the lipid metabolism disorder in nephrotic syndrome are:

- Acquired deficiency in the LDL receptor with the consequent increase in the cholesterol intracellular synthesis due to an increase in the HMGCoAR enzyme activity.
- Increase in the PCSK9 enzyme with a LDL receptor catabolism ensuing increase.
- Increased acyl-CoA-cholesterol acyl-transferase (ACAT-2) hepatic activity catalyzes the cholesterol esters formation from free cholesterol, thus increasing the LDL lipoproteins rich in cholesterol.
- Urinary loss in the lecithin-cholesterol acyl-transferase (LCAT) accompanying proteinuria.
- Decrease in the lipoprotein lipase (LPL) activity.
- Reduction in the 7-alpha-hydroxylase enzyme and the bile acids production, accumulating cholesterol secondary deposits.
- Increase in the Lp (a) synthesis.

The dyslipidemia plasmatic profile in nephrotic syndrome is consequently very varied (de Sain-van der Velden *et al.*, 1998):

- Hypercholesterolemia with increased LDL-C.
- Hypertriglyceridemia with increased VLDL.
- Increase in remnant lipoproteins with increased IDL.
- Increase in lipoprotein (a).
- Frequent decline in HDL-C with cholesterol inversed efflux reduction.

Diabetes Mellitus (DM)

Diabetes mellitus is a clinical model of accelerated atherosclerosis. In general, its frequent connection with risk factors, such as obesity, hypertension and dyslipidemia have to be considered, being very prevalent the association of some of them constituting the metabolic syndrome (Ascaso *et al.*, 1997).

Diabetic dyslipidemia is mainly characterized by increased triglyceride-rich lipoproteins (fasting and postprandial), decreased HDL-C and regularly or slightly increased small and dense LDL-C particles (Taskinen, 2002). The atherogenic triad, constituited by hypertriglyceridemia, low HDL and small and dense LDL is known as atherogenic dyslipidemia.

The fasting hypertriglyceridemia is explained because, in the mechanism of triglyceride production, the insulin resistance roles a determining factor conditioning the lipase activity in adipose tissue. This generates two facts, an increased supply of free fatty acids to the liver, which, once transformed into triglycerides, are heavily deposited (hepatic steatosis); and a VLDL release in excess from the hepatocytes. Otherwise, the postprandial hypertriglyceridemia is explicated because the triglycerides lipolysis, partly lipoprotein lipasa via, occurs thanks to its low action over the chylomicrons (Taskinen, 2003).

The increase of lipoproteins rich in circulating triglycerides is accompanied by an increased activity of the cholesterol esters transfer protein (CETP), whose mission is to exchange triglycerides for cholesterol between different lipoproteins. It means that LDL and HDL particles reduce their cholesterol contents by generating smaller and denser particles because their protein contents remain constant (Taskinen and Boren, 2015).

In diabetes mellitus type 2 individuals, given that their cardiovascular risk is high or very high, depending on whether or not there are previous cardiovascular diseases, the central interest is the diabetic dyslipidemia management (Valdivielso *et al.*, 2009). The primary therapeutic objective is to reach a LDL-C control and, secondarily, a triglycerides and HDL-C management. The LDL-C objective, when the characteristical atherogenic dyslipidemia is present, can be frequently replaced by the non-HDL cholesterol target (total cholesterol minus HDL-C) because it represents the authentic dimension of the atherogenic cholesterol set in all different lipoprotein families (LDL, IDL, chylomicrons, remnant particles). As in other mixed dyslipidemia cases occurs, treatment with hypocholesterolemic and hypotriglyceridemic drugs is usually a very effective therapeutic alternative.

Alcohol

The peculiar dyslipidemia associated with moderate or excessive alcohol intake is an hypertriglyceridemia with an increased triglyceride-rich lipoproteins (VLDL) (Bessembinders *et al.*, 2011). There is an involved combination of external factors, alcohol, and endogenous factors, genetic polymorphisms that condition the alcohol metabolism (Klop *et al.*, 2013).

The production mechanism is based on an increase in the fatty acids supply to the liver from adipose tissue due to a decreased peripheral lipolysis. This contributes to an increase in the triglycerides hepatic synthesis, to which is added a mitochondrial limitation for the oxidation of such fatty acids.

HIV Infection and Treatment With Antiretrovirals

In infected patients with the human immunodeficiency virus (HIV), hypertriglyceridemia is frequently found over and above decreases in LDL-C and HDL-C (Palacios *et al.*, 2003).

Although HIV infection itself is responsible for this dyslipidemia, the antiretroviral effect of treatments is much more determining. In practice, protease inhibitors treatments are proved to be commonly accompanied by atherogenic dyslipidemia, despite that the new generation drugs cause less metabolic changes.

When these circumstances appear, once the lifestyle measures have been optimized, treatment with drugs is required in order to reduce the cardiovascular risk associated with antiretroviral treatments (Santos *et al.*, 2005).

Atherosclerosis

Jesus A Araujo and Aldons J Lusis, University of California Los Angeles, Los Angeles, CA, United States

This chapter is reproduced from Jesus A. Araujo, Aldons J. Lusis, Atherosclerosis, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 288–294.

Glossary

Atherosclerotic plaque Deposit of lipids and cellular and fibrous elements in the artery wall.
Foam cells Lipid-engorged cells, mostly macrophages.
Infarction Tissue necrosis caused by hypoxia or anoxia resulting from insufficient or absent blood perfusion.
Ischemia Insufficient blood flow to satisfy the tissue metabolic needs.
Vascular thrombosis Thrombus formation frequently occurring at the level of an unstable atherosclerotic plaque.

Atherosclerosis is a chronic inflammatory disease characterized by the progressive accumulation of lipids and cellular and fibrous elements in large and medium-sized elastic and muscular arteries.

Introduction

Atherosclerosis is a vascular syndrome that is the primary cause of ischemic heart disease and stroke. In Western societies, it is the underlying cause of approximately 50% of total mortality. For many decades, it was considered a degenerative disease with no major potential for intervention, but it is better understood as a very dynamic, chronic inflammatory condition that is converted to an acute clinical event by the induction of plaque rupture leading to thrombosis, with a great potential for intervention. Epidemiological studies have revealed several important environmental and genetic risk factors. Work with genetically modified mice has made it feasible to experimentally examine mechanistic hypotheses, resulting in a clearer understanding of the cellular and molecular processes involved. Important tools for the management of the various clinical entities have been developed for diagnosis, risk stratification, and therapeutics. Risk factors can be classified as those with a strong genetic component and those that are mostly environmental (Table 1). However, approximately 50% of the casualties related to ischemic vascular disease are not explained by known pathogenic factors, posing a challenge to achieve a more complete understanding.

Pathogenesis

Progression of the Atherosclerotic Lesions

Stary described the microscopical evolution of atherosclerosis. The earliest stage (Stary I lesion), which is not apparent macroscopically, consists of subendothelial accumulations of lipid-loaded macrophages, called foam cells, and is found in 45% of infants up to 8 months of age. By puberty, it is common to see the classical "fatty streak" (Stary II lesions), visualized macroscopically with Sudan IV stain as a flat or slightly raised streak, consisting of lipid-loaded macrophages and smooth muscle cells containing lipid droplets and minimal, scattered, extracellular lipid. More advanced lesions include those with multiple extracellular lipid cores (Stary III lesion) that appear as a raised fatty streak or an atheroma (Stary IV lesion), characterized by a single confluent extracellular lipid core. By the third decade of life, fibrous lesions (Stary V lesions) appear when Stary III or Stary IV lesions are surrounded and/or caped by smooth muscle cells and collagen. These plaques can harbor calcification and areas of microthrombi in different stages of fibrotic organization. Different components of an advanced atherosclerotic lesion are shown in Fig. 1. The majority of acute coronary ischemic events occur as a result of plaque fissuring/ rupture, with exposure of the subendothelial matrix and the subsequent development of an occluding thrombus on the surface of the plaque.

Initial Events: Foam Cell Formation and Generation of the Fatty Streak

The events of atherosclerosis have been greatly clarified by studies in animal models, including rabbits, pigs, nonhuman primates, and rodents. Mice deficient in apolipoprotein E or the low-density lipoprotein (LDL) receptor develop advanced lesions and are the models most used in genetic and physiological studies. Fig. 2 depicts a model of the main events that occur in atherosclerotic plaque formation. The first observable change in the artery wall following the feeding of a high-fat, high-cholesterol diet is the accumulation of lipoprotein particles and their aggregates in the intima at sites of lesion predilection. LDL diffuses passively through endothelial cell (EC) junctions, and it is retained in the vessel wall, which seems to involve interactions between the LDL

 doi:10.1016/B978-0-12-812199-3.00160-2

Table 1 Genetic and environmental factors associated with atherosclerosis and CAD[a]

Factor	*Evidence*
Strong genetic component	
Elevated levels of LDL/VLDL	Epidemiologic studies, studies of genetic disorders, and animal models; Small, dense LDL particles are particularly strongly associated with CAD. Clinical trials have shown benefits of cholesterol reduction.
Reduced levels of HDL	Epidemiological studies, studies of genetic diseases, and studies of animal models.
Elevated levels of Lp(a)	Epidemiological studies: Animal studies have yielded both positive and negative results.
Elevated blood pressure	Epidemiological studies: Clinical trials have demonstrated benefits of blood pressure reduction, with a particularly strong effect on stroke.
Elevated levels of homocysteine	Epidemiological studies: Animal studies have been inconclusive.
Family history	Independent factor in nearly all studies.
Diabetes and obesity	Epidemiological and animal studies.
Elevated levels of hemostatic factors	Associations have been observed with elevated levels of fibrinogen, plasminogen activator inhibitor type 1, and platelet reactivity.
Depression and other behavioral traits	Associations have been observed in several studies. The results are complicated by associated traits.
Gender (male)	Men younger than 60 years of age develop CAD at more than twice the rate as women. Recent trials has raised concerns about the benefits of postmenopausal estrogen replacement.
Systemic inflammation	Elevated levels of inflammatory molecules, such as $sPLA_2$, or inflammation markers, such as CRP, are associated with CAD.
The metabolic syndrome	This cluster of metabolic disturbances, with insulin resistance as a central feature, is strongly linked to CAD.
Environmental factors	
High-fat diet	Population migration studies have revealed very strong associations with lifestyle, and diet appears to be the most significant factor. High-fat, high-cholesterol diets are usually required for development of atherosclerosis in experimental animals.
Smoking	Epidemiological studies: It has been estimated that approximately 30% of CAD deaths are due to smoking. Clinical trials have demonstrated benefits of cessation of smoking.
Low antioxidant levels	Antioxidants protect against atherosclerosis in experimental animals. However, clinical trials with antioxidants are mixed and are not conclusive.
Lack of exercise	A significant independent relationship has been. observed.
Infectious agents	Animal studies: Epidemiological studies have shown associations with various agents, such as Chlamydia pneumoniae. Clinical trials have been inconclusive.

[a]Abbreviations used: CAD, coronary artery disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

constituent apolipoprotein B (apoB) and matrix proteoglycans. In addition to LDL, other apoB-containing lipoproteins, namely lipoprotein(a) and remnants, can accumulate in the intima and promote atherosclerosis.

The buildup of LDL in the subendothelial space is determined by the rate of retention as well as the rate of influx. Trapped LDL is modified by oxidation, lipolysis, proteolysis, and aggregation. Lipid oxidation as a result of exposure to oxidative waste of vascular cells is the most significant modification. Such modifications initially give rise to "minimally oxidized" LDL species, which can stimulate the overlying ECs to produce a number of proinflammatory molecules, including adhesion molecules and growth factors such as macrophage colony-stimulating factor (M-CSF). The retention of LDL and the biological effects of the trapped LDL depend on the extent that they are oxidatively modified, which is related to the balance of pro-oxidant and antioxidant elements. Two important factors in the antioxidant repertoire are heme oxygenase-1 (HO-1) expression and high-density lipoprotein (HDL). HO-1 seems to be both an anti-inflammatory and an antioxidant gene. HDL is strongly protective against atherosclerosis, presumably because of its capacity to remove cholesterol from the vascular tissue and also to inhibit lipoprotein oxidation. The antioxidant properties of HDL derive in part from serum paraoxonase, an esterase carried on HDL that can degrade certain biologically active oxidized phospholipids.

Within days or weeks of diet initiation, monocytes can be observed adhering to the surface of the endothelium. The first step in adhesion, the "rolling" of leukocytes along the endothelial surface, is mediated by selectins that bind to carbohydrate ligands on leukocytes. The firm adhesion of monocytes to endothelium can be mediated by the integrin VLA-4 on these cells, which interacts with both VCAM-1 on the endothelium and the CS-1 splice variant of fibronectin. Monocyte chemotactic protein-1 and its receptor, CCR2, are also important in monocyte recruitment. Once present in the subendothelial space, monocytes are stimulated to proliferate and differentiate into macrophages, a process partly mediated by M-CSF.

LDL is extensively modified to generate the highly oxidized LDL by the action of reactive oxygen species and by several enzymes, such as lipoxygenases, myeloperoxidase, sphingomyelinase, and secretory phospholipase produced by the vascular cells. Oxidized LDL is then rapidly taken up by macrophages through their scavenger receptors, especially SR-A and CD36, to form foam cells. Macrophage scavenger receptor expression is regulated by peroxisome proliferator-activated receptor-g, an important transcription factor whose ligands include oxidized fatty acids, and by cytokines such as tumor necrosis factor-a, interferon-g (IFN-g), and M-CSF. Oxidized LDL can also inhibit the production of nitric oxide, a chemical mediator with multiple antiatherogenic

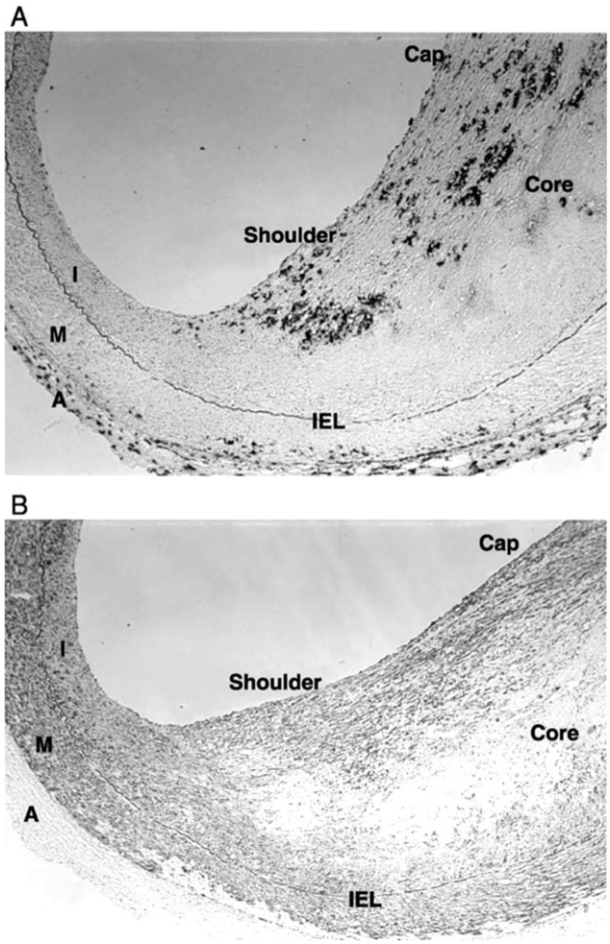

Fig. 1 Human coronary artery lesion. (A) All three main layers of the arterial wall are seen: Intima (I), media (M), and adventitia (A). The internal elastica lamina (IEL) clearly separates the intima from the media. The fibrous plaque core is rich in extracellular lipids and foam cells. Staining with mAb to macrophages (HAM56) allows visualization as dark infiltrates in the atherosclerotic plaque, prominent at the shoulder of the lesion. Notice the remarkable difference in the intima thickness between the neighbor normal arterial wall and the affected wall by the atherosclerotic plaque. (B) Staining with mAb to muscle actin (HHF35) allows visualization of the smooth muscle cells on top of the lesion core.

properties, including vasorelaxation. When sufficient foam cells accumulate in addition to extracellular lipid, a fatty streak lesion can be seen macroscopically by staining with Sudan IV.

Advanced Lesions: Progression to Fibrous Plaques and Complicated Plaques

The increasing number of macrophages and T lymphocytes secrete cytokines and growth factors (e.g., platelet-derived growth factor) that are responsible for smooth muscle cell (SMC) migration, proliferation, and extracellular matrix production. In addition to the growing mass of extracellular lipid, this leads to the formation of fibrous plaques.

Various factors contribute to the development of advanced lesions. The engagement of CD40–CD40L between all major vascular cell types results in the production of inflammatory cytokines, matrix-degrading proteases, and adhesion molecules. Elevated homocysteine levels appear to injure ECs and to stimulate proliferation of vascular SMCs. Activation of the renin–angiotensin system also stimulates SMC growth and the production of extracellular matrix. A vicious cycle of inflammation ensues as inflammatory conditions promote the retention and modification of LDL and increasingly more modified LDL stimulates inflammation.

As the atherosclerotic plaque grows, active intimal calcification, development of new vessels from the media, and rupture of vessels with resulting intramural hemorrhage or thrombosis may occur. The progressive and insidious growth of plaque burden into the lumen of the vessel leads to narrowing of the arterial lumen. When this reaches a critical level, ischemia occurs, causing various symptoms depending on the affected tissue.

However, it is the unstable plaque that ruptures and exposes its subendothelial components with subsequent thrombus formation that has the most significance, at least in the coronary arteries, and is responsible for the majority of myocardial infarctions. Plaque vulnerability is related to the fibrous cap thickness, which reflects the dynamics of matrix production and

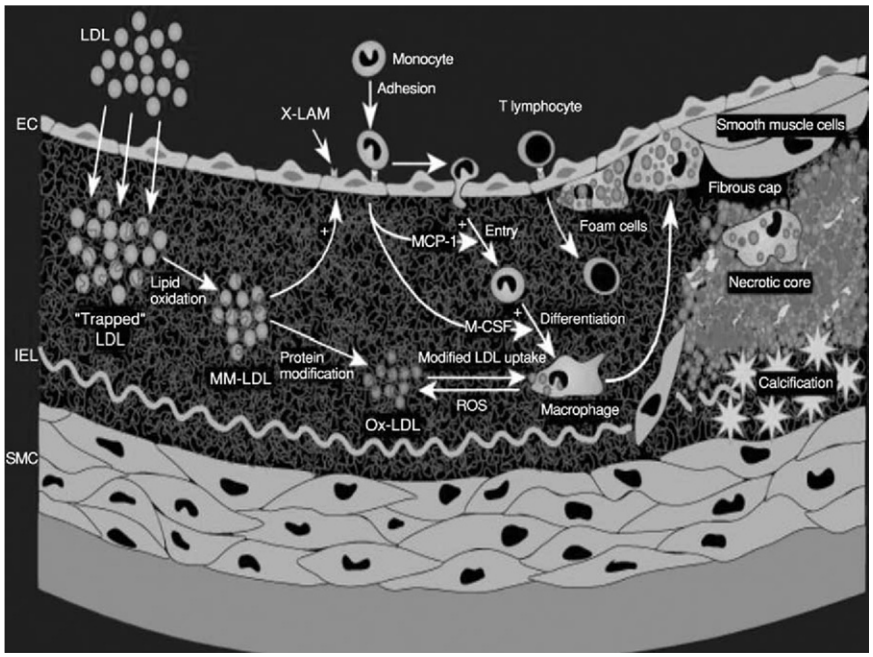

Fig. 2 Atherosclerosis model. The artery wall architecture has three main segments: The intima, from the endothelial cell (EC) monolayer to internal elastica lamina membrane (IEL); the media, consisting of smooth muscle cells (SMC); and the adventitia, which is the outer layer. Low-density lipoproteins (LDL) or other atherogenic lipoproteins enter and accumulate in the subendothelial space. Trapped LDL particles become oxidized probably as a result of interactions with reactive oxygen species (ROS) produced by vascular cells. Such minimally modified LDLs (MM-LDL) induce endothelial cells to express adhesion molecules for monocytes (X-LAM), monocyte chemotactic protein (MCP-1), and macrophage colony-stimulating factor (M-CSF), resulting in more recruitment of blood monocytes and subsequent differentiation into macrophages. With time, LDL particles become highly oxidized (Ox-LDL) and are then recognized by scavenger receptors on macrophages that endocytose them, giving rise to cholesterol-engorged foam cells. Such foam cells, the hallmark of fatty streaks, contribute to the development of advanced lesions by the production of various cytokines and growth factors that stimulate smooth muscle proliferation and fibrous cap formation. Calcification, hemorrhage, and thrombosis complicate plaques at advanced stages.

Table 2 Clinical manifestations due to atherosclerosis

Organ/system	*Clinical entity*
Heart	Coronary artery disease (stable and unstable angina and myocardial infarction) Congestive heart failure.
Central nervous system	Cerebrovascular disease (transient ischemic attacks and strokes).
Peripheral vasculature	Peripheral vascular disease (intermittent claudication, vascular insufficiency, and gangrene).

degradation. Vulnerable plaques generally have thin fibrous caps, increased numbers of inflammatory cells, and frequently rupture at the lesion edges where macrophages produce proteases that degrade extracellular matrix, including collagenases, gelatinases, and stromolysin. At the same time, matrix production by SMCs may be inhibited by IFN-g produced by T lymphocytes.

Clinical Manifestations

Atherosclerotic plaques may compromise the lumen of the vessels and obstruct blood flow to the respective tissue. Ischemia and/or infarction occur depending on the magnitude of the obstruction (partial, subtotal, or total), the duration of the obstruction, the time course (acute versus chronic), the collateral circulation, the degree of reversibility, and/or spontaneous reperfusion of the affected vascular territory. The most common clinical entities are shown in **Table 2**.

Atherosclerosis is a long and silent disease. By the time the patient presents with chest pain due to coronary artery disease or intermittent claudication due to arterial insufficiency, years and decades of lipid deposition and plaque progression have occurred. Atherosclerosis is a debilitating disease. Stroke and congestive heart failure due to ischemic cardiomyopathy incapacitate a large number of individuals, imposing an incredible burden on the patients, their families, and society in general. It is of extreme concern that the first manifestation is frequently sudden death, eliminating opportunities for intervention. Symptomatic patients may be fortunate in the sense that there is an opportunity for diagnosis, risk factor modification, and therapeutic intervention. It is clear that we cannot rely on the clinical manifestations for the diagnosis of these entities since it may be too late by then.

Assessment

In animals, assessment has been performed mostly by postmortem evaluation of atherosclerotic lesions that originate at different levels in the arterial vasculature (aorta, carotid, coronary or femoral arteries, etc.) under the defined experimental variables employed. The evaluation can be quantitative or qualitative and either at the macroscopic or at the microscopic level.

In humans, the situation is much more complex given the necessity of achieving a phenotypic characterization in vivo. Postmortem correlations can also be established and are useful, but they provide only a narrow view of the very dynamic and multifactorial process in question. When present, the specific clinical manifestations in the corresponding clinical scenario help in deciding which diagnostic modality to use. It is even more difficult to approach the asymptomatic individual. The same strategies used with clinical atherosclerosis have been used here, but often these miss the earlier stages of the disease, when preventive actions are desirable. Diagnostic modalities can be classified as invasive and noninvasive techniques. Invasive techniques, such as angiography (the gold standard) and intravascular ultrasound, offer the greatest degree of accuracy available, limited by cost and potential complications. Angioscopy allows direct visualization of the arterial wall, revealing plaque surface traits that are not representative of the internal heterogeneity of the plaque.

Noninvasive techniques can be classified as anatomic methods aimed at detecting the atherosclerotic plaque per se and physiologic methods aimed at detecting a physiologic abnormality created by impairment of blood flow in an arterial bed or impairment of vasodilation. Among the former, transesophageal echocardiography, electron-beam computed tomography, magnetic resonance angiography, and magnetic resonance imaging stand out. Among the latter, stress testing, coronary positron emission tomography, ultrasonic brachial vasodilatation, and the ankle–arm systolic blood pressure index techniques are commonly used. There is no one single and optimal method for phenotypic assessment, and the choice must be based on the specific indication.

Therapeutics

Table 3 lists various treatment strategies for atherosclerosis-related disorders, mainly coronary artery disease. These include drugs that improve symptoms or modify risk factors, invasive medical procedures, and surgical procedures. Some agents improve both symptoms and survival; for example, beta-blockers decrease cardiac work and myocardial oxygen demand by decreasing heart rate

Table 3 Strategies for Treatment of Symptoms or Improvement of Life Expectancy for Atherosclerosis-Related Disorders

Therapy	*Intervention*	*Mechanism*
Lipid-modifying drugs	Statins	Decrease LDL cholesterol, and/or increase HDL cholesterol, and/or decrease triglycerides (varies with the specific drug).
	Gemfibrozil	
	Niacin	
Antiplatelet drugs	ASA	Decrease platelet reactivity.
	Clopidogrel, ticlopidine	Decrease thrombus formation.
	Glycoprotein IIB–IIIA inhibitors	
Antithrombotic drugs	Thrombolytic agents	Lysis of thrombus.
	Unfractioned heparin	Decrease thrombus formation.
	Low-molecular-weight heparin	
Antiangina drugs	Beta blockers	Improvement of myocardial oxygen offer–demand balance.
	Nitrates	
	Calcium channel blockers	
Antihypertensive drugs	Diuretics	Blood pressure control.
	ACE inhibitors	
	Beta blockers	
	Calcium channel blockers	
	Alpha blockers	
	Direct vasodilators	
Antioxidant drugs	Vitamin E	Increase antioxidant reserve.
Interventional techniques	Angioplasty	Mechanical resolution of coronary and peripheral artery blockages.
	Stents	
	Catheter-based endarterectomy	
Surgical techniques	Coronary artery bypass graft surgery	Surgical bypass or repair of coronary, carotid, or peripheral artery blockages.
	Peripheral artery bypass surgery	
	Endarterectomy for carotid and peripheral arteries	
	Aortic aneurysm repair	

and cardiac contractility. Some agents improve symptoms without affecting mortality; thus, nitrates decrease cardiac work and oxygen demand by increasing venous capacitance, decreasing venous return, and decreasing cardiac volume preload. Also, some agents improve symptoms but may have harmful effects (e.g., short-acting calcium channel blockers).

The development of interventional cardiology in recent years has revolutionized the treatment of coronary disease. Angioplasty with or without stent placement is the customary choice of one- and twovessel coronary disease. It is particularly useful after medical therapy has been optimized without resolution of symptoms. With the better understanding of this disease and the development of better agents, surgical cases are decreasing in frequency.

However, cardiovascular disease is still the most common cause of death in the Western world. The known risk factors explain only about 50% of susceptibility to the disease. A better understanding of how to optimize therapy for the individual patient is required.

Genetic Dissection

Atherosclerosis is a multifactorial and complex disease. Risk factors can be classified as those with an important genetic component and those that are largely environmental (**Table 1**). Common forms of coronary artery disease result from the combination of genetic susceptibility and an unhealthy environment.

Rare mendelian forms, such as familial hypercholesterolemia and Tangier disease, have provided important insights into the disease. Studies of candidate genes associated with predisposing conditions, such as hyperlipidemia, low HDL levels, diabetes, hypertension, and pro-coagulant disorders, have revealed a number of genes with significant or suggestive association or linkage with traits relevant to atherosclerosis.

As a result of the genome project and large-scale sequencing, thousands of single-nucleotide polymorphisms are being identified and a catalogue of all common variations in humans will be generated during the next few years. It can be anticipated that profiles of genetic factors, perhaps in the form of risk haplotypes, can be generated and that individuals in the future may be screened for these and therapies may be tailored based on the particular risks for each individual.

New Venues

Active and intense research is being conducted at all levels, from the basic aspects of genetics and molecular and cellular biology to the development of better diagnostic resources and risk-stratifying tools and the formulation of better therapeutic strategies. In the middle of the great genomic revolution, as our understanding of the genetics of the disease grows, genetic diagnosis will become increasingly important. It is hoped that this will allow genetic screening for diagnostic and risk-stratification purposes, which will enable better assignment of management resources and adequate and tailored pharmacological therapy.

Conclusion

Atherosclerosis is a chronic inflammatory disease characterized by progressive accumulation of lipids and cellular and fibrous elements in large and medium-sized elastic and muscular arteries. Elevated cholesterol levels, especially in the LDL fraction, are a principal risk factor. Lipoprotein retention and oxidation in the vascular wall leads to endothelium activation, monocyte infiltration, foam cell formation, inflammation, and proliferation of smooth muscle cells. Subsequently, a necrotic core of lipid and cell debris develops and vulnerable plaques rupture, leading to thrombosis. Clinical manifestations result from ischemia and vascular thrombosis in the respective vessels, leading to myocardial infarction, stroke, vascular insufficiency, and gangrene of the extremities.

Various resources are available for diagnosis and risk stratification, but all are limited and far from ideal. Despite an array of therapeutic options tailored for the different clinical manifestations, better strategies are needed to stop or reverse the disease and to be able to adjust pharmacological agents to each individual. It is hoped that the genetic dissection of this syndrome will allow genetic diagnosis to support screening and tailored therapy.

Atherogenesis☆

L Badimon and V Llorente-Cortés, Cardiovascular Research Center, CSIC-ICCC Hospital Santa Creu I Sant Pau, Barcelona, Spain

Introduction

The American Heart Association classified the various stages of lesion progression into six phases and lesion types (**Fig. 1**). The first stage has been called arterial intimal thickening (AIT) (Type I) and starts with the migration of vascular smooth muscle cells (VSMCs) to the intima and the small accumulation of low density lipoprotein (LDL) and macrophages in the subendothelial–intimal space. Modified LDL is a chemoattractant for monocytes and VSMCs; these cells, by taking up modified LDL in a noncholesterol down-regulated manner, become foam cells initiating the fatty streak formation (Type II). The extracellular lipid accumulation coming from death cells besides the foam cells is characteristic of lesion Type III and lesion Type IV typical of the third decade of life. In more advanced lesions (Types V, VI, and VII), pathological changes occur in VSMCs of the media layer that contain a significant number of foam cells. In Type V lesions, several collagen layers cover the lipid core. These lesions may have a cap of VSMCs and extracellular matrix (ECM) covering the lipid core that modulates their susceptibility to rupture and thrombus formation. The successive accumulation of collagen fibers leads to a progressive lumen narrowing. During the fourth decade of life, lesions can rupture and trigger thrombotic depositions (Type VI lesions). During this stage, the formation of an occlusive thrombus can have dramatic effects. During the fifth decade of life, most of the lesions show an advanced stage and are composed mainly of calcifications (Type VII lesions) or fibrous tissue (Type VIII lesions).

Still not much is known about the disease initiation and progression, and the major risk factors can explain only approximately 50% of the coronary events found in humans. A major mystery in human atherogenesis is the well-known variation in lesion progression among individuals with similar plasma lipid profiles or risk factors. Furthermore, other factors affecting the molecular and cellular mechanisms in the arterial wall may be critical for the pathogenesis of the disease. Various findings suggest a diversity of agents that can induce endothelial injury, leading to a vascular response in a harmful chronic state. Besides LDL, cytokines and growth factors are important regulators of the inflammatory response, cellular growth, and lipid deposition. All of these processes are responsible for atherosclerotic plaque progression. During the final stages of the disease, arterial plaques become complex aggregations of lipids, ECM, and necrotic and apoptotic cells covered by a fibrous cap consisting primarily of smooth muscle cells surrounded by collagens and proteoglycans (PGs). The vulnerable plaques contain a lipid-rich core and a soft fibrous cap.

Role of Inflammation

It has been postulated that inflammation is involved in atherogenesis due to the observation that elevated levels of cytokines can be measured during acute coronary syndrome (ACS) presentation. In fact, one of the hypotheses for the

initiation of atherosclerosis is the so called "response to injury hypothesis" involving the response of the innate immune system to the accumulation and modifications of lipoproteins in the arterial intima. Various constituents of the modified lipoproteins trigger the production of mediators of innate immunity. There are also nonlipid mediators involved in inflammation such as homocysteine, angiotensin II, and microbial products that can induce the elaboration of cytokines from atheroma-associated cells. In normal circumstances, the endothelial monolayer in contact with flowing blood is inert to the adhesion of leukocytes. The situation changes in dysfunctional endothelium. One of the endothelial–leukocyte adhesion molecules involved mainly in the early adhesion of mononuclear leukocytes to arterial endothelium is the vascular cell adhesion molecule-1 (VCAM-1), which binds particularly those classes of leukocytes found in nascent atheroma: the monocyte and the T lymphocyte. In addition to VCAM-1, P-and E-selectin and intercellular adhesion molecule-1 (ICAM-1) also seem to contribute to leukocyte recruitment. As shown in **Fig. 2**, once the leukocyte adheres to the endothelium, it enters into the intima by diapedesis, a process that is facilitated by various chemokines such as monocyte chemoattractant protein-1 (MCP-1), interleukin-8 (IL-8), and a trio of CXC chemokines induced by interferon-gamma. Myeloperoxidase (MPO) has emerged as a potential participant in the promotion and/or propagation of atherosclerosis and other CVD. This enzyme present in activated neutrophils, monocytes and tissue macrophages, catalyzes the formation of reactive oxygen species (ROS). MPO and ROS are abundant in human atherosclerotic plaques and show increased expression levels in the infarct area after an acute myocardial infarction. High plasmatic MPO levels predict endothelial dysfunction and coronary artery disease while low plasmatic levels and certain specific MPO polymorphisms have been described as cardioprotective.

Macrophages are very versatile and, depending on the local microenvironment, can assume different phenotypes and functional characteristics, which is a reversible process termed "polarization". Distinct macrophage subtypes (M2 and M1) have been detected depending on the stage of atherosclerosis development. One differentiated, macrophages exhibit high levels of surface pattern recognition receptors which have the ability to take up modified LDLs, become lipid-laden and convert into foam cells. Many of these lipid-laden macrophages undergo apoptosis at early stages of atherosclerosis development and are promptly removed by M2 macrophages in a process referred to as efferocytosis. Nevertheless, excessive intake of apoptotic cells by macrophages may eventually stress the endoplasmic reticulum leading to the deterioration of efferocytosis, subsequent macrophage death and release of lipids, and pro-inflammatory/pro-thrombotic mediators.

One of the most important clinical markers of inflammation is the C-reactive protein (CRP), a marker of inflammation that has been shown in multiple epidemiological studies to predict incidencia of myocardial infarction, stroke, peripheral arterial disease, and sudden cardiac death. In terms of clinical application, some data indicate that CRP seems to be a strong predictor of cardiovascular events and adds prognostic information at all levels of calculated Framingham risk and at all levels of metabolic syndrome. The feature that distinguishes CRP from LDL cholesterol is the fact that inflammation (but

not elevated cholesterol LDL) plays a major role in nearly all processes associated with metabolic syndrome.

Acquired immunity, mainly dependent on T cells [T helper (Th) 1 and Th2] and antibodies, is also critically involved in the progression of atherosclerosis. In this regard, the cytokine IL-8 has been shown to orchestrate the immunological link between the innate and adaptative immune responses, enhancing atherosclerosis activity and progression.

Recently, the epigenetic regulation has been regarded as a plausible mechanism by which risk factors such as diet, environment of life style contribute to the atherogenic inflammatory response. DNA hypermethylation in the inflammatory mononuclear cells seems to be linked to predisposition to atherosclerosis. However, which genes are directly affected by DNA methylation remains to be determined. Other new players in the link between inflammation and atherosclerosis are microRNAs (miRNAs). miRNAs are endogenous nucleotides that bind to mRNA and induce translation repression. As an example, miR-143 and miR-145 play a crucial role regulating VSMC phenotypes and controlling neointima formation.

Role of Lipoproteins

Cholesterol is transported into the vessel well as a component of the lipoproteins. LDLs are considered the most atherogenic lipoproteins because they accumulate in the intima and carry large amounts of plasmatic cholesterol (up to 70%). The coronary risk lipid profile that uses the total cholesterol/high density lipoprotein (HDL) ratio (or the LDL/HDL ratio) predicts risk of vascular disease and is used as a tool for therapeutic management of patients at risk for vascular disease. Although these methods are predictive of coronary artery disease (CAD) in general, it is also well known that the extent of occlusive disease and CAD varies greatly among individuals with similar cholesterol and HDL lipid profiles. For this reason, the National Cholesterol Education Program Expert Panel revised these guidelines and recommends monitoring LDL and HDL in the context of coronary heart disease (CHD) risk factors and "risk equivalents."

High levels of circulating LDL have shown to be predictive markers of high risk of cardiovascular disease (CVD) in individual persons. It appears that discrete LDL subclasses carry various levels of atherogenicity. The "atherogenic lipoprotein phenotype" describes a combination of moderate hypertriglyceridemia, low HDL cholesterol, and a predominance of small dense LDL particles. This dyslipemia is prevalent in patients with metabolic syndrome, in those with Type 2 diabetes, and in postmenopausal women. In particular, small dense LDL particles have increased affinity by the proteoglycans of extracellular matrix, exacerbating LDL retention and modification. Besides small dense LDL particles, oxidized LDL glycated LDL, and electronegative LDL are increased in diabetes.

Oils, Lipoproteins, and Coronary Risk

Dietary fats and oils differ in the chain lengths of their constituent fatty acids and the number and geometry of their double bands. These differences markedly affect concentrations of lipids in plasma, and differences in the amount and type of fat in the diet can induce differences of 30 to 40% in serum LDL concentrations. **Table 1** shows the main saturated fatty acids (SFAs), monounsaturated fatty acids (MUFAs), and polyunsaturated fatty acids (PUFAs). When SFAs are replaced by unsaturated fats, total plasma cholesterol is lowered. A review of metabolic studies, prospective cohort studies, and clinical trials indicates that there are multiple mechanisms by which diet potentially influences risk of CHD, and there are dietary strategies that are effective in preventing CHD (**Table 2**). As such, the, substitution of nonhydrogenated unsaturated fats for saturated and trans fats; the increase in fruits, vegetables, nuts, and whole grains and the decrease in refined grain products are good strategies to prevent CHD. It has been recently reported that among persons at high cardiovascular risk, a Mediterranean diet supplemented with extra-virgin olive oil or nuts reduced the incidence of major cardiovascular events. These results are consistent with epidemiological studies reporting an inverse association between the Mediterranean diet or olive-oil consumption and incident stroke. It has been proposed that nutrients of the Mediterranean diet promote favorable changes in pathways involved in cardiometabolic risk, blood lipids, insulin sensitivity, resistance to oxidation, inflammation and vasoreactivity. Moreover, in an study focused on gene-diet interactions determining obesity, a genetic score including the *MC4R*rs17782313 and *FTO*rs9939609 variants was associated with body mass index (BMI), higher adherence to traditional Mediterranean diet was associated with lower BMI in genetically susceptible individuals. Mediterranean diet reduced genetic risk of these individuals. Both Mediterranean diets of PREDIMED trial were able to reduce the adverse events of the *TCF7L2*rs7903146 (C>T) polymorphism on intermediate cardiovascular risk factors and mainly on stroke incidence.

Free fatty acids (FFA) play a role in early steps of atherogenesis and have implications on the prevention and treatment of CVD. FFA increase the generation of ROS by the production of cytokines in mononuclear cells. FFA can also induced the activation of pro-inflammatory NF-kB pathway in human endothelial cells. To prove the clinical relevance of FFA, a group of healthy subjects received a 48-h infusion of low-dose lipid to increase plasma FFA to levels of obesity and diabetes. Plasmatic levels of endothelial activation biomarkers (ICAM and VCAM), systemic inflammation biomarkers (MPO) and thrombosis biomarkers (tPAI-1) were increased. These results provide direct evidence in human that mild short-term lipid-oversupply is sufficient to initiate early vascular abnormalities that may lead to atherosclerosis and CVD.

Modified Forms of LDL

Extracellular accumulation of lipids in the arterial intima occurs very early in response to increased plasma lipoprotein level. PGs and protein-bound lipoprotein particles, perhaps in a microenvironment shielded from plasma antioxidants, can undergo modifications. As shown in **Table 3**, such modifications include oxidation, aggregation, and enzymatic and nonenzymatic modifications of LDL. Modified forms of LDL are associated with increased atherogenicity because the physicochemical properties of the lipoprotein become altered. These changes in the biological properties of the LDL increase LDL susceptibility to other types of modifications.

Cellular Effects of Modified LDL

Endothelial dysfunction

Hypercholesterolemia induces an increase of leukocyte recruitment by a higher expression of adhesion molecules, a decreased endothelium-dependent vasodilatation, and alterations in the thrombosis/fibrinolysis balance. Our group has demonstrated that

systemic hypercholesterolemia can induce endothelial dysfunction by altering the expression of genes that are regulated through the down-regulation of sterol regulatory element-binding proteins (SREBPs) in endothelial cells

Synthesis and degradation of extracellular matrix

Modified LDL can modulate the synthesis of PGs in various cell types. The increase of PG synthesis induced by LDL might have important consequences for the intimal LDL retention. In addition, the exposure of endothelial cells to apolipoprotein E (apoE)-containing HDL has been shown to stimulate the production of heparan sulfate proteoglycans (HS-PGs) that have increased sulfation. Intracellular lipids derived from modified lipoprotein uptake reportedly inhibits Src-dependent assembly of fibronectin and Type I collagen in vascular smooth muscle cells. VSMC-intracellular lipids also provoke crucial alterations in VSMC-tropoelastin levels, mechanical properties and elastin capacity to breakdown. Taken together, these results point to lipid-loaded VSMC as crucial players in extracellular matrix alterations during atherosclerosis.

Lipoproteins also modulate the expression of metalloproteinases (MMPs), enzymes that digest various connective tissue components. An increase in metalloproteinase expression and activity is associated with the disruption of the fibrous cap of lesions and plaque rupture. In addition, the ECM break-down products may be biologically active and might increase processes that are fundamental for the pathogenesis of the atherosclerosis. By modulating metalloproteinase activity, LDL may modulate VSMC migration. Atherogenic concentrations of both native and modified LDL have been shown to significantly reduce the migratory capacity of human VSMC.

Mononuclear Cell Recruitment

Modified LDL particles induce endothelial secretion of chemotactic substances and the expression of adhesion receptors including integrins and selectins that favour leukocyte (monocyte and T-cell) recruitment, adhesion, and transmigration into the arterial wall (**Fig. 2**). This is caused by simultaneous expression of different chemotactic and adhesion molecules suggest through a common transcription factor, nuclear factor-kb (NF-kb). For instance, the chemokine monocyte chemoattractant protein (MCP-1) interacts with monocyte receptor CCR2 recruiting the monocytes tohe endothelial layer favouring their entry by diapedesis. Transmigration of monocytes preferably occurs in areas where the basal lamina is enriched with modified LDL particles and takes place mainly through the junctions between endothelial cells. Junction adhesion molecule (JAM)-A and C have been shown to be involved in the control of vascular permeability and leucocyte transmigration across endothelial-cell surfaces.

Foam Cell Formation

Modified lipoproteins are taken up through mechanisms not regulated by cholesterol, leading to high intracellular cholesteryl ester accumulation and foam cell formation. The accumulation of lipid-laden foam cells is one of the earliest steps in the progression of the atherosclerotic plaque. In macrophages, the SRs are mainly responsible for modified LDL uptake. One monocytes reach the intimal space, colony-stimulatinf factor (CSF) induces monocytes to phenotypically transform into macrophages and begin the uptake of modified lipoproteins. Macrophage-related mechanisms and receptors include scavenger receptor class A (SRA)-I and SRA-II, CD36, LOX-1, or CXCL16 for oxidized LDL. For aggregated LDL, the main receptor involved in its uptake by macrophages is low density lipopoprotein receptor-related protein (LRP1). Macrophages become foam cells through the uptake of diversely modified LDLs, whereas the aggregation of LDLs (agLDL) seems to be a key condition for lipid accumulation in VSMCs. AgLDLs obtained by vortexing LDL in vitro share structural characteristics with LDL aggregates present in atherosclerotic lesions. Our previous results demonstrate that hypercholesterolemia might increase the capacity of VSMCs to take up LDL from the intima by regulating cellular low density lipoprotein receptor-related protein 1 (LRP1), the receptor for agLDL uptake in human VSMC.

Most of the modified lipoproteins could lead to a progressive cholesteryl ester accumulation, not only by being taken up through non-down-regulated receptors but also by up-regulating their own receptors. Besides hypercholesterolemia, other cardiovascular risk factors such as hypertension or hypoxia strongly upregulate LRP1 expression in cultured VSMC and in the vascular wall of in vivo models. Transcription factors including sterol regulatory element binding proteins (SREBPs) and hypoxia-inducible factor-1 (HIF-1a) mediate the up-regulatory effects of hypercholesterolemia and hypoxia on LRP1 expression, respectively.

Lipoproteins and Metabolic Syndrome

Metabolic syndrome was defined by the National Institutes of Health in 2001 as a cluster of disorders that include abdominal obesity, insulin resistance, diabetes, endothelial dysfunction, elevated blood pressure, and impaired fibrinolysis. The risk factors that constitute metabolic syndrome consist of atherogenic dyslipemia, elevated blood pressure, elevated

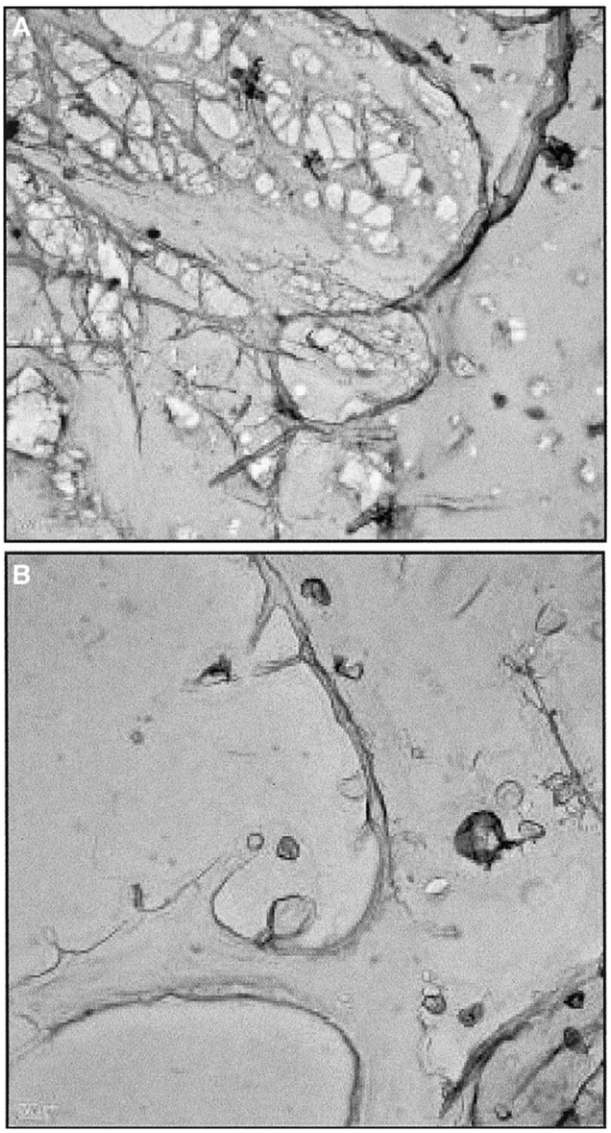

Fig. 3 Extracellular matrix ultrastructure of VSMCs. Cells were washed, fixed, and processed for freeze-drying and replication in electron microscopy. (A) Nonenzymatically treated human VSMCs. plasma glucose, and a prothrombotic state. Metabolic syndrome is closely linked to the metabolic derangement called insulin resistance. This condition is characterized by a generalized defect in the insulin-signaling pathway. Because insulin induces a myriad of metabolic responses, a defect in insulin signaling results in several metabolic changes. The presence of insulin resistance predisposes to the development of Type 2 diabetes. There are four major causes of insulin resistance: genetics, obesity, lack of exercise, and diet composition. Insulin resistance and metabolic syndrome are related to the atherogenic dyslipemia also called "atherogenic lipoprotein phenotype," which is characterized by increased triglyceride-rich lipoproteins, increased small LDL particles, and reduced HDL levels. These changes in lipoprotein and fatty acid profile observed in insulin resistance may influence various proatherosclerotic mechanisms such as membrane lipid composition, metabolism, and signal–transduction pathways. In insulin-resistance patients, there is an increase in plasma small, dense, electronegative LDL [LDL(−)]. LDL(−) has been defined as a pool of LDLs modified by different mechanisms presenting pro-inflammatory activity, reduced affinity to the LDL receptor and increased binding to arterial proteoglycans, among other properties. LDL(−) induces a plethora of deleterious effects on several cell types involved in atherogenesis including the release of cytokines by endothelial cells, monocytes and lymphocytes, the impairment of endothelial progenitor cell differentiation, endothelial apoptosis and platelet activation. Under normoxic conditions, LDL(−) raises intracellular NEFA and TG levels, and upregulates Perilipin5 (Plin5) expression in cardiomyocytes. However, under hypoxia, LDL(−) delivers

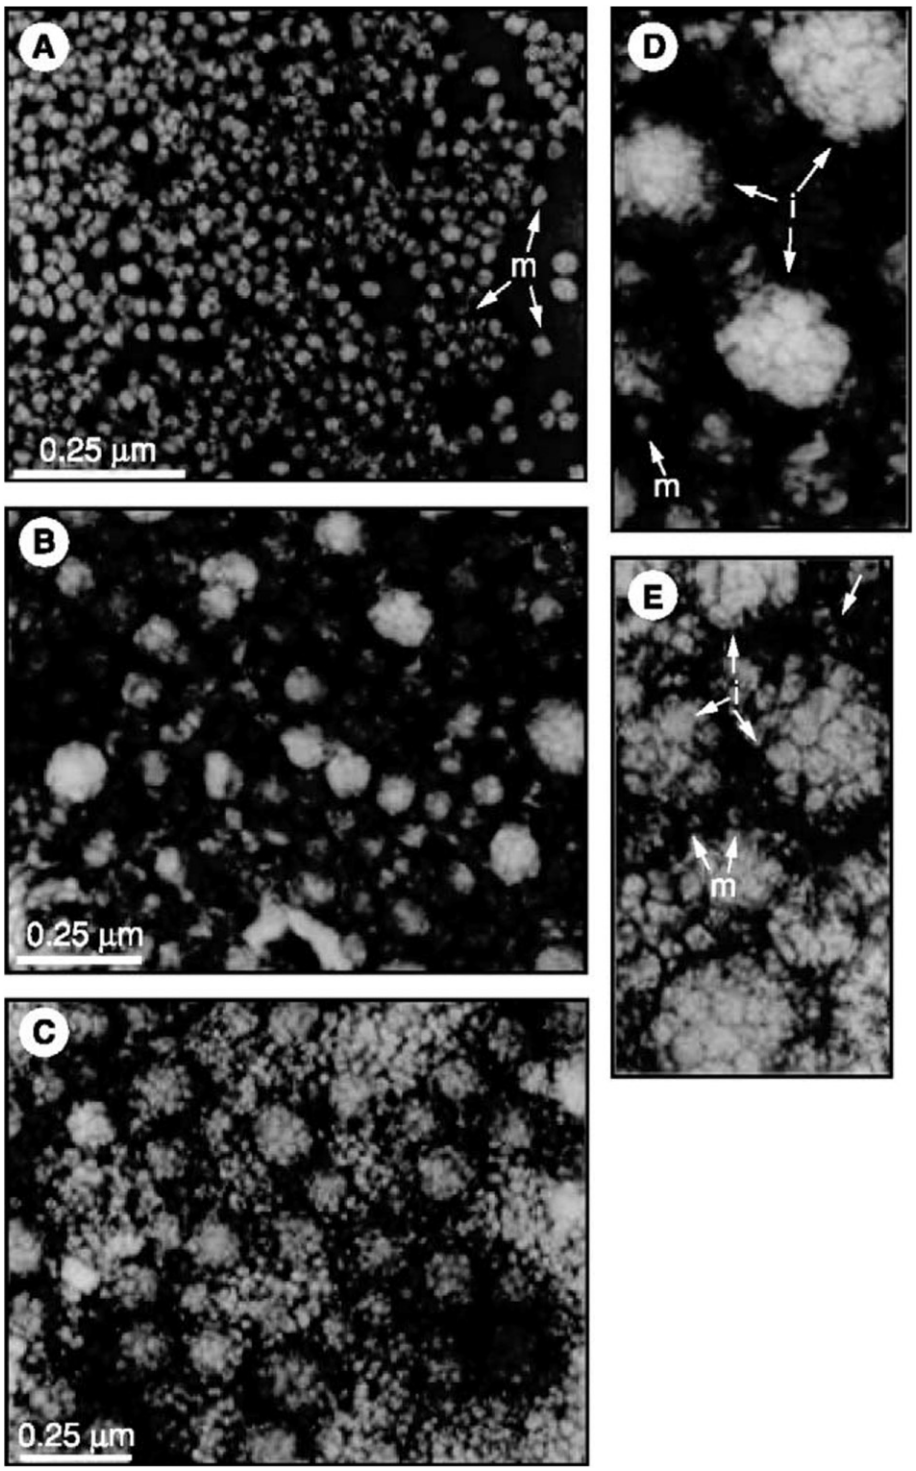

Fig. 4 Electron microscopy of nLDL, agLDL, and versicanmodified LDL. (A) nLDL. (B) Precipitable fraction from vortexed LDL. (C) Precipitable fraction from versican LDL. increased amount of NEFAs to cardiomyocytes and induces higher intracellular TG accumulation but, in contrast, fails to induce Plin5 expression. As a consequence, combined LDL(–) and hypoxia favours a high intracellular NEFA content and promotes ROS production in cardiomyocytes.

Role of the Various Components of the Vascular Wall

Extracellular matrix

The ECM of the arterial intima is a relatively large compartment made of collagen, elastin, complex PGs, hyaluronate, and multidomain proteins such as fibronectin, laminin, and tenascin (**Fig. 3**). The ECM occupies 60% of the arterial intima and regulates numerous cellular functions. The main PGs structuring the ECM are chondroitin sulfate (CS)-PGs, such as versican and biglycan, which have the longest negatively charged glycosaminoglycan (GAG) chains and are synthesized mainly by VSMCs. HS-PGs, such as perlecan, are constituents of the basement membrane and are synthesized mainly by endothelial cells and VSMCs. In addition, other HS-PGs, such as syndecan and glypican, are found in the cell membranes of the vascular cells. Whereas CS-PGs play a major role in LDL retention in the arterial intima, cell surface HS-PGs are dynamic molecules that mediate ligand catabolism. Collagens play a central role not only in maintaining the integrity and stability of the wall but also in many cellular functions.

Heparan sulfate proteoglycans

HS-PGs consist of a protein core and at least one heparan sulfate side chain. HS-PGs can be secreted (perlecan) or shed from the cell surface (perlecan, syndecan, and glypican). Syndecan and perlecan can function as receptors for several growth factors and lipoproteins. HS-PGs act as a receptors for basic fibroblast growth factor (bFGF), which stimulates VSMC proliferation. They may act as potential receptors for atherogenic lipoproteins, such as apoE–triglyceride rich lipoprotein particles and lipoprotein lipase, or may facilitate the uptake of ligands by a process called ligand transfer to lipoprotein receptors, such as the LRP1.

Chondroitin sulfate proteoglycans

CS-PGs are considered to be atherogenic due to their ability to trap and aggregate cholesterol-rich lipoproteins. Because one of the key initiation events in early atherogenesis is the subendothelial retention of atherogenic lipoproteins, CS-PGs play a main role in the initiation of atherogenesis ("response to retention" hypothesis). Apoproteins have been found to colocalize with specific PGs in human atherosclerotic plaques, providing support to the "response to retention" hypothesis. Several studies demonstrate that CS-PGs act as sites for apoB-100 lipoprotein retention by the interaction between positively charged heparin-binding domains on apoB-100 or apoE and negatively charged GAG chains of the PGs. The GAGs of versican induce alterations in the LDL particles that facilitate oxidative enzymatic modification, fusion, and aggregation of LDL particles. **Fig. 4** shows an electron microscopy image of versican modified LDL in comparison with nLDL and agLDL. Versican clearly induces the aggregation of LDL particles. Aggregation substantially increases its binding to arterial PGs due to the creation of a multimeric ligand with better exposure of key positive residues on apolipoprotein B. Modified LDL is avidly taken up by macrophages and VSMCs, leading to foam cell formation. In addition, some CS-PGs such as decorin, a small DS/CS PG, regulate cell growth and growth factor activity.

Collagen

Collagen is the major component of the ECM of the vessel wall and has a critical impact in atherogenesis. Collagen is essential for the maintenance of vessel wall integrity and elasticity. Collagen is involved in the process of cell differentiation, adhesion, migration, proliferation, and apoptosis. It has been reported that the bulk of vascular collagen is produced by smooth muscle cells.

Table 4 Factors synthesized by the endothelium

Factors	*Process*	*Contribution*
PDGF	Growth	Stimulator
TGF-β		Inhibitor
Heparin-like GAG		Inhibitor
NO	Vasodilatation	Stimulator
Endothelin		Inhibitor
Angiotensin II		Inhibitor
TF	Thrombosis	Stimulator
Trombomodulin		Stimulator
vWF		Inhibitor
t-PA	Fibrinolysis	Stimulator
PAI-1		Inhibitor
Prostacyclin	Others	
E-selectin, P-selectin, ICAM-1, VCAM-1. IL-1, IL-6, IL-8, MCP-1, GM-CSF		

However, collagens can also be produced by endothelial cells, adventicial fibroblasts, and macrophages. Among the 19 collagens described, 13 are found in the vessel wall or are expressed by cells of the vessel wall in vitro. The most abundant are Type I and Type III collagen, which form an interconnected network of cross-banded fibers along with smaller amounts of Type VI and Type VIII collagen, associated with the fibers and the elastic lamellae in the blood vessel wall. Type I and Type III collagen seems to play an important role in arterial wall remodeling in response to hypertension. It has also been reported that Type I collagen expression was localized mainly in the adventicia, outer media, and intima and that Type III collagen expression was uniformly localized across the arterial wall in response to an elevation of blood pressure. Type III collagen accumulates in atherosclerotic lesions, and in various in vitro studies in cultured endothelial cells. The involvement of Type VIII collagen in processes of endothelial differentiation and organization and in vitro angiogenesis has been demonstrated.

Cellular Components

Endothelium

In health, the vascular endothelium forms a multifunctional interface between circulating blood and the various tissues and organs in the body. It constitutes a selectively permeable barrier for macromolecules as well as a nonthrombogenic surface that actively maintains the fluidity of blood. The endothelium is a complex and dynamic organ that responds to environmental stimuli and activates vasoactive substances, including vasoconstrictors such as angiotensin II and vasodilators such as nitric oxide (**Table 4**). These vasoactive substances mediate vascular tone, structure, and function influencing

VSMC growth, apoptosis, platelet aggregation, monocyte and leukocyte adhesion, and thrombosis. The homeostasis of vasoactive substances is disrupted by endothelial dysfunction, leading to changes in vascular structure and function. Hypertension and other risk factors for CVD are associated with endothelial dysfunction and vascular remodeling. Elevated angiotensin II activity, which is strongly correlated with hypertension, is a major trigger of endothelial dysfunction in hypertensive patients. Angiotensin II stimulates nicotinamide adenine dinucleotide phosphate (NADPH)/ nicotinamide adenine dinucleotide (NADH) oxidase in the endothelium, VSMCs, and adventicia of blood vessels to generate reactive oxygen species, leading to endothelial dysfunction, cell growth, and inflammation. These changes result in up-regulation of endothelin-1, adhesion molecules, nuclear factor-kB (NF-kB), and other inflammatory mediators as well as increased breakdown of nitric oxide and uncoupling of nitric oxide synthase. Thus, the balance of vasoconstriction and vasodilation

is disrupted, with resultant vascular remodeling and injury. Through these processes, endothelial dysfunction aggravates existing hypertension, accelerating the progression of atherosclerosis. Endothelial dysfunction is now recognized as a key early risk factor for cardiovascular morbidity and mortality. Certain consequences of endothelial dysfunction are directly related to the pathogenesis of atherosclerosis and its complications. Pathophysiological stimuli of arterial endothelial dysfunction that are especially relevant to atherogenesis include activation by cytokines and bacterial endotoxin, infection by viruses, advanced glycosylation end products that are generated in diabetes and with aging, hyperhomocysteinemia, and hypercholesterolemia and oxidized LDL. In addition to these humoral stimuli, it is clear that biochemical forces generated by flowing blood can also influence endothelial cell structure and function, modulating the expression of pathophysiologically relevant genes. The possibility that hemodynamic forces can act as pathophysiological stimuli for endothelial dysfunction provides a conceptual rationale for the long-standing observation that the earliest lesions of atherosclerosis characteristically develop in a nonrandom pattern, the geometry of which correlates with branch points and other regions of altered blood flow. There have been documented a variety of changes in the metabolic and synthetic activities of endothelial cells in response to defined biomechanical forces. These include the production of arachidonate metabolites, growth factors, coagulation and fibrinolytic components, ECM components, and vasoactive mediators. Certain of these more acute shear-induced changes appear to involve regulation at the level of rate-limiting enzymes and/or substrate availability. However, especially in the case of delayed responses in which de novo synthesis occurs, up-regulation of gene expression appears to occur as a direct consequence of exposure to fluid mechanical forces. There are genes, such as platelet-derived growth factor-B (PDGF-B), MCP-1, VCAM-1, and endothelin-1, that have a "shear stress response element" in the promoter.

Monocytes/Macrophages

The state and function of the macrophages in the atherosclerotic lesions may be critical for the development of atherosclerosis. Macrophages play an important role in innate immune responses, cellular adhesion, phagocytosis of apoptotic cells, and lipid uptake. Most of these macrophage functions are mediated by SRs. Since the cloning of the first two macrophage SRs (now called SRA-I and SRA-II), the broad SR family has grown considerably (**Table 5**). On the basis of functional studies and expression in the arterial intima, only some of the SRs are good candidates to contribute to atherosclerotic foam cell formation.

Besides their role in lipid accumulation, macrophages may contribute to atherosclerosis through secretory inflammatory products. In fact, atherosclerosis can be considered a chronic inflammatory process. Activated lymphocytes and macrophages with a wide expression of class II histocompatibility antigen have been found at every stage of atherosclerotic lesions, indicating that macrophages may participate in local immune responses.

Vascular smooth muscle cells

VSMCs represent an average of 50% of the cellular component in advanced atherosclerotic plaque and may reach 90 to 95% in early lesions. In response to multiple stimuli, VSMCs from the arterial tunica media are activated and migrate to the intima, where they proliferate. These seem to be early steps in the onset of the atherosclerotic process. The proliferation and migration of VSMCs from the media to the intima is one of the key events in early atherosclerosis. The understanding of the molecular mechanisms involved in VSMC activation and differentiation requires an accurate mapping of the cascade of transcription factors induced by atherogenic stimuli. Recently, various nuclear receptors, including peroxisome proliferator-activated receptors (PPARs), retinoid receptors, both retinoid X receptors (RXRs) and retinoic acid receptors (RARs), and retinoid-related orphan receptors (RORs), have been identified in VSMC activation/ proliferation and, consequently, have been implicated in atherogenic processes. Our group has identified neuron-derived organ receptor-1 (NOR-1) as a new early-response gene in VSMCs. NOR-1 is strongly increased by growth factors and thrombin. NOR-1 is overexpressed in atherosclerotic lesions from patients with CAD (**Fig. 5**), and balloon angioplasty transiently induces NOR-1 in porcine coronary arteries. These results suggest that NOR-1 may play a role in the molecular mechanisms underlying both spontaneous and accelerated atherosclerosis.

VSMCs also contribute to the lesion by synthesizing ECM. In fact, proliferative VSMCs have a high capacity to synthesize sulfated PGs, and it is well established that PGs in the arterial wall are involved in the focal deposition of cholesterol-rich particles during the early phases of atherogenesis.

Finally, VSMCs also have great importance in foam cell formation. Our group demonstrated that agLDL can cause high intracellular cholesteryl ester accumulation in VSMCs. We demonstrated, for the first time, that in VSMCs, LRP1 mediates the binding and internalization of agLDL. We also demonstrated that in the absence of LRP1 function, VSMCs are unable to accumulate cholesterol. In addition, this receptor is up-regulated by agLDL in cultured human VSMC and by hypercholesterolemia in vivo. Hypoxic conditions cause a strong increase in HIF-1α and LRP1 in VSMC and that HIF-1α and LRP1 protein staining coincides with VSMC in human advanced atherosclerotic lesions. Hypoxic VSMC may thus contribute to the high levels of HIF-1α associated with foam cells in human advanced atherosclerotic lesions. **Fig. 6** shows the consequences of human VSMC lipid loading for VSMC functionality. These foam cells synthesize and release increased amounts of tissue factor, a key element in the prothrombotic transformation of the vascular wall and thus in the progression of atherosclerosis to thrombosis. It has been recently reported that at least 50% of the foam cells previously

regarded as monocyte-derived macrophages in human atherosclerotic plaques originate in fact from VSMCs. Taken together, these findings suggest that generation of hVSMC-derived foam cells through LRP1-mediated AgLDL uptake is a key mechanism for vascular lipid deposition in atherosclerosis.

Introduction

The ability to identify genes that are associated with disease phenotypes represents a cornerstone in molecular medicine. Firstly, it leads to increased knowledge of the underlying mechanisms leading to disease, and secondly may lead to useful markers or therapeutic targets of disease. A representative example is the autosomal recessive pattern of inheritance of the cystic fibrosis transmembrane conductance regulator (CFTR) gene discovered in the late 80s (Riordan *et al.*, 1989). Such findings fuelled genome-wide sequencing efforts and genome-wide association studies (GWAS) that have successfully identified genes causative of ~50% of diseases with Mendelian patterns of inheritance (autosomal recessive, autosomal dominant, co-dominant or sex-linked; Online Mendelian Inheritance in Man, www.ncbi.nlm.nih.gov/omim). Conversely, these approaches have been of limited success with respect to non-communicable diseases, which currently represent the primary causes of death worldwide. In particular, there is a gap between disease risk heritability as inferred by twin-based epidemiological studies and the extent of heritability attributable to DNA sequence variants identified by GWAS. For example, twin-based evidence that cardiovascular disease has a significant genetic component dates back nearly four decades ago (Liljefors, 1970) and more recently, heritability of up2 to 60% has been shown for coronary artery disease, a prominent form of cardiovascular disease (Zdravkovic *et al.*, 2002). In turn, GWAS has been successful in identifying a number of genetic variants that collectively explain only 28% or less of cardiovascular disease risk (Stylianou *et al.*, 2012; McPherson and Tybjaerg-Hansen, 2016). The occurrence of missing heritability suggests that non-communicable diseases show complex genetic inheritance (multi gene, somatic mutations) and/or result from the interplay between genetic and epigenetic mechanisms.

Epigenetic mechanisms refer to chromatin modifications that are linked to changes in gene expression and are independent of mutational events. Such modifications are known to be heritable, reversible and respond to external signals. At the molecular level there are two major types of known epigenetic modifications; i.e. modifications of DNA and histones (the proteinaceous component of chromatin), that both have well established roles in development, X-chromosome inactivation, genomic imprinting and the repression of transposable elements. The most important epigenetic DNA modification is the addition of a methyl group, mostly to a cytosine base (5-methylcytosine, 5mC) in a CpG (cytosine-phosphate-guanine) dinucleotide context. In turn, the N-terminal tails of histones carry specific modifications such as acetylation, methylation, ubiquitination and sumoylation (Bannister and Kouzarides, 2011; Verdin and Ott, 2014). These epigenetic modifications act in a combinatorial fashion that are linked to different transcriptional states (Cedar and Bergman, 2009). As an example, DNA methylation generally coexists with trimethylation of lysine 36 on histone H3 (H3K36me3), a modification that is typically associated with active transcription, while H3K4me3 marks active promoters and is antagonistic to DNA methylation (Sun *et al.*, 2005; Mikkelsen *et al.*, 2007; Hodges *et al.*, 2009).

The following paragraphs include a general introduction to the dynamic changes in DNA methylation that occur during normal development and its potential impact on transcription, followed by a section specifically related to DNA methylation changes in vascular disease.

DNA Methylation Dynamics

Methylating and Demethylating Enzymes

DNA methylation was first discovered in 1948 in higher eukaryotes (Hotchkiss, 1948) and results from the transfer of a methyl group from the donor *S*-adenosylmethionine (AdoMet or SAM) to the 5′ position of the cytosine pyrimidine ring. The enzymes that catalyze this reaction are known as DNA methyltransferases (DNMT). DNMTs are capable of introducing methyl groups to previously unmethylated substrates or maintaining DNA methylation profiles following DNA replication. These distinct activities are performed by the de nov*o* methyltransferases DNMT3A, DNMT3B, DNMT3C, the catalytically inactive DNMT3L and the major maintenance methyltransferase DNMT1, respectively (Bestor, 2000; Goll and Bestor, 2005; Barau *et al.*, 2016). Indeed, the importance of DNA methylation in mammalian development was evidenced by the aberrant phenotypes associated with knockout or insertional mutagenesis of both types of DNA methyltransferases (Li *et al.*, 1992; Okano *et al.*, 1999; Bourc'his *et al.*, 2001; Howell *et al.*, 2001; Barau *et al.*, 2016). Specific domains in the N-terminal regions of DNMTs play an important role in guiding these enzymes to specific genomic locations. The DNMT1 replication focus targeting domain (RFTD) targets DNMT1 to replication foci where it interacts with UHRF1 (ubiquitin-like with PHD and ring finger domains 1), a protein that preferentially binds to hemimethylated DNA (Leonhardt *et al.*, 1992; Bostick *et al.*,

 doi:10.1016/B978-0-12-801238-3.65409-0

2007; Sharif *et al.*, 2007; Bashtrykov *et al.*, 2014; Berkyurek *et al.*, 2014). In this manner, DNMT1 faithfully copies the methylation pattern from the parental DNA strand onto the newly synthesized daughter strand. Similarly the N-terminal PWWP motif of DNMT3A and DNMT3B specifically recognizes H3K36me3 (Otani *et al.*, 2009; Dhayalan *et al.*, 2010; Baubec *et al.*, 2015; Rondelet *et al.*, 2016), while DNMT3L is targeted to unmethylated H3K4 via the ADD domain (Ooi *et al.*, 2007).

Conversely, the removal of DNA methylation can occur either passively by limiting DNMT activity, or actively via the modification of 5mC (deamination or oxidation) followed by glycosylation and base excision repair. Deamination is catalyzed by AID (activation induced cytosine deaminase) or APOBEC1 (apolipoprotein B mRNA editing enzyme, catalytic polypeptide 1), generating thymidine, while the family of ten-eleven translocation (TET) dioxigenases (TET1, TET2 and TET3) convert 5mC to 5-hydroxymethycytosine (5hmC), 5 formylcytosine (5fC) and 5 carboxylcytosine (5caC) (Tahiliani *et al.*, 2009; Iqbal *et al.*, 2011; Wossidlo *et al.*, 2011; Wu and Zhang, 2011). In either case, these 5mC intermediates—excluding 5hmC—are removed by known glycosylases such as TDG (thymine DNA glycosylase) and MBD4 (methyl-CpG-binding domain protein 4) and are replaced with cytosine by base excision repair (Morgan *et al.*, 2004). With respect to the intermediate 5hmC, given that this modification is a poor substrate of DNMT1, DNA methylation is successively diluted during DNA replication (Valinluck and Sowers, 2007; Hashimoto *et al.*, 2012).

Taken together, the relative activities of DNMTs and TETs are important factors in determining the methylation state of a given substrate (**Fig. 1**). For additional and more detailed information on the targeting and function of DNMTs and TETs the readers are referred to the articles under "Further Reading" (Jeltsch and Jurkowska, 2014; Wu and Zhang, 2014; Jurkowska and Jeltsch, 2016; Rasmussen and Helin, 2016).

Genome-Wide Patterns of DNA Methylation and Its Role in Transcription

Looking at the distribution of DNA methylation from a bird's-eye view, most methylation is concentrated in repetitive transposon-derived sequences (LINEs, LTRs, SINEs), in addition to the gene body, defined as the region from the transcription start to transcription termination sites (Ball *et al.*, 2009; Lister *et al.*, 2009; Zemach *et al.*, 2010). With respect to regulatory regions, the majority of promoters are devoid of DNA methylation (Ioshikhes and Zhang, 2000; Lister *et al.*, 2009; Edwards *et al.*, 2010), notwithstanding the fact that these regions are characterized by a high density of CpG dinucleotides (known as CpG islands, CGI) (Cooper *et al.*, 1983; Bird *et al.*, 1985). CGIs are also found within gene bodies or between genes (orphan CGI) where they can function as intragenic or distal promoters, respectively (Illingworth *et al.*, 2010; Maunakea *et al.*, 2010; Sarda *et al.*, 2017). However, in contrast to promoter CGI, intragenic and distal promoters

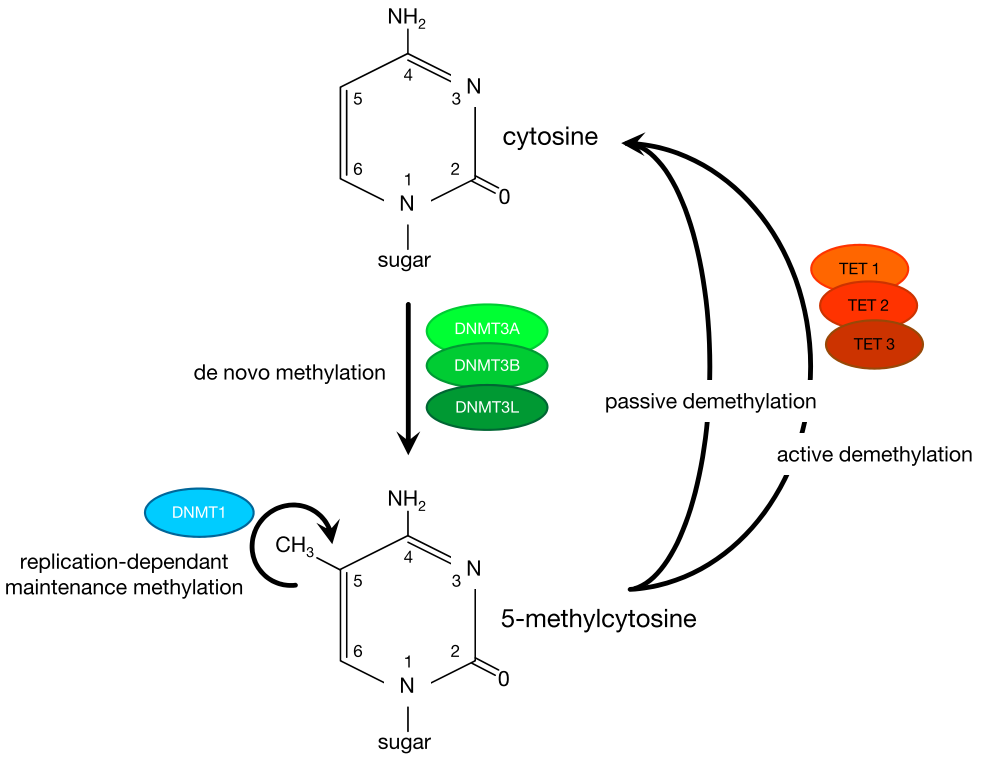

Fig. 1 DNA methylation and demethylation.

show both tissue-specific and developmental specific differences in DNA methylation (Illingworth *et al.*, 2008, 2010; Lister *et al.*, 2009; Rauch *et al.*, 2009). Similar variable methylation has also been documented within DNA regions of lower CpG density, such as CpG shores (2 kb regions flanking CGIs) and CpG-poor promoter regions (Irizarry *et al.*, 2009; Stadler *et al.*, 2011; Long *et al.*, 2013).

The effect of DNA methylation on transcription is complex, as exemplified by observations that promoter CGI are usually unmethylated irrespective of transcriptional activity (Meissner *et al.*, 2008; Illingworth and Bird, 2009; Jones, 2012). Likewise, methylated promoters can also be associated with active transcription (Irizarry *et al.*, 2009). However, such inconsistencies can in part be explained by alternative promoter usage (Rauch *et al.*, 2009; Walter *et al.*, 2016; Sarda *et al.*, 2017) (**Fig. 2**), or by the presence of additional chromatin modifications that are linked to alternative states of gene expression. Despite these complexities, the general consensus is that DNA methylation within regulatory regions is linked to lack of transcriptional activity, while gene body methylation shows the opposite association (Klose and Bird, 2006; Rebhan *et al.*, 2007; Jones, 2012). Accordingly, most transcription factor (TF) families preferentially bind to unmethylated promoters, exceptions being TFs belonging to homeodomain and NFAT families that preferentially bind methylated DNA (Yin *et al.*, 2017). However, whether promoter hypomethylation precedes, or is the consequence of, TF binding is still under debate (Zhu *et al.*, 2016). Conversely, methylation of promoter regions and gene bodies is likely to be the consequence of transcriptional repression and activation, respectively (Adalsteinsson and Ferguson-Smith, 2014). Examples of the latter include Oct3/4 and Liz (long isoform of Zdbf2) that are downregulated prior to promoter de novo methylation (Greenberg *et al.*, 2016; Epsztejn-Litman *et al.*, 2008) and transcription-dependent gene body methylation (Rauch *et al.*, 2009; Baubec *et al.*, 2015).

In essence, these data point to a functional role of methylation in stabilizing gene silencing by inhibiting TF binding, both within canonical and intragenic promoters. For additional and more detailed information on the relationship between TF-binding and methylation states, the readers are referred to the article under "Further Reading" (Schübeler, 2015).

DNA Methylation in Development and Disease

Most somatic methylation patterns are established early in embryogenesis by the concerted actions of DNMT3A, DNMT3B and DNMT3L and are subsequently maintained following DNA replication by DNMT1 (Okano *et al.*, 1999). Specifically, the mammalian genome undergoes two waves of demethylation/methylation: the first wave of demethylation occurs during the migration of proliferating primordial germ cells (PGC), with remethylation occurring in non-dividing prospermatogonia and growing oocytes, respectively, while the second demethylation/methylation takes place between cleavage stage embryos and the blastocyst stage (Monk *et al.*, 1987; Kafri *et al.*, 1992; Smith *et al.*, 2012). During these stages, the transient loss of DNA methylation is prominent for repetitive gene regions. However young CpG-rich transposons and CGI—that remain methylated and unmethylated, respectively—are immune to this methylation reprogramming (Hajkova *et al.*, 2002; Seisenberger *et al.*, 2012; Smith *et al.*, 2012; Ficz and Reik, 2013). In addition, complex regulatory DNA sequences that determine imprinted gene expression (i.e. imprinted control regions, ICRs) only undergo loss of DNA methylation in PGC (Bourc'his *et al.*, 2001; Smith *et al.*, 2012). This implies that exposure to adverse conditions early in development could lead to aberrant programming of DNA methylation that in turn affects disease probability in adulthood. An example of transcription-induced germline programming of DNA methylation that impacts on adult phenotype has recently been described (Greenberg *et al.*, 2016).

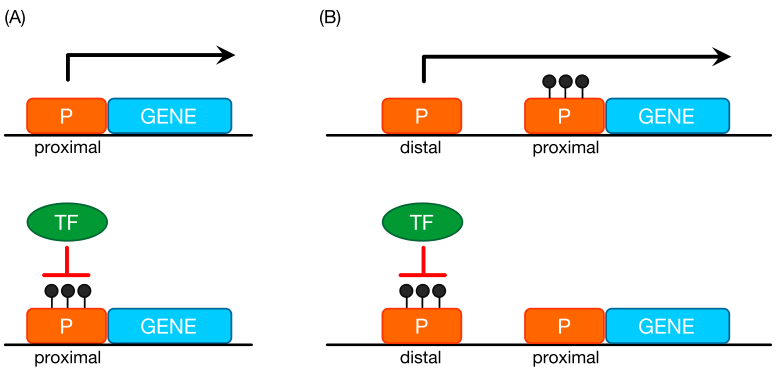

Fig. 2 Associations between DNA methylation and expression. (A) General consensus showing the repressive nature of promoter methylation on transcription factor binding and gene expression. (B) Transcription from an alternative upstream distal promoter (that gives rise to a transcript that overlaps with the gene downstream of the proximal promoter) can in some instances explain the lack of association between proximal promoter DNA methylation and transcription. *P*, promoter; *TF*, transcription factor.

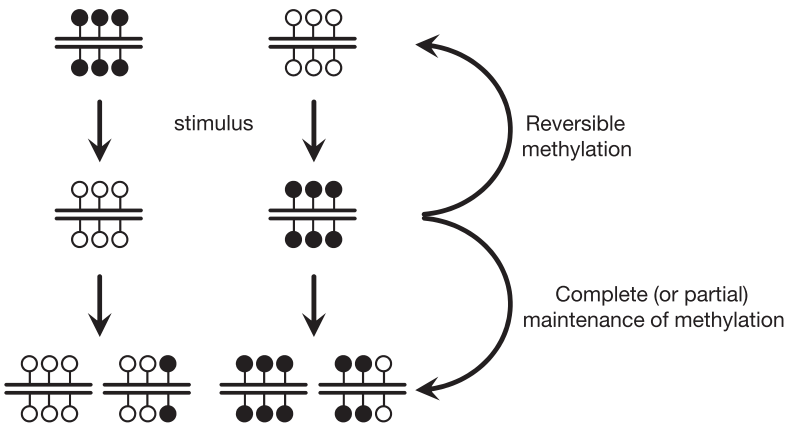

Fig. 3 Transient and stable DNA methylation in response to a given external stimulus. *Filled* or *empty lollipops* represent methylated and unmethylated CpG residues.

The genome also undergoes changes in methylation as a result of aging, disease and/or in response to specific external stimuli. Most complex human diseases such as cancer, diabetes type 1 and 2, atherosclerosis (Rakyan *et al.*, 2011; Dayeh *et al.*, 2014; Zaina *et al.*, 2014; Valencia-Morales Mdel *et al.*, 2015; Feinberg *et al.*, 2016), in addition to known risk factors of these diseases (smoking, obesity, high fat diet) are associated with genome-wide alterations in DNA methylation, some of which are transient in nature (Wang *et al.*, 2010; Jacobsen *et al.*, 2012; Zeilinger *et al.*, 2013; Benton *et al.*, 2015). As an example of the latter, a recent study of past, present and non-smoking individuals found that most smoking-related DNA methylation profiles were reversible in past smokers; i.e. only 7% of smoker-specific DNA methylation was detectable up to 35 years following smoking cessation (Ambatipudi *et al.*, 2016; Joehanes *et al.*, 2016). Such studies underline the largely reversible nature of smoking-related DNA methylation that may be associated with favorable health outcomes following smoking cessation. In addition, these studies illustrate that selected methylation profiles serve as historical footprint of past exposure (**Fig. 3**). That latter may be of particular interest in epidemiological research of environmentally related chronic diseases and for identifying early biomarkers for disease-risk.

Factors that drive disease-associated DNA methylation include, not surprisingly, mutations in both TETs and DNMTs (Xu *et al.*, 1999; Yan *et al.*, 2011; Chan and Majeti, 2013). Furthermore, cellular concentrations of metabolites of Krebs cycle and methionine and folate metabolism, which are known regulators of TETs and DNMT activity, also impact DNA methylation levels (Wellen *et al.*, 2009; Crider *et al.*, 2012; Donohoe and Bultman, 2012; Kaelin and McKnight, 2013; Salminen *et al.*, 2014). Thus, modification of these metabolite levels by dietary intervention may be a promising strategy to reverse disease-related DNA methylation. For additional and more detailed information on the relationship between metabolism, nutrition and DNA methylation, the readers are referred to the articles under "Further Reading" (Sharma and Rando, 2017; Zeisel, 2017).

Atherosclerosis

Atherosclerosis is a chronic-degenerative disease of large and medium size arteries. The anatomical manifestation of atherosclerosis is the development of a lipid-rich, fibrocellular lesion—i.e. composed of living cells and extracellular matrix (ECM) material—that alters the normal histological structure of the intima—one of the layers of the arterial wall—and protrudes into the lumen. The lesion is commonly referred to as atheroma or plaque. The word atheroma was first used in a cardiovascular context by the Swiss scientist Albrecht von Haller in the 18th century and derives from the Greek "gruel-like tumor," which alludes to the loss of the orderly morphology of the healthy arterial wall (Fye, 1995; Pajukanta *et al.*, 2007). The progression of the atheroma is mostly asymptomatic and spans decades in humans. During this phase, the atheroma is contained below the innermost single cell layer of the artery—the endothelium. In a minority of atherosclerotic subjects, the atheroma undergoes structural weakening which exposes its interior to the blood flow (Tabas, 2017). The resulting thrombosis causes impaired blood flow downstream to the site of the ruptured atheroma and is the primary cause of the clinical complications of atherosclerosis: myocardial infarction, cerebrovascular events (stroke) and peripheral artery disease.

Epidemiologically, atherosclerosis is multifactorial. Besides the four risk factors consistently identified by epidemiological studies—cholesterol, blood pressure, glucose and smoking—a plethora of environmental, life style-related and endocrine-related (obesity, diabetes) factors have been identified (Tzoulaki *et al.*, 2016). This complexity is reflected by the intricate molecular and cellular phenomena that accompany the progression of the disease. The current dominant view is

that atherosclerosis is an inflammatory disease (Ross, 1999). The infiltration of small size lipoproteins into the arterial wall accompanied by endothelial dysfunction—i.e. loss of selective barrier function—is an early event in atherosclerosis. Subsequently, circulating monocytes are recruited by specific endothelial receptors and migrate into the arterial wall where they differentiate to macrophages. Macrophages perform their natural duty of scavenging lipoproteins, thus converting into lipid-loaded cells known as foam cells. That initial inflammatory response is self-sustaining rather than resolved. A corollary phenomenon to macrophage invasion is a dramatic change in vascular smooth muscle cell (VSMC) phenotype (Stavenow, 1984). In a healthy vessel, VSMCs are differentiated, quiescent cells specialized in contracting to regulate blood pressure. In atherosclerosis, VSMCs dedifferentiate and recover the ability to migrate and proliferate. As a result, VSMCs migrate from the underlying arterial wall to the macrophage-rich space, where they synthesize and deposit ECM. This latter function identifies the atherosclerosis-associated VSMC phenotype as "synthetic" as opposed to the "contractile" physiological phenotype. The resulting ECM-rich structure is relatively stable until destabilizing factors prevail. Although the cellular/molecular details of atheroma weakening are not fully understood, macrophage-derived proteases seem to play a pivotal role (Tabas and Bornfeldt, 2016; Tabas, 2017).

Atherosclerosis and DNA Methylation

Seminal experiments in animal models showed that the diet can change DNA methylation profiles and that such changes can result in stable phenotypes (Waterland and Jirtle, 2003). A flurry of evidence followed, which demonstrated DNA methylation-modulating activity for a large number of dietary, environmental and life style factors (Waterland *et al.*, 2006; Baccarelli *et al.*, 2009; Breitling *et al.*, 2011). These findings were concomitant with mounting evidence for the existence of a significant missing heritability for cardiovascular disease (see above) (Stylianou *et al.*, 2012). The missing heritability problem prompted researchers to explore other avenues than genetics. Epigenetics is regarded as a promising alternative (Ordovás and Smith, 2010; Zaina, 2014).

Cardiovascular epigenetics research has taken two distinct directions. On the one hand, the GWAS approach has been replicated in epigenome-wide association studies (EWAS) to seek DNA methylation profiles mostly in peripheral blood, which associate with disease risk. This approach focuses on heritability. Examples are EWAS that have successfully demonstrated significant associations with glucose and lipids for a number of CpG loci (Hidalgo *et al.*, 2014; Irvin *et al.*, 2014). This genetic approach to cardiovascular epigenetics is supported by the notion that up to 60% of DNA methylation is DNA sequence-dependent, with effects both *in cis* and *in trans* (Kerkel *et al.*, 2008; Bonder *et al.*, 2017). Yet, this same rationale implies that like GWAS, EWAS might yield epigenetic variants with small effects. This has been so far indeed the case (Zaina and Lund, 2014). Another important issue is that peripheral blood-based EWAS might yield valuable disease markers, but due to inter-tissue DNA methylome heterogeneity, do not necessarily identify vascular tissue-specific pathological DNA methylation profiles of potential therapeutic relevance. This is particularly true in the light of the reported uniqueness of the peripheral blood DNA methylome (Lowe *et al.*, 2015; Silva-Martínez *et al.*, 2016).

The second approach to cardiovascular epigenetics seeks differential DNA methylation between normal and diseased blood vessels. This approach is mechanistic and focuses on seeking DNA methylation profiles that account for pro- or antiatherogenic gene expression and help to identify the effects of risk factors at the genome level in the disease target tissue (Zaina and Lund, 2012). In the following paragraphs, we will review this latter mechanistic approach. For an excellent discussion of the strengths and limitations of the "genetic-like" EWAS approach, the reader is referred to the work by Aslibekyan and coworkers (Aslibekyan *et al.*, 2014).

Participation of Specific DNMTs and TETs in Atherosclerosis

Increased DNMT activity is likely involved in VSMC switch to a synthetic phenotype, as forced hypermethylation induced by expression of the bacterial DNMT HpaII methylase induces smooth muscle proliferation in mice (Carpinteyro-Espín *et al.*, 2011). Also, biochemical inhibition of DNMTs in vivo revealed that DNA hypermethylation plays a causal role in atherosclerosis (Cao *et al.*, 2014; Dunn *et al.*, 2014). Notably, accumulating independent evidence assigns de novo methylation activity to DNMT1 in atherosclerosis, although that DNMT has been traditionally considered a specialized maintenance enzyme (Hermann *et al.*, 2004). Knock-down experiments showed that DNMT1 is responsible for lipoprotein-induced DNA hypermethylation in cultured human macrophages (Rangel-Salazar *et al.*, 2011). In the same study, kinomics identified protein kinase zeta as a mediator of lipoprotein signaling in accordance with an independent study (Lavoie *et al.*, 2011). Furthermore, in vivo studies reached the same conclusions: disturbed blood flow, a pivotal inducer of endothelial dysfunction and atherosclerosis, induces DNA hypermethylation through DNMT1 activation (Zhou *et al.*, 2014). Additionally, DNMT1 overexpression enhances inflammation in a mouse atherosclerosis model by downregulating peroxisome proliferator activating receptor gamma and estrogen receptor alpha, two nuclear receptors that maintain an antiatherogenic transcriptional program (Wang *et al.*, 2012; Yu *et al.*, 2016). DNMT1 is also involved in disturbance of lipid homeostasis by homocysteine, an independent cardiovascular risk factor (Yang *et al.*, 2015).

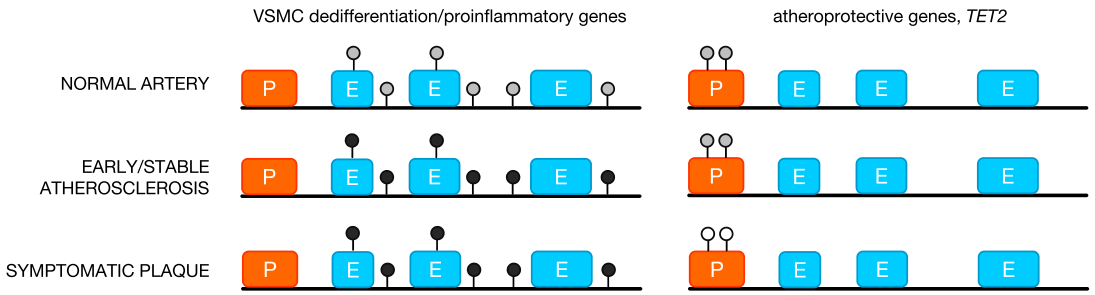

Fig. 4 Main changes in gene DNA methylation at various stages of atherosclerosis. Only profiles in genic regions with significant differential methylation are shown. In proatherogenic genes, changes are mainly in the gene body, i.e. in exons and introns (*blue boxes* and *black line*, respectively), during aorta and carotid stable plaque evolution. In atheroprotective genes, changes are mainly in promoters (P, *orange boxes*) in symptomatic carotid lesions. *White*, *gray* and *black lollipops*, nearly unmethylated, low methylation and high methylation state, respectively.

As for TETs, an atheroprotective role for TET2 has been suggested by a number of studies. TET2 is downregulated in mouse atherosclerotic lesions compared to controls, and its overexpression or knock-down coordinately decreased or decreased DNA methylation and lesion size, respectively (Peng *et al.*, 2016). The study identified monocyte recruitment and proinflammatory genes as specific TET2 targets. Similar data were obtained by TET2 expression manipulation in a cell culture model of oxidized lipoprotein-induced endothelial damage (Peng *et al.*, 2017). Accordingly, TET2 expression decreases as VSMCs shift from the contractile to the synthetic undifferentiated phenotype (Liu *et al.*, 2013). These studies identify TET2 activation as a potential therapeutic strategy.

Dynamics of the Atherosclerotic DNA Methylome

Gene candidate-based searches for differentially methylated loci in atherosclerosis date back to the late 90s (Laukkanen *et al.*, 1999). These early studies showed that altered DNA methylation profiles are present in the arterial tissue before any histologically detectable lesions appear in mice (Lund *et al.*, 2004). More recently, the availability of next generation sequencing and affordable high-density DNA methylation microarrays has allowed epigenome-wide profiling of atherosclerotic vessels (Sandoval *et al.*, 2011). Collectively, those experiments revealed that an increase in DNA methylation—hypermethylation—characterizes the stable, AHA grade III-VII atherosclerotic aorta compared to atheroma-free donor-matched control aortas (Zaina *et al.*, 2014; Valencia-Morales Mdel *et al.*, 2015). Hypermethylation at a portion of those loci is lesion grade-independent and therefore may arise at early phases of atheroma progression or even before any detectable histological change. Hypermethylation targeted mostly the gene body and regions outside of CGIs (**Fig. 4**). Global DNA hypermethylation was also documented in peripheral blood of coronary artery disease patients (Sharma *et al.*, 2008, 2014).

Following the drift towards DNA hypermethylation in stable atheromas, symptomatic (post-cerebrovascular event) carotid lesions undergo a significant loss of methylation (Zaina *et al.*, 2015). This shift does not involve reversal of gene body methylation acquired during stable lesion progression, but rather targets CGIs (**Fig. 4**). A substantial subset of hypomethylated CGIs map to promoters of atheroprotective genes involved in cholesterol efflux and oxidative stress control. Parallel RNAseq—a transcriptome-wide next generation sequencing technology—experiments revealed that CGI demethylation was accompanied by increased expression. Although counterintuitive, the data echo evidence that post-cerebrovascular event lesions undergo compensatory changes towards a relatively stable structure (Peeters *et al.*, 2009). Interestingly, one of the upregulated genes was TET2, an enzyme involved in active DNA demethylation (see above).

Collectively, the epigenomics data presented here and the outcome of DNMT and TET molecular manipulation reviewed in paragraph 3.2 converge to support a causal role of DNA hypermethylation in atherosclerosis. Yet, a number of studies seem to contradict that notion. Early rabbit and mouse atherosclerosis model studies detected genomic DNA hypomethylation (Laukkanen *et al.*, 1999; Hiltunen *et al.*, 2002; Lund *et al.*, 2004). Studies in humans reached the same conclusions (Castillo-Díaz *et al.*, 2010; Aavik *et al.*, 2014; Greißel *et al.*, 2015). These studies have in common that diseased and control vessels were obtained from different individuals or animals, and in some cases from entirely different anatomic locations—for example femoral *versus* mammary arteries. It is therefore possible that inter-individual and inter-tissue differential methylation masks genuine atherosclerosis-specific profiles. This is an important issue that limits our understanding of the atherosclerosis epigenome and therefore warrants further research.

Atherosclerosis Risk Factors and DNA Methylation

One of the early approaches to identify any effects of proatherogenic factors on DNA methylation was to stimulate cultured cells with lipids and lipoproteins. These efforts showed that triglyceride-rich lipoproteins induce DNA hypermethylation in

cultured cells (Lund *et al.*, 2004; Rangel-Salazar *et al.*, 2011). Fatty acids are among the mediators of lipoprotein-induced DNA hypermethylation, as arachidonic acid-induced DNA methylation profiles in cultured macrophages significantly overlap with human atherosclerotic aorta-specific profiles (Silva-Martínez *et al.*, 2016; Silva-Martínez *et al.*, 2017). Furthermore, supplementation of trans fatty acid elaidate in utero induces DNA hypermethylation in the progeny that persists after the stimulus (Flores-Sierra *et al.*, 2016), thus offering another example of a stable epigenetic modification (**Fig. 3**). Also, high-fat diet, a predisposing factor for cardiovascular disease, induces hypermethylation of repeated elements, a surrogate of the whole genome (Yoo *et al.*, 2012). Collectively, these results are supported by evidence that lipids shape the DNA methylome, not *vice versa* (Dekkers *et al.*, 2016).

Atherosclerosis is not regarded as an endocrine disease *per se*, but altered hormone signaling or availability contribute to cardiovascular risk. DNA methylation studies have provided insights into the endocrine component of atherosclerosis at the molecular level. As mentioned above, estrogens have a recognized atheroprotective role. Accordingly, estrogen receptor alpha promoter methylation and expression are increased and decreased, respectively, in atherosclerotic compared with donor-matched and artery type-matched normal controls (Post *et al.*, 1999; Valencia-Morales Mdel *et al.*, 2015).

Diabetes is one of the cardiovascular risk factors most clearly identified by epidemiological studies. Yet, the comparison of DNA methylation profiles yields little overlap between the two diseases. Among differentially methylated genes in atherosclerotic and normal human aorta, the insulin signaling function is enriched with only marginal significance (Zaina *et al.*, 2014). Accordingly, no overlap was observed between stable aortic atherosclerosis-specific DNA methylation profiles and type 1 or type 2 diabetes mellitus-specific peripheral blood counterparts (Rakyan *et al.*, 2011; Toperoff *et al.*, 2012). A pancreatic islet-based DNA methylation analysis of type 2 diabetes patients and healthy controls yielded 276 differentially methylated CpG loci of which only five overlapped with human atherosclerotic aorta counterparts, and all those CpG changed in opposite directions in the two diseases—i.e. hypomethylation and hypermethylation in diabetes and atherosclerosis, respectively (Volkmar *et al.*, 2012). A comparative analysis with a DNA methylation microarray-based profiling of human pancreatic cells revealed similar results (Dayeh *et al.*, 2014; Silva-Martínez *et al.*, 2016; Silva-Martínez *et al.*, 2017). Interestingly, the latter studies also indicate a surprising lack of overlap between diabetes-specific and proinflammatory free fatty acid (arachidonate, palmitate)-induced DNA methylation profiles. Taken together, the data suggest that epigenetic events occurring in the diabetic pancreas and in the atherosclerotic vascular tissue are causally related but distinct. A yet untested fascinating implication of these data is that the epigenetic divergence between the pancreatic islet and the atherosclerotic vessels is increased in comorbid subjects.

As for obesity, the comparative methylome survey described in the previous paragraph indicates a close clustering between differentially methylated profiles in the adipose tissue of obese subjects and human atherosclerotic aortas, with a marked DNA hypermethylation in both conditions (Benton *et al.*, 2015; Silva-Martínez *et al.*, 2016).

Primary Mixed Dyslipidemias

Rafael Carmena, University of Valencia, Valencia, Spain

Abbreviations

Apo B	Apolipoprotein B
Apo E	Apolipoprotein E
CHD	Coronary heart disease
CVD	Cardiovascular disease
FCH	Familial combined hyperlipidemia
FDBL	Familial dysbetalipoproteinemia
FFA	Free fatty acids
FH	Familial hypercholesterolemia
GWAS	Genome-wide association studies
HDL-C	High density lipoprotein cholesterol
HL	Hepatic lipase
IDL	Intermediate density lipoprotein
IR	Insulin resistance
LDL-C	Low density lipoprotein cholesterol
LPL	Lipoprotein lipase
MTTP	Microsomal triglyceride transfer protein
Non-HDL-C	Total cholesterol minus HDL-C values
SNP	Single nucleotide polymorphism
PCSK9	Proprotein convertase subtilisin/kexin type 9
VLDL	Very low density lipoprotein

Introduction

Mixed dyslipidemias are defined as alterations in lipid metabolism characterized by a complex phenotype with plasma triglycerides and low density lipoprotein-cholesterol (LDL-C) elevations, either in isolation or in combination; these are usually associated with low levels of high density lipoprotein-cholesterol (HDL-C) as well as elevated levels of plasma apolipoprotein B (Apo B) and non-HDL cholesterol. Mixed dyslipidemias are clinically important because of their frequent association with premature cardiovascular disease (CVD). In this article we will review the main primary mixed dyslipidemias of genetic origin, including familial combined hyperlipidemia (FCH), familial dysbetalipoproteinemia (FDBL), and hepatic lipase (HL) deficiency. Secondary forms of mixed dyslipidemias, as seen in diabetes mellitus, insulin resistance (IR) states, and metabolic syndrome, are described in the Diabetes Section of this Encyclopedia.

Familial Combined Hyperlipidemia

FCH is a mixed hyperlipidemia which is frequently encountered clinically and is associated with a five-fold increased risk of premature coronary heart disease (CHD). FCH is the most frequent genetic cause of dyslipidemia, with a 1%–2% prevalence in the general population, exceeding that of familial hypercholesterolemia (FH). FCH is also considered the most frequent metabolic cause of premature atherosclerosis; about 20% of patients who present CHD before the age 60—and 38% of those younger than 40 years—have FCH (Goldstein *et al.*, 1973; Ripatti *et al.*, 2016).

Definition

The phenotypic definition of FCH is challenging and the shifting nature of the phenotype in the same individual patients over time has hindered its classification. Affected subjects usually present one of three possible phenotypes: (1) elevations above the 90th or 95th percentile for total cholesterol or LDL-C (including small dense LDL particles), (2) elevated very low density lipoprotein (VLDL) triglycerides, or (3) elevated plasma levels of cholesterol and triglycerides; in all cases, HDL-C levels are usually reduced. These altered lipid profiles shift over time, depending on exogenous factors such as diet, body weight, and exercise. Moreover, FCH is observed within family clusters or in kindreds exhibiting premature CHD (Brahm and Hegele, 2016).

In addition, Apo B is consistently elevated in FCH and so many consider it to be a biochemical marker of the disease (Sniderman *et al.*, 2002). A consensus of opinion acknowledges that the most consistent lipoprotein abnormalities that present over time, within and between different affected individuals, is the combination of both elevated Apo B and triglycerides. This has led to the current proposed definition of FCH: the presentation of Apo B higher than 1.2 g/L and triglycerides exceeding 1.5 mmol/L, both adjusted for age and sex, in at least two family members (Sniderman *et al.*, 2002).

Genetics

As with its definition, the genetic basis of FCH still remains poorly understood. The disorder is neither homogeneous nor dominantly inherited. Genetic susceptibility probably results from the accumulation of multiple variants within the genome of affected family members. These seem to include a combination of rare large-effect variants, plus a high burden of common

 doi:10.1016/B978-0-12-801238-3.65333-3

polymorphisms (van Greevenbroek *et al.*, 2014; Brahm and Hegele, 2016). Two different genetic defects could be involved: rare large-effect variants in genes coding for the LDL receptor and/or hepatic Apo B synthesis, and multiple common small-effect lipid-altering variants which together raise LDL-C and/or triglycerides via multiple mechanisms. In addition, a cluster of other factors, such as poor diet, obesity, fatty liver, or diabetes further modulate the shifting expression of the biochemically defined FCH phenotype. The adjective "familial" may be misleading since FCH seems to be polygenic rather than monogenic and its heredity is almost always non-Mendelian. In fact, after more than 40 years of study, no single monogenic cause has been found to explain the phenotype, even in a subset of patients with FCH (Brahm and Hegele, 2016). However, using the term "familial" to designate this disorder is inserted in clinical practice, is meaningful, and helps to remind clinicians of potential family links, and thus, it should not be abandoned, although a more appropriate term might be polygenic combined hyperlipidemia (Brahm and Hegele, 2016; Rader and Hobbs, 2015).

Genome-wide association studies (GWAS) in kindreds affected by FCH have identified up to 40 genes of interest, some of which are implicated in the various metabolic pathways which are disrupted in this disease (Brouwers *et al.*, 2012; van Greevenbroek *et al.*, 2014; Ripatti *et al.*, 2016). Among these, the genes most frequently found encode lipoprotein lipase (LPL), HL, lecithin cholesterol acyl transferase, the cluster apo-$A_I/C_{III}/A_{IV}/A_V$, and the transcription factor upstream stimulatory factor 1 (*USF1* gene). The latter controls numerous genes involved in lipid and glucose metabolism. Some USF1 variants may affect hepatic triglyceride metabolism by modulating the Forkhead Box protein A2 (FOXA2)-induced microsomal triglycerides transfer protein expression (Auer *et al.*, 2012). Large-scale GWAS have shown that several of these loci—in particular the APOA1-C3-A4-A5 gene cluster, LPL and proprotein convertase subtilisin/kexin type 9 (PCSK9)—are also significant, if modest, determinants of plasma lipid traits in large populations. Recent GWAS analyses have also identified a genetic overlap between type 2 diabetes mellitus and FCH, although the nature of the pathogenic connection between these two conditions is still not well understood (Auer *et al.*, 2012).

To date, these combined findings suggest that the FCH phenotype is genetically very complex and we can only speculate about the mechanism of its inheritance. Attempts to replicate family studies of FCH inheritance employing linkage analysis to find susceptibility loci under the assumption of Mendelian inheritance patterns have generally failed. In contrast with FH, which is largely monogenic, FCH lacks a monogenic component, and it does not have any specific genetic markers, making its diagnosis more difficult.

Nonetheless, the availability of single nucleotide polymorphism (SNP) chips for GWAS has improved our understanding of the genetic architecture of hyperlipidemic disorders. In the case of FCH, it is most likely that its inheritance is polygenic, with the proband inheriting a higher than average dose of triglyceride-raising SNPs (i.e., an elevated triglyceride phenotype) or that they inherit more LDL-C-raising SNPs than average, leading to an elevated LDL-C phenotype (Talmud *et al.*, 2014). Moreover, interaction with secondary factors, such as obesity or diabetes, also modulates individuals' underlying genetic susceptibility to FCH and the expression of its biochemically defined phenotype.

Pathogenesis

The primary defect in FCH appears to be increased hepatic secretion of Apo B, presumably because of decreased hepatic degradation of Apo B-containing lipoproteins. Moreover, the increase in Apo B is not linked to the *Apo B* gene. IR is frequently found in patients with FCH, both in obese and normoweight individuals (Martínez-Hervás *et al.*, 2008). The plasma insulin concentrations in these patients are positively correlated with plasma Apo B and triglyceride but inversely correlated with HDL-C concentrations (Castro-Cabezas *et al.*, 1993; Carmena *et al.*, 1996; Purnell *et al.*, 2001). The adipose tissue in FCH patients is characterized by reduced triglyceride removal and decreased storage rates, compared with healthy controls (Arner *et al.*, 2011); this dysfunction leads to an increased flux of free fatty acids (FFA) into the liver, resulting in hepatic fat accumulation and VLDL and Apo B overproduction. Finally, the clustering of cardiovascular risk factors associated with IR in FCH indicates a common metabolic basis for both the FCH phenotype and IR, which is probably mediated by impaired FFA metabolism (Castro-Cabezas *et al.*, 1993; Carmena *et al.*, 1996). In summary, FCH can be envisaged as a crossroad between lipid and carbohydrate metabolism which generates a dyslipidemic and dysglycemic syndrome with hyper-Apo B status.

Diagnosis

In the absence of a genetic marker, FCH is diagnosed using clinical criteria, including the elevations in Apo B, cholesterol, and triglycerides mentioned in the definition, as well as a shifting lipid phenotype, and a family history of mixed dyslipidemia and premature CHD. Moreover, the disorder is often associated with type 2 diabetes mellitus, arterial hypertension, central obesity, IR, and metabolic syndrome (Ascaso *et al.*, 1999; Aguilar-Salinas *et al.*, 2004). Plasma Apo B levels are also elevated in the condition known as hyperbetalipoproteinemia but in that case, in contrast to the presentation in FCH, the LDL-C remains within the normal range (Durrington, 2007a).

Clinical Manifestations

As previously mentioned, FCH has a complex phenotype whose expression shifts over time in genetically predisposed individuals. It usually presents in the second decade of life, although the increasing prevalence of childhood obesity has recently led to the

appearance of FCH in children and adolescents. About 50% of first-degree relatives show at least one of the abnormal phenotypes (i.e., high LDL-C, and/or triglycerides, along with low HDL-C and elevated Apo B). The lipid phenotype within individual families changes with time and shows high inter- and intraindividual variability which especially depends on exogenous factors including diet, alcohol intake, body weight, and exercise (Ascaso *et al.*, 1999; Durrington, 2007a).

FCH is frequently associated with abdominal obesity, metabolic syndrome, IR, hypertension, type 2 diabetes, gout, non-alcoholic hepatic steatosis, low adiponectin levels, and an increased concentration of plasminogen activator inhibitor-1 (Rader and Hobbs, 2015). The elevated plasma levels of Apo B are disproportionately high relative to the LDL-C concentrations, revealing the presence of small, dense, LDL particles, another characteristic of FCH. The size and composition of VLDL and HDL are also abnormal, resulting in particles with greater atherogenic capacity. Together, these changes contribute to the elevated CVD risk characteristic of FCH. Moreover, increased plasma levels of PCSK9 have recently been identified in FCH patients (Brouwers *et al.*, 2011) and could contribute to the atherogenic potential of this disease.

CHD usually manifests during the fourth decade in males, and a decade later in women. Contrary to other dyslipidemias, patients with FCH do not present tendon xanthomas; xanthelasmas or corneal arcus may occur, but their presence is not helpful in making the diagnosis (Durrington, 2007a).

Treatment

Due to the significantly increased risk of premature CHD in individuals with FCH, these patients should be treated aggressively. Decreased dietary intake of saturated fat and simple carbohydrates, aerobic exercise, and weight loss should all have beneficial effects on the patient lipid profile. Lipid-lowering drug therapy is required in most patients. Statins are effective and should be used as the first-line drug therapy, although many patients will require a second drug (ezetimibe, fibrates, ω-3 supplements, or fish oils) for optimal control of the dyslipidemia. In FCH patients with a very high CVD risk, and in view of their elevated plasma PCSK9 levels, treatment with monoclonal antibodies against PCSK9 can be an important adjuvant to statins to further lower the LDL-C concentration. New selective PPAR-α modulators are currently under study in mixed dyslipidemias with promising early results (Camejo, 2017). In patients at very high risk of CHD events, the target LDL-C level should be $\leq$1.8 mmol/L (Catapano *et al.*, 2016). Identification and management of other CVD risk factors, such as type 2 diabetes, smoking, and hypertension are fundamental to reduce the CVD risk burden.

Familial Dysbetalipoproteinemia

Definition

FDBL is also known as broad beta disease, xanthoma tuberosum, remnant removal disease, or type III hyperlipoproteinemia in the classic Fredickson's classification (Fredrickson *et al.*, 1967). It is a rare autosomal-recessive inherited lipid metabolism disorder characterized by elevated cholesterol and triglyceride plasma concentrations caused by the accumulation of remnant lipoprotein particles (chylomicron remnants and VLDL remnants or intermediate density lipoprotein (IDL), also called β-VLDL). The disease becomes fully expressed in adulthood and is more common in men. FDBL is associated with an increased risk of premature coronary, peripheral vascular (intermittent claudication), and cerebrovascular disease (Carmena *et al.*, 2000; Durrington, 2007b; Stalenhoef, 2011).

Genetics

In the majority of cases, FDBL is an autosomal-recessive disorder resulting from genetic variations in apolipoprotein E (Apo E), most commonly Apo E2 (Davignon *et al.*, 1988). Multiple copies of Apo E are present in chylomicron remnants and IDL and are able to bind to the LDL receptor and the heparan sulfate proteoglycan receptors with high affinity, promoting the uptake and clearance of their remnants by the liver. The Apo E gene is polymorphic, and encodes three common *APOE* alleles (ε2, ε3, and ε4) of which ε3 is the most common in the general population (82%), followed by ε4 (11%) and ε2 (7%) (Mahley and Rall, 1995; Bennet *et al.*, 2007). Together, these alleles make up for six *APOE* genotypes: ε2ε2, ε2ε3, ε2ε4, ε3ε3, ε3ϵ4, and ε4ε4. The Apo E2 protein (associated with the ε2ε2 genotype) has a very low LDL receptor-binding affinity which impairs remnant removal and clearance, thus leading to elevated plasma concentrations of cholesterol and triglycerides. In most cases, FDBL is associated with the ε2ε2 genotype and its inheritance is autosomal recessive. However, approximately 10% of cases are caused by other rare variants of Apo E or a complete absence of Apo E (Apo E 0/0), and the inheritance in these is autosomal-dominant (Blum and Type, 2016; Koopal *et al.*, 2017; Zannis, 1986). Importantly, only about 15% of individuals with an ε2ε2 genotype develop FDBL, and that an additional metabolic disturbance such as obesity, diabetes mellitus, IR, untreated hypothyroidism, pregnancy, or alcoholism are frequently required to trigger it.

Pathogenesis

The pathogenesis of FDBL is explained by the accumulation of remnant lipoprotein particles—which are abnormally rich in cholesterol—in plasma, and is caused by homozygosity for a particular isoform of Apo E, E2. Apo E2, the mutant apolipoprotein,

differs from the wild-type ApoE (E3) by a single amino acid. The most common Apo E2 variant bears the arginine^{158} → cysteine mutation, and accounts for over 90% of FDBL cases (Mahley and Rall, 1995; Blum and Type, 2016). Remnant lipoproteins carrying this Apo E mutation are poorly recognized by its receptors in the liver and so they accumulate in the plasma. Furthermore, they are stripped of the majority of their triglycerides by LPL-mediated hydrolysis, therefore making them cholesterol rich. The inheritance of the homozygous mutation is autosomal recessive and has a low penetrance (about 1% of the general population). However, FDBL only occurs in 5% of these homozygotes and requires the previously mentioned additional disturbances in order to manifest itself. Heterozygotes with the arginine^{158} → cysteine mutation and one normal allele coding for Apo E3 do not develop FDBL.

On the other hand, approximately 10% of patients with FDHL have other, rarer Apo E variants or lack it altogether, but these show high-penetrance autosomal-dominant inheritance and cause FDBL in heterozygotes carrying only one mutant Apo E allele (Blum and Type, 2016).

Diagnosis

FDBL occurs at a frequency of around 1 in 5000 individuals in the general population and is often missed in clinical practice. Many physicians are unaware of the disease, and diagnosis via its lipid profiles is not straightforward. One striking lipid abnormality that should lead to a suspicion of FDBL is elevation of both total cholesterol and triglyceride concentrations to a similar degree if measured in mg/dL, usually between 300 and 600 mg/dL (7.75–15.50 mmol/L for cholesterol; 3.38–6.77 mmol/L for triglycerides) although triglycerides may occasionally rise up to 1000 mg/dL (11.30 mmol/L). Plasma levels of LDL-C are low due to defective metabolism of VLDL to LDL, while HDL-C levels are normal or reduced; the predominant remnant particles in FDBL are β-VLDLs and these are particularly rich in cholesterol. In fact, the name "dysbetalipoproteinemia" stems from the abnormal gel electrophoresis migration pattern of VLDL, identified as a broad-β band, which is continuous from the β to pre-β levels (Fredrickson *et al.*, 1967; Mahley and Rall, 1995).

The gold standard for FDBL diagnosis was a ratio of VLDL-cholesterol to VLDL-triglycerides >0.30, as determined by ultracentrifugation, but this time-consuming method is no longer used in clinical chemistry laboratories (Blum and Type, 2016).

Instead, FDBL can be diagnosed if the Apo B to total cholesterol ratio is <0.15 g/mmol. Another alternative is the use of an Apo B algorithm that defines FDBL as: Apo B <1.2 g/L, triglycerides exceeding 1.5 mmol/L, a ratio of triglycerides to Apo B <10 and a total cholesterol to Apo B ratio of at least 6.2. *APOE* genotyping, determination of the presence of ε2ε2 by DNA analysis, or isoelectric focusing, as carried out in lipid laboratories, will suffice in the presence of mixed hyperlipidemia (Koopal *et al.*, 2017); in autosomal-dominant FDBL, identification of the rare Apo E variants requires full *APOE* gene sequencing.

Clinical Manifestations

Atherosclerotic CVD and xanthomatosis are the main clinical manifestations of FDBL. Cholesterol-rich chylomicron remnants and IDL or β-VLDL are associated with low-grade inflammation and are highly atherogenic. Moreover, remnant cholesterol appears to confer a greater risk than a similar concentration of LDL-C (Carmena *et al.*, 2004; Nordestgaard, 2016). Recent studies have provided more evidence for cholesterol-rich remnant lipoproteins as important contributors to CVD and to the so-called residual cardiovascular risk that is, the risk remaining after adequate pharmacological LDL-C lowering (Varbo and Nordestgaard, 2017).

FDBL patients have a high prevalence of premature CVD, which is 5–10-fold higher than gender and aged matched control subjects (Hopkins *et al.*, 2005). The prevalence of peripheral vascular disease is notable and is almost the same as that of CHD in some series. This is in sharp contrast to observations in patients with in FH, in whom peripheral vascular disease is uncommon. Associated metabolic disorders (type 2 diabetes, obesity, etc.) are infrequent in FDBL patients.

Palmar planar xanthomas are considered to be virtually pathognomonic for FDBL and present as orange-yellow nodular deposits in the palmar creases (Davignon and Dufour, 2008). Tuberous xanthomas (pedunculated nodules) and tuberoeruptive xanthomas (aggregation of eruptive xanthomas) are common in untreated patients. They tend to occur over the tibial tuberosity, the elbows, knees, and the buttocks, and to decrease or disappear with treatment. The occurrence of proteinuria has been described in Apo E2 homozygotes and in these cases renal biopsy displays the presence of foam cells in the glomerulus, that is, so-called lipoprotein glomerulopathy. These alterations are largely resolved upon treatment of the dyslipidemia (Durrington, 2007a).

The coexistence of FDBL and FH (Carmena *et al.*, 2000) results in a combination of physical findings typical of both disorders: arcus corneae, Achilles and extensor tendon xanthomas, tuberous xanthomas, palmar orange-colored striae, and a tendency toward high body mass index values. The prevalence of CHD is lower than in FH alone, but the prevalence of peripheral and carotid artery disease is high in both genders in this mixed disease.

Treatment

FDBL patients are generally very responsive to lifestyle changes including dietary intervention; a reduction in saturated fat, replacing it with unsaturated fat or long chain *n*-6 (omega-6) polyunsaturated fatty acids, can be of benefit. Where FDBL is associated with diabetes, carbohydrate intake must be reduced, and the intake of daily calories should be restricted if the patient is

overweight or obese. The primary lipid treatment target in FDBL should be non-HDL-C, because LDL-C is usually absent or low (Koopal *et al.*, 2017). The levels for non-HDL-C should be set 0.8 mmol/L higher than the LDL-C target, which means $\leq$2.6 mmol/L in very high-risk patients and $\leq$3.4 mmol/L in high-risk patients (Catapano et al., 2016; Verbeek *et al.*, 2015). Pharmacological treatment includes the use of statins, usually also associated with fenofibrate or bezafibrate, especially when triglycerides are high. Unfortunately, there is a lack of randomized clinical trials evaluating the effect of lipid-lowering drugs on clinical endpoints in these patients.

HL Deficiency

HL is a key liver enzyme involved in catalyzing the hydrolysis of triglycerides and phospholipids in remnant lipoproteins and HDL particles, which thus plays an important role in the conversion of IDL to LDL. HL lipid hydrolysis in remnant particles contributes to their hepatic uptake via an Apo *E*-mediated process. In addition, HL is involved in remodeling remnant particles, HDL, and LDL, as well as in the production of small, dense LDL (Carmena *et al.*, 2004; Kobayashi *et al.*, 2015).

HL deficiency is a rare autosomal-recessive disease resulting in mixed hyperlipidemia, characterized by cholesterol and triglyceride elevations caused by the accumulation of lipoprotein remnants, and this may be accompanied by normal or elevated levels of HDL-C (Hegele *et al.*, 1993). Different mutations in the HL gene (*LIPC*) have been shown to give rise to loss of circulating HL activity, causing an increase in plasma remnants and triglyceride-rich HDL, which produces an increased CHD risk (Chatterjee and Sparks, 2011). The phenotype is similar to that found in FDBL, with elevated levels of total cholesterol and triglycerides, premature arcus cornea, palmar and tubero-eruptive xanthomas, and premature CVD (Semenkovich *et al.*, 2016).

The diagnosis requires the demonstration of HL deficiency with in vitro assays of HL activity in postheparin plasma samples or DNA analysis to identify a mutation. As indicated in the treatment of FDBL, statin therapy is recommended to reduce remnant lipoproteins and CVD risk in this disease.

Hypercholesterolemia

Sergio Martinez-Hervas and Juan F Ascaso, University of Valencia, Valencia, Spain and CIBERDEM-Spanish Biomedical Research Center in Diabetes and Associated Metabolic Disorders, Carlos III Health Institute, Madrid, Spain

Definition

Hypercholesterolemia can be defined as the presence of high plasma cholesterol levels, with normal plasma triglycerides, as a consequence of the rise of cholesterol and apolipoprotein B (apoB)-rich lipoproteins, called low-density lipoprotein (LDL). According to the WHO definition (1970), hypercholesterolemia would be included in IIa phenotype (Ramasamy, 2016).

The limits to define hypercholesterolemia can be established according to plasma levels of total and LDL cholesterol (LDL-C) above the 95th percentile corrected for age and gender in each population.

Classification of Hypercholesterolemia

From an etiological perspective, hypercholesterolemia can be classified in (Ramasamy, 2016; Sniderman *et al.*, 2014):

1. Primary: lipid metabolism disturbances with genetic cause, familial (many cases in the same family) or in isolated cases, without known genetic mutation or without family aggregation, when secondary causes have been discarded.
   This group includes:
   - Familial hypercholesterolemia (FH), which includes:
     - Autosomal dominant hypercholesterolemia (ADH)
       FH by mutations of receptor of the LDL (LDLR)
       FH by familial defective apoB 100
       FH by mutations of proprotein convertase subtilisin/kexin type 9 (PCSK9) or FH3
     - Autosomal recessive hypercholesterolemia (ARH or FH2)
   - Polygenic hypercholesterolemia (PH)
     The distinguishing characteristics between these entities are shown in **Table 1**.
   - Hyperlipoproteinemia(a)
2. Secondary: basically, as a consequence of environmental factors or other disease causing dyslipidemia: hypothyroidism, nephrotic syndrome, cholestasis, asymptomatic acute porphyria, nervous anorexia, hepatoma, different drugs: cyclosporine, progestogens, thiazide diuretics, etc.

Familial Hypercholesterolemia

The FH are a group of inherited genetic defects resulting in severely elevated serum cholesterol concentrations and increased risk of premature cardiovascular disease.

Table 1 Distinguishing characteristics between primary hypercholesterolemia

	ADH	*ARH*	*PH*
Beginning	From birth	From birth	From 20 years old
Frequency	0.5%	Rare	>10%
Xanthomas	Yes	Yes	No
Corneal arcus	+++	+++	+
CVD	+++	+++	++
Phenotype	IIa	IIa	IIa
Heredity	Autosomal dominant	Autosomal recessive	Polygenic
Etiology	LDLR ApoB PCSK9	ARH protein	Various polymorphisms and exogenous factors
Gen	LDLR: Chromosome 19 ApoB: Chromosome 2 PCSK9: Chromosome 1	Chromosome 1	Various polymorphisms

ADH, autosomal dominant hypercholesterolemia; *ApoB*, apolipoprotein B; *ARH*, autosomal recessive hypercholesterolemia; *CVD*, cardiovascular disease; *LDLR*, low-density lipoprotein receptor; *PCSK9*, proprotein convertase subtilisin/kexin type 9; *PH*, polygenic hypercholesterolemia.

 doi:10.1016/B978-0-12-801238-3.65340-0

There are two types of FH: autosomal dominant and recessive. The most common form of FH, the heterozygous state (HeFH) of ADH, is the most frequent monogenic disorder of human metabolism (Nordestgaard *et al.*, 2013). Recent genetic studies suggest that the prevalence of HeFH is twofold higher than previously reported (Patterson and Slack, 1972), being 1:200 to 250 individuals (Nordestgaard *et al.*, 2013). Even in certain populations the disease is more prevalent (Raal and Santos, 2012). On the contrary, homozygous ADH (HoFH) affects approximately 1:1,000,000 individuals (Austin *et al.*, 2004), although recent data suggest that the prevalence could be quite higher (Sjouke *et al.*, 2015; Sanchez-Hernandez *et al.*, 2016).

Pathophysiology

The pathophysiology of FH is due to decreased clearance of LDL from the plasma. Under physiological conditions, the synthesized LDLR is transported to the cell surface. Upon binding to the LDL are internalized into clathrin-coated vesicles that form endosomes in the cytosol where the dissociation of the LDLR and LDL particles occurs. The LDL is catabolized in the lysosomes, and the LDLR, depending on the cholesterol concentration and of diverse regulatory proteins, is catabolized (degraded into amino acids), or on the contrary it can be recycled returning to the cell surface. All these steps can be altered in the FH depending on the class mutations.

ADH can be caused by mutations in three different genes:

- Defects in the LDLR. LDLR gene is located in chromosome 19 (19p13.1–13.3) and codifies a membrane glycoprotein which binds to apoB and apolipoprotein E (apoE) contained in the lipoproteins, through its extracellular domain, that is implicated in the uptake of LDL particles removing cholesterol from plasma. Mutations in this gene are the most frequent (>90%) of ADH. More than 1600 mutations have been described (Calandra *et al.*, 2011). The defects in the LDLR have been classified into five categories: defective ligand binding, defective transport, defective internalization, recycling, and complete lack of receptor (Soutar and Naoumova, 2007).

  Due to their physiological function and clinical repercussion, the mutations are divided into null and defective receptor.

  The LDLR mutations can be divided into five classes (De Castro-Orós *et al.*, 2010):

  Class 1 mutations or null alleles. They occur by deletion of the LDLR promoter, by nonsense changes, or by large rearrangements, all of them leading to an absence or abnormal messenger ribonucleic acid (mRNA).

  Class 2 mutations. They are produced by defective alleles involved in the intracellular transport of the LDLR. This defect is usually caused by small deletions or missense mutations.

  Class 3 mutations. In this group, the LDLR is synthesized and transported to the cell surface. However, the LDLR is not able to bind LDL particles. The binding is variable, and usually is lower than 30% of normality.

  Class 4 mutations. These mutations generate proteins that are not able to group into clathrin-coated pits because there is a defect in the internalization of LDLR.

  Class 5 mutations. These are missense mutations causing a defect in the recycling of the LDLR, eluding the receptor return to cell surface.
- Familial defective apolipoproteinB-100 (FDB). The cause is a mutation affecting a critical region of apoB-100. ApoB is essential to bind LDL to the LDLR. It supposes ~3% of mutations of FH (Ejarque *et al.*, 2008). It is an alteration of ligand lipoproteins with normal receptors of LDL.

  The most frequent mutation detected is R3500Q (Arg3500Gln), located in codon 3500 in chromosome 2 (2p23–24). Other mutations responsible of FDB have been described as the change of arginine by tryptophan in the same position R3500W. New mutations described with low frequency in various populations related to this hypercholesterolemia are R3531C R3480W, and H3543Y (Whitfield *et al.*, 2004).

  In FDB, the cholesterol levels and clinical severity are milder than in FH caused by LDLR mutations, due to the normality of the receptor, capable of binding lipoproteins with apoE.
- The PCSK9 gene mutations in chromosome 1 were described studying a family with ADH. PCSK9 is responsible for the degradation of LDLR. Its presence makes possible the association with LDLR and LDL. The LDLR-PCSK9-LDL complex does not dissociate in the endosomes and is degraded into amino acids and individual lipid components, which are released into cytosol (Zhang, 2017).

  Gain-of-function PCSK9 gene mutations increase the LDLR degradation. Thus, the availability of LDLR on the cell surface is reduced and plasma LDL-C is increased. The FH by PCSK9 mutations supposes a very rare mutation (0.1%) (Blesa *et al.*, 2008).

ARH is a rare autosomal recessive form of FH first described in a Lebanese family with clinical manifestations of HoFH with a recessive pattern of inheritance (Kachadurian and Uthman, 1973). ARH is caused by a rare loss-of-function mutation in the LDLR adaptor protein 1 (LDLRAP1) which encodes a protein required for clathrin-mediated internalization of the LDLR (Tada *et al.*, 2015). AHR is a very rare form of FH and most reported cases have come from Lebanon and Sardinia, and from consanguineous marriages.

Thus, any defect in the previous described genes leads to accumulation of LDL-C, in a moderate way if there is a single copy of the defective gene or in an extensive way in the case of two copies of the same defective gene (homozygous) or two coexisting mutations (compound heterozygote) (Bouhairie and Godlberg, 2016).

Clinical Characteristics

FH is a genetic disease with autosomal dominant transmission pattern (except for ARH) that clinically characterizes by high plasma LDL-C levels, xanthomas, corneal arcus, coronary atheroma plaques, and premature cardiovascular disease.

FH is a disorder with a gene dosage effect. Independently of the genetic defect background the severity of the FH phenotype depends on the residual activity of the LDLR (**Table 2**). Subjects with null mutation in the LDLR gene show higher levels of LDL-C and more frequent cardiovascular disease than those with defective mutation.

HoFH

In individuals with true HoFH the LDLR pathway is markedly defective or nonfunctional. As a consequence, the plasma LDL-C levels rise four to eight times above average (>500 mg/dL) and the patients suffer from severe cutaneous and tuberous xanthomas. The presence of xanthomas in children is highly suggestive of HoFH, especially interdigital xanthomas. In the more severe cases, cholesterol can be deposited in the tendons and joints leading to tendinitis and joint pain, requiring surgical removal. In rare cases, patients could present giant ectopic cholesterol xanthomas in the brain, mediastinum, and gluteus muscles.

Other important manifestation is cardiovascular disease, characterized by accelerated atherosclerosis, that affects the aortic root, coronaries arteries, and other territories, such as the carotid, descending aorta, and ileofemoral and renal arteries. These patients show clinical manifestations as acute myocardial infarction, need for revascularization or sudden death, occurring in the first decade of life. Furthermore, the presence of aortic stenosis due to lipid deposition (Cuchel *et al.*, 2014) is also frequent.

HeFH

Subjects with HeFH show plasma LDL-C levels two to three times above average. Tendinous xanthomas, especially in the extensor tendons of the hand, knees, and Achilles tendon, corneal arcus, and cardiovascular disease appear belatedly. There is more variability in clinical manifestations depending on the age, type of LDLR gene mutation (null or defective), interaction with other genes, and the presence of additional risk factors (hypertension, smoking, etc.) (Nordestgaard *et al.*, 2013).

ARH

Overall the clinical features of ARH patients are similar to those found in HoFH with defective receptor mutations. Compared to negative receptor HoFH, although ARH patients have similar prevalence of xanthomas, these subjects show lower levels of LDL-C, lower prevalence of coronary heart disease, and lower prevalence of aortic valve disease (Fellin *et al.*, 2015).

Diagnosis

Many times, clinicians miss FH. Once hypercholesterolemia is detected, secondary causes should be ruled out. FH diagnosis is based on clinical, biochemical, and genetic criteria. FH must be suspected in the presence of high plasma LDL-C levels, first-degree relatives with hypercholesterolemia, premature coronary disease or sudden death, and physical findings. The presence at an early age of corneal arcus (under the age of 45) or xanthomas should prompt suspicion for this genetic dyslipidemia. However, not all the patients with FH show physical findings (Hovingh *et al.*, 2013).

Certainty diagnosis is given by the finding of causative mutations, even in the absence of other criteria. However, the diagnosis of FH does not require genetic testing. There are validated algorithms which are useful for clinical diagnosis of FH. There is no single internationally accepted set of criteria. The most commonly used are the US MEDPED (Make Early Diagnosis to Prevent

Table 2 Phenotypic variability of primary hypercholesterolemia according to genetic background

	Type of mutation	*LDL-C (mg/dL)*	*Clinical severity*
HoFH	Homozygous null LDLR	500–1000	HoFH phenotype (+++++)
	Homozygous defective LDLR	500–750	HoFH phenotype (++++)
	Homozygous ARH		
	Compound heterozygous LDL/ApoB/PCSK9	400–750	HeFH/HoFH phenotype (+++/+++++)
	Homozygous PCSK9	300–450	HeFH phenotype (+++)
	Homozygous ApoB		
HeFH	Heterozygous LDLR	190–450	HeFH phenotype (++)
	Heterozygous ApoB		LDLR = PCSK9 > ApoB
	Heterozygous PCSK9		
PH	Polygenic	160–190	+
Hyperlipoproteinemia(a)	LPA gene	160–300[a]	+/++

[a]As a consequence of Lp(a) rise.

ApoB, apolipoprotein B; *ARH*, autosomal recessive hypercholesterolemia; *HeFH*, heterozygous familial hypercholesterolemia; *HoFH*, homozygous familial hypercholesterolemia; *LDL-C*, low density lipoprotein cholesterol; *LDLR*, low density lipoprotein receptor; *LPA*, lipoprotein (a); *PCSK9*, proprotein convertase subtilisin/kexin type 9; *PH*, polygenic hypercholesterolemia.

Clinical severity is expressed as + to +++++.

Early Death), the Dutch Lipid Clinic Criteria, and the UK criteria (The Simon Broom register). The US criteria only use lipid levels. However, the criteria developed by the groups in The Netherlands and in the United Kingdom include in addition to cholesterol levels, family and personal history, physical signs and genetic studies, classifying the diagnosis as definite, probable, possible, and unlikely (**Tables 3** and **4**; Hovingh *et al.*, 2013). In the case of absence of familial history of dyslipidemia, after discarding ADH, the LDLRAP1 gene should be studied.

When FH is diagnosed, it is recommended a cascade screening in the family of the index patient to identify people carrying a genetic condition. If genetic study is not available, the screening could be carried out by determination of lipid profiles of close relatives of the index patient (Sniderman *et al.*, 2014).

Treatment

FH is characterized by high levels of LDL-C and high risk of cardiovascular disease, higher than 20%, being considered as a high cardiovascular risk by different guidelines and Scientific Societies (Versmissen *et al.*, 2008; Catapano *et al.*, 2016).

The main objective of the treatment is the reduction of cardiovascular disease events. Thus, it is fundamental non-pharmacological and pharmacological therapy for hypercholesterolemia and other risk factors.

It is of great importance the early initiation of the treatment because of the cumulative cholesterol burden. It has been demonstrated that early treatment and long-term drug therapy can reduce or eliminate the risk of coronary heart disease up to similar incidence than general population (Versmissen *et al.*, 2008).

Lifestyle and other cardiovascular risk factors are an important part of the treatment. All the patients should be advised on lifestyle changes, such as dietary modifications (low in trans and saturated fats, cholesterol, and refined sugars), regular physical activity, avoidance of weight gain, and cessation of smoking. Furthermore, other associated cardiovascular risk factors (hypertension, diabetes, etc.) must be treated.

Lipid-lowering drugs should be initiated as soon as possible after the diagnosis of FH. Lowering LDL-C is the principal objective of the treatment. High-dose statins are first-line therapy. Statin monotherapy allows to decrease LDL-C up to 50%–60%. However, many patients with FH will require adding other LDL-lowering agents depending on the baseline LDL-C levels and the responsiveness to therapy. Drugs that can be added to statins in second line are ezetimibe, bile-acid sequestrants, and niacin. These lipid-lowering drugs are also options in the case of intolerance to statins. The most usual approach is the addition of ezetimibe.

Even, some patients will need three or more drugs to lower LDL-C to achieve the goal. In fact, the achievement rate of LDL-C goal in subjects with FH is just 11% according to previous reports. Thus, most of the patients will not reach the target.

Recently, there are available other medications for lowering LDL-C such as PCSK9 inhibitors. Alirocumab and evolocumab are monoclonal antibodies administered by subcutaneous injection. These drugs have shown reductions of LDL-C up to 60%, being expected that most FH patients will get LDL-C goals.

Additional options include lipoprotein apheresis. This procedure involves extracorporeal filtering of lipoproteins from blood, normally performed biweekly. It is used when drug therapy is ineffective or not tolerated. LDL apheresis achieve up to 60%–70% reductions in LDL-C.

Table 3 Criteria for the clinical diagnosis of FH: Dutch lipid clinic network diagnostic criteria

Dutch lipid clinic network diagnostic criteria for FH	
Family history	
First-degree relative with known premature[a] coronary and vascular disease	1
First-degree relative with known LDL-C level above the 95th percentile	1
First-degree relative with tendinous xanthomata and/or corneal arcus	2
Children aged <18 years with LDL-C above the 95th percentile	2
Clinical history	
Patient with premature[a] coronary artery disease	2
Patient with premature[a] cerebral or peripheral vascular disease	1
Physical examination	
Tendinous xanthomata	6
Corneal arcus prior to age 45 years	4
Cholesterol levels mg/dL (mmol/L)	
LDL-C ≥330 mg/dL (≥8.5)	8
LDL-C 250–329 mg/dL (6.5–8.4)	5
LDL-C 190–249 mg/dL (5.0–6.4)	3
LDL-C 155–189 mg/dL (4.0–4.9)	1
DNA analysis	
Functional mutation in LDLR, apo B or PCSK9 gene	8
Diagnosis (based on the total number of points obtained)	
Definite ≥8, Probable 6–7, Possible 3–5, Unlikely <3	

[a]Premature ≤55 years in men; <60 years in women.

Table 4 Criteria for the clinical diagnosis of FH: Simon Broome diagnostic criteria

Simon Broome diagnostic criteria for FH	
Point	*Criteria*
1	Total cholesterol levels >290 mg/dL (7.5 mmol/L) or LDL-C > 190 mg/dL (4.9 mmoL/L) in adults Total cholesterol levels >260 mg/dL (6.7 mmol/L) or LDL-C > 155 mg/dL (4.0 mmol/L)
2	Tendon xanthomas in the patient or tendon xanthomas in a first- or second-degree relative
3	DNA-based evidence of an LDLR mutation, familial defective apoB-100, or a PCSK9 mutation
4	Family history of myocardial infarction before age 50 years in a second-degree relative or before age 60 years in a first-degree relative
5	Family history of elevated total cholesterol >290 mg/dL (7.5 mmol/L) in an adult first- or second-degree relative Family history of elevated total cholesterol >260 mg/dL (6.7 mmol/L) in a child, brother, or sister 16 years or younger
Diagnosis	
Definite FH = 1 + 2 or 3	
Possible FH = 1 + 4 or 5	

The use of LDL apheresis in subjects with HeFH has been reduced after the appearance of PCSK9 inhibitors for HeFH, currently indicated after adequate pharmacologic treatment when LDL-C is above 300 mg/dL or above 200 mg/dL for those with coronary artery disease. In the case of HoFH it is an essential treatment which must be considered in all the cases (McGowan, 2013).

Recently, two lipid-lowering drugs have been approved for HoFH, lomitapide, and mipomersen. Lomitapide is an oral inhibitor of the microsomal triglyceride transport protein, which is responsible for transferring triglycerides and phospholipids onto chylomicron and VLDL during their assembly in the intestine and the liver, respectively. Lomitapide reduces the secretion of these lipoproteins into the circulation, lowering plasma LDL-C levels by 50%. Mipomersen is an antisense oligonucleotide, administered by subcutaneous injection, that targets the mRNA of apoB. Mipomersen reduces translation of apoB mRNA and the synthesis of apoB by the ribosome, leading to reduced secretion of VLDL, lowering plasma LDL-C levels by 20%–30%.

Currently, the liver transplantation is a therapeutic possibility just indicated in the case of failure of pharmacological therapy and LDL apheresis.

Polygenic Hypercholesterolemia

PH is the most frequent primary hypercholesterolemia with IIa phenotype. It is characterized by plasma levels of LDL-C above the 95th percentile corrected for age and gender in each population, with no monogenic inheritance.

The pathogenic mechanisms are not completely known. PH has been associated with an additive effect of common alleles that have minimal effect on the rise of LDL-C when are present isolated. However, the accumulation of different single nucleotide variations with hypercholesterolemic effect can cause phenotype clinically similar to FH, although autosomal dominant pattern cannot be demonstrated. The presence of different genetic variations could explain why approximately 50% of subjects clinically diagnosed of HeFH do not show mutations. In **Table 5** are shown different loci associated with total cholesterol and LDL-C levels (Willer *et al.*, 2013). Furthermore, exogenous factors, especially lifestyle, may increase the hypercholesterolemic effect of single nucleotide variations.

Clinical manifestations are characterized by high levels of LDL-C when subjects are over 20 years old and cardiovascular disease over 50 years old. Tendinous xanthomas and corneal arcus are rare (**Table 1**). Only 10% of the subjects have family history of hypercholesterolemia (Talmud *et al.*, 2013).

Hyperlipoproteinemia(a)

Significant increases in plasma levels of lipoprotein(a) or Lp(a) are another genetic cause of primary hypercholesterolemia. Lp(a) is a lipoprotein constituted by an LDL particle with an apo(a) molecule linked by a disulfide bridge.

The concentration of Lp (a) in plasma is very variable, from almost nonexistent up to above 300 mg/dL, due to variations in the *LPA* gene encoding the apo(a) protein. It is a monogenic alteration transmitted with autosomal dominant pattern.

Although the physiological role of Lp(a) is not well known, it seems to play a protective role for macrophages and platelets, leading to fibrin activation and healing of lesions. On the other hand, the increase in plasma levels of Lp(a) seems to be involved in the development of atherosclerosis, cardiovascular disease, and aortic stenosis. Lp(a) has been found in several studies to be an additional independent risk marker for cardiovascular diseases, especially when Lp(a) is above the 80th percentile (50 mg/dL).

A usual and reasonable option for patients at risk with high Lp(a) is an intensive treatment of the modifiable risk factors, including LDL-C. Lp(a) reduction can only be achieved by few lipid-lowering drugs. PCSK9 inhibitors and nicotinic acid lower Lp (a) up to 30%. Other option with more intense reduction of circulating levels of Lp(a) up to 80% is antisense drugs targeting the LPA gene.

Low HDL and High HDL Syndromes☆

Shizuya Yamashita, Rinku General Medical Center, Osaka, Japan and Osaka University Graduate School of Medicine, Osaka, Japan
Yuji Matsuzawa, Sumitomo Hospital, Osaka, Japan

Glossary

Apolipoprotein Lipoprotein associated proteins that play a critical role in the structure, solubility, antigenicity, transport, enzyme activation, and cellular uptake of lipoproteins.

Atherosclerosis A common form of arteriosclerosis in which deposits of yellow plaques containing cholesteryl esters, and lipid-laden macrophages (foam cells) are formed with large and medium-sized arteries.

Hepatic Relating to or affecting the liver.

Lecithin A phosphoglyceride that is the major component of cell membranes, consisting of esters of glycerol with two molecules of long-chain aliphatic acids and one of phosphoric acid.

Introduction

Plasma high-density lipoprotein cholesterol (HDL-C) level was shown to correlate negatively with the incidence of coronary heart disease (CHD). Low HDL syndrome is a condition in which plasma HDL-C is low, is a dyslipidemia frequently observed in patients with premature CHD. The anti-atherogenic functions of HDL have been demonstrated by a number of experiments in vitro and in vivo. The injection of HDL and its major apolipoprotein (apo) constituent, apoA-I, was shown to attenuate atherosclerosis in some animal models. Lipid-poor apoA-I and HDL remove cholesterol from lipid-laden macrophages (foam cells) via ATP-binding cassette transporter A1 (ABCA1) and ATP-binding cassette transporter G1 (ABCG1), respectively. The cholesterol is esterified by lecithin: cholesterol acyltransferase (LCAT) to form cholesteryl ester (CE). The CE of HDL is subsequently transferred by plasma cholesteryl ester transfer protein (CETP) to very low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), and low-density lipoprotein (LDL) in exchange for triglycerides (TG). The TG in HDL is hydrolyzed by hepatic lipase (HL) and HDL becomes smaller to take up more cholesterol from foam cells. Furthermore, the IDL and LDL are taken up by hepatic LDL receptor. The CE of HDL particle is taken up by the liver via scavenger receptor class B type I (SR-BI). Thus, excess cholesterol in the foam cells of arteries is transported back to the liver, a process called "reverse cholesterol transport (RCT)" (Fig. 1). In the liver, cholesterol is catabolized into bile acid and excreted into the bile.

The plasma levels of HDL-C as well as the biochemical composition and functions of HDL particles are regulated by apolipoproteins, lipolytic enzymes, lipid transfer proteins, receptors, and cellular transporters such as ABCA1 and ABCG1. Furthermore, transcription factors such as liver X receptor (LXR) and farnesoid X receptor (FXR) that regulate the expression of ABCA1 and ABCG1 are also involved in the regulation of plasma HDL-C levels. Low HDL syndrome is caused by abnormalities of a variety of molecules involved in RCT.

The etiology of high HDL syndrome is also based upon abnormalities in the molecules involved in RCT. In contrast to low HDL syndrome, the story of high HDL syndrome is somewhat complicated. Although high HDL syndrome was previously believed to be associated with a longevity due to a reduced incidence of CHD, Matsuzawa et al. reported two cases of hyper-alphalipoproteinemia (HALP) with premature corneal opacity and in one case angina pectoris, and proposed that high HDL syndrome is heterogeneous, not always beneficial, and sometimes rather atherogenic. Recently, evidence supporting this proposal has been accumulated from many experimental and epidemiological studies.

In the current review, we summarize the clinical characteristics and pathophysiology of low HDL syndrome and high HDL syndrome and the dynamics and efficiency of RCT in these conditions are discussed. Due to limitations of space, many data on genetically engineered mice with altered levels of plasma HDL-C are not discussed.

Factors Regulating Plasma HDL-Cholesterol Levels

HDL particles consist of heterogeneous subclasses. They have a density range of 1.063–1.21 g mL^{-1} and are small in size (Stokes' diameter: 5–17 nm). They consist of approximately 50% lipids and 50% proteins. HDL can be classified by density (HDL_2 or HDL_3 fraction), electrophoretic mobility (α- and pre-β-electrophoretic mobility), and apolipoprotein composition (Lp A-I or Lp A-I/A-II). The quantity and quality of HDL particles are regulated by many factors, such as plasma enzymes, lipid transfer proteins, and cell surface receptors as well as transporters.

This article is an update of Ken-ichi Hirano, Shizuya Yamashita, Naohiko Sakai, Yuji Matsuzawa, Low HDL/High HDL Syndromes, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 199-205.

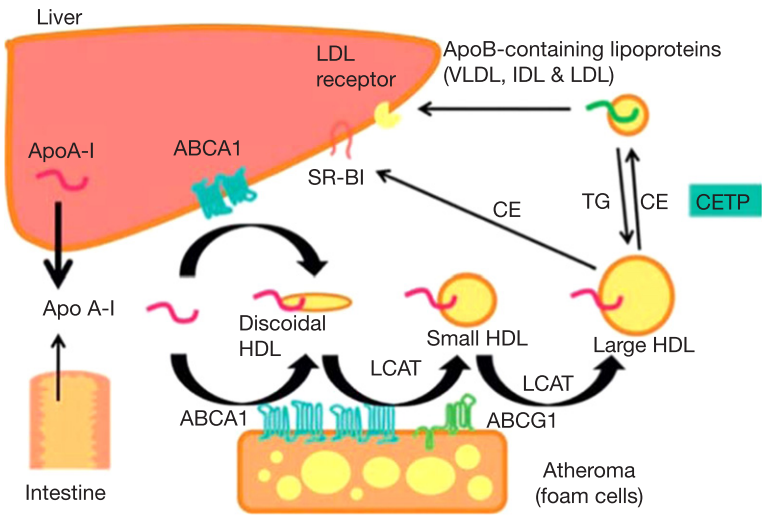

Fig. 1 Metabolic map of apoA-I and HDL-mediated reverse cholesterol transport in humans. *Arrows* denote cholesterol transport in the human body mediated by lipoproteins, plasma lipid transfer proteins, and cell surface receptors and transporters. Cholesterol efflux from peripheral cells is thought to be very diverse. There are some candidates for cell surface receptors such as ABCA1 and ABCG1.

Synthesis and Secretion of HDL

The major constituent of HDL, apoA-I, is synthesized in the liver (~80%) and small intestines (~20%). ABCA1 interacts with apoA-I and is involved in efflux of cholesterol and phospholipids on the plasma membranes, generating "discoidal nascent HDL" particles. The genetic deficiency of ABCA1 causes Tangier disease characterized by enhanced atherosclerosis, hepatosplenomegaly and orange tonsils due to massive deposition of CE in tissues. Transporters such as ABCG1 and other molecules may be involved in HDL-mediated cholesterol efflux, although ABCA1 is requisite for the apoA-I-mediated production of HDL particles. Free cholesterol on nascent HDL particles is esterified to form CE by the action of LCAT. LCAT plays a pivotal role in making HDL particles spherical and mature.

Modification of HDL Particles in Plasma

Several enzymes are involved in modifying the quality and quantity of HDL particles in plasma. The movement of lipids and apoliporoteins during lipolysis is one of the important sources for HDL particles. Two lipases, lipoprotein lipase (LPL) and hepatic lipase (HL), are involved in the lipolysis of chylomicrons/chylomicron remnants and VLDL/IDL, respectively. The hydrolysis of TG-rich lipoproteins by these lipases releases some apolipoproteins, cholesterol and phospholipids into plasma, and these constituents can be used for the formation of new HDL particles. Plasma phospholipid transfer protein (PLTP) transfers phospholipids and cholesterol from apoB-containing lipoproteins to HDL. HL, located on the liver sinusoid, is thought to remodel large and TG-rich HDL particles into smaller less TG-rich ones.

As mentioned earlier, plasma CETP facilitates the transfer of neutral lipids between lipoproteins. CETP transfers CE from HDL to apoB-containing lipoproteins in exchange for TG from apoB-containing lipoproteins to HDL. Plasma CETP deficiency causes a marked elevation of plasma HDL-C levels.

Endothelial lipase (EL) is a phospholipase belonging to the LPL family, which includes LPL and HL. In contrast to LPL and HL, EL mainly regulates HDL metabolism and HDL-C levels in humans and mice. The inhibition of EL activity may elevate the HDL-C level. EL hydrolyzes the phospholipids in HDL and is involved in the remodeling of HDL particles. Although the inhibition of EL activity leads to elevation of HDL-C levels, it has not been established in humans whether EL inhibition may attenuate atherosclerosis.

Hepatic Uptake of HDL and HDL Lipids

As the last step of RCT, at least two distinct pathways are involved in taking up cholesterol from plasma. One is the LDL receptor-mediated pathway and the other is the HDL receptor(s)-mediated pathway. Although the impact and significance of this pathway are not completely understood in humans, SR-BI is the physiologically relevant hepatic HDL receptor established in mice. SR-BI mediates the selective uptake of CE in HDL. There may be other possible pathways, in which whole particles of HDL are taken up and catabolized.

Degradation of ApoA-I or HDL Particles

In the kidney, apoA-I is catabolized by a size-dependent filtration process. Cubilin is thought to mediate the reabsorption of apoA-I from the renal proximal tubule lumen.

Multiple Functions of HDL and ApoA-I

Recently, HDL and apoA-I have been demonstrated to exert a variety of functions, including anti-oxidative, anti-inflammatory, anti- thrombotic, anti-apoptotic, anti-diabetic, anti-infectious, endothelial cell-repairing, vascular endothelial function-improving effects in addition to cellular cholesterol efflux and RCT. These effects may be comprehensively involved in the prevention of atherosclerosis progression.

Recent proteomic analysis of HDL by mass spectrometry identified that HDL is associated with >85 proteins. In addition to proteins consistent with traditionally accepted roles in lipid transport, HDL carries unique constituents such as protease inhibitors involved in hemostasis, acute-phase response proteins, immune function mediators, complement pathway members and metal-binding proteins. This compositional diversity of HDL may suggest the pleiotropic functions of HDL, including roles in lipid transport, oxidation, inflammation, hemostasis, and immune system.

Functional HDL and Dysfunctional HDL

As mentioned earlier, HDL is known to modulate systemic inflammation and is thus anti-inflammatory (functional HDL). In the absence of inflammation, HDL has a complement of antioxidant enzymes that work to maintain an anti-inflammatory state. Conversely, in the presence of systemic inflammation, antioxidant enzymes can be inactivated, resulting in the accumulation of oxidized lipids and proteins that may make HDL proinflammatory (dysfunctional HDL) and increase vascular inflammation. Under these conditions, the apoA-I of HDL particles can be modified by reactive oxygen species. This oxidative modification impairs the ability of HDL to promote cholesterol efflux via ABCA1 and ABCG1. HDL may be a shuttle that can be either anti-inflammatory or proinflammatory, depending on its cargo of proteins, enzymes, and lipids. Under some conditions, HDL can become dysfunctional and even proinflammatory, but this characterization can change with resolution of systemic inflammation or use of certain treatments.

Animal and human studies suggested that measures of the quality and novel functions of HDL might provide an improved means of identifying subjects at increased risk for atherosclerotic events, compared with the current practice of only measuring HDL-C levels. Therapeutic approaches that reduce coronary risk, such as statins and lifestyle changes, can favorably moderate the characteristics of proinflammatory HDL. Furthermore, apoA-I mimetic peptides, delipidated HDL and other compounds that target functional aspects of HDL may provide novel approaches to reduce cardiovascular risk.

Human Genetic Studies as a Tool for Identifying Serum HDL-C Levels and Their Association to CHD

Environmental factors may affect serum HDL-C levels and HDL function, however approximately 40%–60% of the variability of HDL-C can be explained by inherited genetic variations. The study of monogenic diseases showed the impact of selected genes on a certain phenotype of dyslipidemia. The loss of function mutations in the genes *APOA1*, *ABCA1*, and *LCAT* caused conditions of extremely low HDL-C levels. In contrast, the loss of function mutations in *CETP*, *LIPG*, and *SCRB1* underlie extremely high HDL-C levels. Mendelian variants demonstrate a good tool to explore the extreme phenotypes, however they are extremely rare and do not usually explain the great inter-individual population-level variabilities in serum HDL-C levels. Thus, additional tools have been developed to detect the missing heritability of HDL-C levels, including (1) genome-wide association studies (GWAS), (2) whole exome sequencing and target resequencing, and (3) exome-wide genotyping arrays and targeted genotyping panels.

Low HDL Syndrome

Primary Low HDL Syndrome

The etiology of low HDL syndrome can be divided into two; primary low HDL syndrome and secondary low HDL syndrome. The primary or secondary abnormalities in molecules involved in RCT may cause low HDL syndrome. **Table 1** shows the comparison of clinical and biochemical characteristics of primary low HDL syndrome.

Tangier disease

Tangier disease is a familial HDL deficiency characterized by enlarged orange tonsils, mild hepatosplenomegaly, corneal opacification, and a marked reduction of serum HDL-C and LDL-C as well as mild hypertriglyceridemia. Mutations in the *ABCA1* gene

Table 1 Comparison of clinical and biochemical characteristics of primary low HDL syndrome

Affected gene	*Tangier disease*	*Familial HDL deficiency without Tangier disease phenotype*	*Familial LCAT deficiency*	*Fish eye disease*	*ApoA-I deficiency*
	ABCA1	ABCA1 *(some cases)*	*LCAT*	*LCAT*	*apoA-I*
Clinical signs and symptoms					
Typical Tangier phenotype (orange tonsils, hepatosplenomegaly, neuropathy)	+	−	−	−	−
Corneal opacity	+	+	+ + +	+ + +	+ +
Nephropathy	−	−	+	−	−
Risk for coronary heart disease	Moderately increased	Moderately increased	Normal/ increased	Normal/ increased	Increased
Biochemical data					
Plasma total cholesterol	Low	Low	Low	Low	Normal
LDL-cholesterol	Low	Normal	Normal	Normal	Normal
HDL-cholesterol	None	None	Very low	Very low	None
Plasma triglycerides	Increased	Normal	Increased	Increased	Normal
% Cholesteryl ester	Normal	Normal	Low	Low	Normal
Apolipoprotein (apo) A-I	Very low	Very low	Very low	Very low	None
Relative increase in apoA-I precursor	+	+	−	−	−
α-LCAT activity	Normal	Normal	Very low	Very low	Normal
Cell biological data					
Cholesterol efflux from cells (apo A-I-mediated)	Absent	Absent	Normal	Normal	Normal

was identified in patients with Tangier disease. ABCA1 is expressed throughout the body and mediates apoA-I-mediated cholesterol efflux at the plasma membrane. In Tangier disease, cholesterol-laden macrophages are found in various tissues such as liver, spleen, bone marrow, tonsils, nerves, smooth muscle cells, arterial wall, and β cells. The heterozygous parents have about half normal levels of HDL-C. Homozygotes of Tangier disease show a marked increase in the fractional catabolic rate of HDL proteins such as apoA-I, whereas heterozygotes also demonstrate enhanced clearance. Homozygotes have only preβ-1 HDL present in their plasma, while heterozygotes lack large α-1 and α-2 HDL particles, normal preβ-1 HDL, and only 50% of normal cellular cholesterol efflux. It is still controversial whether patients with homozygous Tangier disease develop premature CHD. We previously reported severely calcified coronary arteries visualized by coronary intravascular ultrasonography and impaired insulin secretion in *ABCA1* deficiency. In the Danish general population, two SNPs (V771M and V825I) of *ABCA1* gene were associated with increases in HDL-C, one (R1587K) with decreases in HDL-C, whereas three (R219K, I883M, and E1172D) did not affect HDL-C levels. However, five out of six SNPs (V771M, V825I, I883M, E1172D, R1587K) predicted increased risk of CHD. A stepwise regression analysis showed V771M, I883M, and E1172D as the most important predictors of CHD. Thus, three of six nonsynonymous SNPs in *ABCA1* gene predict risk of CHD in the general population.

Familial LCAT deficiency (FLD) and fish eye disease (FED)

FLD is a very rare autosomal inherited disorder, which includes two distinct clinical syndromes: FLD and FED. Both diseases are caused by the mutations in the *LCAT* gene, leading to a marked reduction in plasma HDL-C. LCAT catalyzes the esterification of free cholesterol on HDL, therefore its deficiency results in accumulation of free cholesterol, but not CE, in a variety of tissues, including cornea and kidneys. Thus, the plasma CE ratio (CE divided by total cholesterol) is markedly reduced. The lipoproteins of familial LCAT deficiency are morphologically abnormal, with the appearance of multilamellar vesicles, rouleaux, LpX-like particles. The major clinical symptoms in FLD are corneal opacities, anemia (red blood cells appear as acanthocytes), and proteinuria, which may eventually progress to renal failure in cases with total LCAT deficiency. Foam cells accumulate in a variety of tissues, including cornea, kidney, liver, spleen, and arteries. Interestingly, patients with FLD are usually not accompanied by premature CHD.

Patients with FED or partial LCAT deficiency present with no clinical signs such as nephropathy except for the characteristic dense age-dependent corneal opacities. The patients are characterized by HDL deficiency and elevated TG levels. They demonstrate an apparently normal activity of LCAT enzyme to esterify cholesterol in plasma, a partial reduction in LCAT concentration, and a nearly normal cholesterol esterification rate. Although the CE content of HDL is very low, the relative CE content of VLDL and LDL is normal. It was postulated that LCAT exhibits two activities: α-LCAT activity specific for HDL that migrate with α-mobility upon gel electrophoresis, and β-LCAT activity specific for pre-β and β-migrating lipoproteins (VLDL and LDL, respectively). Thus, FED was classified as α-LCAT deficiency whereas FLD was due to the lack of both α- and β-LCAT activities. However, after cloning of the LCAT gene, α- and β-LCAT activity represented two functional aspects of the same protein in humans. Total cholesterol and CE levels are relatively higher in FED patients compared with those FLD, despite very low serum HDL-C levels. It is not yet conclusive whether LCAT deficiency is associated with increased risk of CHD. It is possible that other factors such as LDL-C and TG levels may affect the susceptibility to atherosclerosis in patients with FLD and FED.

Apo A-I *genetic mutations and polymorphisms affecting HDL-cholesterol levels*

The human *APOA1* gene is located on chromosome 11 in a cluster with two other apolipoprotein genes, *APOC3* and *APOA4*. Various disruptions and mutations of the *APOA1* gene have been reported. Some *APOA1* gene mutations caused a marked deficiency of plasma HDL-C levels as observed in patients with a genetic deficiency of *ABCA1* or *LCAT* and are associated with premature CHD. However, HDL-deficient patients with *APOA1* mutation do not usually show anemia, proteinuria, orange tonsils, hepatosplenomegaly and premature CHD. Some mutations or polymorphisms in the *APOA1* gene are related to the phenotypic expression of amyloidosis and neuropathy.

Secondary Low HDL Syndrome

Smoking

Low HDL-C syndrome is often observed in subjects who smoke. The reduction of plasma HDL-C by smoking is supposed to be due to the reduced activity of LCAT. Cessation of smoking results in an elevation of plasma HDL-C levels.

Physical inactivity

Low HDL-C syndrome is also observed in subjects who are physically inactive. The mechanism for the decrease of plasma HDL-C by physical inactivity is supposed to be related to the reduced activity of LPL. Aerobic exercise is known to increase HDL-C levels.

Hypertriglyceridemia

Patients with hypertriglyceridemia are often associated with the reduction of plasma HDL-C, but hypertriglyceridemic subjects do not always show the reduction of HDL-C. Hypertriglyceridemia appears to stimulate the lipid exchange and accelerate the catabolism of HDL protein. Reduced activity of plasma lipolytic enzymes causes the impaired catabolism of TG-rich lipoproteins, leading to a reduction of the source of lipids for generating new HDL particles. Patients with low HDL-C have a higher risk for CHD, but a combination of hypertriglyceridemia and low HDL-C is highly atherogenic and markedly increases the CHD risk. The treatment of hypertriglyceridemia by fibrates and nicotinic acids usually increases plasma HDL-C levels.

Visceral fat obesity and metabolic syndrome (insulin resistance syndrome)

Low HDL-C syndrome is often observed in patients with visceral fat obesity. Even in non-obese patients with metabolic syndrome due to increased visceral adiposity, plasma HDL-C level is usually low. The reduction of plasma HDL-C in these subjects may be partly attributed to hypertriglyceridemia and reduction of adiponectin that was shown to increase the hepatic synthesis of HDL via induction of hepatic ABCA1 and apoA-I protein and enhance the cholesterol efflux from macrophages via induction of macrophage ABCA1 protein. After reduction of body weight in patients with visceral fat obesity or metabolic syndrome, plasma HDL-C is usually increased.

Patients with a genetic deficiency of long-chain fatty acid transporter CD36 are often associated with insulin resistance and a clustering of multiple risk factors such as hypertriglyceridemia and low HDL-C levels.

Inflammation

Plasma HDL-C level may be a negative marker for systemic or local inflammation. Some pathological conditions with chronic or acute systemic inflammation (e.g., severe infection and hematological malignancy) are associated with a reduction of HDL-C along with increased serum amyloid A proteins. Several studies have indicated that low HDL-C may be a marker for cardiac events during short-term follow-up in association with an increase in high-sensitivity C-reactive protein (hsCRP).

Cholestatic disorders

In obstructive liver diseases such as end-stage liver cirrhosis, plasma HDL-C levels may be markedly reduced to the same extent as in primary HDL deficiency. The reduction of HDL-C is based upon the decrease in hepatic protein synthesis including LCAT.

Drugs

Some drugs, such as androgens, progesterone, anti-hypertensive drugs (thiazides and beta blockers) or an anti-hyperlipidemic drug, probucol, are known to decrease plasma HDL-C levels. Probucol is a potent antioxidant and anti-hyperlipidemic drug that attenuates xanthelasma and xanthoma formation even in patients homozygous for familial hypercholesterolemia and in Watanabe heritable hyperlipidemic rabbits. Although probucol reduces HDL-C, probucol has a variety of anti-atherogenic functions, which will be discussed later.

High HDL Syndrome

Primary High HDL Syndrome

Etiologies for high HDL syndrome are listed in **Table 2**.

Table 2 Primary and secondary high HDL syndrome

Primary high HDL syndrome
Familial cholesteryl ester transfer protein (CETP) deficiency
Familial hepatic triglyceride lipase (HL) deficiency
Familial hyperalphalipoproteinemia with premature corneal opacity (combined deficiency of CETP and HL activity)
Familial hyperalphalipoproteinemia with genetic abnormalities in scavenger receptor class B type I (SR-BI) gene (*SCARB1*)
Familial hyperalphalipoproteinemia with genetic abnormalities in endothelial lipase (EL) gene (*LIPG*)
Familial hyperalphalipoproteinemia with increased production of apoA-I (*APOA1*)
Familial hyperalphalipoproteinemia with reduced uptake of HDL by lymphocytes
Other genes implicated for high HDL syndrome
Secondary high HDL
Syndrome chronic heavy
Alcohol consumption
Primary biliary cirrhosis
Inhibitors of CETP in plasma
Multiple symmetric lipomatosis
Chronic obstructive pulmonary disease (COPD)
Aerobic exercise
Drugs
Insulin
Estrogen and derivatives
Glucocorticoids
HMG-CoA reductase inhibitor (statins)
Intestinal cholesterol transporter inhibitor (ezetimibe)
Fibrates
Nicotinic acid and its derivative
PCSK9 inhibitors
Cyclosporin etc.

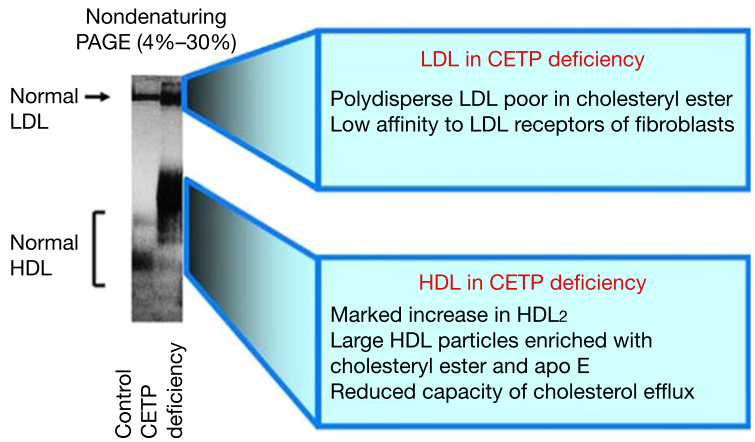

Fig. 2 Lipoprotein abnormalities of CETP deficiency. The functions and composition of both LDL and HDL are abnormal in CETP deficiency. Thus, hyperalphalipoproteinemia due to CETP deficiency is a disorder of RCT.

Familial CETP deficiency and the development of CETP inhibitors

The most important and frequent cause of primary high HDL syndrome is CETP deficiency. In Japan, many patients with HALP due to CETP deficiency have been identified. Patients with homozygous CETP deficiency present with extremely high plasma HDL-C levels (three to six times normal levels). Plasma levels of apoA-I, apoA-II, apoC-III, and apoE are also increased whereas plasma apoB and apoB-containing lipoproteins are a little decreased. As illustrated in Fig. 2, both LDL and HDL from CETP-deficient homozygotes are markedly abnormal in terms of their biochemical compositions and biological functions. Their HDL particles are very large and enriched with CE and apoE. Their LDL particles are small, polydisperse, and enriched with TG and apoB. From the point of biological function, their LDL demonstrates a reduced affinity for LDL receptors of fibroblasts whereas their HDL has a reduced ability to mediate cholesterol efflux from lipid-laden macrophages, suggesting the atherogenicity of both LDL and HDL. HDL isolated from homozygous and heterozygous carriers of *CETP* null mutations were evaluated for their ability to promote NO production in cultured endothelial cells. When compared at the same protein concentration, HDL and HDL fractions from carriers of CETP deficiency were significantly less effective than control HDL and HDL fractions in stimulating NO production, due to a reduced eNOS activating capacity, likely because of a reduced S1P content.

The first and major *CETP* gene mutation identified was an intron 14 splicing defect (IN14), which is a null mutation with a dominant effect on plasma CETP activity/mass and HDL-C levels. The second major *CETP* gene mutation was the missense mutation in exon 15 (D442:G). These mutations are very common in the Japanese population. The effect of D442:G mutation on plasma lipoproteins is less severe than that of IN14. D442:G homozygotes show moderately increased HDL-C levels. In other countries, some genetic variations have also been reported to affect CETP mass and HDL-C levels.

There have been controversies on the atherogenicity of CETP deficiency. We found a unique area (Omagari, Akita Prefecture, Japan) where the subjects with a marked HALP (HDL-C $\geq 100\ \mathrm{mg\ dL^{-1}}$) due to the IN14 mutation are very frequent. A population-based study in this area indicated a U-shaped relationship between plasma HDL-C level and the incidence of ischemic electrocardiographic changes. In subjects with HDL-C $< 1.81\ \mathrm{mmol\ L^{-1}}$ ($70\ \mathrm{mg\ dL^{-1}}$), the incidence increased in proportion to the HDL-C levels. The frequency of the IN14 *CETP* gene mutation was higher in patients with CHD than in control subjects. In subjects aged >80 years, the prevalence of both marked HALP and the IN14 splicing defect was significantly lower than in the younger generation. Thus, a marked HALP caused by IN14 *CETP* gene mutation does not represent a longevity syndrome, suggesting the importance of re-evaluation of the clinical significance and pathophysiology of a marked HALP.

The relationship between *CETP* gene mutations and CHD in Japanese-American men in the Honolulu Heart Program cohort was evaluated. Men, most of whom had a D442:G mutation, showed an increased risk of CHD, but the atherogenic effect of CETP deficiency was observed in subjects with moderately increased HDL-C levels but not in subjects with a marked HALP. In the Framingham Heart Study, plasma CETP activity was measured in 1978 participants and on the average follow-up of 15 years. In multivariable analyses, plasma CETP activity was inversely related to the incidence of cardiovascular disease events. These prospective data suggested that lower plasma CETP activity was associated with a greater cardiovascular disease risk. Similar data were reported from the Ludwigshafen Risk and Cardiovascular Health (LURIC) study in Europe, in which low plasma CETP mass levels were associated with increased cardiovascular and all-cause mortality. In LURIC study, decreased cholesterol efflux capacity was shown in patients with low plasma CETP mass levels. Furthermore, the post hoc analyses of KAROLA study demonstrated a similar tendency in relations between low plasma CETP mass levels and cardiovascular and all-cause mortality. The Ile405Val mutation in the *CETP* gene increases HDL-C levels. Women not treated with hormone replacement therapy who were heterozygous or homozygous for Val405 had a 1.4 to 2.1-fold increase in the risk of CHD, however no significant associations were found in men. Increased HDL-C levels caused by *CETP* gene mutations were associated with an increased risk of CHD in white women.

Regarding the effect of CETP genetic variants on intracerebral hemorrhage (ICH), 12 variants in *CETP* gene showed nominal association with ICH, with the strongest association at the rs173539 locus (OR1.25, $P = 6.0 \times 10^{-4}$). A genetic score of CETP variants found to increase HDL-C by $\sim 2.85\ \mathrm{mg\ dL^{-1}}$ in the Global Lipids Genetics Consortium was strongly associated with ICH risk (OR1.86, $P = 1.39 \times 10^{-6}$). Thus, genetic variants in CETP associated with increased HDL-C raise the risk of ICH. These studies challenge the rationale of pharmacological CETP inhibition.

Inhibiting CETP activity may raise HDL-C and decrease LDL-C levels. Thus, a number of CETP inhibitors have been developed. The initial clinical trial (ILLUMINATE Study) with a CETP inhibitor, torcetrapib, in combination with atorvastatin was prematurely terminated because of an increased cardiovascular event rate and mortality in torcetrapib-treated patients. RADIANCE1 and RADIANCE2 studies examining the effect of torcetrapib on carotid intima-media thickness in patients with familial hypercholesterolemia and mixed dyslipidemia, respectively, were also terminated. No beneficial effect of torcetrapib was observed on carotid intima-media thickness. ILLUSTRATE study also showed a small favorable effect for torcetrapib in the change in normalized atheroma volume, however there was no significant difference in the change in atheroma volume for the most diseased vessel segment, suggesting that torcetrapib may have no significant effect on the progression of coronary atherosclerosis. The lack of efficacy of torcetrapib may be related to the mechanism of action of this drug class or to molecule-specific adverse effects. Torcetrapib significantly increased blood pressure because of the increase in aldosterone levels.

Dalcetrapib is a CETP inhibitor which raises plasma HDL-C levels, but does not decrease plasma LDL-C. Dal-OUTCOMES study investigated the effect of dalcetrapib, at a dose of 600 mg daily, or placebo, in addition to the best available evidence-based care on the risk of recurrent cardiovascular events who had a recent acute coronary syndrome. The study was also terminated because dalcetrapib increased HDL-C levels, but did not reduce the risk of recurrent cardiovascular events. Later, the effect of dalcetrapib on recurrent cardiovascular events in the dal-OUTCOMES study and dal-PLAQUE-2 imaging trial was pharmacogenomically evaluated, using a genome-wide approach. A single-nucleotide polymorphism (SNP) in the adenylate cyclase type 9 (*ADCY9*) gene on chromosome 16 (rs1967309) was identified to be associated with cardiovascular events in the dalcetrapib arm. Patients with genotype AA at rs1967309 showed a significant 39% reduction in the composite cardiovascular endpoint with dalcetrapib compared with placebo. In patients with genotype GG, events rate was increased by 27% with dalcetrapib versus placebo. Thus, the effects of dalcetrapib on atherosclerotic outcomes were determined by correlated SNPs in the *ADCY9* gene.

Studies on another CETP inhibitor evacetrapib also failed because of the absence of cardiovascular event reduction. ACCELERATE trial enrolled 12,092 patients with at least one of the following high-risk conditions: an acute coronary syndrome, cerebrovascular atherosclerotic disease, peripheral artery disease, or diabetes mellitus with CHD. Patients were randomly assigned to receive either evacetrapib at a dose of 130 mg daily or placebo, in addition to standard medical therapy. The primary efficacy end point was the first occurrence of any component of the composite of death from cardiovascular causes, myocardial infarction, stroke, coronary revascularization, or hospitalization for unstable angina. At 3 months, evacetrapib decreased the mean LDL-C level by 31.1% compared with a 6.0% increase with placebo. The mean HDL-C level was increased by 133.2% with evacetrapib versus 1.6% increase with placebo. Although evacetrapib had favorable effects on LDL-C and HDL-C levels, it did not reduce cardiovascular events than placebo among patients with high-risk vascular disease.

A controversial result on another CETP inhibitor anacetrapib has recently been reported. REVEAL trial included 30,449 adults with atherosclerotic vascular disease who were receiving intensive atorvastatin therapy with a mean LDL-C level of 61 mg dL^{-1} and a mean HDL-C level of 40 mg dL^{-1}. The patients were randomly assigned to receive either 100 mg of anacetrapib once daily or placebo. The primary outcome was the first major coronary event, a composite of coronary death, myocardial infarction, or coronary revascularization. During the median follow-up period of 4.1 years, the primary outcome occurred in significantly fewer patients in the anacetrapib group than in the placebo group (Hazard ratio: 0.91; 95% confidence interval, 0.85–0.97; $P = 0.004$). At the trial midpoint, the mean HDL-C level was higher by 43 mg dL^{-1} in the anacetrapib group than in the placebo group (104% increase). Anacetrapib lowered the incidence of major coronary events than placebo, however the development of anacetrapib was finally terminated by the developer Merck. A recent evidence suggests that CETP inhibitors form a complex between themselves, CETP and HDL particles, which might interfere with many physiological functions of HDL. Therefore, CETP inhibition is not a good target of HDL-modifying therapy. We predicted the failure of development of CETP inhibitors based upon the lipoprotein abnormalities and clinical manifestations of patients with CETP deficiency. The details why CETP inhibitors failed are summarized in other reviews.

In contrast to CETP inhibitors, an enhancement of RCT may be a promising strategy. A lipid-lowering drug, probucol, has a long history of clinical application with established efficacy and safety profiles. It is a potent antioxidant drug that has been in clinical use during the past few decades for the treatment and prevention of cardiovascular diseases. As mentioned above, probucol is a unique drug because it reduces plasma HDL-C levels, but attenuates xanthomas. Its mechanism of pharmacologic actions at the molecular level has recently been elucidated. HDL-C reduction by probucol is based upon the increase in plasma CETP activity and hepatic SR-BI expression, and may not be a "side effect" but it most likely might reflect an acceleration of RCT. Probucol inhibits the oxidation of LDL and enhances the cholesterol efflux capacity and anti-oxidative function of HDL particles because it transforms HDL particles to cholesterol-poor small ones and it increases the expression of PON-1 on HDL. The molecular bases of the various anti-atherogenic effects of probucol are illustrated in Fig. 3. Probucol could be reconsidered as an option at least in case statins, which are known to be effective for lowering LDL-C levels and CHD risk, are not effective. A marked CHD risk reduction has recently been reported in long-term probucol treatment of patients with heterozygous familial hypercholesterolemia FH as well as those after coronary revascularization. Therefore, there is more than enough reason to believe that this old drug has much more to offer than known so far.

HL deficiency

HL plays a role in the conversion of IDL into LDL by its TG lipase activity. HL also has the function for the remodeling of large, TG-rich HDL particles into smaller ones by hydrolyzing TG of HDL. HL also enhances the hepatic uptake of HDL lipids. Several mutations have been reported in the human HL gene. Human HL deficiency is characterized by increased IDL-cholesterol levels as well as large and TG-rich HDL particles. Some patients with HL deficiency were reported to have premature atherosclerosis. The subjects from the Copenhagen City Heart Study were genotyped for the -216, -480, and -729 SNPs in the HL promoter. Compared with wild-type, HDL-C levels were 4% and 10% higher in heterozygotes and homozygotes. In prospective and case-control studies, mutation homozygotes versus wild-type had odds ratio for CHD of 1.5 (95%CI: 1.0–2.2) and 1.4 (95%CI, 1.1–1.9) when adjusted for age, gender, and HDL-C. Thus, HL promoter SNPs were associated with increased HDL-C, but an increased risk of CHD.

Familial HALP with premature corneal opacity (combined deficiency of CETP and HL activity)

Several patients with a combined reduction in CETP and HL activity were reported to present with corneal arcus and suffer from CHD. The impact of the combined reduction on atherosclerosis appears to be stronger than that of CETP deficiency alone. One of

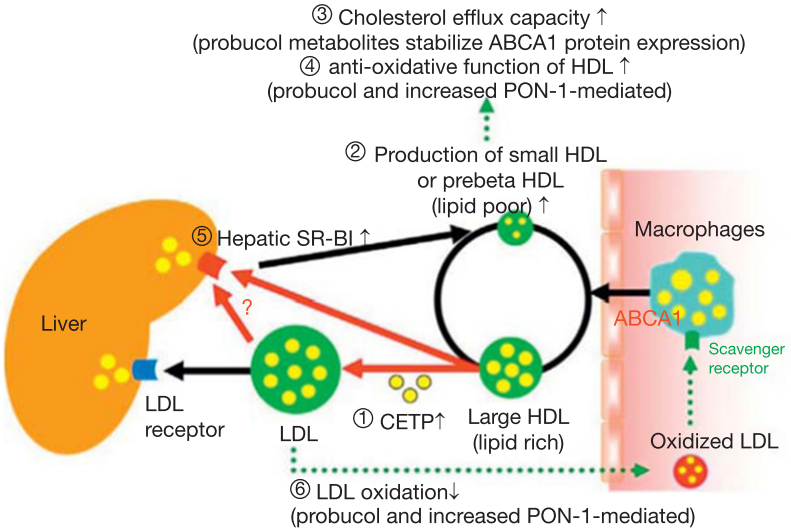

Fig. 3 Molecular mechanisms for anti-atherogenic effects of probucol.

the possible mechanisms is that both CETP and HL play important roles in the remodeling of HDL particles from large to small particles, which are relatively more active for cholesterol efflux. The combined reduction of CETP and HL leads to the marked elevation of HDL-C, with the appearance of very large HDL particles, which are not active for cholesterol efflux.

Familial HALP with genetic abnormalities in SR-BI *(*SCARB1*) gene*

Hepatic SR-BI takes up CE from HDL particles. Adenovirus-mediated hepatic overexpression of *SR-BI (SCARB1)* gene in mice resulted in virtual disappearance of plasma HDL and a substantial increase in biliary cholesterol. In contrast, the deletion of hepatic SR-BI increased plasma HDL-C, but enhanced the development and progression of atherosclerosis in mice. From subjects with elevated HDL-C levels, a family with a missense mutation (P297S) in the *SCARB1* gene was identified. Cholesterol uptake from HDL by primary murine hepatocytes that expressed mutant *SR-BI* was reduced to half of that of hepatocytes expressing wild-type *SR-BI*. The P297S carriers showed increased HDL-C levels and a reduced capacity for cholesterol efflux from macrophages. However, the carotid artery intima-media thickness was similar in carriers and in family noncarriers. Platelets from carriers had increased unesterified cholesterol content and impaired function. In carriers, adrenal steroidogenesis was attenuated. Two point mutations in human *Scarb1* gene, S112F or T175A, were also identified in subjects with high HDL-C levels. More recently, a rare variant in *Scarb1* gene was shown to raise HDL-C and increase the risk of CHD. Targeted sequencing of coding regions of lipid-modifying genes in individuals with extremely high HDL-C levels identified a homozygote for a loss-of-function variant P376L in *Scarb1* gene. The P376L variant impairs post-translational processing of SR-BI and attenuates the selective HDL cholesterol uptake in transfected cells, in hepatocyte-like cells derived from induced pluripotent stem cells from the homozygous subject, and in mice. Subjects heterozygous carriers of the P376L variant showed significantly increased levels of plasma HDL-C and a significantly increased risk of CHD (OR 1.79).

*Familial HALP with genetic abnormalities in EL gene (*LIPG*)*

LIPG encodes EL, a member of triglyceride lipase family. EL mediates HDL catabolism through hydrolyzing the phospholipids of HDL particles, generating smaller HDL particles and enhancing the clearance of HDL in vivo. Targeted sequencing of *LIPG* gene in individuals with extremely high HDL-C showed 17 rare nonsynonymous coding or noncoding variants in the proximal promoter of *LIPG* gene. Similar data were reported which show the association of *LIPG* variants with high HDL-C. Recent a Mendelian randomization study revealed that carriers of the *LIPG* Asn396Ser allele had higher HDL-C levels across the cohorts. However, the 396Ser allele was not associated with a reduced risk of myocardial infarction, suggesting that lifetime elevated HDL-C via *LIPG* loss-of-function does not protect from the risk of myocardial infarction in humans. These data challenge the concept that raising of plasma HDL-C by inhibition of EL to reduce the risk of myocardial infarction.

Familial HALP with increased production of ApoA-I

A family with a marked HALP was reported to have an overproduction of apoA-I. The primary cause(s) is not known. We reported a HALP family with predominant increase in HDL3. The cause of this HALP is speculated to be an increased production of apoA-I. This condition may be protected from atherosclerosis.

Familial HALP with reduced uptake of HDL by lymphocytes

A case of a marked HALP due to a reduced uptake of HDL by lymphocytes was reported. The molecular mechanisms for the reduction of HDL uptake by lymphocytes are unknown.

Other genes implicated for high HDL syndrome

GWAS techniques have identified the causal genes and mechanisms at newly implicated loci associated with HDL-C. Among them, *TTC39B*, *GALNT2*, and *KLF14* will be described as below.

TTC39B

TTC39B denotes tetratricopeptide repeat domain protein 39B. A common variant in the first intron of *TTC49B* was reported to be linked to HDL-C in a large GWAS study. Alleles associated with increased HDL-C were also associated with reduced expression of *TTC39B* in human liver. The product of *TTC39B* gene was shown to be a scaffolding protein, regulating the degradation of the transcription factor LXR through ubiquitination. Chow-fed mice lacking *TTC39B* displayed increased HDL-C levels in association with increased enterocyte *ABCA1* expression and increased LXR protein without change in LXR mRNA. When loaded with a high fat/high cholesterol/bile salt diet, *TTC39B*-deficient mice or mice with hepatocyte-specific *TTC39B* deficiency demonstrate increased hepatic LXR protein and target gene expression, but protection from steatohepatitis and death. Mice fed a Western-type diet and lacking both *LDLR* (LDL receptor) and *TTC39B* showed decreased fatty liver, increased HDL-C, decreased LDL-C, and reduced atherosclerosis. Although this locus was not associated with CHD in GWAS, further studies are necessary to prove *TTC39B* in the development of atherosclerosis and non-alcoholic steatohepatitis.

GALNT2

The *GALNT2* locus was reported to be associated with blood lipid levels in 2008. The *GALNT2* locus was later shown associated with both HDL-C and TG levels. The *GALNT2* encodes an enzyme GalNAc-T2 which exerts the *O*-glycosylation of specific protein

substrates. However, the specific targets and physiological functions of glycosylation by GalNAc-T2 has not been clarified yet. The heterozygous variant of *GALNT2* gene, D314A, was identified in two subjects with HALP. This variant was shown to lead to modest loss of GalNAc-T2 enzyme function and improve postprandial TG clearance in addition to changes in apoC-III glycosylation. However, recent studies indicate contrasting results. Loss-of-function of GalNAc-T2 was associated with lower HDL-C in humans and animal models. PLTP was shown to be one of the targets of GalNAc-T2 glycosylation in humans and deletion of *GALNT2* in humans results in reduction of plasma PLTP activity. The *GALNT2* SNP alleles associated with lower HDL-C were linked to reduced GALNT2 expression human liver. Thus, *GALNT2* is strongly involved in regulation of HDL metabolism, however the possible role of *GALNT2* in atherogenesis remains to be investigated.

KLF14

GWAS studies demonstrated that SNPs about 14 kb upstream of *KLF14* on human chromosome 7 was associated with HDL-C, type 2 diabetes mellitus, additional metabolic traits and CHD. Overexpression of *KLF14* in vivo increased HDL-C and apoA-I levels, whereas deletion of hepatic *KLF14* reduced serum HDL-C and apoA-I levels. *KLF14* mRNA is expressed abundantly in human adipose tissues, however the roles of KLF14 in human liver and adipose tissues and contribution to HDL metabolism remain to be investigated.

Secondary High HDL Syndrome

Chronic heavy alcohol consumption

Chronic heavy alcohol consumption is known to increase plasma HDL-C levels. Some enzymes and transfer proteins, such as CETP and HL, are altered in chronic heavy alcohol drinkers. CETP activity is reduced in these drinkers, but is normalized after cessation of alcohol. The association between alcohol intake and mortality is U-shaped, suggesting that the beneficial effect of alcohol intake is only observed in mild to moderate drinkers.

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a primary cholestatic liver disease, but its primary defect is unknown. In the end-stage of PBC, patients have very low HDL-C with the appearance of Lp-X, similar to other obstructive or cholestatic liver diseases. In the early stage of PBC, patients often demonstrate high HDL syndrome. In some cases, plasma HDL-C is markedly increased to the same extent as that in patients with CETP deficiency. In contrast to CETP deficiency, both activities and protein mass of CETP are markedly increased, whereas HL is reduced in patients with PBC.

Inhibitors of CETP in plasma

Defect in cholesteryl ester transport in serum of patients with uremia receiving maintenance hemodialysis was reported, suggesting an increased inhibitor activity against CETP in these patients.

Other factors or disease states accompanied by HALP

Aerobic exercise increases plasma HDL-C levels. Thus, HALP is sometimes observed in subjects who are continuously doing aerobic exercises. Patients with multiple symmetric lipomatosis, chronic obstructive pulmonary disease (COPD) and hypothyroidism are sometimes accompanied by HALP, but its mechanism is unknown except that HL activity is reduced in hypothyroidism.

Drugs

Some drugs, such as insulin, glucocorticoids, estrogen derivatives, fibrates, HMG-CoA reductase inhibitors (statins), nicotinic acids and their derivatives, intestinal cholesterol transporter inhibitor (ezetimibe), PCSK9 inhibitor and cyclosporin were reported to increase plasma HDL-C levels. Prospective studies using a fibrate, gemfibrozil, demonstrated that increases in HDL-C during treatment were correlated with the prevention of cardiac events.

Recent Epidemiological Observations on the Clinical Implications of High HDL Syndrome

Recently, a marked HALP has been shown to be paradoxically associated with high mortality. In the combination of two prospective population-based studies, the Copenhagen City Heart Study and the Copenhagen General Population Study, the association between HDL-C concentrations and all-cause mortality was U-shaped for both men and women, with both extreme high and low concentrations being associated with high all-cause mortality. The concentration of HDL-C associated with the lowest all-cause mortality was 1.9 mmol L^{-1} (73 mg dL^{-1}) in men and 2.4 mmol L^{-1} (93 mg dL^{-1}) in women. When compared with the groups with the lowest risk, the multifactorially adjusted hazard ratios for all-cause mortality were 1.36 for men with HDL-C of 2.5–2.99 mmol L^{-1} (97–115 mg dL^{-1}) and 2.06 for men with HDL-C $\geq$3.0 mmol L^{-1} (116 mg dL^{-1}). For women, corresponding hazard ratios were 1.10 for HDL-C of 3.0–3.49 mmol L^{-1} (116–134 mg dL^{-1}) and 1.68 for HDL-C $\geq$3.5 mmol L^{-1} (135 mg dL^{-1}). Similar U-shaped association between HDL-C and cardiovascular mortality was demonstrated for both men

and women. Thus, men and women in the general population with extreme high HDL-C paradoxically have high all-cause mortality.

Similarly, a pooled analysis of six cohort studies examined the relation of HDL-C level with CHD and total mortality across a broad range of HDL-C, including values in excess of 80 mg dL^{-1}. In men, the association between HDL-C and CHD events was inverse and linear across most HDL-C values; however, there was a plateau effect in the pattern of association at HDL-C values >90 mg dL^{-1}. In women, the association between HDL-C and CHD events was inverse and linear across lower values of HDL-C, however at HDL-C values >75 mg dL^{-1} there were no further reductions in the hazard ratio for CHD. In unadjusted models, there were increased total mortality risks in men with very high HDL-C, however mortality risks observed in participants with very high HDL-C were attenuated after adjustment for traditional risk factors. Thus, further reductions in CHD risk were not observed with HDL-C values higher than 90 mg dL^{-1} in men and 75 mg dL^{-1} in women, respectively.

In Japan, NIPPON DATA90 followed up 7019 individuals from the Japanese general population and examined the association between HDL-C and all-cause mortality or stroke. HDL-C levels were defined as follows: low (HDL-C <1.04 mmol L^{-1}), reference (1.04–1.55 mmol L^{-1}), high (1.56–2.06 mmol L^{-1}), very high (≥ 2.07 mmol L^{-1}). No significant association was observed between HDL-C and all-cause mortality. Serum HDL-C also showed no association with stroke. The risk for CHD among high HDL-C was lower than reference, however very high HDL-C did not show significant association with CHD and other cause-specific mortality.

An observational cohort study using The CANHEART (Cardiovascular Health in Ambulatory Care Research Team) data set examined the association of HDL-C level with cardiovascular and non-cardiovascular mortality by a "big data" approach. Individuals with lower HDL-C levels were independently associated with higher risk of CV, cancer, and other mortality compared with individuals in the reference ranges of HDL-C levels. Individuals with higher HDL levels (>70 mg dL^{-1} in men, >90 mg dL^{-1} in women) had increased hazard of non-cardiovascular mortality. Previous data suggested that elevations in serum HDL-C may increase the risk of spontaneous ICH. Moreover, as described above, genetic variants in *CETP* gene associated with increased HDL-C raise the risk of ICH.

The mechanisms for the increased atherogenicity in a marked HALP subjects with CHD were investigated. HDL phospholipid composition was significantly lower in HALP patients with CHD than in controls. HDL cholesterol efflux capacity was also significantly lower in HALP patients with CHD than in controls. Therefore, people with very high HDL-C, reduced HDL phospholipid content and cholesterol efflux capacity are associated with the enhanced development of CHD.

Conclusion

Various factors are involved in the etiology of low HDL syndrome and high HDL syndrome. A marked HALP caused by genetic CETP deficiency may not be protected from atherosclerotic cardiovascular diseases, therefore strategies to raise plasma HDL-C levels by CETP inhibitors have been challenged without a success. The enhancement of RCT by drugs such as probucol may have a greater potential as an anti-atherosclerotic treatment despite reduction of plasma HDL-C. The pleiotropic functions of HDL and efficiency of HDL-mediated RCT should be tested when we develop an HDL-targeted drug therapy for prevention of atherosclerosis.

Hypertriglyceridemias and Their Treatment

José T Real, University of Valencia, Valencia, Spain and CIBERDEM-Spanish Biomedical Research Center in Diabetes and Associated Metabolic Disorders, Carlos III Health Institute, Madrid, Spain

Definition and Clinical Consequences of Hypertriglyceridemia

Hypertriglyceridemia (HTG) is a hyperlipemia characterized by increased triglycerides plasma or serum values (TG). In the case, when this increase is accompanied by high levels of cholesterol, we consider mixed dyslipidemia. In the case that the TG increase is associated with low HDL cholesterol plasma levels (HDL-C), we discuss atherogenic dyslipidemia (NCEP Panel, 2002). In this article, we focus on pure HTG.

Normal TG plasma values vary among populations, gender, and age. It is difficult to define cut points for pathological high TG plasma values (NCEP Panel, 2002). We usually accept as a pathological cut point value the 90 percentile for the TG plasma distribution observed in a defined population. For Western populations, different guidelines and recommendations accept a level below 200 mg dL^{-1} as adequate TG plasma values, and TG values below 150 mg dL^{-1} as an ideal recommended level (Jacobson *et al.*, 2015).

HTG is frequently detected in individuals who have had a lipid profile as part of their cardiovascular risk assessment (NCEP Panel, 2002). The prevalence of HTG varies among populations. In the NHANES study (American population), 33% of the subjects presented values >150 mg dL^{-1}, 18% >200 mg dL^{-1}, and 1.7% higher than 500 mg dL^{-1} (Ford *et al.*, 2009). The incidence of HTG is particularly high in men aged 40–50 and is calculated to be around 35% (Carroll *et al.*, 2015). This incidence also varies by race, being highest in Hispanic populations.

Several studies have shown a relation between elevated plasma TG values and atherosclerosis and cardiovascular events (Miller *et al.*, 2011, Sarwar *et al.*, 2007). However, the TG increase is usually associated with other cardiovascular risk factors (abdominal obesity, insulin-resistance, metabolic syndrome, or diabetes) and low levels of HDL-C. In such situations, HTG is associated with qualitative alterations of LDL, remnants of VLDL and chylomicrons, hypercoagulability, blood hyperviscosity, and insulin-resistance, all factors related to endothelial dysfunction, atherosclerosis, and cardiovascular disease (Hargreaves *et al.*, 1992; Fukushima *et al.*, 2001).

High TG plasma values are independently associated with increased risk for cardiovascular disease (CVD) events (Miller *et al.*, 2011). This causal relationship has been supported by several observational studies. Mendelian randomization studies supported this causal effect, with odds ratios for CVD events of about 1.6 (Rosenson *et al.*, 2014). Classical prospective studies in large populations have also found this association, when comparing upper to lower tertiles o quintiles (Sarwar *et al.*, 2007). In addition, HTG is associated with increased mortality in patients with established atherosclerotic coronary heart disease and reduced event-free survival after cardiac bypass surgery (Sprecher *et al.*, 2000).Some authors, assuming this risk, suggest four categories to classify individuals according to fasting TG values (NCEP Panel, 2002), although there are slight differences according to different guidelines in the definition of mild, moderate, and severe HTG. We can accept this classification, which is as follows:

- normal (or ideal): TG $<$ 150 mg dL^{-1};
- borderline high: 150–199 mg dL^{-1};
- high: 200–499 mg dL^{-1};
- very high (or severe): $\geq$500 mg dL^{-1}.

On the other hand, very high TG plasma values ($\geq$500 mg dL^{-1}) have been considered as a risk factor for acute pancreatitis (Pedersen *et al.*, 2016). It is assumed that in a postprandial state, subjects with such fasting values can obtain, after diet intake, values of $>$2000–3000 mg dL^{-1}. Acute pancreatitis is associated with very high TG values caused by elevation of chylomicrons. The exact mechanism of how HTG produces pancreatitis is not known. This disease is a life-treating condition and generates elevated morbidity. The risk of repeated acute pancreatitis is particularly high in individuals with genetic forms of severe hyperchylomicronemia (see below) (Brahm and Hegele, 2013). About 1%–4% of cases of acute pancreatitis are thought to be caused by HTG.

Physiopathology

TG elevations may be caused by an increase in the synthesis of TG-rich particles such as chylomicrons, VLDL or its remnants, or by reduced catabolism of them. The reduced catabolism can be produced by a decrease in the lipolitic action of enzymes such as lipoprotein lipase (LPL), hepatic lipase, or activators of these enzymes (apoCIII), or decreased action of receptors that catabolized these lipoproteins (Brahm and Hegele, 2013).

Causes of Hypertriglyceridemias

The causes of HTG are secondary to other diseases, to the intake of ethanol or drugs (**Table 1**), or primarily genetically based (**Table 2**).

 doi:10.1016/B978-0-12-801238-3.66179-2

Table 1 Causes of hypertriglyceridemia

Lifestyle	*Disease*	*Drugs*	*Genes*
Alcohol intake	Diabetes	Atypical anthipycotics	LPL
Sedentarism	Obesity (abdominal obesity)	Bile acids sequestrans	APO C2
High sugar intake	Polycystic ovary syndrome	Corticoids	APO A5
Reduce physical activity	Metabolic syndrome	Ciclosporine	LMF-1
Weight gain	Chronic kidney disease	Immunosuppressive agents	GIPHBP-1
	Renal insufficiency	Oral estrogens	
	Hypothyroidism	Protease inhibitors	
	HIV infection	Beta blockers	
		Interferon	
		Cyclophosphamida	
		Tamoxifeno	
		Rosiglitazone	
		Retinoids	
Menopause, pregnancy, elderly			

Abbreviations: *LPL*, Lipoprotein lipase; *APO*, apolipoprotein; *LMF-1*, Lipoprotein maturation factor 1; *GIPHBP-1*, Glycosylphosphatidylinositol-anchored HDL binding protein 1.

Table 2 Principal characteristics of primary monogenic hypertriglyceridemias

	Family history	*Lipid phenotype*	*Eruptive xantomas*	*Genetic mutations*	*CVD*	*Pancreatitis*
Hyperchylomicronemias	No	↑TC y ↑↑↑TG	Yes/No	LPL, APOC2, APO A5	No	Yes
Familial hypertriglyceridemia	Yes	N TC y ↑TG	No	LPL	Yes	No
Hepatic lipase deficiency	No	↑TC y ↑↑TG	Yes	HL	Yes/No	No

Abbreviations: *TC*: Total cholesterol; *TG*, Triglycerides; *LPL*, Lipoprotein lipase; *APO*, Apolipoprotein; *HL*, Hepatic lipase; *CVD*, cardiovascular disease.

Secondary Hypertriglyceridemias

Secondary HTG is the most frequent cause of increased TG values. It is often secondary to other diseases or exogenous factors capable of altering TG metabolism (Hegele *et al.*, 2014) (**Table 1**). Some causes are very prevalent in our population, such as diabetes (8%–12% in the adult population).

Lifestyle has become the major cause of TG elevation. A sedentary lifestyle with a diet containing high saturated fat and refined carbohydrates is the principal cause of obesity increase, which is associated with HTG. Particularly interesting is the fact that visceral fat accumulation in obese patients is strongly associated with HTG and atherogenic dyslipidemia. Visceral adiposity is accompanied by insulin-resistance that generates increased free fatty acids due to acquired deficiency of LPL action. In this situation, the liver secretion of VLDL increases, and cannot be suppressed by insulin, thus generating high VLDL values and HTG.

About one-third of diabetic patients have TG plasma values $>200\ \mathrm{mg\,dL^{-1}}$, as a result of visceral adiposity and insulin-resistance. In diabetic patients, HTG is associated with qualitative alterations of LDL and low HDL-C values, known as atherogenic dyslipidemia. This atherogenic dyslipidemia is in part responsible for the high cardiovascular risk of type 2 diabetic patients. The quantitative and qualitative lipid alteration found in these patients is associated with insulin-resistance, poor glycemic control, and obesity. Insulin-resistance facilitates a decrease of TG rich lipoprotein catabolism via interaction with LPL and other lipolitic enzymes. In these patients, an increase in VLDL secretion is also found. The elevation in TG plasma levels results in increases in non-HDL-C lipoproteins such as chylomicrons, VLDL, and their remnants.

A secondary cause of HTG is obesity and being overweight, which have a prevalence in the adult population of >30% and 17%, respectively. Abdominal obesity with metabolic syndrome is a very common cause of HTG with low HDL-C values. Other situations that can raise the TG are pregnancy, hypothyroidism, and renal failure.

Lipid abnormalities occur in 40%–60% of patients with chronic kidney disease and are responsible in part of the high CVD risk observed in these patients. HTG occurs in the first stages of renal insufficiency.

The most frequent factor related to HTG is the consumption of alcohol, which must always be dismissed in all cases. Drugs associated with HTG are hormone replacement therapy with estrogens, tamoxifen, glucocorticoids, cyclosporine, and antiretrovirals (**Table 1**).

Genetically Based Hypertriglyceridemia

Primary hypertriglyceridemia includes genetically based HTG due to mutations in the principal genes implicated in TG metabolism (monogenic HTG). There are also polygenic HTGs that include polymorphism or mutations in several genes implicated in TG metabolism and their interaction with exogenous factors or conditions related to HTG (Hegele *et al.*, 2014).

Monogenic HTG

Hyperchylomicronemias

Hyperchylomicronemia courses show very high values of TG, usually >1000 mg dL^{-1} at fasting. Clinically, they can be accompanied by occasional eruptive xanthomas, lipemia retinalis, hepatosplenomegaly, abdominal pain, or acute pancreatitis (Brunzell and Deeb, 2001). Most patients with hyperchylomicronemia have a secondary form, in which other dyslipemia (partial lipoprotein lipase deficiency) is exacerbated by secondary causes of HTG, such as drugs-related causes (**Table 1**) or poor diabetic glycemic control in type 2 diabetic patients.

We differentiated two phenotypes of hyperchylomicronemias: type I, which occurs in pediatric age, and the increase of TG, which is related to an increase of fasting and postprandial chylomicrons. These forms are autosomal recessive and cause mutations of the lipoprotein-lipase (LPL) gene (complete absence of LPL activity, type Ia), apo C-II gene, lipoprotein maturation factor 1 (LMF-1), apolipoprotein 5, and glycosylphosphatidylinositol-anchored HDL binding protein 1 (GPIHBP-1). These proteins are necessary for the adequate lipolitic function of LPL.

These mutations produce an absence of LPL activity. LPL is an enzyme found in cell surface of capillaries that hydrolyzes TG transported by chylomicrons and VLDL into free fatty acids.

"Classical" type Ia hyperchylomicronemia is a rare genetic disorder characterized by a complete deficiency of LPL activity. Mutations in LPL gene or apo CII, its regulation protein, due to homozygous heritability are responsible for this complete deficiency. Patients are detected in pediatric age with clinical signs such as eruptive xanthomas, lipemia retinalis, recurrent acute pancreatitis, and extremely high TG values with an increase of chylomicrons factions. For this condition there is an approved genetic therapy using LPL (S447X) gene variant in an adeno-associated viral vector that is administered intramuscularly (Gaudet *et al.*, 2010).

In type V forms, HTG is due to an increase of chylomicrons and VLDL, appear in patient carriers of LPL gene mutations that causes partial LPL deficiency, and is diagnosed in the context of other dyslipemias (familial combined hyperlipidemia), in which the presence of exogenous factors, such as those previously discussed (**Table 1**), rise very significantly in TG values and generate this lipoprotein phenotype.

Familial hypertriglyceridemia

Familial hypertriglyceridemia is a rare autosomal dominant disease. Affected subjects presented moderate to severe TG with normal total cholesterol values (Brunzell and Deeb, 2001, Hegele *et al.*, 2014). This disease is often associated with resistance to insulin and high blood pressure. Some studies have demonstrated that affected subjects are carriers in heterozygosis of inactivating mutations in the LPL. These subjects have elevations ranging from 20% to 80% of TG, accompanied by low levels of HDL-C.

Hepatic lipase deficiency

This dyslipidemia originated as a result of a deficiency action of hepatic lipase (LH) (Brunzell and Deeb, 2001). The disease has an autosomal recessive transmission pattern. Numerous studies suggest that LH is significantly involved in the metabolism of remnant lipoproteins and HDL. Patients with LH deficiency have an increase of different particles such as VLDL, chylomicrons, and their remnants. Therefore, the plasma lipoprotein pattern is usually characterized by the presence of moderate HTG. An increase in the incidence of premature coronary heart disease (Kobayashi *et al.*, 2015) has been described in patients with a complete deficiency of LH.

Polygenic HTG

These forms are more prevalent than the previously described classical monogenic HTG. Approximately 26% of pure HTG has as its base some mutations or variants that affect different genes implicated in TG metabolism (Hegele *et al.*, 2014). Some authors have demonstrated in large populations using different molecular analysis methods that 32 loci are associated with HTG (Hegele *et al.*, 2014).

In these subjects, fasting TG values ranged from 200 to 800 mg dL^{-1}, and some of them have a high risk of cardiovascular disease.

Diagnosis of Hypertriglyceridemia

Many patients with HTG have no symptoms; the detection will be carried out by a lipid profile in the context of global cardiovascular risk assessment. Sometimes the lipid alteration is discovered after studying the lipid profile in the evaluation of other diseases that are secondary causes of HTG (Brunzell, 2007). For example, in a patient with diabetes, it is mandatory to perform a lipid profile for evaluating cardiovascular risk, and then the HTG may be discovered.

In patients with primary forms, we can observe clinical signs of HTG: eruptive xanthomas, lipemia retinalis, xanthelasmas, and abdominal pain (Brunzell and Deeb, 2001). In the hyperchylomicronemia syndrome, acute pancreatitis can be the presentation form of the HTG.

In all patients with hypertriglyceridemia, we try to identify the cause (**Tables 1** and **2**) and evaluate other cardiovascular risk factors. In patients with HTG, anamnesis is very important to discover alcohol taking, a diet rich in saturated fat, a history of

diabetes and obesity, and taking drugs involved in TG metabolism such as estrogen, cyclosporine, and corticosteroids (Hegele *et al.*, 2014).

Physical examination of patients with HTG is required to measure their weight, height, BMI, waist circumference, and blood pressure. We also can find xanthelasmas and eruptive xanthomas, and explore the presence of goiter (Brunzell, 2007).

In subjects with HTG, it is necessary to study blood glucose, kidney function, thyroid function, and albuminuria to rule out frequent secondary causes. In patients with a history of abdominal pain and severe HTG, we should suspect acute pancreatitis and look for a cause of hyperchylomicronemia.

When a monogenic form of HTG is suspected, it will be necessary to draw up a family tree and study first-degree relatives in forms that involve dominant inheritance patterns. With the diagnosis of primary HTG, we can study the mutations of genes implicated in its etiology, such as the LPL, apo CII, and apolipoprotein 5 (**Tables 1** and **2**).

Treatment of Hypertriglyceridemia

There are few intervention studies that answer the question about which patients with HTG should be treated. On the other hand, it is not clear if the treatment of HTG may modify CV disease risk, prevent CV events, or prevent acute pancreatitis (Dallinga-Thie *et al.*, 2016).

The treatment of HTG is based on nonpharmacological interventions (lifestyle changes) and pharmacological treatment.

Goal

Most guidelines recommended a desirable TG level of <150 mg dL^{-1}, but unless HTG is severe, the primary treatment goal is LDL-C or non-HDL-C for CVD prevention (Chapman *et al.*, 2011). In patients with severe HTG the primary goal is to reduce TG plasma values to <500 mg dL^{-1} in order to prevent acute pancreatitis.

Nonpharmacological Interventions

In general, we recommend that all patients with mild-to-moderate HTG should avoid taking alcohol and trans fatty acids, and reduce their intake of saturated fat ($<7\%$ of total caloric daily intake), fructose, and simple sugars (Dallinga-Thie *et al.*, 2016). Ingestion of polyunsaturated fat (omega 3–6) is accepted in the form of fish and nuts, since these foods decrease plasma TG levels. Guidelines also recommend increasing complex carbohydrates intake. Diet modifications can obtain up to a 50% decrease in plasma TG.

Obese or overweight subjects must follow a low-calorie diet looking initially for weight loss and then for obtaining a normal weight as a medium-long goal. Reducing weight by 5%–10% can decrease TG plasma values by 20%.

In patients with severe hyperchylomicronemia, their diet should be very low in all kinds of fats (20–40 g per day), whether unsaturated or not. In these cases, to improve the tolerability of the diet, medium chain fatty acids can be useful, since these fatty acids do not raise the chylomicrons.

Aerobic exercise practiced on a regular basis obtains declines of up to 30% of plasma TG. Therefore, we recommend that all patients with HTG perform moderate-to-intense aerobic physical activity for at least 30 min, three times per week.

In secondary HTG, it is necessary to prevent or control the responsible factor for HTG—for example, optimizing glycemic control in a diabetic patient or avoiding drugs related to HTG in subjects who take them (Chapman *et al.*, 2011).

Pharmacological Treatment

Indications of pharmacological treatment

Pharmacological treatment is indicated for the prevention of CVD and pancreatitis (Abourbih *et al.*, 2009).

In subjects with TG $>$ 500 mg dL^{-1}, the risk of acute pancreatitis is high, so we shall indicate, in addition to the discussed changes in lifestyle, the taking of drugs. In patients with a personal history of acute pancreatitis and TG $>$ 500 mg dL^{-1}, pharmacological treatment is also indicated (Chapman *et al.*, 2011).

On the other hand, there is no clear evidence that the treatment of HTG improves CVD risk. Some studies found cardiovascular prevention using drugs that specifically decrease total cholesterol and also TG (statins) or the association of statins with fibrates in selected subgroups of patients (type 2 diabetes, metabolic syndrome).

In all patients with high CV disease risk, the primary aim for CVD prevention is to obtain a decrease in LDL-C or in non-HDL-C with statins (Martin *et al.*, 2012). In subjects with very high cardiovascular risk such as diabetics, patients with multiple cardiovascular risk factors, or patients in secondary prevention, the aim of LDL-C is <70 and <100 mg dL^{-1} in non-HDL-C values (Martin *et al.*, 2012).

In some cases, high-dose statins can decrease TG up to 35% (Martin *et al.*, 2012). In some subgroups of patients, intervention studies suggest that they may benefit from combination therapy of statins with fibrates for cardiovascular prevention. This has

Table 3 Pharmacological treatment of hypertriglyceridemias

Drug	*LDL-C%*	*HDL-C%*	*TG%*	*Mechanism*
Fibrate	↓5–20	↑10–15	↓20–50	Enhance catabolism of TG rich lipoproteins via activating LPL Reduce secretion of hepatic VLDL
Omega 3 fatty acids	↓10	↑5–10	↓20–50	Activation of LPL Inhibition of hepatic dyacilglycerol acyltransferase-1 and 2
Nicotinic acid	↓5–25	↑15–35	↓20–40	Inhibition of hepatic dyacilglycerol acyltransferase-2
Statins	↓30–50	↑5–10	↓10–30	Enhance expression of LDL-R Decrease in hepatic VLDL secretion Inhibition of APO B100 hepatic synthesis

Abbreviations: *LDL-C*, Low density lipoprotein cholesterol; *HDL-C*, High density lipoprotein cholesterol; *TG*, Triglycerides; *LPL*, Lipoprotein lipase; *VLDL*, Very low density lipoprotein; *LDL-R*, Low density lipoprotein receptor; *APO*, Apolipoprotein.

been demonstrated in subjects with TG $> 200\ mg\ dL^{-1}$ and low HDL-C (HDL-C $< 40\ mg\ dL^{-1}$ in men and $50\ mg\ dL^{-1}$ in women), especially in type 2 diabetic subjects and subjects with metabolic syndrome (Abourbih *et al.*, 2009).

In the Helsinki Heart Study, a benefit using gemfibrozil was confirmed in a high risk group with TG levels $>200\ mg\ dL^{-1}$ and LDL-C/HDL-C ratio > 5. In the ACCORD Lipid trial in type 2 diabetic patients, fenofibrate showed no benefit when adding it to a statin in CVD prevention; however, it tended to improve outcomes in a subgroup of patients showing TG $> 204\ mg\ dL^{-1}$ and low HDL-C (ACCORD Study Group *et al.*, 2010).

Drugs

Fibrates

Fibrates (gemfibrozil, fenofibrate) reduce TG 30%–50% (**Table 3**), reaching the maximum reduction between 4 and 6 weeks of treatment (Abourbih *et al.*, 2009). These drugs activate LPL, via the PPAR gamma, which activates the lipolysis of TG-rich particles (VLDL and chylomicrons) (Staels *et al.*, 1998).

In general, fibrates are well-tolerated drugs, although they can cause muscular alterations, especially if they are associated with statins. The best option if you opt for a combination therapy will be to associate fenofibrate with pravastatin, fluvastatin, or pitavastatin (Abourbih *et al.*, 2009).

The risks in terms of side effects of statins increase steeply when used in combination with gemfibrozil. Gemfibrozil interferes with the renal elimination of statins (glucoronization) and reduces the statin catabolism via CYP3A4.

Nicotinic acid

Nicotinic acid in doses of 1.5–2 g per day can reduce total cholesterol and TG (15%–25%). We rarely use this drug in monotherapy to reduce TG levels. Fibrates are more potent and have a better side effect profile. Nicotinic acid induces flush and worsened glycemic control in type 2 diabetic patients (Grundy *et al.*, 2002).

Fish oil

Eicosapentaenoic acid, docosahexaenoic acid, and omega 3–6-rich fish oils can reduce TG plasma values up to 50%. Omega 3–6 can be used in severe forms of HTG associated with fibrates or in patients with moderate HTG and fibrates intolerance (Harris *et al.*, 1997).

Other nonconventional therapies

In cases of severe HTG, severe hyperchylomicronemias with acute pancreatitis or abdominal pain, we use plasma exchange/plasmapheresis if plasma TG values are $>1000\ mg\ dL^{-1}$ and refractory to fibrates or association therapy with fish oil supplements (Chapman *et al.*, 2011).

Genetic therapy with an adenovirus vector modified LPL variant has been approved in adult patients with LPL deficiency and repeated pancreatitis (Gaudet *et al.*, 2010). Emerging therapies are APOC3 messenger RNA inhibitors and ANGLPLT3 inhibitors.

Conclusions

In the general population, hypertriglyceridemia is a very common hyperlipemia and is secondary to very prevalent causes such as diabetes, metabolic syndrome, and obesity.

These lipid alterations, according to the presented phenotype, may be associated with increased risk of cardiovascular events (phenotypes IIb, III, and IV with low HDL-C) or acute pancreatitis (phenotypes I and V).

The diagnosis of the hypertriglyceridemia must focus on the search for the cause.

The treatment of hypertriglyceridemia is based on lifestyle changes (low fat diet, avoiding ingestion of alcohol, and performing regular aerobic physical activity) and pharmacological treatment, usually with fibrates in selected patients.

Glossary

Central dogma of molecular biology The central dogma of molecular biology explains the flow of genetic information, from DNA to RNA, to make a functional product, a protein. It was first proposed in 1958 by F. Crick. However, many exceptions to this dogma are now known.

Copy number variations (CNV) Refers to the duplication or deletion of stretches of a chromosomal region. These can be as large as megabases or smaller than 1000 base pairs.

Genome-wide association study (GWAs) A GWAs is a non-targeted approach that involves rapidly scanning markers across the whole genome, of many people to find genetic variants associated with a particular disease.

Gene–environment interaction Refers to a different effect of a genotype on disease risk in persons with different environmental exposures.

Linkage disequilibrium Describes the association of two alleles more frequently than would occur by chance.

Next generation sequencing (NGS) Is the catch-all term used to describe a number of different modern sequencing technologies that allow us to sequence DNA and RNA much more quickly and cheaply than the previously used Sanger sequencing.

Omics integration Is the integration of omics data obtained for different biological molecules in order to understand their interrelation and the functioning of larger systems.

Single nucleotide polymorphism (SNP) Is a variation at a single position in a DNA sequence among individuals.

Introduction

Knowledge on the genetic basis of obesity has undergone significant development in recent years as a result of optimization, greater speed and reduction in the costs of omics technologies. However, despite this development, many question marks still remain on which genes are the most important in increasing obesity risk and what the contribution of environmental factors is in increasing or decreasing genetic susceptibility. Research into the environmental factors that may promote or neutralize genetic susceptibility to obesity is also increasing in complexity, given that every day more potential contributors are revealed. Hence, we have moved on from investigating the main classic environmental factors (the environmental factor being understood as all that which is not genetic), mainly focusing on diet physical activity, to now consider a wider range of environmental factors, outstanding among which are socio-economic status, educational level, drug consumption, stress, tobacco, sleep habits, meal times or microbiota, among others. Obesity, therefore, even though it may have a strong genetic basis in some individuals, is, for the majority of the population, the result of the interaction between genetic and environmental factors, and so greater genetic susceptibility to obesity can be modulated by environmental factors and vice versa. Despite several initial studies on twins providing percentages of environmental and genetic contributions to obesity (e.g., 40% genetic and 60% environmental), it must be said that these estimates in percentages vary considerably and change a great deal depending on the population analyzed and the methodology employed. For that reason, it is now accepted that, apart from in very few cases of monogenic obesity in which a very strong genetic component exists alongside strong heredity, under most circumstances the obesity phenotype is the result of the interaction between the genetic and the environmental contribution in a balance that appears to vary over time. This introduces a dynamic factor to the genetics of obesity which is not fully understood yet and is still being investigated. It is known that several genetic variants have a greater influence on obesity phenotypes in the early stages of life, whereas others seem to have a greater influence in later life. Nevertheless, more longitudinal studies are required that include individuals from birth to old age in order study the variability of the genetic contribution more accurately from a more dynamic point of view, as well as to study the main interactions with environmental factors during different stages of life. Apart from age, gender may also be another of the factors that have an additional influence on contributing to genetic susceptibility. The additional modulations of gene–environment interactions depending on gender have not been widely studied, so a greater number of studies are required. Recently there has been more interest shown in investigating the genetic and environmental contribution to obesity from a gender perspective, which will provide important data in the not too distant future. Likewise, the possible differences between ethnic groups for some of the genetic variants related with obesity and their environmental modulation need to be researched in greater detail. It is clear from all this that, quite apart from the great genetic heterogeneity that exists in obesity, there are also other factors such as age, gender and ethnicity that together with multiple environmental factors may be capable of modulating genetic susceptibility, so giving rise to a wide range of phenotypes and interactions related with obesity, and that these are different in each individual. Understanding these individual characteristics in detail is essential in the new framework of so-called Precision

 doi:10.1016/B978-0-12-801238-3.66084-1

Medicine. In this article we shall review the most recent knowledge on the genetic bases of obesity, also taking into account that these genetic variants cannot be studied in isolation, but have to be integrated into the study of environmental factors.

Genetic Variants Associated With Obesity

The human genome has approximately 6 billion base pairs (adenine, thymine, guanine and cytosine) and it is organized into 23 pairs of chromosomes. It is estimated that there are about 20,000 genes in the human genome, many fewer than those originally planned, due to the fact that the same gene can give rise to several proteins, as we will detail later. Genes constitute the transcriptionally active part of chromosomes. In the structure of a gene we basically distinguish introns and exons. Introns are non-coding sequences, whereas exons are coding. In the DNA sequence, variations can occur that can be of different types (insertions, deletions, duplications, etc.). The best known are the changes of a single nucleotide, so-called SNPs (single nucleotide polymorphisms). The human genome counts >10 million of SNPs. These SNPs are distributed throughout the genome and their effects depend on the biological role (e.g., exon or regulatory) and state (e.g., silent or active) of the genomic regions where they occur. Interestingly, some of the SNPs are not independent and the linkage disequilibrium (LD) parameters are relevant indicators in the genetic studies. LD, defined as the nonrandom association of alleles at different loci is commonly used to indicate that two SNPs are associated. Thus, sometimes, in a study the researchers show statistically significant associations between one SNP and the disease phenotype, however the polymorphism tested is not directly casual but is in LD with an adjacent polymorphism that is. The non-random association of alleles at more than two loci constitutes an LD block (haplotype) and can predict the allele of adjacent (not genotyped) polymorphism. A commonly used measure of association between alleles, r^2, may be used to represent LD. Large values of r^2 indicate stronger association between alleles. A threshold based on r^2 ($r^2 \geq 0.8$) can be used to determine whether two SNPs are associated. A practical advantage of the LD in epidemiological studies is that because of LD in many regions of a gene, every SNP in a genome does not need to be genotyped. Instead, LD-tagging SNPs can be selected that cover the major LD blocks. Likewise non-determined genotypes can be imputed so increasing the genotyping density. Aside from the SNPs, there are other types common polymorphisms that affect more than a pair of bases. These polymorphisms may be insertions of several bases, deletions of several bases or also other polymorphisms known as "copy number variations" (CNV). The CNVs are DNA segments of one kilobase or larger that is present at a variable copy number in comparison with a reference genome. The CNV have been associated with different diseases, among them obesity. Thus, Kutalik and co-workers published in 2017 a large-scale CNV association meta-analysis on anthropometric traits in up to 191,161 adults from 26 cohorts. The study revealed five CNV associations at 1q21.1, 3q29, 7q11.23, 11p14.2, and 18q21.32 with anthropometric traits. In addition the authors confirmed findings previously shown at 16p11.2 and 22q11.21, for at least on obesity-phenotype.

Although there are several types of obesity that present a clear genetic influence through variations in a single gene or a small set of genes, most cases of obesity seem to have a multi-genic influence with variations in multiple genes and whose effects can be additive. Hence two types of obesity have been established the so-called monogenic type that follows the former pattern and the polygenic type in which, there would also be a modulation by environmental factors. Observed in monogenic obesity is a high level of penetrance and at times a SNP in the DNA may give rise to a functional variation whose effects are enough for obesity to develop. There are several well-documented types of SNPs related with monogenic obesity, such as those found in the leptin gene (LEP), the leptin receptor (RLEP), in the melanocortin 4 receptor (MC4R), etc. These SNPs, characterized by low prevalence are associated with very early signs of monogenic obesity and require early and highly personalized treatment. On other occasions, instead of a SNP being involved, there are alterations of larger pieces of the DNA, as, for example, the microdeletion in the segment 15q11–q13 in Prader–Willi syndrome, which affects one in every 25,000 births and leads to well characterized monogenic obesity. There are other well-characterized types of monogenic obesity that have been presented in detail in other articles. However, there are also other types of monogenic obesity that either because they are less frequent or are clinically more heterogeneous, are more difficult to characterize. In these cases, the possibility of undertaking direct DNA sequencing of the patients at low cost and quickly is very useful and in the near future we will be able to gather more knowledge on new types of monogenic obesity.

Nonetheless, despite the advances in technology for analyzing the genome, most cases of obesity respond to a polygenic pattern that is more difficult to investigate. Initially, the first studies on the genetics of obesity focused on the analysis of so-called candidate genes, that is, those that either physiologically or biochemically were known to codify for known proteins that were well-characterized and implicated in the pathways related with obesity. However, the emergence of the genome-wide association studies (GWAS) has led to further advances in gene identification. Interestingly, there is some partially overlapping continuum between monogenic and polygenic forms of obesity with several genes involved in the two conditions. Some loci that were found to be associated with polygenic obesity include a gene that is mutated in a monogenic form of obesity. The MC4R gene is a well-studied example. Several rare loss-of-function coding mutations in the MC4R have been associated with monogenic obesity. In addition, common polymorphisms at the MC4R gene (e.g., SNP rs17782313 near MC4R) have been associated with an increased risk of common obesity.

Obesity Phenotypes

When investigating genetic influence in obesity risk, both for the candidate gene or for the GWAs approaches, the definition of obesity is very important. Most studies have analyzed the obesity phenotype following the World Health Organization (WHO)

definition, that is, a body mass index (BMI) $\geq$ 30 kg/m^2. However, other studies have focused on abdominal obesity, based on the measurement of waist circumference. Also, the use of BMI as continuous variable without categorizing it as presence or absence of obesity, has been frequently used as phenotype. Less frequent have been studies that use the more complex measurements of adiposity, fat distribution, etc. Although various genetic variants are associated at the same time with a number of these phenotypes, others may be more specific for the phenotype analyzed. Additionally, the study design is important as it is known that genetic variants associated with prevalent obesity may be distinct from those associated with incident obesity and it seems there may be still ore difference in the variants associated with greater or lower weight loss in obese individuals following a lifestyle intervention.

Candidate Genes Associated With Obesity

Although the candidate genes approach was employed at the beginning of research into the genetic bases of obesity, this was later replaced by other strategies employing the screening of the whole genome. However, the candidate gene approach is now beginning to resurface as more data on new genes and the metabolic pathways related to obesity become known. Thus several classifications have been used to define the candidate genes related to obesity. Among them, we can consider a big group those genes involved in: (A) genes encoding factors regulating food intake; (B) genes encoding factors implicated in energy expenditure and (C) genes encoding factors implicated in adipogenesis. Greater than 300 polymorphisms in these candidate genes have been associated with several obesity phenotypes. Some of them have been consistently replicated in more than four studies.

Among the genes encoding factors regulating food/energy intake (A), although there are still many unidentified features concerning energy homoeostasis and energy balance, it is accepted that hypothalamic and brain stem centers are involved in the regulation of these processes. Thus, variations in the LEP and LEPR genes were extensively investigated. It is well known that monogenic human leptin deficiency has been identified in children showing severe early-onset obesity with intense hyperphagia and undetectable levels of serum leptin due functional mutations resulting in a premature codon stop. In the general population, common polymorphism in the LEP or RLEP gene have been associated with a small or moderated increased risk of obesity or higher BMI. Similarly, mutations in proopiomelanocortin (POMC) gene are associated with hyperphagia and early-onset obesity due to the deficient activation of the MC4R gene. Common SNPs in the POMC gene have also been associated with higher BMI or obesity risk in subjects from the general population. Following the same pattern, mutations in the proprotein convertase 1 (PC1) gene (associated with hypocortisolaemia); neuropeptide Y (NPY) gene or the ghrelin receptor gene have been reported to be associated both with early-forms of obesity as well as with a relatively small increased risk of common obesity phenotypes. The list of candidate genes encoding factors regulating food intake is increasing and even novel genes recently discovered by GWAs are being included once the potential mechanisms have been investigated. Also in this group are included the genes related to taste perception and food preferences. Taste perception has been suggested as a key component of food preferences and choice. Five taste modalities (bitter, sweet, umami, salty, and sour) are generally accepted as basic tastes. In recent years, a sixth taste-that of fat taste-has also been proposed. Taste perception has a strong genetic component, this being greater for the bitter taste. Functional variants in the TAS2R38 gene have been strongly associated to bitterness and the common SNPs in the TAS2R16 gene, to astringency. Less strong associations but still statistically significant have been reported between the TAS1R2 and TAS1R3 genes and sweet taste. Similarly, variation in umami taste depends on TAS1R1 and TAS1R3 polymorphism. Genes determining salty and sour tastes are less investigated. However, the fat taste seems consistently associated with SNPs in the CD36 gene. Overall several studies have associated SNPs in the taste genes with obesity phenotypes using a Mendelian randomization approach. Some of them have found statistically significant associations, however there is a great heterogeneity and more research has to be done.

Regarding variations in genes encoding factors implicated in energy expenditure (B), several candidate genes have been consistently associates with obesity phenotypes taking into account that adaptive thermogenesis in related to the mobilization of lipids form fat tissues. Polymorphisms in the B-adrenoceptor genes (ADRB1, ADRB2, ADRB3) have been massively studied, and dozens of statistically significant associations among ADRBs SNPs and obesity phenotypes, reported. Likewise, uncoupling proteins (UCPs) gene polymorphisms, mainly in the UCP1 and UCP2, mediating mitochondrial proton leak releasing energy stores as heat (energy metabolism efficiency) have been associated with obesity phenotypes in several studies. Regarding candidate genes encoding factors implicated in adipogenesis (C) this is a dynamic area and the list of these candidate genes is increasing. There are several transcription factors involved, the PPARs, mainly the PPARG2 gene having a key role in determining obesity phenotypes and related diseases.

Recently, genes related with circadian rhythms (CLOCK, BMAL1, PER1, PER2, RORA, etc.) have been other emerging candidate genes associated with obesity being involved in several of the main functional groups previously described.

Genome-Wide Approach

Unlike the earlier approach in which specific variants in certain candidate genes are investigated with a specific hypothesis, in the genome-wide approach there is no specific hypothesis but an analysis of polymorphisms in all the chromosomes to see which of them are more significantly associated with obesity or related phenotypes. In order to carry out genotyping, high-density arrays are used. In recent years technology has allowed us to determine a greater number of SNPs at an increasingly faster and cheaper rate.

While the first arrays to be called complete genome arrays provided an analysis of 10.000 SNPs distributed in all the chromosomes, later this density increased up to the point to now when we can quite easily determine 2 million or more SNPs for each person. Basically what one does in these studies is genotyping using high-density arrays a group of cases of obesity and compare the frequency with that which each SNPs presents in a non-obese control group. These studies are known as GWAs, as previously mentioned. Sample sizes have to be large in order to achieve a sufficient statistical power and often meta-analyses from various GWAs studies are used to increase statistical power. In statistical analyses, besides cases and controls, anthropometric measurements can be analyzed as continuous variables. Manhattan Plots are often used to show the results. The higher a SNP ($-\log10$ of the association *P*-value), the more associated it is the corresponding SNP with the obesity phenotype (its *P* value of association is smaller). To consider an association as statistically significant, the nominal value of statistical significance ($P < 0.05$) is not used but rather that value is corrected by the number of comparisons made in order to minimize false positives. The commonly accepted value as the threshold for considering an association as being statistically significant on the GWAs level is $P < 5 \times 10^{-8}$. To date hundreds of GWAs and meta-analysis of GWAs (by several International Consortia) have been undertaken with different obesity phenotypes, and dozens of genes associated with obesity have been identified which were not revealed through the candidate gene approach. Although initial GWAs reported promising associations between common variants in the INGIG2, GAD2 and ENPP1 genes and BMI, the results have not been widely replicated. Hence, the first gene consistently associated with common obesity was identified by Frayling and co-workers in 2007 by a GWAs undertaken in the U.K. using a small sample size and a relatively low density array (compared to present metrics), which allowed us to analyze approximately 500.000 SNPs. The SNP that was most significantly associated with common obesity was the famous rs9939609, situated in intron 1 of the fat mass and obesity (FTO) gene. Although this SNP was not apparently functional, given that it is in an intron, on replicating the association in another 13 cohorts (with 38,759 participants), in the meta-analysis estimations, the risk allele was significantly associated with a 1.67-fold increased odds of obesity when compared with those not inheriting a risk allele. Later GWAs have found new genetic variants associated with obesity phenotypes (some of the main genes initially identified were: TMEM18, MC4R, GNPDA2, BDNF, NEGR1, SH2B1, ETV5, MTCH2, KCTD15, SEC16B, TFAP2B, FAIM2, NRXN3, RBJ, GPRC5B, MAP2K5, QPCTL, TNNI3K, SLC39A8, FLJ35779, LRRN6C, TMEM160, FANCL, CADM2, RKD1, LRP1B, PTBP2, MTIF3, RPL27A and NUDT3, among others). This number increased as the sample size increases in new meta-analyses that now include hundreds of thousands individuals. Moreover, these meta-analyses of GWAs have been extending from the initial ones carried out mainly on Caucasian populations to other less well studied populations, such as Asian, Afro-American, etc. so that we now have more specific information. A few GWAs have also analyzed possible gene-sex and gene-age interactions at the genome-wide level and have detected some heterogeneous effects that require deeper study of their mechanisms. Thus, Winkler and co-workers, in 2015 carried out a meta-analysis of 114 studies (up to 320,485 individuals) with GWAs data in determining BMI in waist-to-hip ratio (adjusted for BMI, WHRadjBMI). Four strata (men $\leq$50years, men $>$50years, women $\leq$50years, women $>$50years) were considered. For BMI they identified 15 loci (11 previously established for main effects, 4 novel) that showed age-specific effects. For WHRadjBMI, they identified 44 loci (17 novel) with sex-specific effects (28 showing large effects in women).

Beyond GWAs: Genetic Risk Scores, Next Generation Sequencing and More

GWAs allow us to discover the main SNPs associated with the phenotype of interest in a separate way. To discover the joint contribution of various SNPs to obesity risk or related phenotypes, so called GRS (genetic risk scores) are used. **Fig. 1** presents the calculation of the GRS in their two main modalities: (a) unweighted and (b) weighted. In the unweighted, the score calculation is done by adding up the number of risk alleles that the individual has, whereas in weighted GRS, one also has to take into account the effect (magnitude of the association with the obesity phenotype: regression coefficient, etc.) of each genetic variant and that not all genetic variants have the same association with obesity traits, some being more relevant than others. Multiple studies have analyzed and quantified the influence of various GRS with obesity in different populations. Among them, Song and co-workers recently focused on a GRS including 96 SNPs associated with adult BMI. The authors analyzed the trajectories of body fatness from age 5 years up to 65 for women (Nurses' Health Study) and men (Health Professionals). They concluded that individuals with higher GRS at baseline were more likely to maintain a heavy BMI and gain weight throughout life. This GRS has been used in other studies and the SNP included for Caucasian are as follows: AGBL4(rs657452), ATP2A1(rs3888190), BCDIN3D(rs7138803), BDNF(rs11030104), C18orf8(rs1808579), C6orf106(rs205262), C9orf93(rs4740619), CADM1(rs12286929), CADM2 (rs13078960), CLIP1(rs11057405), DMXL2(rs3736485), EHBP1(rs11688816), ELAVL4(rs11583200), EPB41L4B(rs6477694), ERBB4(rs7599312), ETV5(rs1516725), FHIT(rs2365389), FLJ30838(rs1016287), FOXO3(rs9400239), FPGT-TNNI3K (rs12566985), FTO(rs1558902), FUBP1(rs12401738), GBE1(rs3849570), GNAT2(rs17024393), GNPDA2(rs10938397), GPRC5B(rs12446632), GRID1(rs7899106), GRP(rs7243357), HHIP(rs11727676), HIF1AN (rs17094222), HIP1(rs1167827), HNF4G(rs17405819), HSD17B12(rs2176598), KAT8(rs9925964), KCNK3(rs11126666), KCTD15(rs29941), LINGO2 (rs10968576), LMX1B(rs10733682), LRP1B(rs2121279), MAP2K5(rs16951275), MC4R(rs6567160), MTCH2(rs3817334), MTIF3(rs12016871), NAV1(rs2820292), NEGR1(rs3101336), NLRC3(rs758747), NRXN3(rs7141420), NT5C2(rs11191560), OLFM4(rs12429545), PARK2(rs13191362), PGPEP1(rs17724992), PMS2L11(rs2245368), POC5(rs2112347), PRKD1 (rs11847697), PRKD1(rs12885454), PTBP2(rs11165643), QPCTL(rs2287019), RABEP1(rs1000940), RALYL(rs2033732), RARB (rs6804842), RASA2(rs16851483), RPTOR(rs12940622), SBK1(rs2650492), SCARB2(rs17001654), SEC16B(rs543874), SLC39A8

(rs13107325), STXBP6(rs10132280), TCF7L2(rs7903146), TDRG1(rs2033529), TFAP2B(rs2207139), TLR4(rs1928295), TMEM18(rs13021737), TOMM40(rs2075650), TRIM66(rs4256980), UBE2E3(rs1528435), ZC3H4(rs3810291).

Currently, the SNPs selected to be included in a GRS are mainly based on the *P*-value obtained in the GWAs (top-ranked). However, this is a limitation. Other analytical strategies such as pathways and networks will be ideally employed to integrate data from several omics. Briefly, in pathway analysis, gene sets corresponding to biological pathways are tested for significant relationships with a phenotype. Networks can also collect genes and other biological elements for quantitative and visual assessment of relationships. These approaches can improve the GRS construction and validation and more work in needed. However, a limitation of the pathway-based studies is the absence of guidelines, leading lack of optimal methods, high variability in results, and barriers to further application. At the same time, we also have also enjoyed a great technological improvement in direct sequencing, now called NGS (next generation sequencing), as instead of being based on the rudimentary techniques applied in the Human Genome Project (traditional Sanger method of sequencing capillary electrophoresis, considered as first generation) NGS technologies provide a greater yield of data at a lower cost. At present, the sequencing of exomes is already widespread in genetic studies of obesity and various individual and meta-analysis studies have been undertaken to identify various low-frequency genetic variants associated with obesity. Moreover, with the emergence of NGS, this is a covenant moment for drawing targets on gene enrichment and pathways analysis for future development in the obesity field.

Genetic Modulation

Despite the great strides taken in sequencing the genome, pathways analysis, etc., knowledge of gene variants is insufficient to predict the risk of obesity, as here are other more dynamic regulatory elements known as the epigenome that are in turn capable of regulating the expression of DNA sequences. Today, therefore, it is essential to jointly study the genome and epigenome for a better understanding of the molecular bases in cardiovascular risk phenotypes. The existence of these regulations helps us to understand

why the fundamental dogma of biology (Fig. 2) is not fulfilled. Panel A shows the classic process in which a DNA is transcribed to a RNA and the latter results in a protein, while panel B shows the now recognized more complex situation through which a single DNA may give rise to different proteins due to the influence of differing regulatory processes. Epigenomics is the study of the key functional elements that regulate the genetic expression of a cell. Unlike the genome that is the same in all somatic cells, the epigenome is specific for each type of cell, so adding complexity to the study and making the origin of the sample that has been taken for analysis more important. There are many types of epigenetic modifications. The most studied ones are methylations and regulations by non-codifying RNAs, among which are microRNAs, but also other types of RNAs. Modifications of histones (acetylations, phosphorylations, glycations, etc.), another type of epigenetic regulation, have a still higher level of complexity and have been little studied in epidemiological studies of obesity in humans. The huge interest in deepening our knowledge of epigenetic regulators lies in the fact that they are dynamic. Unlike SNPs in DNA, epigenetic markers can be modified and the knowledge of the factors that intervene in that modification may be crucial for prevention and/or treatment of obesity. It is at this point where environmental factors seem to be decisive by exercising epigenetic influences and, therefore, modulating genetic susceptibilities. Although not well-known, many of the effects of diet, physical activity, drug consumption, sleep, stress, etc. on modulating genetic expression appear to act through epigenetic mechanisms and so it is necessary to study both genetic and environmental factors jointly by employing an integrated omic approach.

Although their mechanisms are unknown, for more than a decade various gene–environment interactions have been described in the main genes associated with obesity. Outstanding, therefore, are the gene-diet interactions with the FTO gene (and other obesity genes in form of GRS) with total fat intake, saturated fat, proteins, etc. that can modulate the genetic effect. All these interactions have been widely reported in the nutrigenetic filed. Also the gene–environment interaction of the FTO gene with physical activity is also very consistent and relevant. According to this interaction, subjects with the FTO-risk allele do not present the corresponding obesity phenotype.

Summary and Conclusions

Developments in technology, with the possibility of increasing the sample sizes in association studies of the complete genome as well as the number of polymorphisms analyzed, will allow us to identify new genetic variants associated with the different phenotypes of obesity. These genetic variants may be incorporated into already existing GRS and contribute to increasing the

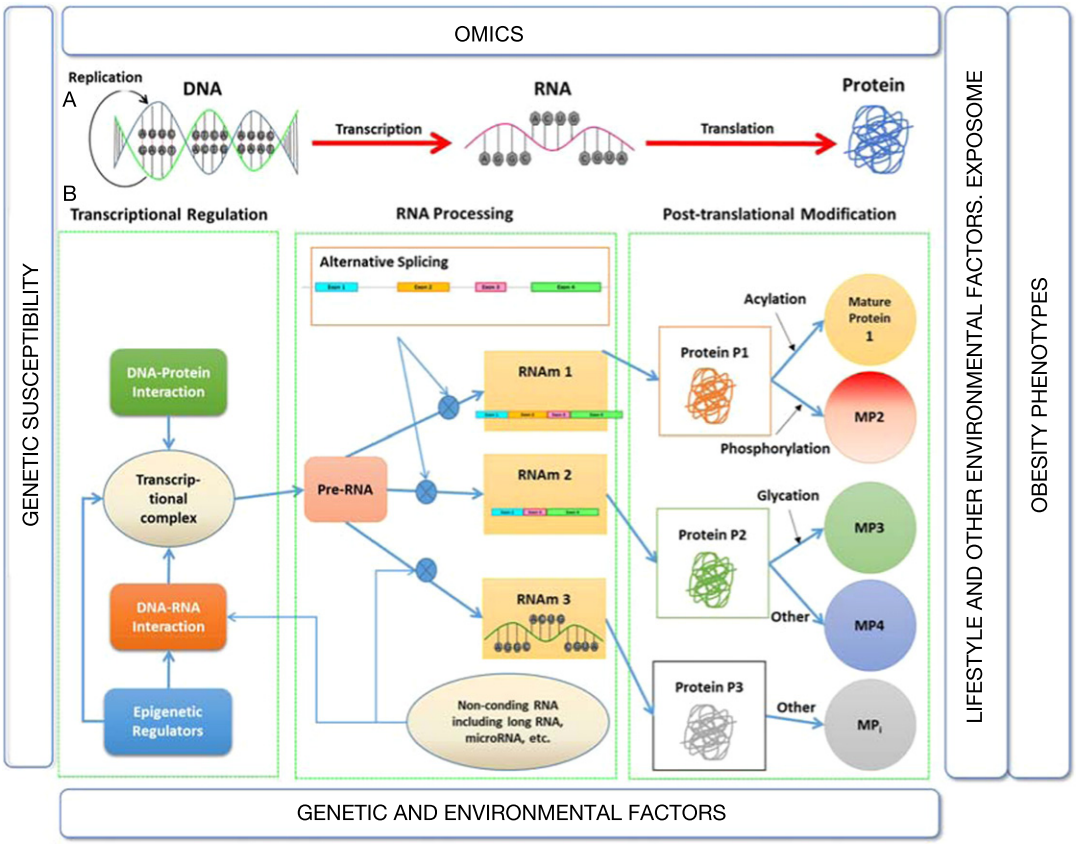

Fig. 2 The central dogma of biology and the current approach.

percentage of explained variability. Nevertheless, this, we know, only constitutes a partial approach and new strategies are required, as, in common obesity the percentage of explained variability continues to be very low. Among these new strategies, besides having to take into account interactions with environmental factors, it is also essential to go deeper into the analysis of pathways and undertake more specific and directed statistical analyses, whilst at the same time bearing in mind other additional variables such as gender, age, health-disease phenotypes and the dynamic approach over time. In addition the integration of omics, also considering epigenetic factors in genetic scores, may be of use in better understanding the genetic bases of obesity.

Gut Microbiota; Its Importance in Obesity

Araceli Muñoz-Garach, Isabel M Cornejo-Pareja, and Francisco J Tinahones, Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Introduction

The term microbiota, gut bacteria, refers to the community of microorganisms living gathered in a particular ecological niche. This ecosystem includes native species that permanently colonize the gastrointestinal tract and a variable group of microorganisms that transit temporarily through the digestive tube. Gut microbiota is heterogeneous. It is composed predominantly of bacteria, with a minority of viruses, fungi and eukaryotic cells. The number of microbial cells in the lumen is 10 times greater than the number of eukaryotic cells in the entire organism. They represent about 1.5 kg of total body weight. The gut microbiome, set of microbial genes, is 100 times larger than the human genome. The acquisition of gut microbiota at childbirth from the mother's microbiota can be considered as the inheritance of a parallel genome (Lozupone *et al.*, 2012; Eckburg *et al.*, 2005).

The gut microbiota plays an important role both locally and systemically. There is a symbiotic relationship between microbiota and its host. Under normal conditions, gut microbiota contributes to the anatomical and physiological gut structure. It improves the absorption surface, promotes the renewal of villi cells, increases the intraluminal content and accelerates intestinal transit. In addition, these microorganisms constitute an enormous enzymatic potential in the gut with a wide variety of metabolic functions. They participate in digestion and obtaining energy through the hydrolysis of diet components (carbohydrates, proteins, and lipids), vitamin synthesis (K, B12, biotin, folic acid, and pantothenic acid), and favor the absorption of minerals (calcium, phosphorus, magnesium, and iron) (Bik, 2009). The gut microbiota is also involved in immunomodulation. It interacts with the immune system and favors immune cell maturation and toxin and carcinogen destruction. It also prevents our gut from being colonized by pathogenic bacteria. Thus, the gut can be considered a metabolically adaptable, flexible and quickly renewable virtual organ that plays an important role in obtaining energy and nutrients from the diet (Chow *et al.*, 2010).

Composition, Estructure and Major Characteristics of Human Gut Microbiota

Microbes colonize all surfaces of the human body exposed to the environment. Most of them reside in the intestinal tract, although they also live in the mouth, vagina and skin. There is more similarity between the oral bacterial communities of different individuals than between the bacterial communities of the skin and mouth of a single individual (Costello *et al.*, 2009). However, there is also considerable inter-individual variability (Costello *et al.*, 2009; Robinson *et al.*, 2010). Gut microbiota varies along different gastrointestinal portions. These microorganisms increase in quantity and complexity the gastrointestinal tract. See **Table 1**.

The greatest number of bacteria in the human gastrointestinal tract resides in the large intestine. There are several factors that facilitate bacterial development: the elevation of pH close to neutrality, a decrease in bile salt concentration and remnants of pancreatic secretion. Moreover, transit time is slow in the colon. It gives microorganisms the opportunity to proliferate by fermenting the available substrates derived from the diet or endogenous secretions (Guamer, 2007).

The bacterial component of the microbiota has been deeply studied over the past years, with large-scale projects such as the Human Microbiome Project (Peterson *et al.*, 2009; Turnbaugh *et al.*, 2007) and MetaHIT (Qin *et al.*, 2010). During the last decade, a lot of information on gut ecosystem diversity has been obtained with the introduction of 16S ribosomal RNA and whole genome (WGS) sequencing (Turnbaugh *et al.*, 2009a,b). They provide an overview of the commensal microbial communities and their functional capacity. They have shown a great variability in the microbiota composition in healthy individuals. Even twins share less than 50% of their bacterial taxa at the species level (Turnbaugh *et al.*, 2010). However, this does not mean that genetics do not play a role in the establishment and conformation of the gut microbiota. It has been shown that the composition of the bacterial community is influenced by specific genomic loci in the host (Benson *et al.*, 2010). Metagenomic studies have established that, in spite of extensive interpersonal variability, there are groups of bacteria that share functionalities (Turnbaugh *et al.*, 2009a,b; Burke *et al.*, 2011; Guirro *et al.*, 2018).

The main bacteria correspond to three major phyla: *Firmicutes* (gram-positive), *Bacteroidetes* (gram-negative) and *Actinobacteria* (gram-positive). *Firmicutes* are the most common phylum (60%), including about 200 genera. The most important are Mycoplasma, Bacillus, and Clostridium. Each genus has different species. *Bacteroidetes* and *Actinobacteria* represent 10% of gut microbiota. The rest of the microorganisms belong to 10 minority families.

The establishment of microbial populations that colonize the gut accompanies the development of the human from childbirth. The most drastic changes in composition occur during early childhood. Although it has been traditionally argued that the acquisition of the intestinal microbiota begins at birth (Adlerberth and Wold, 2009) and is consolidated throughout the life of the individual, some evidence shows that the fetal gastrointestinal tract may be inhabited by some microorganisms (Jiménez *et al.*, 2008). The mother probably represents the most important influence for the development of the infant microbiome due to

Table 1 Predominant microorganisms in the human gastrointestinal tract

Stomach (10^4 UFC/g of gut content)	*Helicobacter pylori* (phyla: *Proteobacteria*) *Lactobacillus* (phyla: *Firmicutes*) *Streptococcus* (phyla: *Firmicutes*)
Duodenum (10^3–10^4 UFC/g of gut content)	*Bacteroides* (phyla: *Bacteroidetes*) *Lactobacillus* (phyla: *Firmicutes*) *Streptococcus* (phyla: *Firmicutes*) *Staphylococcus* (phyla: *Firmicutes*)
Jejunum (10^5–10^7 UFC/g of gut content)	*Bacteroides* (phyla: *Bacteroidetes*) *Lactobacillus* (phyla: *Firmicutes*) *Streptococcus* (phyla: *Firmicutes*) *Bacillus* (phyla: *Firmicutes*)
Ileum (10^7–10^8 UFC/g of gut content)	*Bacteroides* (phyla: *Bacteroidetes*) *Clostridium* (phyla: *Firmicutes*) *Enterobacteriaceae* (phyla: *Proteobacteria)* *Enterococcus* (phyla: *Firmicutes*) *Lactobacillus*(phyla: *Firmicutes*) *Veillonella* (phyla: *Firmicutes*)
Colon (10^{10}–10^{11} UFC/g of gut content)	*Bacteroides* (phyla: *Bacteroidetes*) *Bacillus* (phyla: *Firmicutes*) *Bifidobacterium* (phyla: *Actinobacteria*) *Clostridium* (phyla: *Firmicutes*) *Enterococcus* (phyla: *Firmicutes*) *Eubacterium* (phyla: *Firmicutes*) *Fusobacterium* (phyla: *Fusobacteria*) *Peptostreptococcus* (phyla: *Firmicutes*) *Ruminococcus* (phyla: *Firmicutes*) *Streptococcus* (phyla: *Firmicutes*)

intimate contact during childbirth and early feeding (Palmer *et al.*, 2007; Dominguez-Bello *et al.*, 2010; Matamoros *et al.*, 2013). The constitution of gut microbiota is affected by many variables including type of delivery (vaginal or cesarean), diet (breast-feeding or formula feeding), environment, cultural, geographical factors, and family environment (Palmer *et al.*, 2007; Dominguez-Bello *et al.*, 2010; Matamoros *et al.*, 2013). Infants born vaginally have communities similar to those found in their mother's vaginal microbiota. In contrast, those born by cesarean have a similar microbiota to the skin and predominated by taxa such as Staphylococcus and Propionibacterium spp. (Dominguez-Bello *et al.*, 2010). Some results hypothesize that type of delivery influences immune function during the first year of life through the development of gut microbiota. Breastfeeding is one of the key factors in the development of the neonatal gut microbiota, ensuring a continuous supply of bacteria throughout the lactation period (Matamoros *et al.*, 2013; Vaishampayan *et al.*, 2010; Le Huërou-Luron *et al.*, 2010).

The following major changes in gut microbiota composition occur after introduction of solid food and weaning, when a microbiota of greater richness and diversity is developed. At the same time, the immune system "learns" to differentiate between commensal and pathogenic bacteria. The bacterial composition begins to converge towards an adult microbiota profile at the end of the first year of life and completely resembles the adult microbiota at two and a half years (Palmer *et al.*, 2007). *Firmicutes* and *Bacteroidetes* predominate from this stage, whereas in the first days after childbirth the *Proteobacteria* and the *Actinobacterias* are dominant. Once the microbiota reaches maturity, it remains largely stable until old age, when this stability is reduced (Claesson *et al.*, 2011).

Dietary changes have important effects on the microbiota. Diet can enhance, inhibit, or even change the composition and functions of the gut microbiota. These changes in microbiota composition in response to dietary intake could be related to the fact that different bacterial species are genetically better equipped to use different substrates. Many studies have shown that an increased fat intake leads to a higher gram-negative to gram-positive bacteria rate in gut microbiota. The association between type of diet and different microbial groups is still unclear (De Filippo *et al.*, 2010). The microbiota of western communities, characterized by higher fat and animal protein intake and lower fiber content, appear to contain reduced *Bacteroidetes* and increased *Firmicutes* (especially Mollicutes), compared to those of Eastern communities (Harakeh *et al.*, 2016). Specifically, a high-fat diet is associated with a decrease in the *Lactobacillus* genus, and an increase in microbial populations that secrete pro-inflammatory products and alter the gut barrier. A high-fat diet favors an increase in systemic endotoxemia and inflammation, and improves energy harvest, with a positive energy balance, and tends to induce insulin resistance and obesity (Shen *et al.*, 2014; Guirro *et al.*, 2018).

De Filippo *et al.* (2010) found important differences in the composition of gut microbiota in rural African children compared to European children. There was a different proportion of *Firmicutes* to *Bacteroidetes* and of gram-negative to gram-positive bacteria. This was attributed to a low dietary fiber intake in Europeans. African children had greater microbial richness with a higher proportion of *Bacteroidetes* in their gut, whereas the Western lifestyle led to increased *Firmicutes*.

Another study demonstrated how the Bacteroides and Prevotella enterotypes were strongly associated with dietary habits. In particular, diets rich in animal proteins and fats were highly related to the Bacteroides enterotype and those rich in plant fiber with Prevotella (Wu *et al.*, 2011). Both authors (De Filippo *et al.*, 2010; Wu *et al.*, 2011) postulated that gut microbiota develops with a vegetarian diet maximizes energy extraction from dietary fiber and, at the same time, protects against inflammation. Certain diets predispose to acquiring diseases, and this relationship between diet and disease could be mediated by microbiota (Cani and Delzenne, 2009; Cani *et al.*, 2007). Therefore, diet is a key factor that maintains or not a healthy commensal relationship (Zhang *et al.*, 2018).

Dietary interventions, nutritional modulation strategies and the consumption of probiotics and prebiotics can change gut microbiota, improving the integrity of the gut barrier and decreasing metabolic endotoxemia and inflammatory markers (Requena *et al.*, 2018). These factors are important because of their relationship with insulin resistance, systemic inflammation and increase in fat mass, key aspects in the development of diseases such as obesity or diabetes. The modifications in the microbial populations after dietary intervention with probiotics suppose a greater bacterial abundance of gut barrier function modulators such as *Lactobacillus* and *Bifidobacterium*, as live micro-organism or fermented products, achieve proper gut environment and an important reduction in opportunistic pathogens such as the Enterobacteriaceae, Desulfovibrionaceae, and Streptococcaceae families (Xiao and Zhao, 2014). The species *Akkermansia muciniphila* has also been associated with improved metabolic profiles. In addition, its daily oral administration or its increase after nutritional intervention through the use of prebiotics reverses metabolic disorders induced by a high-fat diet (Everard and Cani, 2013). In addition, administration of prebiotics along with probiotics improves the body weight, abdominal fat and intestinal barrier function (Pothuraju and Sharma, 2018).

The proposed mechanisms by which prebiotics improve intestinal health and reduce metabolic complications of obesity include: (1) increased *Bifidobacterium* population, correlated positively with gut health and negatively with obesity and diabetes. (2) Reduced metabolic endotoxemia through improved gut barrier function. (3) Increased intestinal satiety signals through YY peptide or ghrelin reduction. (4) Improved insulin action increasing GLP-1 secretion, and (5) reduced adipogenesis by synthesis of short chain fatty acids (SCFA) (Shen *et al.*, 2014).

Pre-, pro-, and synbiotics could prove useful, but further research is needed to clarify their clinical relevance for the prevention and management of metabolic disease. (Barengolts, 2016).

Loss of Gut Microbiota Biodiversity

Over the last few decades, existing evidence has shown a significant change in gut microbiota with an increase in certain species and a decrease in all the rest. The most surprising finding is the loss of microbial diversity observed in developed countries. Factors that have influenced this change in our microbiota are: water sanitation, increased cesarean sections, higher use of pre-term antibiotics, reduced breastfeeding, smaller family sizes, increased use of antibiotics and toilet and antibacterial soaps.

Available evidence suggests that there are significant changes in the microbiota after antibiotic treatment. We found a decrease in phylogenetic diversity and changes in the proportions of different families, which may alter the development of the immune system and predispose the host to developing bacterial or viral infections, or allergies (Ubeda and Pamer, 2012). Overuse of antibiotics is linked to an increase in antibiotic-resistant pathogens (Dethlefsen *et al.*, 2008; Sullivan *et al.*, 2001). Although the particular taxon affected varies among individuals, some taxa do not recover even after months of treatment, and in general there is a long-term decline in the biodiversity of bacteria after use.

Many studies have been published in this regard; Neyrinck and Delzenne (2010) observed how after administration of a broad-spectrum antibiotic in obese rodents there was an improvement in metabolic alterations and changes in phyla such as *Firmicutes*, *Bacteroidetes*, and *Proteobacteria*. Other experiments (Hansen *et al.*, 2012) have shown that the use of broad-spectrum antibiotic treatments such as vancomycin may increase the abundance of *A. muciniphila* in rodents, reducing the incidence of diabetes. Cani *et al.* support that broad spectrum antibiotic therapy significantly reduces plasma levels of lipopolysaccharide (LPS) in animal models (Cani *et al.*, 2008). Membrez *et al.* (2008) observed how genetically obese rodents with insulin resistance and on a high-fat diet improved glucose and weight tolerance upon antibiotic treatment. The use of antibiotic therapy reduced the degree of inflammation, infiltration of macrophages and oxidative stress in the adipose tissue.
