The third condition is competition for the T4- binding site of TBG by substances such as phenytoin, high doses of salicylate, and free fatty acids (FFAs). Phenytoin, rifampicin, and carbamazepine also alter T4 metabolism by accelerating its hepatic metabolism, inducing the cytochrome P450 complex. Other drugs stimulating the cytochrome P450 may act likewise, yet few are sufficiently potent to be clinically relevant.

Of particular clinical importance is the displacing of T4 from TBG by high FFA levels. This may occur in vivo, particularly under heparin treatment, which activates serum lipase activity. More important, FFAs can also be generated in vitro either in the presence of heparin or by repeated freezing and thawing of serum. This can result in increases of FFA levels to 3 mmol l^{-1} or more, and such values result in an increase of the free T4 levels.

Normal thyroid function is dependent on an adequate intranuclear concentration of triiodothyronine (T3) that is again a function of the transfer of T3 and T4 from plasma to the cell. For both hormones, only the free fraction can enter the peripheral cell. If the free concentration falls, the pituitary will be stimulated to secrete thyroid-stimulating hormone (TSH) in order to restore adequate free T4 and T3 concentrations. This will occur when free T4 concentrations change due to altered TBG levels. The kinetics of the protein changes are slow (half-life = 6 h for transthyretin and 4 days for TBG).

For a long time, it was believed that the changes in serum concentrations of TBG would not affect thyroid hormone economy. Recently, it has been shown that in treated but severely hypothyroid patients, pregnancy or estrogen treatment increases the demands of T4 treatment as evidenced by an increase in serum TSH values. This is the first evidence that the increased total T4 pool under estrogen treatment cannot be achieved solely by decreasing the metabolic rate and metabolism of T4. Therefore, under physiological circumstances, there is a discrete adaptation of thyroidal secretion to ensure an unchanged thyroid function. Consequently, in hypothyroid patients treatment must be adjusted.

TBG binds T3 with a lower affinity than T4, the affinity constant for T3 being 5×10^{-8} M. The T3 serum levels are less affected by changes in serum TBG. Despite the fact that T3 is the active thyroid hormone, other factors markedly reduce the diagnostic value of T3:

1. T3 is mainly an intracellular hormone, and the circulating pool represents no more than 15–20% of its whole body pool.
2. T3′s production is mainly non-thyroidal and is markedly influenced by the metabolic state of the organism.
3. T3′s production is controlled by monodeiodination, and its degradation mainly by conjugation.

☆*Change History:* December 2014. ER Christ and AG Burger made changes to the text.
This article is an update of Albert G.Burger, Thyroid Function Tests, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 442–452.

Monodeiodination plays a crucial role in the control of serum T3 levels. Three enzymes – deiodinase types 1, 2, and 3 – have been characterized. They belong to the very rare selenoproteins. They differ markedly concerning their functional characteristics. Quantitatively, the most important enzyme is deiodinase type 1, which mainly is found in the liver and kidney but in small amounts it is ubiquitously present. It is localized at the inner plasma membrane. Under physiological conditions, approximately 30% of T4 is converted by this enzyme to T3. The expression and activity of this enzyme are stimulated by T3; for example, in hyperthyroidism the activity is very high, whereas in hypothyroidism it is very low. However, many other non-thyroidal factors affect its activity. In any catabolic state – malnutrition, starvation, severe infections, or metabolic or malignant diseases – its activity is decreased and this is reflected in decreased serum T3 levels. Another example is drug interferences such as glucocorticoids and amiodarone, which are potent inhibitors of deiodinases. Stimulation of deiodinase type 1 can be observed with overfeeding and/or a high-carbohydrate intake.

The activity profile of deiodinase type 2 is very different. It has a very low affinity constant (Km). The enzyme that is found in the pituitary and brain is most active when T4 is absent. It is inhibited with increasing T4 concentrations. It is directly implicated in the control of serum TSH. Both enzymes attack the outer ring of T4. The third enzyme, deiodinase type 3, deiodinates only at the inner ring, a function that it shares with deiodinase type 1 under particular conditions. Interestingly, deiodinase type 3 is localized at the outer cell membrane, and by degrading T4, it reduces its entry into the cell.

Thyroidal production of T3 is minimal compared with that of T4. Without iodine deficiency, T3 represents less then 5% of the secreted T4. There are at least two conditions where this percentage can increase: in iodine deficiency and in hyperthyroidism. In hyperthyroidism, the thyroidal deiodinase is strongly stimulated so that some of the T4 is converted to T3 during the process of secretion. In iodine deficiency, this mechanism is also operating. In addition the poorly iodinated thyroglobulin (Tg) has a high percentage of T3 that can be up to 50% of the amount of T4. This contributes to a higher proportion of T3 in serum, and the T3-to-T4 ratio can increase from the physiological ratio of approximately 2–4% in hyperthyroidism and to much higher values in severe iodine deficiency. If selenium deficiency is associated with iodine deficiency, the increased ratio of T3 to T4 is not seen because the lack of selenium affects the activity of the deiodinases. Clinically, the increased T3-to-T4 ratio was previously of diagnostic value for T3 toxicosis that is now diagnosed more adequately by a suppressed serum TSH in the presence of a still normal free T4. For practical purposes, one can conclude that the serum levels of T3 are influenced by many factors other than thyroidal secretion and are, therefore, of lower diagnostic value than free T4 values.

rT3 is the inactive counterpart of T3 and has been advocated as a diagnostic tool, but today none of them remains valid. Nevertheless, it is an interesting parameter that gives a good mirror image of T4-to-T3 conversion. If deiodinase type 1 is inhibited, serum rT3 levels increase. There are two reasons for this. First, rT3 needs deiodinase type 1 to be degraded and accumulates if the enzyme is low. Second, there may be some shift from T4-to-T3 conversion to rT3.

Methods of Serum Free T4 and T3 Measurements

As mentioned previously, free T4 represents an extremely small fraction of the total T4. Today, for routine purposes, no fully satisfactory free T4 measurement is available. The best, but cumbersome methods use ultrafiltration or equilibrium dialysis. The latter technique was the first reliable method; however, it can yield falsely elevated values if FFAs are artificially increased by the presence of in vitro heparin or by repeated freezing and thawing. Both methods cannot be used in routine practice.

Two different approaches for measuring the free T4 indirectly are available: the free T4 or T3 index test, which is based on the fact that the product of total serum T4 times the result of the T3 resin uptake gives an arbitrary index that roughly correlates with free T4 values. Artifactual results with T3 resin uptake methods are frequently used and the results are similar to the findings using commercial free T4 methods.

The so-called direct measures of free T4 and T3 are methods based on chemiluminescent assays. They cannot measure directly the free fraction since these concentrations are far too low to be measured. Therefore, commercial companies have developed T4 analogs that do not bind to TBG and are distributed only within the free hormone fraction. In addition, this fraction is artificially increased by competitors of T4 for TBG. These methods have the advantage over the free T4 index in that they yield absolute concentrations of free T4 and their interpretation is straightforward. However, because of technical limitations, they are also prone to artifactual values, where unknown competitors for T4 binding to TBG have been described. Consequently, some commercial methods will have a tendency of too low values in severe illnesses. Some of these problems can be overcome by more cumbersome techniques (two step methods), but even these methods are not free of artifactual results, since theyhe tend to give too high values in severe illness.

In ambulatory medical practice, these commercial methods are satisfactory and render total T4 and T3 methods unnecessary. In addition, the clinician should rely first on serum TSH, with serum free T4 and T3 levels being useful adjuncts for the refinement of diagnosis and monitor treatment and for excluding some extremely rare thyroidal conditions.

These are TSHomas (pituitary tumors secreting TSH) and thyroid hormone resistance. In TSHomas, serum TSH values are normal or slightly increased, yet both serum free T4 and T3 are increased and are associated -with clinical signs of hyperthyroidism. In thyroid hormone resistance, serum TSH can be normal, low, or slightly increased in the presence of increased free T4 and T3. However, the clinical picture is composite, with the heart often being the sole organ with signs of hyperthyroidism.

Serum TSH

Measurement of serum TSH values is the first line diagnostic test. Its sensitivity is very high, whereas its specificity is slightly lower (90%) because drugs and severe illness can decrease serum TSH levels in euthyroid patients. The predominant role of serum TSH as a diagnostic parameter is due to the fact that it is the most sensitive parameter of peripheral thyroid hormone action. It increases exponentially when serum free T4 decreases. It differs from the clinically more relevant effects of T3 on heart, liver, brain, and other tissues for the following reasons:

1. The intracellular regulation of thyroid hormone metabolism in the pituitary and brain does not exist in peripheral tissues.
2. The action of thyroid hormones in the pituitary is inhibitory (on dejodination?). In the periphery, T3 has multiple actions some stimulatory, others are inhibitory.
3. TSH secretion is controlled by the hypothalamus: thyrotropin-releasing hormone (TRH), somatostatin, dopamine and leptin to mention some of these factors.

Clinical Use of Serum TSH Measures

Serum TSH is measured with immunometric assays using chemiluminescent probes. Progress has been constantly made in this field, and the lower detection limit of the newest assays is 0.02 mU l^{-1} or less. Yet At 0.02 mU l^{-1}, most immunometric assays have a coefficient of variation of 20%, whereas at higher TSH values, this decreases to 5% or less. A coefficient of variation of 20% is the upper limit of what is clinically acceptable.

The clinician should be aware that these assays measure only the immunological, and not the biological properties of TSH. This is not relevant when hyperthyroidism is diagnosed, but there is good evidence of discordance between immunological and biological effect in hypothalamic hypothyroidism, in the fetus and (possibly) in severely ill patients.

It also appears that antibodies recognize variable degrees of TSH glycosylation that occur in several thyroid pathologies. Different results in the range of serum TSH from 3 to 7 mU l^{-1} have been reported and are possibly related to such differences in antibodies.

TSH is secreted in a pulsatile manner and has a circadian rhythm. TSH spikes do not exceed 0.5 mU ml^{-1}. Serum TSH levels are highest during the evening (at 23:00 h), that is, during the first hours of sleep. The peak is displaced in shift workers at night. In young individuals, the mean serum TSH levels are in the morning (0.9 ± 0.3 mU l^{-1}) and at 23:00 h (1.9 ± 0.6 mU l^{-1}). In the elderly, serum TSH levels tend to be slightly lower (0.7 ± 0.6 and 1.3 f 0.9 mU l^{-1}, respectively). These fluctuations are rarely critical for the clinical evaluation of thyroid function. The normal range extends from 0.4 to 4.0 mU l^{-1}. Recent studies tend to narrow the normal range to 0.4–2.5 mU l^{-1}, with a median of 1.0–1.5 mU l^{-1}. African American population have a slightly higher mean serum TSH than the Caucasian population (**Figure 1**). From the clinical point of view, a serum TSH of 0.4 mU l^{-1} or less needs investigation. One study suggested that serum TSH values of 2.5–4 mU l^{-1} already represent an increased risk of developing overt thyroid disease, with the annual incidence of clinically open disease being approximately 5%. The concomitant presence of thyroid autoantibodies probably increases this risk. The significance of low serum TSH depends on the degree of serum TSH suppression that can be classified into three different degrees:

1. Serum TSH of 0.1–0.4 mU l^{-1} (for some authors, to 0.6 mU l^{-1}). This is frequently seen in subclinical hyperthyroidism. Serum free T4 values are normal and serum free T3 values are only rarely increased. Such serum TSH values are not fully specific for subclinical hyperthyroidism because they can also be found in severe non-thyroidal illness with or without glucocorticoid or dopaminergic treatment. In these latter situations, serum free T4 and T3 levels tend to be decreased or in the lower normal range. The differential diagnosis can be established by clinical observation and repetitive measures. If repeatedly detected, a slight decrease of serum TSH is compatible with partial thyroid autonomy, caused by a hot nodule, a multinodular goiter, or euthyroid Graves' disease. For the differential diagnosis thyroid scintigraphy can be helpful in these situations. Recent iodine contamination may play an important role in this situation and can be the origin of transient subclinical hyperthyroidism. Rarely, such serum TSH Ievels can be measured in pituitary or hypothalamic insufficiency, but in these conditions the changes in thyroid function are mostly accompanied by other pituitary hormone insufficiencies.
2. Serum TSH 0.05–0.1 mU l^{-1} (for some authors, 0.02–0.1 or 0.2 mU l^{-1}). The differential diagnosis is similar to the previously mentioned one. In addition, serum free T4 and/or T3 levels tend to be at the upper limit or slightly increased. Some authors consider that even a small increase in free T3 stands for overt and not subclinical hyperthyroidism. Suppressed serum TSH levels are the goal of T4 treatment in some patients with differentiated thyroid cancer. These patients present with serum free T4 levels at the upper limit of normal, and in one-third of these patients free T4 levels will be slightly increased. Serum T3 levels are in the normal range because of absent thyroidal T3 secretion. Low serum TSH levels are frequent in panhypopituitarism but not in hypothalamic disease. In serious systemical disease it is rare to find such low serum TSH levels unless the patients are treated with large doses of dopamine and/or glucocorticoids.
3. Serum TSH less than 0.02 mU l^{-1}, such values are encountered only in endogenous hyperthyroidism. Some assays will allow measuring levels as low as 0.002 mU l^{-1}. There are no data correlating the very low serum TSH Ievels with the clinical severity of hyperthyroidism. It is now well established that reactivation of TSH secretion after successful therapy for hyperthyroidism lag

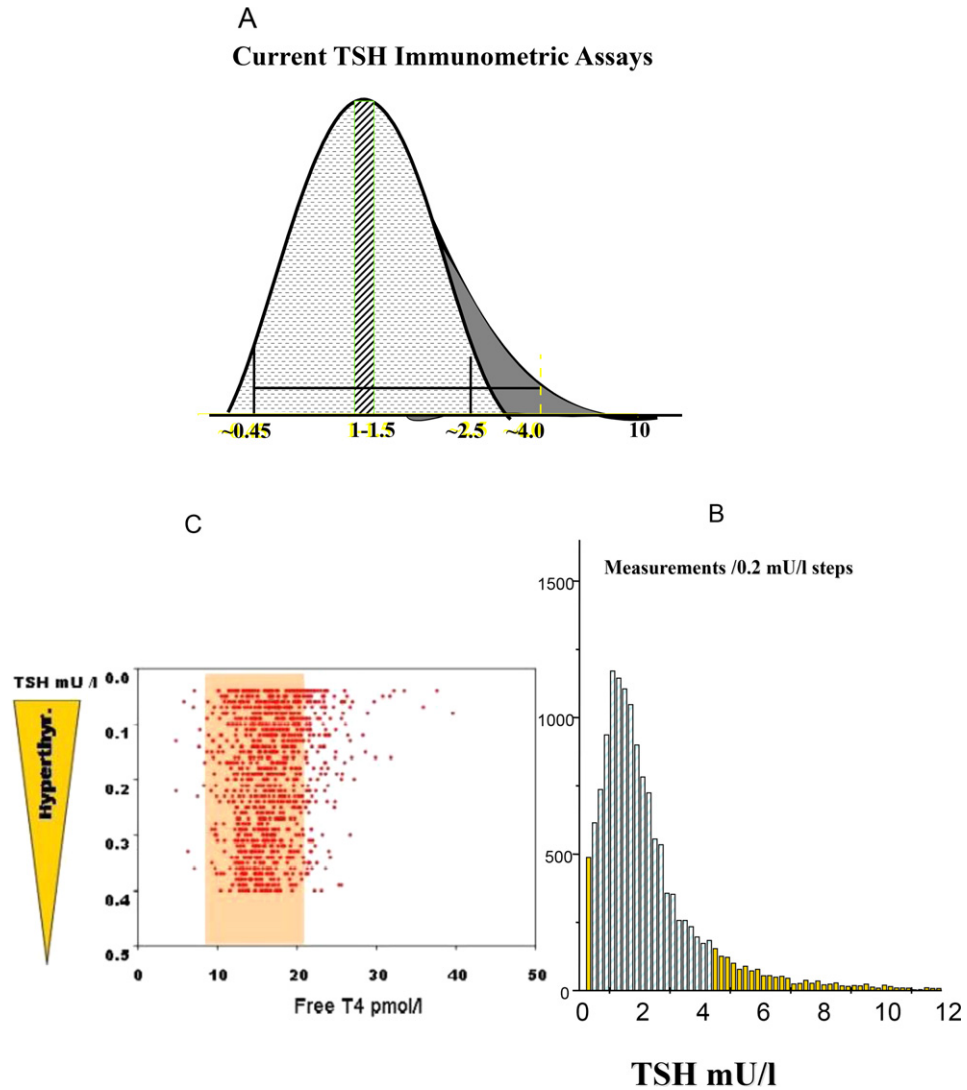

Fig. 1 Current TSH immunometric assays. (a) The area between 0.45 and 2.5 mU l^{-1} represents the values for a population (mean $\pm$ 2 SD) with documented absence of thyroid diseases. The bordering tails indicate that this population is not separated from the borderline pathological cases that present with TSH levels above 2.5 mU l^{-1} The majority of these cases have an euthyroid autoimmune thyroiditis (figure courtesy of Professor Carole Spencer). (b) Free T4 values in the subclinical hyperthyroid range are shown as a function of decreasing serum TSH values. Even though some free T4 values are above the normal range, the majority fall within the normal limits. (c) Consecutive serum TSH determinations (16000) over 10 months in a diagnostic laboratory are shown. It includes known and unknown pathologies, the limit being arbitrarily set at 12 and 0.2 mU l^{-1}. It documents what is shown in panel a: the groups of euthyroidism, subclinical hyper- or hypothyroidism do not present as individual peaks. The free T4 values shown in panel b are extracted from the lower end of TSH values in panel c. The data in b and c were obtained by courtesy of UNILABS, SA, Geneva.

behind the normalization of peripheral thyroid hormones and the improvement of the clinical condition by several weeks. There is no clear explanation for this finding, but it is important to realize that in this situation serum TSH only cannot be used as a valid parameter of euthyroidism.

Use of TSH Measurements in the Case of Artifactual Free T4 Values

Two diagnostic pitfalls can occur when serum TSH measurements are the only thyroid hormone parameter measured.

Serum TSH measurements are essential for excluding thyroid dysfunction in two situations with apparently increased free T4 levels. One abnormality involves T4 binding to albumin or transthyretin. These proteins have a high binding capacity but low affinity for T4. There exist however congenital variants with high affinity for T4. In addition, some neuroendocrine tumors secrete very large amounts of normal transthyretin (familial dysalbuminemic hyperthyroxinemia (FDH and familial or acquired

hyperthyroxinemia due to transthyretin excess). Today most methods for free T4 measurement yield normal free T4 values but former kits measured erroneously high free T4 values. Few laboratories are equipped to identify the modified albumin or transthyretin. If this methodology is not available, differential diagnosis with pituitary tumors or thyroid hormone resistance should include serum T3, serum TSH alpha-subunit, a TRH test (rarely necessary), and possibly magnetic resonance imaging.

Serum T3 and the alpha-subunit are increased in TSHomas and in thyroid hormone resistance. Basal serum TSH and the TRH test are normal in the case of abnormalities in serum transport proteins, whereas the response to TRH tends to be exaggerated in thyroid hormone resistance. In most but not all cases of TSHomas, there will be no response to TRH stimulation.

Another artifactual increase of free T4 values is encountered in the presence of autoantibodies to T4 or T3, even though most modern kits are no longer affected by such antibodies.

Artifacts of TSH Measures

There is only one condition where serum TSH values can be artifactually increased, namely in the presence of antibodies against mouse immunoglobulin (IgG) in the patient's serum. Monoclonal mouse IgGs are part of ail immunometric assays and, therefore, will be trapped by these antibodies. Recently, immunometric assays have overcome this problem. If necessary, the artifactual increase in serum TSH can be diagnosed by omitting anti-TSH antibodies in the assay and/or by a TRH test.

The well established overwhelming diagnostic power of serum TSH measurements can raise two questions. First, should one restrict the first line diagnostic parameters of thyroid dysfunction to TSH only, thereby omitting free T4 measures? This might be justified for systematic screening, yet free T4 measurements are inexpensive and will be ordered mostly during further workup of the patient's thyroid disease. Second, should serum TSH be used systematically as a screening test of the adult female population over 50 or even over 35 years of age and be repeated at regular intervals (e.g., every 5 years)?, At present the scientific societies do not recommend such procedures.

Special Techniques

The main indications for the TRH test (200 jug intravenously, blood sampling at 0, 15, 30, 60, and 120 min) are pituitary diseases. For primary thyroid dysfunction, it has lost all of its indications except those mentioned previously. In most countries, intravenous TRH is no longer available, with the nasal spray being used instead. This way of testing represents a stronger and more prolonged TSH stimulation. Blood should be sampled before and 30 and 60 min after the TRH for measuring TSH or 3 h later for measuring an increase in serum T3.

Measuring the alpha-subunit of TSH, the common subunit of all pituitary glycoproteins, is important in the case of TSHomas and can be used in the gonadotropinomas as well.

Thyroglobulin

Physiologically, Thyroglobulin (TG) is released in small amounts from the thyroid. It is estimated that 1 g of tissue corresponds to 1 $\mu g\,l^{-1}$ serum TG if serum TSH is in the normal range. Disruption of the normal thyroid structure results in leakage of TG, and high serum levels are found in goitrous patients. In multinodular goiter, TG levels can reach very high levels that overlap with those found in metastatic thyroid cancer patients. Marked and transient increases can be seen after ^{131}-iodine (^{131}I) treatment and after thyroid surgery. High levels are also found in Graves' disease and in functioning (and occasionally even nonfunctioning) thyroid adenomas.

The measurement of serum TG levels has benefited from the advances in immunometric assays. Today, an assay should have a functional sensitivity (with a coefficient of variance of 20%) of less than 0.5 $pg\,l^{-1}$, and interference of TG antibodies should be kept to a minimum. In practice, there are considerable differences among the commercial kits, and each laboratory should determine the sensitivity of its assay. Two additional controls are, therefore, recommended:

1. TG antibodies should be measured, and some authors recommend not using serum concentrations of TG if anti-Tg antibodies are present.
2. Another control consists in adding pure TG to a separate sample of the patient's serum. A recovery of 80–120% of the added TG excludes major interference. Adding small amounts of external TG (1 $\mu g\,l^{-1}$ rather than 50 $\mu g\,l^{-1}$) is recommended. Some authors consider that the recovery test does not guarantee absence of interference. It is hoped that technical improvements of immunometric assays will allow to minimize most of these problems.

Indications

TG measurements are useful in neonatology if a dysthyroid condition is suspected. Low levels are found in thyroid agenesis or dysgenesis whereas high levels are measured in thyroid hormone resistance and in some rare inborn errors of thyroid hormone synthesis. They are a valuable adjunct to scintigraphy and thyroid ultrasound.

Low TG values allow to differentiate between thyrotoxicosis facticia and endogenous hyperthyroidism. In the presence of a normal-sized or even moderately increased thyroid, the ingested L-thyroxine will suppress TG levels to values of less than 10 $\mu g\,l^{-1}$. Yet in the presence of very large goiters, TG levels will often not be suppressible.

In addition, in subacute thyroiditis, an increase TG levels has been documented. The measurement of TG values is, therefore, not recommended in these conditions.

Importantly, TG measures are not useful in the differential diagnosis between benign nodular goiter and thyroid carcinoma because TG levels tend to be increased and overlap in both conditions. In an occasional patient with an unidentified pulmonary or bone metastasis, a very high TG level may help to establish the origin of the tumor.

Besides the rare indications for TG measurements mentioned before, the main indication for TG measurements remains in the context of the surveillance of differentiated follicular or papillary thyroid cancer. It allows to easily detect recurrences (**Table 1**). TG levels are a function of the tumor mass and tumor differentiation. TG levels tend to be lower in tumors that are more aggressive and are absent in undifferentiated cancers.

The surveillance of well differentiated thyroid cancers using TG concentrations measurements is now established. In this context, it is critical not to rely only on basal TG levels but also interprete the values in the context of TSH stimulation as well. The use of recombinant TSH has greatly facilitated the surveillance because its use is equally valuable than inducing severe hypothyroidism.

If TG values are more than 2 $\mu g\,l^{-1}$, the presence of thyroid tissue is certain, indicating the presence of neoplastic tissue in the case of complete surgical or ^{131}I ablation. The changes in its concentration over time parallel the evolution of the tumor. TG levels are particularly important for diagnosing absence of disease. For this purpose, one cannot always rely on non-measurable TG levels ($<0.5\ pg\,l^{-1}$) under T4 treatment. If the patient is rendered hypothyroid, or if the patient receives recombinant TSH and serum TG values do not exceed the critical limit of 2 $\mu g\,l^{-1}$, the patient can be considered cured. In these situations, thyroid scintigraphy is not necessary.

Recently, a complementary method for determining the presence of tumor tissue has been advocated in cases of interference in serum measurements of TG by anti-Tg antibodies. The presence of circulating thyroid follicular tells is obtained by using real-time quantitative reverse transcription – polymerase chain reaction (RT-PCR) based on the amplification of TG mRNA. If normal thyroid tissue has been destroyed, the presence of TG mRNA strongly supports recurrence of disease. The method is sensitive and independent of circulating anti-Tg antibodies, but it is currently limited to specialized research laboratories.

Autoantibodies

For clinical use, three types of antibodies are of interest: the antithyroperoxidase (anti-TPO), the anti-thyroglobulin antibodies antibodies (anti-Tg), and the anti-TSH-receptor antibodies antibodies (anti-TRAb). Among the TRAb, one can distinguish blocking and stimulating antibodies. The recently discovered anti-sodium-iodide symporter antibodies do not seem to play an important diagnostic role.

The thyroid antibodies belong to the IgG class, and only for anti-TPO antibodies complement fixing and cytotoxic activity have been described. The antigenic sites of the TPO have been well characterized; there are six of them. For anti-Tg and anti-TRAb, this is less well known because the antigenic sites are mainly conformational and not linear. Recently, it has been possible to produce functioning anti-TRAb.

Indications to measure thyroid antibodies can serve diagnostic, follow-up, and screening purposes. TPO antibodies are the most sensitive antibodies for the diagnosis of any thyroid autoimmune process, and they are widely used in combination with the TSH for diagnosing the etiology of a thyroid disease. They are also useful in the follow-up of Graves' disease because their titer may reflect the activity of the disease. In Hashimoto's thyroiditis, the follow-up of these patients measuring antibodies may lead to confusion and is not generally recommended. There is no specific indication for TG antibodies except the clinical condition mentioned before (follow-up differentiated thyroid cancer) However, in rare occasions, the TPO antibodies may be negative, whereas TG antibodies will reveal thyroid disease.

The TRAb are not always useful for the diagnosis of Graves' disease. Similarly to TPO antibodies, their titer may follow the activity of the disease. They can also be present in primary hypothyroidism and in postpartum thyroiditis; therefore, they are not always a reliable tool for the diagnostic of Graves' disease.

Table 1 Diagnostic use of serum Thyroglobulin (TG) levels in well differentiated thyroid cancer

TSH< 0.1 mU l^{-1} *TG value*	*TSH> 30 mU l^{-1}*	*TG antibodies*	*^{131}I scintigraphy*	*Loco-regional tumor*	*Distant metastasis*	*'Cure'*
	$<2\ \mu g\,l^{-1}$	negative	negative	excluded	excluded	most likely
$<2\ \mu g\,l^{-1}$		negative	–	not excluded	Unlikely	not proven
2–10 $\mu g\,l^{-1}$		negative	positive or negative	certain	Unlikely but possible	No
	2–10 $\mu g\,l^{-1}$	negative	positive or negative	certain	Unlikely	No
$>10\ \mu g\,l^{-1}$		negative or positive	mostly positive	certain	not excluded	No

There is one rare but clear indication for measuring these antibodies, namely in pregnant patients with Graves' disease in whom the thyroid has been removed. In these cases, one has no clinical indication about the severity of the autoimmune process and, on rare occasions, placental transfer of a high titer of TRAb may cause neonatal hyperthyroidism.

Screening with anti-TPO antibodies is advocated during pregnancy because their presence indicates increased risk of post-partum thyroiditis.

In Vivo Isotope Imaging

Diagnostic in vivo isotopic imaging will yield information on thyroidal uptake of the isotope and functional morphology of the thyroid. Two isotopes, ^{123}-iodine and Tc^{99m} pertechnetate are used. There is still some indication for ^{131}I for whole body scintigraphy of patients with thyroid cancers. The place for other isotopes, such as thallium and gallium, has not been established. Thallium has been used for identifying thyroid metastases, and gallium 67 is taken up by inflammatory cells, particularly mast tells, and therefore can be used in some cases of destructive thyroiditis such as subacute thyroiditis (Table 2).

^{123}-Iodine

The physical characteristics of ^{123}I are given in Table 2. It is close to an ideal isotope in so far that the irradiation of the thyroid is minimal. Iodide, is taken up specifically by the gastric mucosa. Thyroidal uptake occurs very rapidly. In the case of concomitant food intake, the uptake is delayed and occurs by intestinal absorption.

The iodine uptake depends on the activity of the sodium – iodide symporter (NIS), formally called iodide trapping of the thyroid. Once transported into the cell, the free intrathyroidal iodide is immediately incorporated into TG. the free iodide pool of the thyroid is only increasedin pathological conditions This can be tested by the perchlorate discharge test. Once stored in the colloid as TG, the labeled T4 will remain in the thyroid for a long time, depending on the total amount of stored colloid. In most conditions, the reserve in TG is huge; therefore, the turnover of this iodide is slow, even though the most recently formed colloid is preferentially resorbed and secreted. As a rule of thumb, only 1–2% of the accumulated dose will be secreted per day. Therefore, the disappearance of the isotope will be mainly a function of its physical half-life.

Most of the iodine is secreted as T4 and to a lesser extent as T3, and only a minor part of iodide is lost.

Iodine contamination is one of the major technical problems resulting in invalid thyroid imaging. In individuals with a normal thyroid and a daily iodide intake of 200 μg or more, a single dose of 30 mg iodide together with the tracer will reduce the uptake to background levels. A similar effect can be obtained with half the dose of iodide given over several days. However, it should be noted that this applies only to a completely normal thyoird gland. In areas of moderate iodine deficiency where small multi-nodular goiters are frequent, the suppression of ^{123}I uptake by iodine needs higher and longer treatment with similar or higher doses. Iodine contamination is a frequent event because large amounts of iodine containing contrast media are injected during axial CT tomography. These substances are highly water soluble and are eliminated within 4 to 6 weeks. Iodide is rapidly eliminated by the renal route (clearance of 50 ml min^{-1} and more). Accordingly, elimination is decreased in renal insufficiency.

Today, the major culprit of long-term iodine contamination is amiodarone. This substance and its biologically active metabolite, desethylamiodarone, have an approximate half-life of 4–6 weeks. However, iodine contamination from its degradation products can last for months or up to 1–2 years. Historically, other organic iodine compounds can be responsible for even longer lasting contaminations. For instance, dyes used for myelography give rise to lifelong contamination and can even pass the placenta resulting in a low iodine uptake into the thyroid gland of children.

Among the non-iodinated substances interfering in thyroidal uptake, methimazole, propylthiouracil, and perchlorate should be mentioned, with the latter being a specific inhibitor of the iodide symporter. In severe non-thyroidal illness, thyroid function and thyroid uptake may be depressed. Drugs such as glucocorticoids (30–60 mg of prednisone) dopamine and its analogs as well as the sandostatin analogue octreotide have multiple impacts, but the most significant one is a reduction of TSH secretion with a

Table 2 Isotopes for thyroid imaging

	^{123}I	^{131}I	^{99m}Tc	F^{18} Thioglucose
Half-life	13 h	8 days	6 h	110 min
Emission	Gamma	Beta, Gamma	Gamma	Gamma
Radiation exposure (rad)mCi^{-1}	13	1300	0.13	
Diagnostic dose (μCi)	300	50 (or 5–10 000)	2000	
Route	Oral	Oral	iv	iv
Absorption	Gastric	Gastric		
Particularities				Uptake by metabolically active cells
Maximal uptake	4–8 h	4–8 h	20–40 min	

subsequent reduction in thyroid function. Older literature also mentions sulfonamides, but the more modern drugs of this class have not been reported to interfere.

$Tc^{99}m$ Pertechnetate

$Tc^{99}m$ is close to ideal for studying the trapping of iodide by the thyroid. It is easily available and cheap. Because it can only give information on anion trapping, the measurements are performed within 1 h after intravenous injection. The thyroidal uptake of$Tc^{99}m$ is approximately 10 times lower than that for ^{123}I (0.4–4%). The precise normal range is also dependent on iodine intake; therefore, it must be validated for each laboratory. As compared with ^{123}I, $Tc^{99}m$ may occasionally result in false positive imaging of nodules that may erroneously be taken for functioning nodules.

It should be noted that on many occasions thyroid imaging with isotopes has been replaced by ultrasonography. The indications for scintigraphy could be summarized as follows. In hyperthyroidism, $Tc^{99}m$ is as valid as ^{123}I for the differential diagnosis of nodular or diffuse goiter. If the thyroid is diffusely enlarged without concomitant exophthalmos or pretibial myxedema, a positive uptake will allow excluding acute and/or subacute thyroiditis and will help establishing a diagnosis of thyrotoxicosis factitia and/or iodine contamination. In the case of a multinodular goiter with a moderate decrease of serum TSH (<0.6 mU l^{-1}), the scintigraphy may confirm autonomous regions. In the case of very painful thyroid and inflammatory symptoms, an absent thyroid uptake may confirm the diagnosis of subacute thyroiditis. In the case of an isolated euthyroid thyroid nodule, the uptake will identify a cold nodule, even though $Tc^{99}m$ may give false positive results and the predominant position of this investigation has been superseded by cytology (fine needle aspiration).

In most cases, ultrasound evaluation of the thyroid gland is as useful as or gives even more information than scintigraphy. Nevertheless, the two examinations can be complementary. Scintigraphy will allow identifying an inactive nodule of the thyroid that the ultrasound may reveal to be cystic, mixed, or solid. In multinodular goiter, the scintigraphy will clearly give the patchy appearance of the functioning and (possibly) autonomous tissue. However, its value in describing inactive or cold nodules in this situation is limited.

^{131}-Iodine (^{131}I)

The disadvantage of the ^{131}I isotope is the rather large delivered dose of irradiation to the patient. In thyroid cancer patients, ^{131}I has kept its place for diagnostic procedures, even though the use of TG is reducing its indications. During the follow-up of these patients, whole body scintigraphies are obtained with ^{131}I. Ideally, TSH levels have to be increased (>30 mU l^{-1}). This classically obtained by stopping T4 or T3 substitution or, more recently, by injecting recombinant human TSH.

Hypothyroidism is obtained by switching 7 weeks before ^{131}I treatment to T3 substitution that has to be stopped 12–14 days before radioisotope therapy. Serum TSH levels should increase to more than 30 mU l^{-1}, and the efficiency of the whole body scan or treatment can be increased by concomitant regimen recommendations such as avoidance of iodized salt and iodine rich bread, eggs, and fish. A small dose of diuretics (thiazides) can also be recommended to decrease the circulating iodide pool. Large diagnostic doses of ^{131}I are used (5–10 mCi) because the uptake of the cancerous cell is much lower than normal and is mostly markedly below 0.5% of the administered dose. The whole body scintigraphy is performed 3–4 days after administration of the radioactive iodide. A ^{131}I scintigraphy or therapy should not be repeated before 8–12 weeks because it induces a stunting effect (i.e. transiently abolished uptake). This technique is very sensitive for detecting small metastases and in most cases correlates very well with the measured serum TG levels. However, it has been reported that there can be some dissociation and that serum TG levels can be increased even in the absence of residual ^{131}I iodide uptake. It is thought that these patients have metastasis and should benefit from a more complete workup with subsequent surgery and/or ^{131}I treatment.

Rare and/or Experimental Methods for Thyroid imaging

The perchlorate discharge test can be performed with ^{123}I or ^{131}I. It is a rarely used test that was described initially for detecting inherited defects of intrathyroidal iodine metabolism (absence of sodium – iodide symporter, absence of Tg, and dehalogenase defect). It allows detection of organification defects that can be seen in autoimmune thyroiditis and Graves' disease treated with ^{131}I. Today, this test is not performed in routine practice.

Positron emission tomography with fluorodeoxyglucose is a very promising technique for detecting metabolically active tissue. The active principle, Deoxyglucose, can be taken up by cells but cannot be metabolized. Malignant cancer cells have an increased glucose rnetabolism. Initially, it was thought that this test would yield the best results in poorly differentiated, and hence metabolically very active tumors. However, experience has shown that even differentiated thyroid cancers can occasionally be identified with this technique.

Epidemiology of Thyroid Disease☆

Mark PJ Vanderpump, The Physicians' Clinic, London, United Kingdom

Glossary

Epidemiology The study of the distribution and determinants of disease prevalence and incidence.

Hyperthyroidism The earliest measure of thyroid overactivity is a decline in serum thyrotropin (TSH) (subclinical hyperthyroidism) followed by an increase in serum triiodothyronine (T_3) and an increase in serum thyroxine (T_4).

Hypothyroidism The earliest biochemical abnormality in hypothyroidism is an increase in serum TSH associated with normal serum T_4 and T_3 concentrations (subclinical hypothyroidism or mild thyroid failure), followed by a decline in serum T_4, at which stage most patients have symptoms and benefit from treatment (overt hypothyroidism).

Screening The identification of unrecognized disease by a test or examination that can be applied rapidly to differentiate apparent well persons who probably have a disease from those who probably do not.

Iodine Deficiency Disorders

Iodine is an essential component of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) produced by the thyroid gland. The ideal dietary allowance of iodine recommended by World Health Organization (WHO) in adults is 150 μg of iodine per day which increases to 250 μg per day in pregnancy and lactation. Iodine deficiency impairs thyroid hormone production and has adverse effects throughout life, particularly early in life as it impairs cognition and growth (WHO, 2017) (**Table 1**).

Iodine deficiency is recognized as a global problem with large populations at risk who are living in an environment where the soil has been deprived of iodine. This arises from past glaciation, compounded by the leaching effects of snow, water, and heavy rainfall, which removes iodine from the soil. The mountainous regions of Europe, the Northern Indian Subcontinent, the extensive mountain ranges of China, the Andean region in South America, and the lesser ranges of Africa are all iodine deficient. Iodine deficiency remains a significant problem despite major national and international efforts to increase iodine intake, primarily through the voluntary or mandatory iodization of salt. In 2007, the WHO estimated that 2 billion people, including 285 million school-age children, still had iodine deficiency, defined as a urinary iodine (UI) excretion of less than 100 μg/L (**Fig. 1**). Recent epidemiological data suggest that iodine deficiency is an emerging issue in industrialized countries, previously thought of as iodine-sufficient. International efforts to control iodine deficiency are slowing, and reaching the third of the worldwide population that remains deficient poses major challenges (Vanderpump, 2017).

In areas where the daily iodine intake is less than 50 μg, goiter is usually endemic, and when the intake falls below 25 μg/day, congenital hypothyroidism is seen. The prevalence of goiter in areas of severe iodine deficiency can be as high as 80%. Iodization programs are of proven value in reducing goiter size and in preventing goiter development and cretinism in children. Autonomy can develop in nodular goiters, occasionally leading to thyrotoxicosis, and iodization programs can also induce thyrotoxicosis, especially in those older than age 40 with nodular goiters (Zimmermann and Boelaert, 2015).

Severe iodine deficiency results in congenital hypothyroidism which is a condition associated with severe learning disabilities, deafness, and impaired motor development. Endemic congenital hypothyroidism had been long recognized to be associated with severe iodine deficiency when the daily iodine intake falls below 25 μg. Severe iodine deficiency may be associated with impairment in the psycho-neurological outcome in the progeny because both mother and offspring are exposed to iodine deficiency during gestation (and the postnatal period). Controlled studies performed in iodine-deficient regions have confirmed that iodine supplementation eliminated new cases of congenital hypothyroidism, reduced infant mortality, and improved cognitive function in the general population (Pharoah *et al.*, 1971). The effects of mild-to-moderate iodine deficiency on cognition are less well known than those of moderate-to-severe deficiency but it is assumed that there is a continuum of disability with more subtle impairments of the intelligence quotient (IQ) and motor ability associated with less severe deficiency (Zimmermann and Boelaert, 2015). A systematic review of available published studies from 1980 to 2011 examined the relationship between iodine and mental development of children 5 years old and under and found that regardless of study design, iodine deficiency had a substantial impact on mental development which translated into 6.9–10.2 IQ points lower in iodine deficient children compared with iodine replete children (Bougma *et al.*, 2013). Methodological concerns included weak study designs, the omission of

important confounders, small sample sizes, the lack of cluster analyses, and the lack of separate analyses of verbal and nonverbal subtests.

Hypothyroidism

The earliest biochemical abnormality is an increase in serum thyrotropin (TSH) concentration associated with normal serum free T_4 and T_3 concentrations (subclinical hypothyroidism or mild thyroid failure), followed by a decrease in serum free T_4 concentration, at which stage, most patients have symptoms and benefit from treatment (overt hypothyroidism). Hypothyroidism is an insidious condition with a significant morbidity, and the subtle and nonspecific symptoms and signs may be mistakenly

attributed to other illnesses, particularly in postpartum women and the elderly (Chaker *et al.*, 2017). In iodine-replete communities, the cause is either chronic autoimmune disease [atrophic autoimmune thyroiditis or goitrous autoimmune thyroiditis (Hashimoto's thyroiditis)] or destructive treatment for hyperthyroidism, which may account for up to one-third of cases of hypothyroidism in the community (Vanderpump, 2011).

Congenital Hypothyroidism

Congenital hypothyroidism affects approximately 1 newborn in 3500–4000 births and is the most treatable cause of mental retardation (Ford and LaFranchi, 2014). There is an inverse relationship between age at diagnosis and IQ in later life. In iodine-replete areas, 85% of the cases are due to sporadic developmental defects of the thyroid gland (thyroid dysgenesis), such as the arrested migration of the embryonic thyroid (ectopic thyroid) or a complete absence of thyroid tissue (athyreosis). The remaining 15% have thyroid dyshormonogenesis defects transmitted by an autosomal recessive mode of inheritance. Iodine deficiency (<25 μg/day), particularly in preterm infants, accounts for many cases in Europe, Asia, and Africa. Clinical diagnosis occurs in $<5\%$ of newborns with hypothyroidism because symptoms and signs are often minimal. As a result, it is not possible to predict which infants are likely to be affected. Without prompt diagnosis and treatment, most affected children gradually develop growth failure, irreversible mental retardation, and a variety of neuropsychological deficits.

The apparent incidence of congenital hypothyroidism has more than doubled in recent years because of several factors, including more inclusive diagnostic criteria, shifting demographics, and increasing survival of preterm infants (Wassner and Brown, 2015). The greatest increase has occurred in mildly affected children. Congenital hypothyroidism may be transient or persistent, but the natural history cannot be predicted by severity at diagnosis. In premature infants, who are especially vulnerable to hypothyroidism, the rise in serum TSH may be delayed and therefore detected only by routine follow-up screening.

Spontaneous Hypothyroidism

In iodine-replete communities, the prevalence of spontaneous hypothyroidism is between 1% and 2%, and it is more common in older women and 10 times more common in women than in men (Vanderpump, 2011). Studies in Northern Europe, Japan, and the United States have found the prevalence to range between 0.6 and 12 per 1000 women and between 1.3 and 4.0 per 1000 in men investigated. The prevalence is higher in surveys of the elderly in the community. A lower prevalence is seen in areas of iodine deficiency. The testing of hospital inpatients, predominantly elderly women, might be expected to reveal a higher proportion of unsuspected hypothyroidism, but this is not supported by the available studies, which confirm a prevalence of 2%.

Subclinical Hypothyroidism

A substantial proportion of the population, particularly elderly women who live in iodine-replete areas, have circulating thyroid antibodies [antithyroid peroxidase (microsomal) and antithyroglobulin antibodies] and normal thyroid function. The presence of these antibodies correlates with the presence of focal thyroiditis in biopsy and in postmortem material of patients with no evidence of hypothyroidism during life. Patients with hypothyroidism caused by either atrophic or goitrous autoimmune thyroiditis usually have high serum titers of the same antibodies (Biondi and Cooper, 2012).

With respect to epidemiological studies, the definition of subclinical hypothyroidism varies from any increase in serum TSH to values >10 mU/L or, more stringently, a serum TSH value >10 mU/L and a positive test for circulating thyroid antibodies in serum. The term implies that patients should be asymptomatic, although symptoms are difficult to assess, especially in those in whom thyroid function tests have been checked because of nonspecific complaints such as tiredness.

There has been controversy about the upper limit of the reference range for serum TSH (Wartofsky and Dickey, 2005; Surks *et al.*, 2005). Reference ranges are derived from a reference population that comprises a large group of subjects who do not have thyroid disease and are otherwise well. By convention, a reference range usually only comprises 95% of a reference population. Thus, 2.5% of "normal" individuals will fall above the reference range and 2.5% will fall below the range. For serum TSH, the reference population shows a log normal distribution and has a diurnal variation with the reference range in thyroid disease-free individuals typically cited as between 0.4 and 4.0 mU/L. The serum TSH reference range varies in different ethnic communities, trimesters of pregnancy and progressively shifts toward higher concentration with age. Analysis of the National Health and Nutrition Examination Survey (NHANES) III data suggest that the reference range for serum TSH rises with age as the 97.5 centile for those subjects aged >80 years was 7.49 mU/L and 70% had a serum TSH $>$ the population defined upper limit of the reference range of 4.5 mU/L of whom only 40% were antithyroid antibody positive (Surks and Boucai, 2010).

Spontaneous recovery has also been described in subjects with subclinical hypothyroidism, although the frequency of this phenomenon is unclear. In 1 study, 37% of patients normalized their serum TSH levels over a mean follow-up time of 32 months (Meyerovitch *et al.*, 2007). Normalization of serum TSH concentrations is more likely to occur in patients with negative antithyroid antibodies and serum TSH levels <10 mU/L, and within the first 2 years after diagnosis (Biondi and Cooper, 2012).

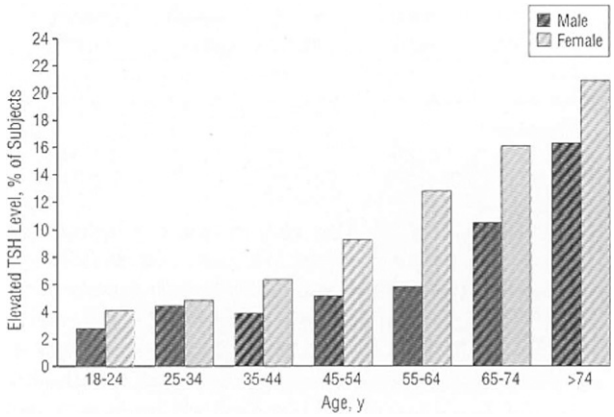

Fig. 2 The percentage of 25,682 subjects with a high serum TSH concentration, by sex and decade of age, in the Colorado Thyroid Disease Prevalence Study (Canaris et al., 2000).

Table 2 The effect of environmental iodine intake on the prevalence of subclinical thyroid disease

Iodine status	*Subclinical hypothyroidism*	*Subclinical hyperthyroidism*
Deficient	1%–4%	6%–10%
Replete	4%–9%	1%–2%
Excess	18%–14%	<1%

In the Whickham survey, 8% of women (10% of women older than age 55) and 3% of men had subclinical hypothyroidism (Tunbridge *et al.*, 1977). A cross-sectional screening survey of 25,682 subjects older than age 18 attending a health fair in Colorado found that 9% of the population, excluding 1525 on levothyroxine therapy, had an elevated serum TSH level; of these, <1% had overt hypothyroidism. Among those with a high serum TSH concentration, 74% had a value between 5.1 and 10 mU/L and 26% had a value greater than 10 mU/L. The percentage of subjects with a high serum TSH concentration was higher for women than men in each decade of age, and ranged from 4% to 21% in women and 3% to 16% in men (Canaris *et al.*, 2000) (**Fig. 2**). In the NHANES III survey serum TSH concentrations increased with age in both men and women and were higher in whites than blacks, independent of serum antithyroid antibody concentrations (Hollowell *et al.*, 2002). Approximately 2% of adolescents aged 12–19 years had a serum TSH greater than 4.5 mU/L. Subclinical hypothyroidism is found at higher frequency in areas where iodine intake is high, but most cases are not of autoimmune origin (Laurberg *et al.*, 2010) (**Table 2**).

Incidence of Hypothyroidism

In the 20-year follow-up of the Whickham cohort, the mean annual incidence of spontaneous hypothyroidism in surviving women was 3.5 per 1000, increasing to 4.1 per 1000 if all cases are included, including those who had received destructive treatment for hyperthyroidism (Vanderpump *et al.*, 1995). The probability of a woman developing hypothyroidism at a particular time (i.e., the hazard rate) increased with age to 14 per 1000 in women aged 75–80. The mean annual incidence in men (all spontaneous except for one case of lithium-induced hypothyroidism) was 0.6 per 1000. Either raised serum TSH or positive thyroid antibodies alone or in combination were associated with a significantly increased risk of hypothyroidism in women and men. The odds were greatly increased when both risk factors were present and each had a similar effect (**Table 3**). In the surviving women, the annual risk of developing spontaneous hypothyroidism was 4% in those who had both raised serum TSH levels and were thyroid-antibody positive, 3% if only serum TSH was raised, and 2% if only thyroid antibodies were positive. The cumulative incidence of hypothyroidism over 20 years was 55%, 33%, and 27%, respectively. The probability of developing hypothyroidism in women increases linearly when serum TSH is higher than 2 mU/L; this is further increased if women are antithyroid antibody positive or decreased if antithyroid antibody negative (**Fig. 3**). The development of hypothyroidism also correlated with the strength of titer of antithyroid microsomal antibodies at first survey. A positive family history of any form of thyroid disease, the presence of a goiter at either the first or the follow-up survey, or parity at first survey were not associated with an increased risk of hypothyroidism. The prognostic importance of positive thyroid antibody tests and increasing serum TSH levels has been confirmed in other cohort studies (McGrogan *et al.*, 2008).

Data from a large population study in Tayside, UK, have demonstrated that the standardized incidence of primary hypothyroidism varied between 3.90 and 4.89 per 1000 women per year between 1993 and 2001. The incidence of hypothyroidism in men significantly increased from 0.65 to 1.01 per 1000 per year ($P = 0.0017$). The mean age at diagnosis of primary hypothyroidism decreased in women from 1994 to 2001 (Flynn *et al.*, 2004; Leese *et al.*, 2008).

Table 3 Development of spontaneous hypothyroidism in surviving women and men at 20-year follow-up of Whickham survey: odds ratios (with 95% confidence interval) (Vanderpump et al., 1995)

Women	
Serum TSH raised, regardless of thyroid antibody status	14 (9–24)
Thyroid antibody positive, regardless of serum TSH status	13 (8–19)
If thyroid antibody negative, effect of raised serum TSH alone	8 (3 – 20)
If thyroid antibody positive, additional effect of raised serum TSH	5 (2 – 11)
If serum TSH normal, effect of thyroid antibody positive alone	8 (5–15)
If serum TSH raised, additional effect of thyroid antibody positive	5 (1–15)
Serum TSH raised and thyroid antibody positive combined	38 (22–65)
Men	
Serum TSH raised, regardless of thyroid antibody status	44 (19–104)
Thyroid antibody positive, regardless of serum TSH status	25 (10–63)
Serum TSH raised and thyroid antibody positive combined	173 (81–370)

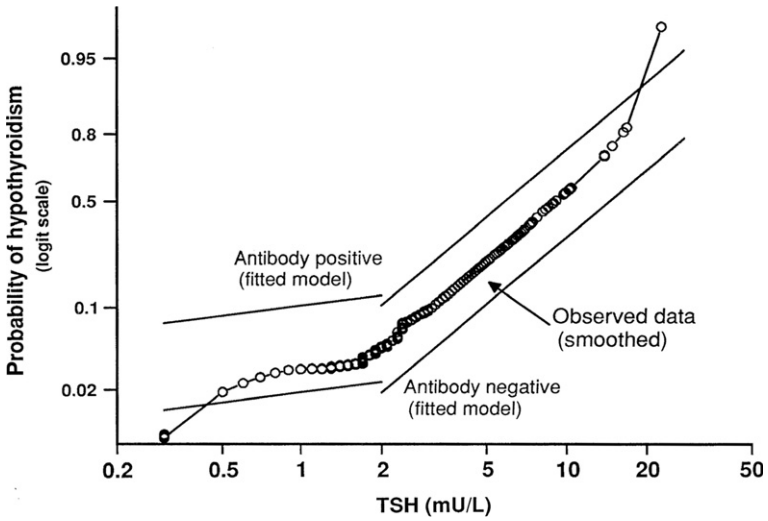

Fig. 3 Probability for development of hypothyroidism within 20 years with increasing values of serum TSH at first Whickham survey in 912 survivors (Vanderpump et al., 1995).

Iatrogenic Hypothyroidism

After destructive treatment for hyperthyroidism (either radioiodine therapy or surgery), the incidence of overt hypothyroidism is greatest in the first year (Vanderpump, 2011). Factors that influence outcome are age, gland size (small glands are more likely to lead to hypothyroidism postoperatively), remnant size, and iodine intake (high intake is associated with recurrence). Radioiodine therapy for Graves' hyperthyroidism, toxic or nontoxic nodular goiter, or autonomously functioning thyroid adenomas can cause hypothyroidism months or years later. A fixed high dose of radioiodine (550 MBq), administered with the intent of ablating the thyroid and inducing early hypothyroidism, results in permanent hypothyroidism in at least 50% of patients by 1 year. Subclinical hypothyroidism is commonly found either post-radioiodine therapy or post-surgery in up to 50% of apparently euthyroid patients. It may be evident for only a few months, but more often it represents a stage in the progression toward overt thyroid failure. If serum TSH remains raised, then the rate of progression toward overt hypothyroidism is 2%–6% per year after either treatment. Treatment of Graves' disease with antithyroid drugs alone is also associated with the eventual development of hypothyroidism from either autoimmune thyroiditis or the presence of TSH-blocking antibodies in 5%–20% of cases.

Other iatrogenic causes of hypothyroidism are surgery and external irradiation for head and neck cancer and drugs used to treat nonthyroid conditions, including amiodarone, lithium carbonate, tyrosine kinase inhibitors, interferon-α, interleukin-2, and immune checkpoint inhibitors. In addition, patients with hypothyroidism who are taking levothyroxine may become hypothyroid if given drugs that decrease absorption (e.g., cholestyramine and iron salts) or drugs that increase its clearance (e.g., phenytoin and carbamazepine or an estrogen-induced increase in the serum concentration of thyroxine-binding globulin). Poor compliance with levothyroxine therapy or suboptimal treatment may also result in hypothyroidism (Vanderpump, 2011).

Hyperthyroidism

In epidemiological studies, the clinical diagnosis of thyrotoxicosis should be supported by measurements of serum T_4 or T_3 and TSH concentrations. Biochemical tests of thyroid function may reveal the diagnosis before it is clinically apparent. A rise in serum T_3 and fall in serum TSH are the earliest measures of thyroid overactivity, followed by a rise in serum T_4. Hyperthyroidism has a significant short-term morbidity and long-term morbidity and mortality. The most common cause of hyperthyroidism in iodine-replete communities is Graves' disease, followed by toxic multinodular goiter, whereas rarer causes include an autonomously functioning thyroid adenoma, thyroiditis, excessive levothyroxine replacement or drugs including amiodarone, lithium carbonate, tyrosine kinase inhibitors, interferon-α, and immune checkpoint inhibitors (De Leo *et al.*, 2016). In epidemiological studies, however, the etiology is rarely ascertained.

The prevalence of hyperthyroidism in women is between 0.5% and 2%, and is 10 times more common in women than in men in iodine-replete communities (Vanderpump, 2011). In NHANES III, in those subjects who were neither taking thyroid medication nor reported a history of thyroid disease, 2 per 1000 had "clinically significant" hyperthyroidism, defined as a serum TSH concentration <0.1 mU/L and a serum total T4 concentration >170 nmol/L (Hollowell *et al.*, 2002). The prevalence data in elderly persons show a wide range between 0.4% and 2.0% and a higher prevalence is seen in iodine deficient areas (Laurberg *et al.*, 2010). The reported prevalence rates for previously undiagnosed hyperthyroidism in hospitalized patients, between 0.3% and 1%, are consistent with community surveys (Vanderpump, 2011).

Subclinical Hyperthyroidism

The introduction of assays for serum TSH that were sensitive enough to distinguish between normal and low concentrations allowed subjects with subclinical hyperthyroidism to be identified. Subclinical hyperthyroidism is defined as a low serum TSH concentration and normal serum T_4 and T_3 concentrations, in the absence of hypothalamic or pituitary disease, nonthyroidal illness, or ingestion of drugs that inhibit TSH secretion such as glucocorticoids or dopamine (Biondi and Cooper, 2012). Epidemiological studies differ in the definition of a low serum TSH concentration and whether the subjects included were receiving levothyroxine therapy.

In studies using sensitive serum TSH assays (detection limit, 0.01 mU/L), approximately 2% of subjects have subnormal serum TSH and 1% have an undetectable serum TSH (Vanderpump *et al.*, 1995). The Colorado study, which screened more than 25,000 healthy volunteers found 2% of the population to have a subnormal serum TSH, with more than half on levothyroxine therapy (Canaris *et al.*, 2000). In the NHANES III study the prevalence was highest in those subjects aged 20–39 years and those aged greater than 79 years (Hollowell *et al.*, 2002). In this study the percentage of subjects with serum TSH concentrations less than 0.4 mU/L was significantly higher in women than men, and black subjects had significantly lower mean serum TSH concentrations, and therefore a higher prevalence of subclinical hyperthyroidism (0.4%) than whites (0.1%) or Mexican Americans (0.3%). The prevalence of subnormal serum TSH concentrations is higher in iodine-deficient populations (6%–10%), due to functional autonomy from nodular goiters (Laurberg *et al.*, 2010) (**Table 2**).

Among subjects with subclinical hyperthyroidism, those with low but detectable serum TSH values may recover spontaneously when re-tested. Nonthyroidal illness is an important cause of false positive serum TSH test results. There are limited data on the risk of progression of subclinical hyperthyroidism to overt hyperthyroidism. In those subjects with an undetectable serum TSH and a confirmed etiology as determined by thyroid scintigraphy due to Graves' disease or nodular disease, it has been calculated that the annual incidence is approximately 5%–8% (Schouten *et al.*, 2011). A large population study in Tayside, Scotland, followed 2024 subjects with at least 2 serum TSH measurements below the reference range for at least 4 months for up to 7 years (Vadiveloo *et al.*, 2011). Few subjects developed hyperthyroidism (0.5%–0.7%) and the percentage of those reverting to normal increased with time and this was more common in those with a baseline serum TSH between 0.1 and 0.4 mU/L.

Incidence of Hyperthyroidism

In the 20-year follow-up of the Whickham cohort, the mean annual incidence of hyperthyroidism in women was 0.8 per 1000 (Vanderpump *et al.*, 1995). No new cases were detected in men. The estimated probability of developing hyperthyroidism in women at a particular time (the hazard rate) averaged 1.4 per 1000 between the ages of 35 and 60. The incidence data for overt hyperthyroidism in men and women from large population studies are comparable at 0.4 per 1000 women and 0.1 per 1000 men per year, although the age-specific incidence varies considerably (McGrogan *et al.*, 2008). The peak age-specific incidence of Graves' disease was between 20 and 49 years in two studies but increased with age in Iceland and peaked at 60–69 years in Malmö, Sweden. The only available data for a black population from Johannesburg suggest a 10-fold lower annual incidence of hyperthyroidism in black Africans than in European whites: 0.09 per 1000 women and 0.007 per 1000 men (Vanderpump, 2011). In a large population study in Tayside, Scotland, 620 incident cases of hyperthyroidism were identified with an incidence rate of 0.77 per 1000 per year (95% confidence interval (CI), 0.70–0.84) in women and 0.14 per 1000 per year (95% CI, 0.12–0.18) in men (Flynn *et al.*, 2004). The incidence increased with age, and women were affected two to eight times more than men across the age

range. Further analysis suggested that the incidence was increasing in women but not in men between 1997 and 2001 (Leese *et al.*, 2008).

Postpartum Thyroiditis

Postpartum thyroiditis (PPT) is a transient, destructive autoimmune thyroiditis that occurs between weeks 12 and 16 postpartum in 40%–50% of women and the presence of antithyroid microsomal antibodies early in pregnancy increases the risk of developing PPT (De Leo and Pearce, 2017). It presents as a temporary, usually painless, episode of hypothyroidism, occasionally preceded by a short episode of hyperthyroidism. Approximately 10% of women entering antenatal clinics at 16 weeks of gestation are antithyroid peroxidase antibody (antithyroid microsomal antibody) positive, which is comparable to the prevalence of thyroid antibodies in community surveys (Vanderpump, 2011). A proportion of these women will have subclinical hypothyroidism with a high serum TSH, but most will be euthyroid. However, after delivery a transient, destructive autoimmune thyroiditis that occurs between the 12th–16th week postpartum will develop in 50% of antithyroid peroxidase positive women, as ascertained in early gestation, clinically apparent as PPT. Up to about 25% of women progress to permanent hypothyroidism within approximately 5 years following an episode of PPT, particularly those with high antibody titers. It is not clear whether pregnancy alters the final incidence of autoimmune thyroid disease or merely quickens the development of thyroid disease (Alexander *et al.*, 2017).

Diffuse and Nodular Goiter

The most common thyroid disease is simple (diffuse) goiter. The clinical grading of thyroid size is subjective and imprecise. The WHO grading system recognizes that an enlarged thyroid gland may be palpably but not visibly enlarged. Examiner variation is greatest in deciding whether a thyroid that is palpable but not visible is normal (WHO stage O-A) or enlarged (WHO stage O-B). Interexaminer variation may also lead to differences in classifying goiter as diffuse or multinodular. There is also considerable overlap between the five WHO grades based on clinical criteria and thyroid volume estimated by ultrasonography. Ultrasonography has been used in epidemiological studies to assess thyroid size, resulting in much higher estimates of goiter prevalence than in studies in which goiter size was assessed by physical examination.

In cross-sectional surveys, the prevalence of diffuse goiter declines with age, the greatest prevalence is in premenopausal women, and the ratio of women to men is at least 4:1. In the Whickham survey, among the women 26% had a goiter; the frequency ranged from 31% in those aged less than 45 years (mostly diffuse) to 12% in those aged over 75 years (who had a higher proportion of nodular goiter) (Tunbridge *et al.*, 1977). Longitudinal studies confirm the decreasing frequency of diffuse goiter with age (Vanderpump *et al.*, 1995).

This decline in frequency of diffuse goiters with age is in contrast to the increase in frequency of thyroid nodules and antithyroid antibodies with age. In the Whickham survey, $<1\%$ of the men but 5% of the women had thyroid nodules detected clinically, and the frequency increased to 9% in women aged >75 (Tunbridge *et al.*, 1977). A higher prevalence of nodular goiter is found in areas of iodine deficiency in Europe, such as Italy, Germany, and Denmark. The only available longitudinal data suggest an annual incidence for nodules of 1 per 1000 and that, once formed, they tend to remain present and benign for a long period of time (Vanderpump, 2011).

With the increasing use of sensitive imaging techniques, an increasing proportion of thyroid nodules are detected incidentally. Many nodules are detected because of their size or anterior position in the neck, or the skill of the physician performing the examination but most thyroid nodules will not be clinically recognized. Up to 50% of nodules >1 cm detected by ultrasound are undetected by clinical examination. The prevalence of thyroid incidentaloma as an unexpected, asymptomatic thyroid nodule discovered during the investigation of an unrelated condition, is 67% with ultrasonography imaging, 15% with computed tomography or magnetic resonance imaging of the neck, and 1%–2% with fluorodeoxyglucose positron emission tomography (Russ *et al.*, 2014).

Thyroid Cancer

The clinical presentation of thyroid cancer is usually as a solitary thyroid nodule or increasing goiter size. Although thyroid nodules are common, thyroid cancers are rare. The four major histological types are papillary, follicular, medullary, and anaplastic, and each displays a different epidemiology. The annual incidence of all thyroid cancers ranges between 1 and 10 per 100,000 population in most countries and is two to four times more frequent in women than men (Perros *et al.*, 2014; Haugen *et al.*, 2016). Papillary and follicular tumors, which comprise 60%–90% of the total, are rare in children and adolescents, but their incidence increases with age in adults.

Papillary thyroid carcinoma (PTC) is the most common thyroid malignancy and worldwide constitutes 50%–90% of differentiated follicular cell-derived thyroid cancers. Papillary thyroid microcarcinomas (diameter, ≤ 1 cm) are found in 4%–36% of adults postmortem in population-based studies. Most diagnoses of PTC occur in patients 30–50 years old (median age, 44 years),

and the majority (60%–80%) occur in women. The reported increase in the incidence of these carcinomas in recent years may be attributed to an improvement in pathological techniques. The increasing incidence may partially reflect earlier and increased detection of small (subclinical) papillary cancers secondary to more widespread use of neck ultrasonography and fine-needle aspiration of very small thyroid nodules. An analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results database found an increase in the rates of differentiated thyroid cancer of all sizes, including tumors >4 cm. In addition, incidence-based mortality increased between 1974 and 2013, from 0.40 to 0.46 per 100,000 person-years. This suggests a true increase in the incidence of papillary thyroid cancer (Lim *et al.*, 2017), Although the incidence of thyroid cancer is rising, death rates (0.5 per 100,000 men and women per year) have not changed significantly between 2003 and 2012. External radiation exposure, particularly in childhood, is a major risk factor for papillary cancer. Four years after the nuclear accident at Chernobyl, a dramatic increase in the incidence of childhood thyroid cancer (almost exclusively papillary tumors in which a translocation of the RET gene occurs) was recorded in the regions most exposed (Tuttle *et al.*, 2011). There is no documented association between radioiodine therapy for thyrotoxicosis and subsequent development of thyroid cancer in adults.

Follicular thyroid cancer occurs relatively infrequently compared to papillary cancer and accounts for approximately 15% of all thyroid cancers. There is an increased frequency of follicular to papillary carcinoma (5:1) in iodine-deficient endemic goiter areas. It tends to be a malignancy of older persons, with a peak incidence of between ages 40 and 60 years and is approximately three times more common in women than in men.

Medullary thyroid cancer (MTC) occurs in both sporadic and hereditary forms. The highest incidence of sporadic disease occurs in the fifth decade. Hereditary MTC can be inherited as an autosomal dominant trait with a high degree of penetrance associated with multiple endocrine neoplasia type 2 syndrome or as familial MTC without any other endocrinopathies. It can be diagnosed before clinical presentation by genetic and biochemical screening. Anaplastic thyroid cancer is very rare and is more frequent in populations with endemic goiter. Thyroid lymphoma is also uncommon, constituting approximately 2% of extranodal lymphomas and occurring predominantly in older women. Up to one-third of patients have a history of goiter, whereas some have established autoimmune thyroiditis and may be taking levothyroxine therapy.

Screening for Thyroid Disease

In the 1970s, screening programs for congenital hypothyroidism were developed in which TSH was measured in heel-prick blood specimens to detect this condition as early as possible. The value of screening for congenital hypothyroidism is unquestioned, but only done routinely in approximately 30% of the world's birth population (Ford and LaFranchi, 2014).

Certain groups within the adult population who should have an assessment of thyroid function at least once to detect thyroid dysfunction include those with a goiter or thyroid nodule, atrial fibrillation, dyslipidemia, subfertility, or osteoporosis. There is a high frequency of asymptomatic thyroid dysfunction in unselected patients with diabetes mellitus, and assessing thyroid function in the annual review of patients with diabetes appears cost-effective. The threefold increase in the prevalence of thyroid antibodies in patients with breast cancer suggests that it may be worth screening this group for thyroid dysfunction. There is no consensus on whether healthy pregnant women should be screened for thyroid disorders or PPT although it has been shown to be cost-effective in analytical models (Dosiou *et al.*, 2012). However, because women with type 1 diabetes are three times more likely to develop postpartum thyroid dysfunction, it is recommended that all such diabetic women should be tested in the first trimester for thyroid antibodies.

Any woman with a history of PPT should be offered annual surveillance of thyroid function due to the possible long-term risk of permanent hypothyroidism. Because of the high prevalence of hypothyroidism in people with Down syndrome and Turner syndrome, an annual check of thyroid function is recommended. Thyroid function tests are indicated every 6 months for those receiving amiodarone, lithium and immune checkpoint inhibitor therapy and every 12 months following head and neck irradiation. Following destructive treatment for thyrotoxicosis by either radioiodine or surgery, indefinite annual surveillance for the development of hypothyroidism is required.

Controversy exists as to whether healthy adults living in an area of iodine sufficiency benefit from screening for thyroid disease. The benefit from a screening program must outweigh the physical and psychological harm caused by the test, diagnostic procedures, and treatment (Tunbridge and Vanderpump, 2000; Rugge *et al.*, 2015). The prevalence of unsuspected overt thyroid disease is low, but a substantial proportion of subjects tested will have evidence of thyroid dysfunction, with approximately 10% with subclinical hypothyroidism and 1% with subclinical hyperthyroidism. No appropriately powered prospective, randomized, controlled, double-blinded interventional trial of either L-T4 therapy for subclinical hypothyroidism or antithyroid therapy for subclinical hyperthyroidism exists (Biondi and Cooper, 2012).

Although epidemiological studies have shown an association between subclinical hypothyroidism and coronary heart disease in younger people (<65 years) or those with high serum TSH (>10 mU/L) (Rodondi *et al.*, 2010), recent evidence suggests that in older people, higher serum TSH and lower free T_4 concentrations within the euthyroid range are associated with lower risk of multiple adverse events including mortality (Cappola *et al.*, 2015). Treatment in those who are symptomatic, pregnant, or preconception, aged <65 years appears justified (Pearce *et al.*, 2013).

A meta-analysis demonstrated that endogenous subclinical hyperthyroidism was associated with increased risk of total, coronary heart disease (CHD) mortality and incident atrial fibrillation (AF) (Collet *et al.*, 2012). The highest risk of CHD mortality and AF is noted when the serum TSH is <0.10 mU/L. Subclinical hyperthyroidism might be associated with an increased risk for

hip and non-spine fractures, but additional large, high-quality studies are needed (Wirth *et al.*, 2014). Treatment may be indicated in patients older than 65 years with serum TSH < 0.1 mU/L to potentially avoid these serious cardiovascular events, fractures, and the risk of progression to overt hyperthyroidism (Biondi *et al.*, 2015). Any potential benefits of therapy in subclinical hyperthyroidism must be weighed against the morbidity associated with the treatment of hyperthyroidism.

From the available evidence, the following recommendations may be justified for an iodine-replete community:

- Screening for thyroid dysfunction in women younger than age 50 and in men is not warranted in view of the relatively low point prevalence of unsuspected overt thyroid dysfunction.
- Case-finding in women during menopause or during visits to a primary care physician with nonspecific symptoms is justified due to the high prevalence of subclinical hypothyroidism.
- If increased serum TSH is found at screening, then measurement should be repeated 2 months later together with free T_4 measurement after excluding nonthyroidal illness, drugs, etc.
- Treatment with levothyroxine is recommended if the serum TSH is ≥ 10 mU/L, irrespective of whether free T_4 is low.
- Subjects with a serum TSH between 5 and 10 mU/L and normal free T_4 are at increased risk of developing hypothyroidism, and repeat measurement of serum TSH is warranted at least every 3 years if not annually.
- If a suppressed serum TSH is found at screening, it should be remeasured 2 months later, and if it is still suppressed, free T_3 should be measured.
- After levothyroxine replacement is initiated, for whatever indication, long-term follow-up with at least an annual measurement of serum TSH is required.

Genetic Factors in Thyroid Disease☆

Marina Muzza and Laura Fugazzola, University of Milan, Milan, Italy and IRCCS Italian Auxological Institute, Milano, Italy

Glossary

Genetic association analysis The most frequently used method for detecting predisposing genes; it compares the frequency of a certain allele in the affected population with its frequency in a control population. Genetic association analysis is quite sensitive and detects genes with a small predisposing effect (risk factors).

Genetic heterogeneity The presence of multiple genes causing the same phenotype.

Linkage analysis A procedure that employs polymorphic genetic markers whose precise location in the genome is known. By following the cosegregation of alleles of these markers with the disease phenotype in families, linkage establishes the likelihood that the genetic locus examined contains the unknown gene responsible for the disease phenotype. Genetic linkage was originally designed for purely Mendelian disorders but theoretical work supports its use in polygenic diseases. Linkage detects necessary genes with substantial effects on the predisposition to disease. It is therefore relatively insensitive when compared with genetic association analysis. However, its results are robust when the data set is large and stringent statistical criteria are used for significance.

Linkage disequilibrium A phenomenon whereby two alleles at two loci in close spatial relationship in the genome are found associated more often than predicted by their individual population frequencies and by the distance between them on the genome. Linkage disequilibrium indicates one of two phenomena: selective advantage of the two alleles combined together or an admixture of two populations with different frequencies of the two alleles.

LOD score In its classical form, linkage yields an LOD (logarithm of differences) score, an absolute number that represents the logarithm of the likelihood of linkage of a given phenotype with a genetic location. An LOD score of 3 or more is considered a strong evidence for linkage in a complex disease and represents an absolute likelihood of 1000 to 1 in favor of linkage.

Microsatellite markers Short sequences of tandem repeats (multiple repeats of the same couple of bases) that are ubiquitous within the genome. Alleles of microsatellite markers are readily detected by polymerase chain reaction amplification. Given their high degree of polymorphism (8–20 known alleles on average at each locus), microsatellite markers are especially suitable for linkage analysis.

Online Mendelian Inheritance in Man (OMIM) The National Center for Biotechnology Information maintains an online, searchable catalogue of inherited human diseases publicly available on the World Wide Web at www.ncbi.nlm.nih.gov. All registered diseases and disease loci are given a unique identifying number.

Single nucleotide polymorphisms (SNPs) Single base substitutions found across the whole genome (in both coding and noncoding regions). SNPs are mostly detected by restriction fragment length polymorphism analysis. The degree of polymorphism of SNPs is much lower than in microsatellite markers and therefore SNPs are more suitable for use in association studies.

Whole genome screen A technique for scanning the whole genome for linkage with a known phenotype. Whole genome screening employs a set of multiple microsatellite markers evenly spaced across the genome and tests each location for linkage to the target phenotype in well-characterized families. Cosegregation of each single marker with the disease phenotype is then analyzed using computerized linkage algorithms. Eventually, a map of the likelihood of linkage across the genome is obtained.

Introduction

When ancient vertebrates migrated from the iodine-rich oceanic environment to the iodine-poor terrestrial environment, evolution provided the new organisms' thyroid with an extremely complex and specialized machinery, completely devoted to the avid collection and storage of iodine, for the sole purpose of continuously providing enough substrate for the synthesis of thyroid hormone. As a very specialized organ, the thyroid therefore expresses, along with common housekeeping genes, a unique subset of genes, whose products are mostly enzymes involved in iodine metabolism and/or thyroid hormone synthesis. On one hand, some of these enzymes serve as unique and possibly confined targets (antigens) for the immune aggression characteristic of autoimmune

☆*Change History*: February 2018. Marina Muzza and Laura Fugazzola updated the sections: "The Monogenic Diseases of the Thyroid Gland," "Genetic Factors in Simple and Multinodular Goiter," "Genetic Factors in Nonmedullary Thyroid Cancer Genetic Factors in Nonmedullary Thyroid Cancer" and "Familial Medullary Thyroid Cancer, shortened the section "Evidence for a Role of Genetic Factors in the Pathogenesis of Autoimmune Thyroid Disease", deleted "Gene Loci Identified by Whole Genome Screens" and added novel predisposing genes in AITD; included updated References within the text and added the section "References."

This article is an update of Giuseppe Barbesino, Thyroid Disease, Genetic Factors in, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 409–421.

 doi:10.1016/B978-0-12-801238-3.96020-3

thyroid diseases (AITD), which are very common conditions in humans, whose etiology is still incompletely understood. The susceptibility to these diseases has long been recognized to be largely hereditary in nature. Because of the high prevalence in the general population and because of the large amount of available data on genetic factors, AITD are given special emphasis in this article.

On the other hand, a wide range of thyroid disorders have been described in which a single inherited point mutation in one thyroid-specific gene causes clinically significant derangements in thyroid physiology and function, with or without hereditary goiter. Given their strong negative effect on survival, the latter conditions are distinctly rare but are usually inherited in a Mendelian fashion and therefore represent an important part of the genetics of thyroid disease. Thyroid cancer and goiter are also quite prevalent. Although epidemiological studies indicate that environmental factors are by far predominant in causing these disorders, emerging evidence shows significant inherited susceptibility to these disorders as well.

The Monogenic Diseases of the Thyroid Gland

Inherited Diseases of the Thyrotropin Receptor

The human thyrotropin receptor (TSHr) was cloned in 1989. The TSHr is a protein receptor, one of the G protein-coupled, seven-transmembrane domain receptors. The TSHR gene is located on chromosome 14q31. The primary structure of the TSHr is closely related to that of the follicle-stimulating hormone and luteinizing hormone receptors. Activation of the TSHr is the key event leading to both increased thyroid hormone secretion and growth. Because of its central role in the regulation of thyroid physiology, the TSHr has been the focus of constant research in the history of endocrinology. In more recent studies, however, inherited defects of the TSHr have been described as a cause of clinically relevant thyroid disease.

Activating Mutations of the TSHR

Site-directed mutagenesis initially showed that single-point mutations in critical regions of the TSHR were capable of constitutively activating the TSHr, in the absence of its natural ligand, thyrotropin [or thyroid-stimulating hormone (TSH)]. Such mutations, if found in vivo, would be expected to cause thyroid growth and hyperthyroidism. Indeed, naturally occurring, activating mutations of the *TSHR* have been described in a significant fraction of human toxic adenomas and toxic multinodular goiters (Kleinau and Biebermann, 2014). Mutations of the *TSHR* causing distinct hyperfunctioning nodules are always somatic, that is, are found only within the nodular tissue. The nodules containing the mutation therefore represent monoclonal expansions of an initially mutated single thyroid cell and the condition is not hereditary. Since activation of the TSHr induces not only thyroid growth but also differentiation, these neoplasms are only very rarely malignant. More rarely, however, germ-line activating mutations of the *TSHR* have been described. The phenotype caused by these mutations is termed autosomal-dominant nonautoimmune hyperthyroidism [Online Mendelian Inheritance in Man (OMIM) 603372]. Although in many cases, this disease is inherited in a dominant fashion, at least half of the cases described thus far (>20) in the literature are sporadic; that is, the mutation is found only in the index case and not in the parents (de novo mutation) (Hébrant *et al.*, 2011). The classical phenotype is characterized by severe congenital or neonatal hyperthyroidism and goiter. TSHr antibodies are usually negative and this helps differentiate the disorder from the other relevant cause of neonatal hyperthyroidism, the transplacental passage of maternal TSHr-stimulating antibodies. Treatment with antithyroid drugs can usually control hyperthyroidism, but relapses are the rule. Thyroid growth is not contrasted by antithyroid drugs and the goiter evolves from initially diffuse to multinodular early during childhood, requiring surgery. Milder cases have been described, with later onset of hyperthyroidism and goiter. Several mutations of the *TSHR* have been identified as being responsible for the syndrome ("SSFA-GPHR" http://www.ssfa-gphr.de/). The relationship of genotype to phenotype has been found to be somewhat inconsistent in large families with multiple members carrying the same mutation. This indicates that other factors (genetic or environmental) play a role in determining the phenotype, at least with some of the known mutations.

More rarely, inherited mutations of the *TSHR* cause an inordinate responsiveness of the receptor to the placental hormone β human chorionic gonadotropin (β-HCG), which is closely related to TSH. In these cases, the effect of the mutation becomes evident only when high levels of β-HCG are present, that is, during pregnancy, hence the appellation of familial gestational hyperthyroidism for this peculiar disease (OMIM 603373). Other than in pregnancy, the carriers of this rare mutation have a completely normal thyroid function.

Inactivating Mutations of the *TSHR*

Inactivating mutations of the *TSHR* manifest themselves with the clinical phenotype of resistance to TSH (OMIM 275200). Patients have often been detected at birth with severe primary congenital hypothyroidism (elevated TSH and low thyroxine) and a normally located but hypoplastic thyroid. In other cases, only mild, subclinical hypothyroidism has been found. Clinical phenotypes of TSH resistance correlate with the residual mutant receptor activity (Grasberger and Refetoff, 2017). Nonfunctional mutations in the two alleles produce severe hypothyroidism (uncompensated TSH resistance), while mutations in at least one allele with residual receptor function produce either mild hypothyroidism (partial compensation) or isolated hyperthyrotropinemia (full compensation). More recently, a new subgroup of TSH resistance (nonclassic TSH resistance) that is characterized

by paradoxically high thyroidal iodine uptake has been reported. The inheritance of TSH resistance is typically recessive, though heterozygous *TSHR* mutations play a more prominent role in the pathogenesis of isolated nonautoimmune hyperthyrotropinemia diagnosed after the neonatal period.

Inherited Defects of Thyroid Hormone Biosynthesis and Processing

Defective synthesis of thyroid hormone from the thyroid results in overt or compensated primary hypothyroidism. Since thyroid growth is largely independent of the enzymatic pathways involved in the biosynthesis of thyroid hormone, an ongoing TSH elevation as a consequence of low circulating thyroid hormone results in goiter. Therefore, the clinical phenotype of this group of diseases is characterized by hereditary goiter, usually early in onset, and various degrees of impairment of thyroid function, ranging from euthyroidism to overt primary hypothyroidism. Additional clinical features may be observed when the defect has consequences on other organs, as in Pendred syndrome. The phenotype may be further characterized by the application of sophisticated thyroid function tests, such as the perchlorate challenge test or the measurement of thyroid hormone by-products. Because of their great impact on the overall health and survival of affected individuals, some of these diseases are quite rare and mostly recessive. However, their recognition has greatly enhanced the understanding of thyroid gland metabolism.

Pendred Syndrome

Pendred syndrome (OMIM 274600) is an autosomal-recessive disease characterized by congenital deafness, early-onset goiter, and euthyroidism, though subclinical hypothyroidism is frequently observed in iodine-deficient areas (Wémeau and Kopp, 2017). The prevalence of Pendred syndrome is estimated at 1/1000. The sensory deafness is often due to a malformation of the inner ear in which the cochlea is replaced by a single cavity (Mondini's defect). However, an enlarged vestibular aqueduct (EVA), endolymphatic sac, and endolymphatic duct on magnetic resonance imaging (MRI) of the ear have been shown to be more specific signs. Except for its unusually early onset, the goiter is clinically not distinguishable from the more common endemic multinodular goiter. A positive perchlorate discharge test with typical malformations on MRI imaging of the inner ear establishes the diagnosis. The disease has been mapped by linkage analysis to chromosome 7q31. The cloned gene (termed *SLC26A4*) encodes a multifunctional anion exchanger protein (pendrin) expressed in the adult human thyroid and in the human cochlea and kidney. In the thyroid gland, pendrin is expressed at the apical membrane and functions as an iodide/chloride exchanger involved in iodide efflux into the lumen. Close to 200 different mutations in the *SLC26A4* gene have been reported. Individuals with true Pendred syndrome are either homozygous or compound heterozygous for mutation in the *SLC26A4* gene. Biallelic mutations in the *SLC26A4* gene have no or only a mild thyroidal phenotype, indicating that other components are likely involved in iodide efflux. Intriguingly, some patients with nonsyndromic EVA harbor monoallelic mutations in the *SLC26A4* gene, suggesting an oligogenic mechanism with concomitant mutations in either the *KCNJ10* or the *FOXE1* genes (Wu *et al.*, 2010; Yang *et al.*, 2009), although this seems to be a rare event.

Sodium–Iodide Symporter Defect (OMIM 601843)

This extremely rare disease is characterized by an autosomal-recessive mode of inheritance, severe congenital hypothyroidism, and multinodular goiter. The diagnosis is clinically established on the basis of a very low thyroidal uptake of radioiodine in the presence of goiter. An additional feature is a partial response in terms of thyroid hormone production to high oral doses of potassium iodide. The disease is caused by homozygous or compound heterozygous inactivating mutations of the sodium–iodide symporter gene, located on chromosome 19p33.2–p12 (Targovnik *et al.*, 2017).

Thyroglobulin Defects (OMIM 274900)

Patients with this autosomal-recessive condition display a wide range of thyroid dysfunction, ranging from severe hypothyroidism to euthyroidism, low serum thyroglobulin concentration, congenital goiter, or goiter appearing shortly after birth and elevated thyroidal radioiodine uptake. Thyroglobulin is a very large protein whose gene is located on chromosome 8q24.2–q24.3. To date, more than one hundred deleterious mutations, including splice-site, nonsense, and missense, have been identified and characterized in patients with the disease (Targovnik *et al.*, 2017).

Thyroperoxidase Defects (OMIM 274500)

Patients with thyroperoxidase defects have severe congenital hypothyroidism and various degrees of goiter. The disease is autosomal-recessive and is diagnosed by a positive perchlorate discharge test, in the absence of clinical features of Pendred syndrome. The gene for thyroperoxidase has been mapped to chromosome 2p25 and about one hundred deleterious mutations that cause iodide organification defect, total in most cases, have been identified and characterized (Ris-Stalpers and Bikker, 2010).

Dual Oxidase 2 Defects (OMIM 606759)

In the thyroid gland, dual oxidase 2 (*DUOX2*) is responsible for H_2O_2 generation which is used by thyroid peroxidase for the iodine organification. The prevalence of *DUOX2* mutations in thyroid dyshormonogenesis is variable among different series but invariably high. To date, near one hundred mutations have been reported, with a high inter and intrafamilial phenotype variability. In particular, there is no correlation between the class of mutation (truncated, missense, monoallelic, biallelic) and the phenotype in terms either of TSH levels or of discharge rate or of CH duration (transient or permanent). Genetic, epigenetic, and environmental modulators may account for the lack of genotype–phenotype correlation (Muzza and Fugazzola, 2017).

Dual Oxidase Maturation Factors 2 (OMIM 612772)

Dual oxidase maturation factors (DUOXA) 2 form functional heterodimeric complexes with DUOX2, which enable the exit of the dimer from ER and the translocation to the plasma membrane. The prevalence of *DUOXA2* variants in cases with congenital hypothyroidism is very low; indeed, only seven different variants have been reported in eight unrelated cases showing the same phenotype variability observed for *DUOX2* mutations (Muzza and Fugazzola, 2017).

Dehalogenase Defects (OMIM 274800)

Deiodinases (or dehalogenases) are a group of enzymes capable of deiodinating metabolites of thyroid hormone degradation, such as diiodotyrosine (DIT) and monoiodotyrosine (MIT). As such, they greatly contribute to the intrathyroidal pool of iodine by deorganifying "used" organic iodine and making it available for new hormone synthesis. Patients with a dehalogenase defect are incapable of reusing MIT or DIT and develop hypothyroidism and goiter secondary to urinary loss of iodine. The defect is inherited in an autosomal-dominant fashion and is diagnosed by an elevated urinary excretion of administered labeled diiodotyrosine and monoiodotyrosine. Also characteristic is a prompt resolution of hypothyroidism when dietary supplementation with high doses of iodine is given (Targovnik *et al.*, 2017).

Developmental Defects of the Thyroid and Congenital Hypothyroidism

Congenital hypothyroidism (CH) has an incidence of approximately 1 in 2000–3000 newborns. Universal screening for the disease is available in most countries and allows early detection and treatment. Although CH can be observed in any severe form of the defects of thyroid synthesis described above, it is most often due to an abnormal in utero development of the thyroid gland, varying from its complete absence (thyroid agenesis) to various degrees of ectopy and hypoplasia (thyroid dysgenesis). Hereditary forms of the latter are very rare, most likely due to the severity of the consequences of CH, which include infertility. A number of genes involved in thyroid organogenesis have been identified and their role in the pathogenesis of CH has been partially clarified (Abu-Khudir *et al.*, 2017). The thyroid transcription factor 1 (*TTF-1*; OMIM 600635), mapped to chromosome 14q21, has been shown in animal models to be necessary for normal early thyroid organogenesis. Despite its central role, mutations in *TTF-1* have been identified in only a few patients with congenital hypothyroidism due to thyroid dysgenesis. TTF-2, also known as FOXE1 (on chromosome 9q22; OMIM 241850), is also highly expressed during thyroid ontogenesis. A familial case of thyroid agenesis associated with cleft palate and spiky hair has been shown to be due to homozygous missense mutations of *TTF-2* and was named Bamforth–Lazarus syndrome. Paired-box gene 8 (PAX-8; OMIM 167415) is another transcription factor involved in thyroid organogenesis and regulation of the transcription of thyroid-specific genes, such as thyroglobulin and thyroid peroxidase. Nonsense and missense mutations of *PAX-8* have been observed in both sporadic and familial cases of thyroid dysgenesis. In addition, newly discovered predisposing genetic factors (e.g., *GLIS3*, *JAG1*) are described in familial CH cases associated mainly with a normal or small thyroid in situ.

Despite these encouraging findings, the etiology of the large majority of cases of CH and thyroid dysgenesis remains unknown. It is likely that, in addition to other genetic factors, epigenetic or environmental factors play an important role.

Genetic Factors in Thyroid Autoimmune Diseases

The Clinical Phenotype

It is important to recognize that these diseases represent a group of diseases rather than a homogenous entity and that several clinical features may occur independently of one another, defining a variety of possible phenotypes. In general, the autoimmune thyroid diseases (AITD) are defined by the presence of a thyroid lymphocytic infiltrate, associated with serological evidence of thyroid autoimmunity in the form of circulating antibodies reactive to thyroid antigens and various degrees of thyroid dysfunction, ranging from profound hypothyroidism, as in the case of atrophic Hashimoto's thyroiditis (OMIM 140300), to severe hyperthyroidism, as in the typical Graves' disease (OMIM 275000). A number of other features may or may not be associated, such as the presence of Graves' ophthalmopathy, an autoimmune disease of the orbital tissues, typically observed in a relevant number of patients with hyperthyroid Graves' disease but occasionally also found in patients with Hashimoto's thyroiditis. Pretibial

myxedema is a puzzling inflammatory process of the dermis, localized to the pretibial regions, that is also associated (more rarely than ophthalmopathy) with Graves' disease. Finally, depending on various factors that are not completely understood, the thyroid gland may be enlarged as a consequence of either massive lymphocytic infiltration or ongoing stimulation; it may be normal in size or it may be strikingly reduced in size, as in the case of primary myxedema.

Evidence for a Role of Genetic Factors in the Pathogenesis of Autoimmune Thyroid Disease

A number of lines of evidence strongly indicate an important influence of genetic factors in the etiology of these diseases. Indeed, the prevalence of the disease in first-degree relatives of patients with the disease (probands) is significantly higher than in the general population. In early studies conducted in the late 1950s and 1960s, the prevalence of positive antithyroglobulin or antimicrosomal antibody tests in relatives ranged from 45% to 55%, compared to a general population prevalence of approximately 15%. More stringent classical segregation analysis in families with autoimmune thyroid disease confirmed these earlier results, indicating a Mendelian dominant mode of inheritance for thyroid autoantibodies, at least in some families. In a further refinement of these findings, some investigators have indicated that in some families not only the predisposition to form thyroid autoantibodies is strongly hereditary, but also that even the fine molecular specificity of such antibodies can be inherited. In summary, there seems to be a clear role for genetic factors in the formation of thyroid antibodies, at least in families in which the clinical disease exists in one member. The situation was different when normal subjects with thyroid autoantibodies but without clinical Hashimoto's thyroiditis were selected as probands. In one such study, only 30% of relatives had a positive result, compared to approximately 16% expected from population data, indicating at best a polygenic inheritance with low penetrance. Thus, the relatively common antithyroid autoantibody phenotype may represent the consequence of a strong genetic influence only in families with overt AITD. Less clear data are available when one looks at the inheritance of the full AITD phenotype. Approximately 33% of relatives of patients with AITD were found to be affected, resulting in a relative risk for the disease in sibs, also termed λ(s), as high as 16.9.

Another way of estimating the role of the genetic contribution to the etiology of a disease is studying twins. In both Graves' disease and Hashimoto's thyroiditis, studies in twins have shown concordance rates well below 100% in identical twins (approximately 30% in Graves' disease and 55% in Hashimoto's thyroiditis). However, much lower concordance rates (close to zero) have been observed in dizygotic twins. Thus, whereas a lower concordance rate in dizygotic twins indicates the presence of genetic factors, the less-than-100% concordance rate observed in identical twins indicates a role for environmental factors as well (incomplete penetrance). Interestingly, 80% of identical twins and 40% of dizygotic twins of Hashimoto's thyroiditis patients had circulating thyroid autoantibodies. Again, these data suggest a dominant mode of inheritance with high (80%) penetrance for the thyroid autoantibody trait, within a framework of a general predisposition to thyroid autoimmune disease.

Predisposing Genes in AITD

The evidences summarized above have encouraged in the past few decades studies aimed at the identification of the genes involved in the genetic predisposition to AITD. The majority of the susceptibility genes include genes of thyroid autoantigens and genes involved in the immune response. Aberrant activity of these immune-regulatory genes due to polymorphisms would potentially lead to a breakdown in immune tolerance and ultimately to autoimmunity. Through linkage and association analyses, genome screening, and genome wide association studies (GWAS), several single nucleotide polymorphisms (SNPs) in genes including *TSHR*, *FOXP3*, *CD25*, *CTLA-4*, *CD40*, and the *HLA* have been identified as possible candidates.

TSHR

GWAS studies allowed to establish a strong association of the *TSHR* gene with Graves' disease. Subsequent fine-mapping studies narrowed the disease-susceptibility region to a 40 kb sequence in intron 1, where at least five Graves' disease-associated SNPs in tight linkage disequilibrium were identified (rs179247; rs2284720; rs12101255; rs12101261; and rs2268458). Further functional analyses of *TSHR* intron 1 polymorphisms provided direct evidence of a link between central tolerance and *TSHR* intron 1 SNPs (Stefan *et al.*, 2014).

FOXP3

FOXP3 (forkhead box P3) is an X-linked gene that can act as both a transcriptional repressor and an activator for primarily immunological genes. The mouse mutant *Scurfy*, a line defective in FOXP3, is characterized by massive hyperproliferation and multiorgan infiltration of CD4 + T cells and is lethal in hemizygous males. In humans, mutations in *FOXP3* lead to an X-linked syndrome which includes immune dysregulation, polyendocrinopathy, and enteropathy. Various *FOXP3* single nucleotide polymorphisms and microsatellite markers have been reported to be associated with autoimmune thyroiditis (AITD), though the role of these variants in thyroid autoimmunity has not been clarified (Lee *et al.*, 2015).

CD25

CD25, also known as the α-subunit of the IL-2 receptor, is involved in the regulation of T cell function. Similar to mice with impaired FOXP3, IL-2Rα deficient mice exhibit lethal lymphoproliferative disorder and a severe autoimmunity. Case-control and GWAS studies from the UK reported that CD25 was significantly associated with Graves' disease with elevated serum concentrations of sIL-2Rα (Lee *et al.*, 2015).

CD40

CD40 is a tumor necrosis factor receptor (TNF-R) predominantly expressed on antigen presenting cells (APC) like B cells, but also on thyroid epithelial cells, and plays a fundamental role in B-cell activation and antibody secretion. Defective or absent CD40 activity results in a variety of profound immune system deficiencies. Moreover, several single nucleotide polymorphisms within the *CD40* gene have emerged as causative genetic variants that predispose to GD. The most well-studied polymorphism, a-1C/T polymorphism (rs1883832) in the 5′ UTR Kozak sequence, was found to have significant association with GD with a relative risk of 1.6 among individuals carrying the CC genotype. The C allele has been associated with higher persistent levels of thyroid peroxidase and thyroglobulin antibodies, while the T allele and TT genotype were found to carry a protective effect and even linked to later-age onset of GD. Functional studies indicated that the -1C/T *CD40* SNP increases the translation efficiency of CD40 synthesis of 13%–35%; this could potentiate the activation of APCs, the costimulation of the T cell, and the CD40 expression on thyroid cells leading to an overall proinflammatory and autoimmune response (Lee *et al.*, 2015).

CTLA-4

The human *CTLA-4* gene is located on chromosome 2q33 and produces a protein expressed on T cells only after antigen or mitogen stimulation. It subsequently interacts with activated T cells carrying a CTLA-4 receptor (B-7) causing their silencing or death. Therefore, CTLA-4 acts as a key downregulator of the immune response and represents an excellent candidate for an autoimmunity gene. Consistently, mice defective in CTLA-4 function (CTLA-4 −/−) develop rapidly fatal multiorgan lymphocytic infiltrates, a condition that resembles human autoimmune diseases. Several *CTLA-4* SNPs have demonstrated risk for thyroid autoimmunity. An A/G SNP at position 49 in exon 1, an (AT)n microsatellite polymorphism in the 3′ untranslated region of exon 4, and the CT60 polymorphism in the 3′UTR have consistently been associated with both Graves' disease and Hashimoto's thyroiditis. Functional studies have shown that these polymorphisms lead to a reduced CTLA-4 expression and/or stability that would predispose to autoimmunity by decreasing suppression of T cell activation and proliferation.

The *HLA* Genes

The *HLA* gene complex is located on the short arm of the sixth chromosome (6p21) and encodes a large number of genes mostly (but not only) involved in the regulation of the immune response. In general, genes within the HLA complex have been subdivided into three classes. Class I includes the HLA class A, B, and C antigens, which are widely expressed on several tissues. Class I genes are mostly involved in direct cytotoxic reactions leading to the killing by the immune system of epithelial cells carrying exogenous antigens, mostly viral in nature. Class II includes the HLA DR, DP, and DQ antigens, mostly expressed on immune cells. These antigens are mostly involved in the presentation of antigen within the immune system. This process is central to the development of the normal immune response and, depending on several factors, it will lead to either the selection and amplification of antigen-specific T and B cells or to the silencing of these cells (tolerance). Class III includes genes coding for complement factors, heat shock proteins, tumor necrosis factor α, and several other proteins not directly involved in the immune response. The *HLA* genes (especially class I and class II) are highly polymorphic and some alleles show striking linkage disequilibrium. Because of its function, the HLA complex has been widely studied in relation to autoimmune diseases, including AITD. Graves' disease was initially shown to be associated with the HLA-B8 allele in several studies involving Caucasian patients with relative risks from 1.5 to 3. However, the HLA-B8 antigen has been subsequently recognized to be in linkage disequilibrium with the class II allele HLA-DR3. Indeed, additional association studies have shown a slightly higher relative risk (2.5–4) when this allele was studied in Caucasian Graves' disease patients. It was concluded that the HLA-DR3 allele was more relevant than HLA-B8 in determining the inherited susceptibility to GD. GD has also been found to be associated with (relative risk 3.8) the allele HLA-DQA1*0501, also in linkage disequilibrium with DR3, as well as with the allele DRB1*0301, in linkage disequilibrium with DR3. Hashimoto's thyroiditis has been occasionally found to be associated with HLA-DR3, HLA-DR4, and HLA-DR5, with similarly low relative risks, ranging from 2 to 7. It is interesting that different haplotypes of the HLA have been involved, as Graves' disease and Hashimoto's thyroiditis are often found in different members of the same family, portending a common genetic background. In keeping with the low relative risks obtained in association studies, linkage studies, including a whole genome screen analysis, have shown no evidence in favor of linkage with the HLA. In summary, genes within the HLA complex have been consistently shown to be involved in the genetic predisposition to AITD. However, as exemplified by low relative risks and negative linkage, the HLA complex failed to explain the large hereditary predisposition to the diseases shown by family studies. This shows that mutations within the HLA system are not absolutely required or sufficient to cause AITD, representing risk factors with a small overall effect.

Genetic Factors in Simple and Multinodular Goiter

The main etiologic factor in goiter is indisputably iodine deficiency, a worldwide problem that affects almost 1 billion people around the world. In areas with iodine deficiency, the prevalence of goiter in the general population is >10%. Epidemiologists have traditionally distinguished "endemic" goiter, observed in geographic areas of iodine deficiency, from "sporadic" goiter, observed in areas of iodine sufficiency. The accuracy of the distinction is, however, questionable, as the clinical phenotype of the two forms of the disease is indistinguishable, except for areas of extreme iodine deficiency, where large goiters are associated with cretinism and hypothyroidism. In addition to iodine deficiency, other factors are likely involved in the pathogenesis of this common disease. This hypothesis stems from several circumstantial observations. In areas with iodine deficiency, not all exposed subjects develop goiter. Universal iodine supplementation strikingly reduces but does not abolish the disease and goiter is observed in the absence of iodine deficiency, as mentioned above. Additional environmental factors, such as tobacco smoking, naturally occurring goitrogens, and pharmacologic goitrogens, have been demonstrated. Sex hormones are also likely to be involved as goiter is more prevalent in women living in areas with mild iodine deficiency. The observation of familial clustering of the disease is a daily experience of all endocrinologists, especially in areas with mild or no iodine deficiency, and this has led to the hypothesis that inherited factors coincide in the predisposition to the development of goiter. The familial clustering of the disease has also been reported in several epidemiological surveys, mostly from areas of endemic iodine deficiency. As in the case of the AITD, a number of twin studies have been performed. These have shown that the environmental factors are largely predominant when cases are drawn from endemic regions, as shown by similar concordance rates between dizygotic and monozygotic twins. However, large, population-based studies in twins have shown significantly different and overall higher concordance rates between monozygotic and dizygotic twins (**Table 1**). Interestingly, the intrinsic population prevalence of goiter in these latest studies is much lower than in the two older studies, performed in the 1960s in areas of iodine deficiency. One possible explanation for these apparently discrepant data is that once the effect of the major environmental factor (iodine deficiency) is removed from the population, cases with a stronger genetic effect emerge. In this view, the distinction between endemic and sporadic goiter seems to be justified. Despite evidence in favor of relevant genetic influences, these have not been clarified yet. As in many common diseases, there is no identifiable mode of inheritance and multiple, relatively frequent gene variants are likely to play a role. Among thyroid-specific genes markers, polymorphisms in the genes for thyroid peroxidase, thyroglobulin, sodium iodine symporter, pendrin, and thyrotropin receptor have been associated with goiter. Genetically linked nonthyroid-specific loci in familial goiter have been reported in several studies. Studies in single large kindreds with highly prevalent and apparently dominant transmission of multinodular goiter have indicated linkage of the phenotype to a locus (termed *MNG-1*) located on chromosome 14q31. The same studies have ruled out the *TSHR* (which resides in the same chromosomal region) from the linked region. *MNG-1* has been confirmed as a susceptibility locus in other large families. Interestingly, *MNG-1* overlaps with *GD-2*, a susceptibility locus for Graves' disease. It is therefore possible that the region contains a novel thyroid-specific growth factor and/or antigen. *MNG-2* was mapped on chromosome X by linkage analysis in an Italian family with goiter across three generations. *MNG-3*, located on chromosome 3, has been identified in two independent Japanese pedigrees. Other loci on chromosome two, three, seven, and eight have been identified by linkage analysis in Danish, German, and Slovakian families (Knudsen and Brix, 2014). These findings are encouraging but were obtained in a small subset of families with a seemingly large genetic effect and their epidemiological relevance to goiter found in the general population is unknown. Monogenic disorders of thyroid hormone metabolism represent a rare cause of hereditary goiter, with or without hypothyroidism. These conditions, described in some detail above, are distinct from the commonly encountered sporadic or endemic goiter in that there is usually an earlier appearance of goiter, a more distinct familial pattern (usually autosomal-recessive), and several degrees of thyroid dysfunction. Although it is conceivable that more subtle defects in any of these genes might be involved in the pathogenesis of goiter, extensive screening of the general population for association and/or linkage to known genes is lacking.

In summary, genetic predisposition is probably important in the etiology of simple goiter, both sporadic and endemic. In endemic areas, though, the effect of environmental factors (iodine deficiency) is predominant and widespread, making goiter very prevalent. In contrast, in areas with normal iodine intake, genetic factors are more relevant, but with a smaller prevalence. As a consequence, the prevalence of goiter is strikingly reduced and the phenotype is more clearly clustered in families. It is likely that multiple different genes are involved in the predisposition to simple goiter, but thus far only a few of these have been identified.

Table 1 Available studies in twins in populations with different prevalence of goiter

Year of the study	*Geographic location*	*Concordance rate in monozygotic twins*	*Concordance rate in dizygotic twins*	*Population prevalence of goiter*
1967	United Kingdom	24%	12%	25.3%
1967	Greece	89%	73%	53.0%
1999	Denmark	42%	13%	1.5%
2005	Denmark	67%	17%	1.5%

Note. In populations with a lower prevalence, a higher concordance rate is observed in monozygotic twins when compared with dizygotic twins, suggesting a stronger genetic predisposition.

Genetic Factors in Nonmedullary Thyroid Cancer

Thyroid cancer of follicular origin (OMIM 188550) is the most frequent endocrine tumor and more than 90% cases are sporadic, due to somatic genetic alterations mostly affecting the mitogen-activated protein kinase pathway. Only 3%–9% of all thyroid cancers are familial nonmedullary thyroid cancer (FNMTC) cases, defined by the presence of thyroid cancer in 2 or more first-degree relatives, in the absence of predisposing environmental factors (Peiling Yang and Ngeow (2016)). Clinically, FNMTC has been reported to be more aggressive and more often multifocal than its sporadic counterpart. Only 5% of all FNMTCs in the syndromic form have well-defined driver germline mutations; the associated syndromes include Cowden syndrome, familial adenomatous polyposis, Gardner syndrome, Carney complex type 1, and Werner syndrome. Cowden disease (OMIM 158350) is an autosomal-dominant disease, characterized by multiple hamartomas of the skin, breast, thyroid, brain, and endometrium. Facial trichilemmomas are a distinctive feature of the syndrome. Other findings include craniomegaly, scrotal tongue, and cerebellar neoplasias. A significant increase in the incidence of breast cancer is seen in Cowden syndrome families. Up to 25% of patients have thyroid cancer, and 60% of cases have thyroid nodules benign thyroid nodular disease. Cowden syndrome has been mapped to chromosome 10q23.31 and the mutated gene, termed *PTEN* for phosphatase (OMIM 601728), has been isolated. The PTEN protein is expressed in several tissues and functions as a tyrosine phosphatase able to dephosphorylate activated regulator proteins, thus downregulating proliferation pathways. Several mutations of *PTEN* have been found in families with Cowden syndrome, without a clear-cut genotype–phenotype relationship. Several in vitro studies suggest that PTEN acts as a tumor suppressor gene. This observation is in keeping with an autosomal-dominant mode of inheritance and with the observation that most of the mutations identified thus far cause a loss of function. Moreover, in several families with many features of the syndrome, no mutation of the gene has been found. Germline mutations in *SDHB-D*, *PIK3CA*, or *AKT1* genes and *KILLIN* promoter methylation have been identified in *PTEN* mutation-negative patients. Familial adenomatous polyposis (FAP; OMIM 175100), also termed Gardner syndrome, is inherited in an autosomal-dominant fashion. The most prominent feature of the syndrome is early-onset colonic cancer and multiple widespread, preneoplastic polyps of the colon. Extracolonic manifestations include congenital hypertrophy of the retinal pigment epithelium in up to 90% of affected persons and have been used as a marker of the disease before genetic testing became available. Other features of the syndrome include benign bone tumors and hepatoblastomas. In women with the syndrome, the risk of papillary thyroid cancer has been estimated to be 160-fold higher than in the general population. Papillary thyroid cancer in the setting of FAP is often detected before age 30, is multifocal, and displays unusual pathological features. The gene responsible for FAP has been mapped to chromosome 5q21 and was designated adenomatous polyposis of the colon (APC). As expected by the autosomal mode of inheritance, APC functions as a tumor suppressor gene and detected mutations associated with the phenotype cause a loss of function of the gene product. The adenomatous polyposis of the colon (APC) gene product, expressed on the membrane of several epithelial cell types, is part of the regulatory β-catenin destruction complex in the Wnt/beta-catenin pathway. The inactivating APC mutation promotes gene transcription leading to cell proliferation. Carney complex type 1 is an autosomal-dominant disease characterized by the following features: myxomas of soft tissues; skin and mucosal pigmentation (blue nevi); schwannomas, tumors of the adrenal and pituitary glands and testicle. A patient is considered to have Carney complex if two major criteria are present or if one major criterion is present and a first-degree relative has Carney complex or an inactivating *PRKAR1A* mutation. Mutations in *PRKAR1A* gene were identified in 73% of cases. This gene encodes the type 1A regulatory subunit of protein kinase A (PKA) and its loss of function leads to enhanced signaling by PKA.

Werner syndrome is an autosomal-recessive disease, associated with mutations of the *WRN* gene on chromosome 8p11-21. It is characterized by premature aging, scleroderma-like skin changes, cataracts, premature graying and/or thinning of scalp hair, short stature, which onset over 10 years of age. Thyroid cancer was observed in 16% of patients and occurred at a younger age.

Nevertheless, 95% of FNMTC is nonsyndromic with less well-defined genetic susceptibility. To date, four susceptibility genes have been identified: *SRGAP1* (12q14), *TITF-1/NKX2.1* (14q13), *FOXE1* (9q22.33), and *HABP2* gene (10q25.3). In particular, the role of SRGAP1 and TITF-1/NKX2.1 remains to be validated in a larger FNMTC cohort, while data supporting the association between *FOXE1* gene variants and FNMTC are not entirely consistent. Finally, the G534E variant of the *HABP2* gene was reported as the underlying genetic defect in large kindred with FNMTC; nevertheless, this postulated role was not confirmed in additional cohorts. Chromosomal loci reported to be associated with nonsyndromic FNMTC include *TCO* (19q13.2), *fPTC/PRN* (1q21), *FTEN* (8p23.1-p22), *NMTC1* (2q21), *MNG1* (14q32), 6q22, 8q24, and 4q32. However, the candidate genes at these genetic loci remain unknown. In summary, though the vast majority of cases of NMTC are sporadic, a few cases present in the setting of recognized hereditary syndromes. Knowledge of these clinical conditions is important to the clinician, in order to perform appropriate screening for associated conditions and to provide genetic counseling to individuals at risk.

Familial Medullary Thyroid Cancer

Approximately 5% of thyroid cancers originate from the parafollicular cell lineage. These cancers are termed medullary thyroid cancer (MTC) and account for approximately 15% of all thyroid cancer-related deaths. In contrast to NMTC, MTC is quite often familial (in approximately one-fourth of the cases). Familial medullary thyroid cancer (FMTC) arises in the setting of multiple endocrine neoplasia (MEN) type II syndromes or as an isolated disease. In MEN IIA (OMIM 171400), FMTC is associated with pheochromocytomas and parathyroid adenomas, and in MEN IIB (OMIM 162300), patients present a marfanoid habitus,

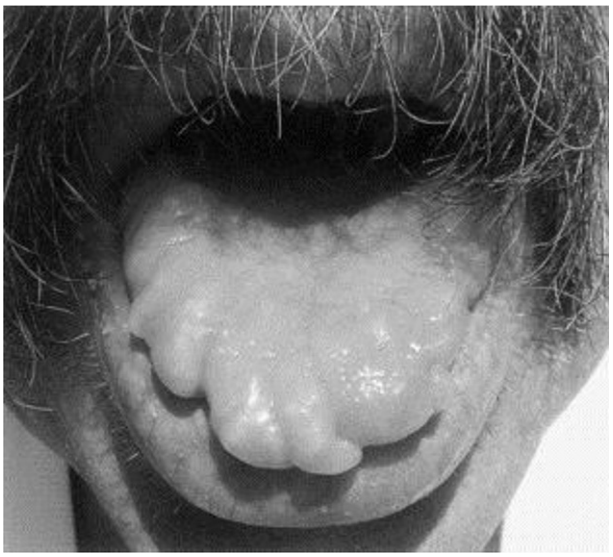

Fig. 1 Typical lingual neuromas in a patient with MEN IIB

mucosal neuromas, and ganglioneuromatosis, in addition to the above-described features (see **Fig. 1**). In isolated FMTC (OMIM 155240), there are no extrathyroidal manifestations. The inheritance of these closely related conditions is autosomal-dominant, with high penetrance. In MEN IIA and MEN IIB, MTC is found in almost 100% of carriers by the end of third decade of life if sought by biochemical screening, whereas pheochromocytomas occur in 50% of carriers and parathyroid tumors in 25% of carriers. Despite these clearly distinct phenotypes, all three conditions are due to germline mutations in the *RET* proto-oncogene sequence. The *RET* proto-oncogene maps to chromosome 10q11.2 and encodes a membrane-bound tyrosine kinase receptor. Specific mutations have been associated with the different subtypes of MEN II (Accardo *et al.*, 2017). Causative mutations detected thus far in MEN IIA are almost entirely limited to a few cysteine residues located in the extracellular domain. These mutations induce critical conformational changes in the gene product, causing constitutive activation of the receptor with ongoing production of intracellular proliferative signals. Interestingly, there is quite a strict genotype–phenotype relationship. Mutations involving codons 609, 611, 618, 620, and 634 are found exclusively in families with MEN IIA or with FMTC and mutations involving noncysteine codons 768, 804, and 891 have been found only in families with FMTC, although even in these families, occasional cases of pheochromocytoma and hyperparathyroidism are found. Since the molecular genetics of the two conditions partially overlap, other genes must be involved in determining the phenotype. In contrast, mutations at codon 918 (M918T) are found in almost all families with MEN IIB. This mutation causes a conformational change in the intracellular tyrosine kinase binding pocket and allows for constitutive kinase activation in the absence of dimerization. The *RET* gene is also mutated in many cases of Hirschsprung's disease, although most mutations detected in this disorder induce the loss of function of the mutant allele. Surprisingly, Hirschsprung's disease has been found in some families with MEN IIA.

Detailed knowledge of the molecular genetics of these aggressive diseases has greatly enhanced the ability of clinicians to detect persons at high risk for MENs. Genetic testing for RET mutations has become widely available for family members of patients and allows early, preventive treatment, which is expected to greatly increase the life expectancy of patients.

Glossary

Goiter An abnormally enlarged thyroid gland, detected either by palpation or by ultrasound.

Goitrogen A substance that induces goiter formation.

Introduction

Goiter is a heterogeneous term that refers to diffuse or nodular enlargement of the thyroid gland. Goiters are commonly seen in populations with mild to moderate iodine deficiency. Although iodine deficiency is recognized as the primary driver of goitrogenesis, several other genetic and environmental factors are also known to contribute. Environmental goitrogens are naturally occurring or synthetic substances that interfere with normal thyroid physiology. Most do so by inhibiting the sodium-iodide symporter (NIS), thyroid peroxidase (TPO) activity, or peripheral conversion of thyroxine (T4) into triiodothyronine (T3) by type 1 5′-deiodinase (Gore *et al.*, 2015). Other potential mechanisms of environmental goitrogens include increased thyroid hormone clearance, binding to binding proteins, or transmembrane thyroid hormone transport (Gore *et al.*, 2015).

Types of Goitrogens

Perchlorate

Perchlorate is an inorganic anion used in the manufacturing of rocket propellant, fireworks, airbags, and other explosives. There is extensive evidence of contamination of surface and groundwater with perchlorate, and it has been detected in a variety of food types. Perchlorate has been a historical treatment for Graves disease and continues to be used in the treatment of amiodarone-induced thyrotoxicosis (Gharib *et al.*, 2016). As shown through animal studies, perchlorate competitively inhibits the NIS, potently reducing thyroidal iodide uptake. This leads to decreased thyroid hormone levels and increased thyroid cell hypertrophy, hyperplasia, and thyroid mass (Ting *et al.*, 2006). There appears to be a rebound increase in radioactive iodine uptake (RAIU) following discontinuation of perchlorate exposure, suggesting that the perchlorate-induced NIS inhibition is reversible (Braverman *et al.*, 2005).

Studies of human volunteers have shown that single doses of perchlorate as low as 2.2 mg or repeated administration of doses as low as 5.2 μg/kg/day for a 2-week period reduce iodide uptake in a dose-dependent fashion (Ting *et al.*, 2006; Greer *et al.*, 2002). However, human studies of volunteers given perchlorate and of workers occupationally exposed to perchlorate have not shown changes in thyroid hormone or thyroid-stimulating hormone (TSH) levels at similar levels of perchlorate exposure (Eisenbrand and Gelbke, 2016). Interestingly, Braverman *et al.* (2005) showed that workers in an ammonium perchlorate production plant, who had chronic intermittent exposure to perchlorate, had similar RAIU to non-exposed controls after several shifts at the plant, but increased RAIU and decreased iodine excretion compared to controls after several days off, suggesting that long-term adaptation is present. Furthermore, thyroid volume was not enlarged in exposed workers compared to controls.

Although clinical studies of perchlorate exposure have not consistently shown an impact on thyroid function tests, epidemiological evidence suggests an association between perchlorate exposure and thyroid dysfunction, with decreased T4 and increased TSH (Eisenbrand and Gelbke, 2016). For example, data from the 2001–2002 National Health and Nutrition Examination Survey (NHANES) showed a significant positive association between urinary perchlorate and serum TSH levels in women, and a significant negative association between urinary perchlorate and serum total T4 levels in women with urinary iodine <100 μg/L (Blount *et al.*, 2006). While these results suggest that perchlorate exposure in the population is associated with a rise in TSH and fall in total T4 levels, another NHANES analysis of a slightly different population did not confirm this relationship (Bruce *et al.*, 2013). Epidemiologic studies of pregnant women have had conflicting results about whether urinary perchlorate levels correlate with changes in serum T4 and TSH levels, as have studies comparing perchlorate levels in drinking water with neonatal

☆*Change History*: February 2018. Veena Agrawal, Sana Ghaznavi and Ralf Paschke substantially revised the body of the article, and introduced keywords, abstract, and references sections. Figures 1 and 2 and Table 1 were removed.

thyroid function testing (Steinmaus, 2016). It has been theorized that NIS may be upregulated in response to exposure to substances inhibiting iodide uptake, which could explain the discrepancy between the clearly documented inhibition of iodide uptake and the lack of change in thyroid function tests in humans.

In 2011, the United States Environmental Protection Agency determined that perchlorate should be regulated as a contaminant, as outlined in the Safe Drinking Water Act (United States Environmental Protection Agency, 2011). However, considerable controversy exists regarding defining a safe level for perchlorate, and determining how much attention should be given to this substance compared to other NIS inhibitors such as thiocyanate and nitrate, as these substances exist at substantially higher environmental levels than perchlorate (Eisenbrand and Gelbke, 2016).

Thiocyanate

Thiocyanate is one of the breakdown products of glycosinolates and cyanide. Glycosinolates are thioglycosides found in cruciferous vegetables of the *Brassica* family, including cabbage, bamboo shoots, kale, sprout, broccoli, brussel sprouts, turnips, and mustard. Cyanide is a metabolite of cyanogenic glucosides found in plants such as cassava, corn, apricot, almond, cherries, lima beans, linseed, bamboo shoots, and sweet potatoes. Cyanide is also found in cigarette smoke, which is thus a major source of thiocyanate. Thiocyanate has also historically been used in the treatment of hypertension. Thiocyanate is frequently found in human urine samples, suggesting its significant absorption from the environment (Corey *et al.*, 2017).

Thiocyanate competitively inhibits NIS, leading to decreased iodide uptake. Thiocyanate also inhibits TPO-mediated organification and appears to increase iodide efflux. The effect on TPO-mediated coupling is less clear (Willemin and Lumen, 2017). Although thiocyanate is a less potent inhibitor of NIS than perchlorate, the substantially higher environmental levels and longer half-life of thiocyanate as compared to perchlorate results in its greater contribution to environmental goitrogenic risk (Corey *et al.*, 2017; Eisenbrand and Gelbke, 2016).

Both animal and human data support the role of thiocyanate in goitrogenesis. Animals fed diets high in glycosinolates can develop goiter in a dose-dependent fashion. This holds true across multiple different species (Eisenbrand and Gelbke, 2016). In humans, several studies have suggested higher rates of goiter in smokers compared to non-smokers (Brix *et al.*, 2000), which is believed to be a consequence of the higher burden of thiocyanate in this population. This effect seems to be reversible, as former smokers have goiter rates similar to that of lifelong non-smokers (Knudsen *et al.*, 2002). The finding of persistent goiter after correction of iodine deficiency has been shown to be positively correlated with higher urinary thiocyanate levels (Marwaha *et al.*, 2003). However, evaluation of NHANES data showed only a modest association between higher urinary thiocyanate levels and lower T4 levels (Steinmaus *et al.*, 2013), and administration of thiocyanate-fortified milk to human volunteers did not have any impact on thyroid function tests (Dahlberg *et al.*, 1984).

Cassava is amongst the most well-known dietary sources of thiocyanate, and is a staple food in many parts of the world, including the Democratic Republic of Congo, where it is thought to contribute to high rates of goiter (Gaitan and Dunn, 1992). In regions of endemic goiter, ingestion of cassava has been shown to reduce iodide uptake compared to ingestion of a control rice meal, while ingestion of cassava in non-endemic regions did not (Delange and Ermans, 1971). This suggests regional variation in the goitrogenic potential of these plants. Different processing methods alter the degree of thiocyanate formation from cassava-containing foods (Mlingi *et al.*, 1996; Gaitan and Dunn, 1992).

Other breakdown products of glycosinolates found in cruciferous vegetables include isothiocyanate and 5 vinyl oxazolidine-2-thione (also known as goitrin). Isothiocyanate can be metabolized in a number of ways leading to thiocyanate or other antithyroidal substances with thiourea-like effects (Gaitan, 1990). Goitrin has also been shown to reduce iodide uptake in the thyroid gland in humans and animals (Felker *et al.*, 2016).

Overall, it is likely that dietary thiocyanate exposure from a typical diet including *Brassica* vegetables is not sufficient to cause significant inhibition of iodide uptake. However, thiocyanate exposure may exacerbate the effect of iodine deficiency, and lead to hypothyroidism in a dose-dependent manner (Felker *et al.*, 2016). This has been illustrated in a case report of an 88-year-old women who presented with myxedema coma after ingesting up to 1.5 kg of raw bok choy per day for several months (Chu and Seltzer, 2010). This patient had no history of thyroid dysfunction, and the presumed cause of her profound hypothyroidism was the antithyroidal effect of prolonged high dose exposure to glycosinolates and their breakdown products in bok choy.

Nitrates

Nitrates are found throughout the environment, occurring in certain vegetables, preservatives, and as contaminant from fertilizers. Nitrates can also be synthesized by humans, animals, and by certain microorganisms. Varying levels of nitrates have been documented in food sources such as lettuce, as well as in drinking water. Epidemiological studies have shown an association between high nitrate levels (>50 mg/L) in drinking water and larger thyroid glands associated with subclinical thyroid disease in children (Eisenbrand and Gelbke, 2016; De Groef *et al.*, 2006). The association between high nitrate levels in drinking water and thyroid hypertrophy has also been found in adults. This relationship appears to hold true especially in the setting of iodine deficiency.

Similar to perchlorate, nitrates inhibit thyroidal iodide uptake by NIS. Although they are much less potent at NIS inhibition than both thiocyanate and perchlorate, their relatively higher environmental concentration conveys a potentially greater risk towards goitrogenesis. Furthermore, while urinary thiocyanate and perchlorate levels have been decreasing over time, urinary

nitrate levels have remained stable. Thus, the relative contribution of nitrates towards environmental goitrogenesis risk is increasing (Corey *et al.*, 2017).

Flavonoids

Flavonoids are phenolic compounds that exist in several forms, and are found in various foods. The most prevalent source of flavonoids in the Western diet is soy. Flavonoids inhibit the activity of TPO, preventing organification and iodotyrosine coupling, and thus decrease thyroid hormone synthesis. They have also been shown to decrease the activity of type 1 deiodinase, inhibiting peripheral metabolism of thyroxine to triiodothyronine. Soybeans contain isoflavones and coumestans, both types of phytoestrogens, which also inhibit the activity of TPO. They are associated with goiter development in animals (Matovinovic, 1983); however, this goiter development appears to be mitigated by increasing iodine intake.

The majority of evidence does not support an association between soy intake and overt thyroid dysfunction in human adults (Eisenbrand and Gelbke, 2016). However, soy does appear to interfere with the absorption of oral levothyroxine used in the treatment of hypothyroidism. Moreover, a retrospective study of hypothyroid infants showed a greater proportion of infants with persistently elevated TSH levels in those fed soy formula versus milk formula. Soy intake in infancy may also be associated with an increased risk of developing autoimmune disease in adolescence (Fort *et al.*, 1990). Infants in general appear more susceptible to the effects of soy, as evidenced by higher serum isoflavone concentrations in infants on soy formula than in adults consuming soy foods. Despite this, there is no evidence to support the development of goiter in soy-fed infants since the introduction of iodine fortification (Messina and Redmond, 2006).

C-glycosylflavones are a different type of flavonoid found in pennisetum millet (pearl millet), a common food item in areas of Asia and Africa, including rural western Sudan. Goiter prevalence has been found to be significantly higher in these rural areas than in nearby urban areas, where rates of borderline iodine deficiency are similar, but dietary millet ingestion is reduced (Gaitan *et al.*, 1995). However, assessment of the effect of pearl millet is complicated by the fact that this mill*et al*so contains thiocyanate, which, as discussed above, can cause NIS inhibition. Vitexin, a type of C-glycosylflavone in millet, has been shown to inhibit coupling and organification of iodine in rodents. This effect may be even more pronounced in humans due to the breakdown of vitexin to a more potent metabolite (Gaitan *et al.*, 1995). As with cassava, different methods of processing the millet may alter its goitrogenic potential. Dehulling the millet leaves behind a flour with a much lower amount of C-glycosylfavones and thiocyanate, but is not a particularly desirable processing technique as it also removes most of the millet's protein content (Gaitan and Dunn, 1992).

Other types of flavonoids found in different types of millet have also been shown to have antithyroidal properties (Sartelet *et al.*, 1996). As a final example of the potential impact of flavonoids on the thyroid, catechins, a type of flavonoid found in green tea, have been shown in animal studies to significantly decrease levels of T3 and T4 and increase levels of TSH. Histologic examination of rats injected intraperitoneally with catechins revealed thyroid follicular hypertrophy and hyperplasia (Chandra and De, 2013). Human data on catechins is not yet available.

Resorcinol

Resorcinol is a phenolic chemical found in dermatologic medications, used in several industrial applications (e.g. photography, tanning, tire manufacturing), and found in roasted barley, canned molasses, adhesives, hair dyes, and cosmetics, among other products. Coal and shale deposits lead to higher levels of resorcinol in drinking water.

Resorcinol is thought to inhibit TPO activity. As reviewed by Lynch *et al.* (2002), animal studies demonstrate conflicting impact of resorcinol on thyroid weight and function. Some studies support the goitrogenic effect of resorcinol, but only when exposed to persistently high levels, either through daily oral exposure, subcutaneous administration in oil (but not aqueous solutions), or very high-dose twice-daily dermal application.

Studies of humans with occupational exposure to resorcinol have not shown any impact on thyroid function. Epidemiologic support for the goitrogenic effect of resorcinol in humans comes from data showing higher resorcinol levels in drinking water in areas with a high prevalence of goiter as compared to nearby areas with lower prevalence of goiter but similar urinary iodine levels. However, this is confounded by several other differences in the study populations and their drinking water, precluding any firm conclusions.

There are several case reports of hypothyroidism and/or goiter resulting from extremely high-dose (>30 mg/kg/day) long-term topical application of resorcinol-containing medications to extensive areas of the body, especially when applied to areas with open sores or ulceration. Goiter and hypothyroidism resolved upon discontinuation of resorcinol in these cases. Reassuringly, standard dose application of resorcinol-containing medications to intact skin does not appear to have an impact on thyroid function (Lynch *et al.*, 2002).

Phthalates

Phthalates are chemicals used as plasticizers and in adhesives, solvents, cosmetics, and other products. The mechanism by which phthalates interfere with thyroid function is not entirely understood. Animal studies have shown enhancement of NIS expression and iodide uptake but antagonism at the thyroid receptor (Gore *et al.*, 2015).

Both animal and human epidemiologic data support the hypothesis that phthalates lead to reductions in thyroid hormone levels (Eisenbrand and Gelbke, 2016). Several studies have also shown a positive association between urinary phthalates and serum TSH, although the overall strength of this association is weaker than that between urinary phthalates and serum thyroid hormone levels (Gore *et al.*, 2015; Dirtu *et al.*, 2013; Wu *et al.*, 2013). As with resorcinol, phthalates are among the many chemicals found to be present at higher levels in drinking water consumed in areas with higher goiter prevalence (Lynch *et al.*, 2002).

Fluoride

Many countries have environmental sources of excess fluoride, such as from drinking water, or household and agricultural agents. Fluoride exposure is associated with dysfunction of several organ systems. The mechanism by which fluoride influences the thyroid gland is currently unclear. It may relate to reduction in thyroid hormone synthesis, altered hormone transport, or decreased peripheral conversion of T4 into T3 (Barberio *et al.*, 2017). Animal models suggest that the goitrogenic effect of fluoride may be mediated through increased levels of nitric oxide and vascular endothelial growth factor (VEGF), as increased deposition of VEGF in thyroid tissue has been demonstrated in response to fluoride intake (Liu *et al.*, 2012).

Animal models support the hypothesis that high doses of fluoride can impair thyroid function and are associated with reduced levels of T3, T4 and TPO. However, human data has been mixed. Some, but not all, epidemiologic studies show a positive association between higher fluoride concentration and serum TSH levels. Larger population studies from England and Canada have yielded conflicting results about a potential association between higher fluoride levels and prevalence of overt hypothyroidism (Barberio *et al.*, 2017; Peckham *et al.*, 2015). More studies are needed to better understand the impact of fluoride on thyroid function.

Calcium

Excess calcium, as can be found in hard water, has also been postulated to contribute to goitrogenesis. Animal studies show that high levels of administered calcium can lead to an increase in thyroid weight, hypertrophy and/or hyperplasia of thyroid follicular cells, and higher T4 and TSH levels but lower T3 levels. This is accompanied by assays demonstrating inhibition of TPO activity, increase of thyroidal Na^+/K^+-ATPase activity, and reduced type 1 deiodinase activity (Chandra *et al.*, 2012). In humans, several studies have suggested an association between the presence of hard water and an increased prevalence of goiter (Chandra *et al.*, 2016). Calcium is also known to interfere with the absorption of oral levothyroxine, and patients should be counseled to take their thyroid pills several hours apart from any calcium-containing products (Garber *et al.*, 2012).

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) are industrial chemicals previously used for a wide variety of reasons, such as the synthesis of plasticizers, carbonless copy paper, adhesives, paints and inks. Despite being banned since 1979 due to teratogenic and carcinogenic concerns, these chemicals remain measurable in the environment, including in fish, animals, and humans. PCBs have been suggested to interact with the thyroid hormone receptor, alter binding to transport proteins, and affect hepatic clearance of thyroid hormone (Miller *et al.*, 2009).

Several animal studies suggest that PCBs have a goitrogenic effect. For example, salmon exposed to PCBs in their environment were observed to have higher rates of goiter than those that were not exposed (Brucker-Davis, 1998), and rats experimentally exposed to PCBs also demonstrated goitrogenesis. However, there does not appear to be a link between PCBs and goitrogenesis or thyroid dysfunction in humans, even when exposed to potentially lethal levels (Matovinovic, 1983).

Cadmium

Cadmium is a heavy metal found in batteries, dye pigment, and used in manufacturing plastic. Human exposure is through tobacco and contaminated food and water, or occupational exposure during cadmium processing. Cadmium can accumulate within organs, including the thyroid gland. Animal studies have shown that cadmium can lead to goitrogenesis and follicular hyperplasia, inhibition of TSH secretion, and reduction in serum T4 levels; the effect of cadmium on T3 levels varies between studies. C-cell hyperplasia has also been reported. Human data regarding the impact of cadmium on thyroid function and goitrogenesis is extremely limited (Jancic and Stosic, 2014).

Bisphenol A

Bisphenol A (BPA) is a synthetic compound found in many products, including plastic toys, food packaging, and in the lining of canned foods and beverages (Gore *et al.*, 2015). It is a common contaminant in food and water, and nearly all Americans have detectable levels of BPA in their urine. Animal studies suggest that BPA may have both agonistic and antagonistic effects on the thyroid hormone receptor (Gore *et al.*, 2015). Human epidemiologic studies have shown conflicting associations between BPA and T4 levels (Gore *et al.*, 2015), but a neutral or inverse association between BPA and serum TSH levels (Gore *et al.*, 2015; Meeker and

Ferguson, 2011; Meeker *et al.*, 2010). BPA is among the list of endocrine-disrupting chemicals believed to be associated with obesity. One proposed mechanism of this link between BPA and obesity is through BPA-induced thyroid dysfunction (Gore *et al.*, 2015). Overall, there is no convincing data in humans to suggest that BPA has a goitrogenic effect.

Other

A number of other synthetic substances have been identified, which may interfere with various steps in thyroid hormone synthesis, transport, and metabolism (Howdeshell, 2002). Polybrominated diphenyl ethers (PBDEs) are one example. PBDEs are used as flame retardants, and have been shown in animal studies to alter binding of thyroid hormone to its receptor and to be associated with decreased T4 levels. However, the effect of PBDEs on TSH has been inconsistent and human data is lacking (Gore *et al.*, 2015). Triclosan and paraben have been inconsistently associated with higher thyroid hormone and/or lower TSH levels, but generally not with overt hypothyroidism or goitrogenesis (Eisenbrand and Gelbke, 2016). Overall, the interaction of these substances with the thyroid hormone receptor is thought to be complex, and the in vivo effects of these substances is not yet clear (Gore *et al.*, 2015).

Summary

Many natural and synthetic environmental factors have been found to be associated with disruption of normal thyroid physiology and thus potentially the development of goiter, often in the setting of iodine deficiency. Perchlorate, thiocyanate, nitrate, and flavonoids are the most well-studied, but much remains to be discovered regarding their clinical impact on thyroid disease. Infants and iodine-deficient individuals appear to be most sensitive to the exposure to goitrogens. However, direct causation is often difficult to establish between various substances and goiter formation, given the ethical limitation of performing randomized controlled trials using potentially toxic substances in humans. Thus, the bulk of available literature comes from animal studies, which must be interpreted with caution given important differences in thyroid physiology between animals and humans, and epidemiologic data, which is often subject to confounding and bias. Furthermore, attempts to look at the simultaneous effect of multiple environmental agents is complicated by their potential interactions with one another. For example, higher perchlorate intake may lead to increased iodine excretion, thus masking concomitant iodine deficiency. Safety predictions based on assessment of potential goitrogen levels in food and water often conflict with associations drawn from exposures estimated from urinary levels. Moreover, identifying a specific environmental exposure as the root cause of goiter development in an individual patient remains challenging, except perhaps in cases of exposure to extraordinarily high levels of a known environmental goitrogen. Given the growing number of chemicals we are exposed to in modern society, it is important to improve our understanding of the impact of various environmental exposures on our health, including their effects on goitrogenesis and thyroid functioning. Future studies should focus on elucidating the source, mechanism of action, and endocrine effects of environmental goitrogens; defining a safe level of exposure to these substances will be crucial.

Iodine Deficiency☆

Peter Taylor, Onyebuchi Okosieme, Lakdasa Premawardhana, and John H Lazarus, Cardiff University, Cardiff, United Kingdom

Glossary

Endemic goiter Thyroid enlargement due to iodine deficiency in a community.

Iodized salt The addition of iodine to dietary salt to correct iodine deficiency.

Urinary iodine The concentration of iodine in urine, the recommended measure for monitoring iodine nutrition.

Optimal Iodine Nutrition

Need for Iodine

Iodine is an integral part of the thyroid hormones, thyroxine (T4) and 3,5,3′-triiodothyronine (T3) its importance in thyroidology has been established for over a century. Thyroid hormones are essential for health making optimal iodine nutrition a key determinant of health in the individual and the population. Iodine was first identified in the thyroid in 1895 (Baumann, 1896) and in 1917 it was demonstrated that goiters were caused by iodine deficiency and could be prevented by iodine supplementation (Marine and Kimball, 1917).

The effects of iodine deficiency are translated through inadequate thyroid hormone production. Most ingested iodine is broken down into iodide (I^-) in the stomach and duodenum and transferred across the gut mucosa into the bloodstream. In healthy individuals the absorption of iodide can be as high as 90%. Following absorption, it is either excreted via the kidney or concentrated by the thyroid, where a sodium/iodide symporter transports it as iodide into the thyroid gland (**Fig. 1**).

The concentration gradient varies with the availability of iodide and other factors. Under conditions of iodine sufficiency, approximately 10%–20% of a radioactive iodine dose is retained by the thyroid 24 h after administration.

Once in the thyroid, iodide migrates to the apical surface of the cell, where a complex series of reactions oxidizes and attaches it to tyrosyl residues of thyroglobulin, a large glycoprotein (molecular size 660 kDa) that is synthesized on the endoplasmic reticulum of the thyrocyte, glycosylated in the Golgi, and processed by molecular chaperones. Key factors in the iodination of thyroglobulin include thyroperoxidase, a 103 kDa protein synthesized by the thyroid, hydrogen peroxide, the production of which requires both calcium and NADPH, and NADPH oxidase. Further action of the thyroperoxidase results in a coupling of two iodinated tyrosyls to form thyroxine. At this point, the thyroglobulin molecule is mature and contains the inactive precursors diiodotyrosine and monoiodotyrosine and the thyroid hormones thyroxine and triiodothyronine. Approximately one-third of thyroglobulin's iodine is in one or two residues of thyroid hormone.

Thyroglobulin is stored in the lumen of the thyroid follicles, where it makes up the bulk of the colloid. For retrieval, it reenters the thyroid cell, where endosomal and lysosomal proteases break it down and release free T4 and T3 into the circulation. The remaining iodine in thyroglobulin, from diiodotyrosine and monoiodotyrosine, is removed by a deiodinase and returned to the thyroid pool for recycling. This is an important mechanism for iodine conservation.

Iodine insufficiency results in substantial adaptation by the thyroid in response to increased secretion of TSH. Higher TSH results in increased plasma iodide clearance through NIS expression. As a result, there is reduced renal iodide excretion. TSH also stimulates the breakdown of thyroglobulin and results into preferential secretion of T3. If iodine deficiency cannot be compensated for by these approaches, many individuals will then develop a goiter.

Amounts of Iodine Required

Experimental and clinical observations have produced recommendations for daily iodine intake. These include iodine turnover and thyroidal radioiodine uptake studies. They are also based on calculations of daily thyroid hormone production and metabolism in balance studies, the amount of thyroxine required for adequate replacement in subjects who are athyreotic, and metabolic disposal rates. The estimated average requirement (EAR) of iodine in men and nonpregnant or lactating women has been set at 95 μg/day. The corresponding recommended daily allowance (RDA) (defined as the EAR plus twice the coefficient of variation in the population, rounded to the nearest 50 μg) is 150 μg/day. **Table 1** shows recommendations by the Food and Nutrition Board of the U.S. National Academy of Sciences for daily iodine intake. The World Health Organization, the Iodine Global Network (IGN) and UNICEF have recommended almost identical values. Setting an upper limit for iodine ingestion has been more difficult. The Food and Nutrition Board recommended 1100 μg/day as a safe upper dose for adults.

O. eds. *Comprehensive Clinical Endocrinology*, 3rd edn., p. 132, Copyright 2002, with permission from Elsevier.

Most people can tolerate much higher doses without apparent ill effects. Large amounts of iodine inhibit the thyroid's ability to make thyroid hormone, producing goiter and hypothyroidism, but many people can tolerate several milligrams per day. People with autoimmune thyroid diseases, such as Graves' disease and Hashimoto's disease, and many of their relatives are more sensitive to iodine excess.

Assessment of Iodine Nutrition

In practice there are four methods for assessing iodine nutrition in populations: urinary iodine concentration the goiter rate, serum TSH and serum Tg levels. To an extent they reflect different periods of iodine deficiency. Urinary iodine is a sensitive indicator of recent iodine intake (days) whereas Tg shows an intermediate response (weeks to months), while changes in the goiter rate reflects much longer term iodine nutrition (months to years).

Urinary Iodine Concentration

Over 90% of ingested iodine eventually appears in the urine. Thus, in the steady state, the urinary iodine excretion is a good marker of iodine nutrition. For epidemiological purposes, the concentration itself, in micrograms per liter, is usually satisfactory

Table 1 Recommendations on dietary intakes of iodine

	RDA (μg/day)	*AI (μg/day)*	*UL (μg/day)*
Adult men	150		1100
Adult women	150		1100
Pregnancy	220		1100
Lactation	250		1100
Children			
1–3 years	90		200
4–8 years	90		300
9–13 years	120		600
14–18 years			900
Infants			
0–6 months		110	
7–12 months		130	

Iodine requirements during pregnancy, lactation and the neonatal period and indicators of optimal iodine nutrition (Delange, 2007).

Note. RDA, Recommended daily allowance; *AI*, adequate intake (estimated when insufficient data for RDA; values set high to avoid possible insufficiency); *UL*, tolerable upper limit (infants not included; insufficient data).

for gauging the nutritional status of a community. Changes in hydration affect the urinary iodine concentration in individuals but these tend to smooth out in the population median. Occasionally, urinary iodine is expressed as micrograms of iodine per gram of creatinine, but other nutritional abnormalities, such as low protein intake, influence creatinine excretion and the concentration alone is satisfactory and simpler.

The urinary iodine concentration is the single most useful test in assessing populations. **Table 2** relates median urinary iodine concentration to different degrees of iodine nutrition; for deficiency it also presents an index of its severity and, therefore, the priority for corrective action. Urinary iodine concentration also detects excess as well as deficiency. However UIC does not represent an individual's iodine status and at least 10 spot samples are needed to reliably identify an individual's iodine status.

Thyroid Size

Iodine deficiency diminishes thyroid hormone production. The pituitary responds with increased TSH secretion, causing the thyroid to increase hormone production, and the gland enlarges as part of this adaptive response. The degree of enlargement, called "goiter," is proportional to the severity of the iodine deficiency and can be assessed by palpation, classifying it as "no enlargement," "palpable goiter," or "visible goiter," the latter two constituting the "total goiter rate." Thyroid enlargement is one of the earliest and most apparent features of iodine deficiency and palpation is a simple technique that requires some skill but no special instruments. Rapid surveys can be carried out in schools. When the iodine deficiency is severe, such surveys provide a quick and satisfactory basis for recognizing the presence of iodine deficiency and the need for its correction. This was the most common form of assessment for much of the 20th century. However, as iodine nutrition has improved, the degree of thyroid enlargement in such surveys has become more subtle and the results have become correspondingly less accurate.

Ultrasonography provides a quantitative and reproducible assessment of thyroid size. The technique is simple. Portable instruments can easily be used in the field and require only several minutes for each measurement. Normative data exist for iodine-sufficient individuals, related both to age and to body surface area, and can be used for comparison.

TSH

Serum TSH rises with iodine deficiency and the threat of hypothyroidism. In populations the median serum TSH increases, but frequently remains within the normal range of the TSH assay, unless the iodine deficiency is quite severe. For this reason, the TSH is not a very sensitive indicator of iodine deficiency in the general population, but its use in newborns is an exception. Most developed countries have neonatal screening for early detection and treatment of congenital hypothyroidism, which occurs in approximately 1 in 3000 births in iodine-sufficient populations. Iodine deficiency causes transient neonatal hypothyroidism and a resulting rise in TSH, so the incidence of transient hypothyroidism, as detected on neonatal screening, increases and correlates with the degree of deficiency in the community. Introducing neonatal screening only to detect iodine deficiency is not cost-effective, but if this program is already in place, valuable information about iodine nutrition can be obtained.

Table 2 The median urinary iodine concentration as an index of community iodine nutrition

Median urinary iodine concentration (μg/L)	*Corresponding approximate iodine intake (μg/day)*	*Iodine nutrition*
<20	<30	Severe deficiency
20–49	30–74	Moderate deficiency
50–99	75–149	Mild deficiency
100–199	150–299	Optimal
200–299	300–449	More than adequate
>299	>449	Possible excess

Serum Thyroglobulin

The normal thyroid secretes small amounts of thyroglobulin into the bloodstream, detectable by serum assays. Increased thyroid activity from any cause (including iodine deficiency) increases serum thyroglobulin and this correlates well with the degree of iodine deficiency. Urinary iodine is a more practical measure for iodine nutrition, but the serum thyroglobulin is worth considering if blood if being obtained for other purposes.

Serum Thyroid Hormone Levels

Iodine deficiency causes the median serum T4 to decrease and the serum T3 to increase. However, these changes may be subtle and the altered values may still be within the normal range. In practice, these have not been cost-effective measures to assess population iodine deficiency.

Radioactive Iodine Uptake

Iodine deficiency increases the thyroid's uptake of iodine and this can be demonstrated by administering a tracer dose of radioactive iodine (^{131}I or ^{123}I). The test is cumbersome, particularly in the field, and is not recommended for assessing the iodine nutrition of a population.

Survey Technique

School-age children are a convenient group to study, because they are easy to assemble and reflect recent rather than remote iodine nutrition in a community. The study sample must be representative, take into account the degree of homogeneity within the population being sampled, and address school attendance, rural location, and socioeconomic status. Failure to consider these factors may lead to an unrepresentative survey that does not sufficiently assess the poorer, remote rural areas that are likely to harbor the worst iodine deficiency. The most important sample is the urinary iodine. The most spartan surveys can simply collect urine samples and transfer them to a central laboratory. More extensive data may include an estimate of thyroid size, particularly if obtainable by ultrasonography. Many countries select a few sentinel sites and monitor them periodically to detect trends. Older female school children are particularly useful to study as they reflect likely iodine status of women who may potentially become pregnant and has revealed important iodine deficiency in the United Kingdom (Vanderpump *et al.*, 2011).

Overview of Iodine Deficiency

Consequences of Iodine Deficiency

Thyroid hormone, and therefore iodine, is essential for health. The thyroid hormones modulate many chemical reactions in the body and are necessary for development of the brain and proper growth. Failure to have adequate iodine causes goiter, hypothyroidism, cretinism, reproductive failure, decreased child survival, iodine-induced hyperthyroidism, and socioeconomic deprivation. Whilst it is well established that correction of severe iodine deficiency has clear benefit, there is also emerging evidence that correction of mild-moderate iodine deficiency has modest benefits (Taylor *et al.*, 2013) although a recent large randomized blinded controlled trial failed to establish clear benefits on obstetric and offspring cognitive outcomes (Gowachirapant *et al.*, 2017).

Goiter

Thyroid enlargement is an early and easily recognized feature of iodine deficiency. It results from increased TSH stimulation. It can be regarded as an adaptation, and if the iodine deficiency is mild, further damage does not necessarily follow. Goiter is not the worst result of iodine deficiency, but it is not inconsequential. The enlarged thyroid may compress adjacent structures, requiring eventual surgery or other treatment. Prolonged thyroid hyperplasia causes thyroid nodules (lumps), which may occasionally be malignant or become autonomous and overproduce thyroid hormone. This is a particular problem in individuals who have been exposed to chronic iodine insufficiency.

Damaged Reproduction

This is the most severe consequence of iodine deficiency. Its spectrum begins with infertility and includes complications of pregnancy and neonatal death. The need for iodine increases in pregnancy to supply the fetus and also because maternal renal losses are greater. The iodine-deficient pregnant woman may experience gestational hypertension, abnormal fetal presentation, stillbirths, and goiter.

Her offspring faces additional severe risks, with death being the worst. Several epidemiological studies have shown dramatic improvement in child survival with correction of iodine deficiency. For example, child mortality decreased by 50% after iodization of irrigation water in China. Other studies found that child survival increased when iodine was administered during pregnancy and during the first 6 months of life. An extensive literature shows similar results in animals, where stillbirths and abnormal progeny are a common consequence of iodine deficiency.

The developing brain needs thyroid hormone for proper maturation. It is particularly crucial in the first trimester. Iodine through thyroid hormone is necessary for the myelination, neuronal differentiation and migration as well as synaptogenesis.

Failure to have adequate thyroid hormone during this critical period, which extends from the first trimester until age 2 can result in permanent mental retardation. In fact, iodine deficiency is the most common cause of preventable mental impairment.

The extent of the brain damage varies over a wide spectrum. Occasionally, it is subtle, requiring specific testing to show impairment. At the other end is cretinism, characterized by severe mental retardation, various other neuromuscular abnormalities, short stature, and deaf–mutism. The incidence of cretinism in severely iodine-deficient areas is uncertain, because many die early or are secluded by defensive family members. Some severely deficient villages have reported incidences of $>10\%$ and in such communities the probability is great that most of the population has some degree of impairment.

Data from two large randomized controlled trials of correcting low thyroid function identified after 12 weeks during pregnancy (Lazarus *et al.*, 2012; Casey *et al.*, 2017) failed to show clear benefits on offspring IQ which further indicate that early or preconception iodine correction is essential.

Iodine-Induced Hyperthyroidism

Iodine-induced hyperthyroidism, (Jod-Basedow phenomenon), can occur in individuals receiving iodine supplementation or from sudden high exposure to iodine for example, radiographic contrast. It is most common in elderly individuals with long standing nodular goiter exposed to chronic iodine deficiency undergoing iodine supplementation. Iodization programs temporarily increase the risk of iodine induced hyperthyroidism; particular in the elderly.

Fortunately, this trend is usually short-lived and the individual can be adequately treated by the usual techniques available for hyperthyroidism from other causes. Although this complication is regrettable, its damage to the community is mild compared to that from continuing iodine deficiency and iodine-induced hyperthyroidism should not be used as an argument for preventing the correction of iodine deficiency. This complication occurs because of preceding iodine deficiency, so it is reasonable to regard it as another of the iodine deficiency disorders.

Interestingly effects may vary between countries when correcting mild-to-moderate iodine deficiency. In Denmark, they observed an increase in rates of hypo and hyperthyroidism. In China increases were observed in the incidence of subclinical hypothyroidism and autoimmune thyroiditis, but not in overt hypo- or hyperthyroidism.

Socioeconomic Damage

Iodine deficiency not only hurts the individual, but also the community in which he or she lives. Their domestic animals risk similar complications from iodine deficiency and they have more stillbirths and produce fewer eggs, less meat, and less wool. Correction of iodine deficiency in a community can result in dramatic improvement in work performance, per capita income, and school performance. For example, one metaanalysis concluded that an average of 13.5 IQ points were lost from moderately severe iodine-deficient communities when compared with iodine-sufficient peers.

Means for Correcting Deficiency

Vehicles available for delivering iodine to deficient communities include salt, vegetable oil, water, tablets, drops, and occasionally others. The following features are important in selecting a vehicle: (Baumann, 1896) provision of physiological amounts of iodine at regular, preferably daily, intervals; (Marine and Kimball, 1917) easy distribution; (Delange, 2007) affordable cost; (Vanderpump *et al.*, 2011) acceptability to target population; and (Taylor *et al.*, 2013) safety. In principle, the problem is straightforward: the population is deficient, so iodine must be provided; the critical issue is to see that the prescribed iodine reaches the target correctly.

Iodized Salt

Iodization of salt has is the most common strategy for supplementing a population's iodine intake and has several advantages over other fortification vehicles. Almost uniquely salt is consumed by almost everyone consistently throughout the year. Iodine fortification of salt is inexpensive, easy to monitor and does not affect the taste. An additional benefit is that salt manufacturing in a country is usually limited to a few countries allowing easy implementation at scale.

Salt should be fortified with an iodine concentration depending on a regions salt intake. A level of between 20–40 mg iodine/kg is usually recommended. Iodine can be added to the salt as either potassium iodide or as potassium iodate. Iodate is more resistant to humidity and salt impurities and is therefore the preferred choice in tropical countries and in those with salt of poorer quality. Effective storage is also essential as substantial losses (up to 90%) can occur if porous packing is used.

Iodization of salt can be utilized throughout the food chain (universal salt iodization). This is the ideal strategy for correcting iodine deficiency however certain challenges need overcoming. Key challenges include overcoming reluctance from industry and lack of ongoing political support.

Success in implementing the use of iodized salt varies tremendously. Countries that import all their salt can achieve effective iodization by enforcing strict quality control at the borders or at designated processing plants. This situation has made it possible for a number of countries, for example, Nigeria and Zimbabwe, to achieve universal use of iodized salt fairly quickly. Other countries may have numerous salt deposits scattered throughout their territories and introducing iodization into the local salt trade is a much more daunting task.

Constant vigilance and political will is necessary even in high income countries retail outlet surveys conducted in the United Kingdom demonstrated that most commercial salt brands lacked adequate iodine (Bath *et al.*, 2013; Lazarus and Smyth, 2008). Another issue is that successful public health campaigns have aimed at preventing cardiovascular disease through reduced salt consumption. To address this WHO forum has indicated that strategies to reduce salt intake and increase iodine fortification are not contradictory (George Institute for Global Health, 2013).

Iodized Oil

Iodinated vegetable oils have been used as X-ray contrast materials for over 70 years. The most common of these, Lipiodol, has 480 mg of iodine per milliliter. Its first use for prophylaxis in iodine deficiency, in the 1950s, proved dramatically effective. For the next 20 years, its administration was principally by intramuscular injection, with a single dose providing adequate coverage for several years. Subsequently, oral use has been more popular. Capsules containing 200 mg iodine, one or two capsules per administration, provide satisfactory coverage for approximately 1 year. Iodized oil has the advantage of bringing iodine supplementation instantly to the subject on administration and avoids the complexities of altering commercial patterns of salt. Its greatest use has been for women and young children with moderate to severe deficiency, to buy time while awaiting the implementation of effectively iodized salt. The disadvantages are that iodized oil requires direct contact with each person, is more expensive than iodized salt, and provides uneven amounts of iodine over the duration of its effects, with a large amount being lost in the first few days. Well over 50 million people have received iodized oil and it remains a useful alternative under specified conditions.

Iodized Water

Water, like salt, is necessary for all humans, regardless of geographic or socioeconomic situation. As in salt, the addition of iodine to water can provide a constant physiologic dose.

Several approaches have been used. One of the simplest is to add a concentrated iodine solution to vessels containing drinking water. A program using this approach has been used in schools and homes in northern Thailand for several decades. Addition of iodine to running drinking water has been used in several countries (e.g., Italy, Malaysia, Thailand) by diverting some water through a bed containing iodine as crystals or on a solid support and then reintroducing it to the main stream. Another approach uses diffusers, commercially available polypropylene baskets containing iodide that is slowly released into a water source, such as wells. Finally, an innovative system in western China periodically drips potassium iodate into irrigation water. Follow-up studies have shown impressive benefits to people and domestic animals, at a cost of approximately US $0.02 per person per year.

Molecular iodine (I_2) has powerful bactericidal properties and is frequently used for water purification. Many communities needing water purification are also iodine deficient, so a system delivering molecular iodine can solve two problems at the same time.

Iodization of Milk

This traditionally has been an adventitious source of iodine which occurs due to the use of iodophors in the dairy industry for cleaning milk cans and teats rather than through deliberate fortification. This is likely to be a declining source of iodine for two reasons; school children in particular are drinking less milk, and the increasingly widespread of organic milk which contains less iodine.

Iodine Tablets and Solutions

Tablets containing potassium iodide are occasionally used for iodine supplementation. They can be taken daily at 100 or 200 μg, weekly at 1 mg iodine, or at less frequent intervals up to several months, in correspondingly larger doses. The aim is to provide approximately 150 μg iodine/day. The smaller doses may be used as supplements in special circumstances, such as pregnancy, and are also frequently incorporated into antenatal vitamin and mineral preparations. However the iodine content of prenatal multivitamins is very variable (Bath *et al.*, 2014) and many do not contain less than 150 mcg.

Some countries, such as the United States, stockpile tablets containing 65 or 130 mg potassium iodide to block thyroidal uptake of radioactive iodine in case of a nuclear event, but these amounts are far too excessive for routine prophylaxis against iodine deficiency.

Even remote health posts in developing countries frequently have iodine solutions for topical antisepsis. These can be appropriately diluted and used for iodine supplementation, again aiming at approximately 150 μg iodine/day. Such programs can be quite effective, but require responsible oversight to see that the correct dose is actually taken.

Choice of Iodine Vehicle

Iodized salt is by far the favored vehicle for most situations. It does not require individual contact, is technologically simple, is low in cost, and provides a constant daily supplement. However, implementation of an effective iodized salt program is not always easy. In some countries, it requires a massive reorganization of the salt trade, so that an iodization step can be reasonably interpolated. For countries that import salt or have only a few large producers, introducing iodization is usually straightforward. Other countries may have many small salt farmers scattered over a large area who harvest the product simply and sell it locally. Some progress has been made by iodizing their product through cooperatives and other methods, but with only partial success.

When iodized salt cannot be effectively introduced within a reasonable time, other methods need to be recruited. Oral iodized oil can be distributed rapidly through community health systems and provides a stopgap while awaiting salt iodization. Iodized water should be considered, depending on water sources and appropriate supervision. Iodized tablets and solutions are effective for individuals, but require careful administration.

More recently bread has been used as iodine fortification, this is an attractive target as bread is widely consumed with similar intakes throughout the year. This approach has been introduced successfully in Australia, Denmark, and New Zealand (Seal *et al.*, 2007; Clifton *et al.*, 2013; Skeaff and Lonsdale-Cooper, 2013). However follow on studies in New Zealand indicate that whilst effective it is still not as good as universal salt iodization (Edmonds *et al.*, 2016).

Many other vehicles have been occasionally used and may have a niche in certain locales. Examples are brick tea, sugar, candy, fried bananas, and fish sauce. For each, one must ask whether its iodization will reach the right part of the population, especially the poor, women, and children, and in the right amounts. A possible danger is that several different forms of iodine supplementation may converge in an individual and produce iodine excess.

Iodine Supplementation Strategies for Pregnancy and Lactation

Women of child-bearing age are a key target for iodine supplementation programs. The correction of iodine deficiency in pregnancy results is in reduced infant mortality and reduced incidence of cretinism and is economically advantageous. Iodine requirement are increased by around 50% in pregnancy due increased renal losses and the need to maintain FT4 levels. As a result iodine deficiency can occur in pregnancy, despite iodine sufficiency in the general population. Universal salt iodization remains the best strategy for ensuring iodine sufficiency in pregnancy. Key guidelines are shown below in **Table 3**. It is also intriguing that both European and American Thyroid associations recommend 150 mcg daily for iodine supplements, even though the United States is more iodine sufficient than most of Europe. Patient education is key and planning prior to pregnancy may be essential as iodine supplementation may need to be undertaken well in advance of pregnancy for maximum benefit. Observational data suggests that consumption of iodized salt may need to be undertaken 2 years prior to pregnancy (Moleti *et al.*, 2008).

Iodine Deficiency Disorders Control Programs

Background

Programs for controlling iodine deficiency are organized by national governments or Health Ministries, as they relate to the public health of a country or region, and are best underpinned by government statute. This provides these programs with a legal

Table 3 Summary of key guidelines for iodine supplementation in pregnancy

Guideline	*Guidance*
American Thyroid Association Stagnaro-Green *et al.* (2011)	To achieve a total of 250 mcg iodine ingestion daily in North America all women who are planning to be pregnant or are pregnant or breastfeeding should supplement their diet with a daily oral supplement containing 150 mcg of iodine
Endocrine Society De Groot *et al.* (2012)	Preconception and during pregnancy and breastfeeding, women should increase their daily iodine intake to 250 mcg. Iodine intake during pregnancy and breastfeeding should not exceed 500 mcg/day
European Thyroid Association Lazarus *et al.* (2014)	Women who are pregnant, lactating, or planning a pregnancy should ingest daily supplements containing 150 mcg iodine
WHO Andersson *et al.* (2007)	Women who are pregnant or breastfeeding take a daily oral iodine supplement so that the total daily intake is 250 mcg

framework, a sense of direction and the organizational capability that is required for such a task. Furthermore, governments have the ability to enforce mandatory legislation, ensuring their sustainability in the long term. However, national or regional governments need to be convinced of the need for controlling iodine deficiency, by individual experts and local or international "expert" organizations (e.g., WHO, IGN—previously ICCIDD—and UNICEF). Although governments take a lead role, the task of organizing successful programs requires a coordinated effort between many governmental and nongovernmental agencies for example, food and salt industries, education and health authorities. The involvement of the private sector has been a feature in many countries with successful programs.

Components of An Iodine Control Program

The WHO in a joint declaration with UNICEF and the ICCIDD (de Benoist and Delange, 2007), recommended the following principles for devising a successful national iodine deficiency control program:

(a) Assessment—Assessment of the magnitude of the problem of iodine deficiency involves collection of regional and national data with adequately powered surveys giving an accurate picture
(b) Communication—The findings of these assessments need to be conveyed to political authorities, health professionals and the public. Political authorities understand the socio–economic consequences of iodine deficiency best, while health professionals appreciate its health consequences and their easy prevention. The public should be educated about the advantages of iodized salt and their use in preventing damage to their children, thereby creating a demand for iodized salt. The importance of establishing channels of communication with the government and public health education programs cannot be overestimated.
(c) Action Plan—Developing an action plan is largely the responsibility of the government in association with national and international stakeholders. A national multidisciplinary committee involving experts from medicine, nutrition, education, salt and food industries, media etc. needs to be established and should be chaired by a senior Ministry of Health appointed officer, who is responsible for devising the action plan. The active involvement of the food and salt manufacturing industries is vital at this stage.
(d) Implementation—The implementation of the action plan for controlling iodine deficiency should be primarily focused on maximizing household access to iodized salt. If quality control measures for salt iodination and other well defined criteria are met, this would help in the elimination of iodine deficiency from regions that implement such programs
(e) Monitoring—this phase of iodine deficiency control is often neglected, sometimes because of economic reasons. Monitoring requires logistical support and laboratory expertise, often not available in low income countries. The lack of monitoring has led to the failure of previously successful programs in the past. An important principle in monitoring is that it needs to be done both at the level of the salt manufacturer and the household and needs to be done reasonably frequently. The availability of iodine can change frequently and unpredictably with alterations in the physical, political, commercial, and cultural landscape. Natural disasters and civil unrest can disrupt salt plants and distribution patterns, a new government may overturn established patterns of health care and regulatory enforcement, changes in the management and structure of salt companies may profoundly affect the market for iodized salt, and understanding and concern about iodine nutrition and the importance of iodized salt may wax and wane with policy makers and consumers. Because at least some of these factors are likely to occur in any country, careful monitoring of iodine nutrition is essential to maintain effective optimal iodine intake in a population.

Sustaining Optimal Iodine Nutrition

The sustainability of a successful salt iodination program depends on many factors. Consistent and strong government support is of prime importance. Governments should be committed to enforcing penalties in the event of failure to follow legislation. The food and salt industries should continue to be totally committed to the task at hand. Regular monitoring of the adequacy of salt iodination and availability of iodized salt to households, and population surveys using modern technology (such as

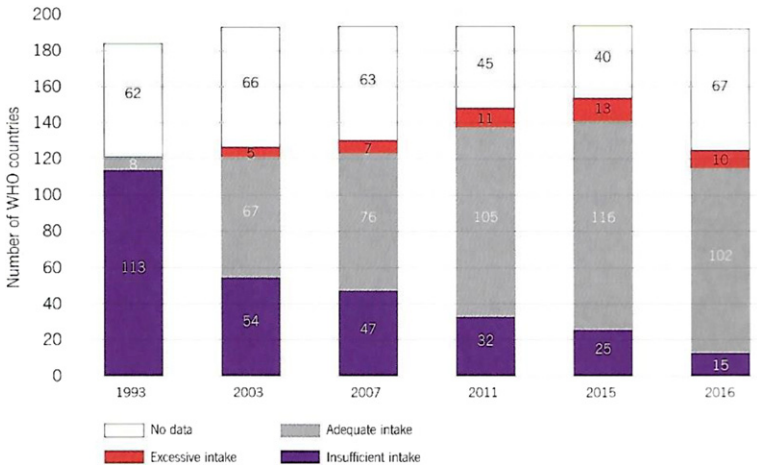

Fig. 2 Number of iodine deficient countries between 1993 and 2016.

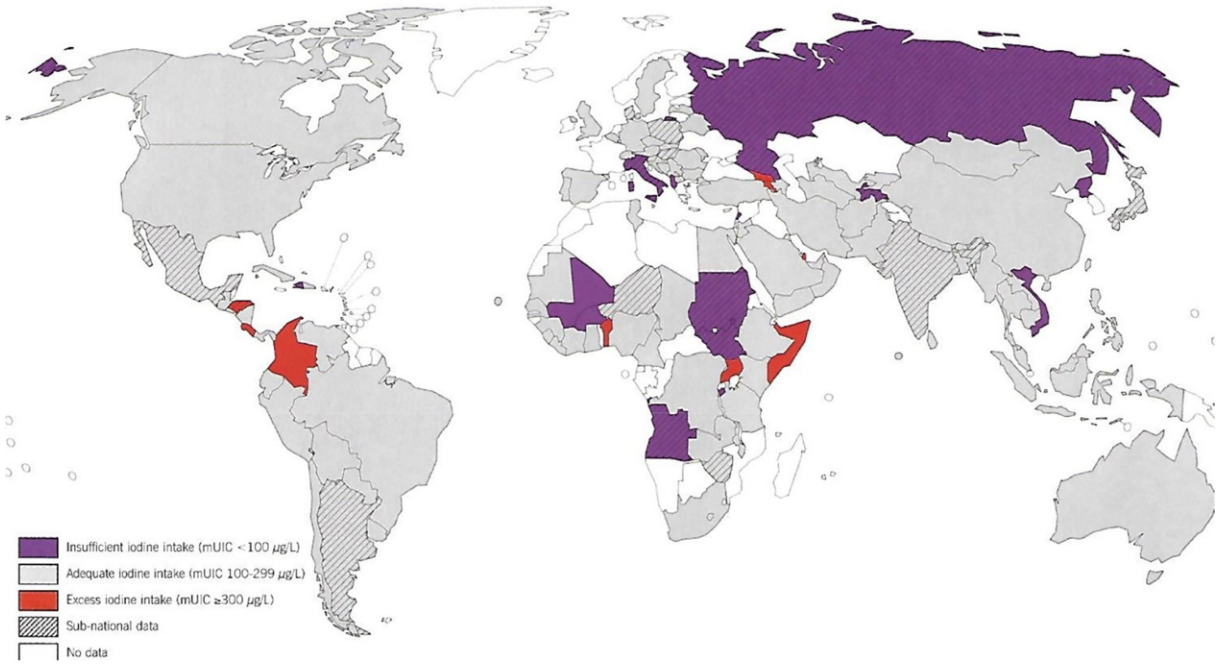

Fig. 3 An overview of current global iodine status.

ultrasound thyroid volume measurement in schoolchildren; urinary iodine measurement etc.) should be undertaken to identify failing areas. Remedial action would then need to be undertaken if necessary. Health education of the consequences of iodine deficiency, and the cheap and effective remedy of iodized salt, should be consistently and continuously conveyed to both health professionals and the general public. The public need also to be convinced that salt iodination and salt reduction are compatible health policies.

Global Status

Until recently, very few countries were iodine sufficient with key exceptions being the United States, Canada, Australia, and Switzerland. Severe iodine deficiency occurs in new mountains (e.g., the Andes, Alps, Himalayas), in zones with frequent flooding (e.g., India, Bangladesh), and in far inland areas (e.g., Central Asia, Central Africa). However, other places are not immune and even inhabitants of small islands (e.g., the Azores, Cape Verde) may have significant deficiency. Thus, inadequate iodine is the baseline condition for most parts of the world and poses a constant threat, unless corrected either by natural means, that is, availability of foods from iodine-sufficient regions, or by intention—that is, prophylactic programs, usually with

iodized salt. The largest concentrations are found in occasional natural deposits, especially in northern Chile, and in association with oil and gas deposits (e.g., in Japan).

More recently iodine deficiency has been declining (Fig. 2) as evidenced by reduced goiter rates and increased urinary iodine concentrations although areas of deficiency still remain (Fig. 3).

Obstacles to the Global Elimination of Iodine Deficiency

The past decade has seen remarkable progress in working toward the elimination of iodine deficiency. At the same time, approximately half the world's population still live in countries that harbor some deficiency. In 1990, the World Summit for Children, sponsored by the United Nations and attracting heads of state from most countries in the world, pledged the virtual elimination of iodine deficiency by 2000. That goal failed. A second conference, in May 2002, repeated the pledge, changing the target date to 2005. Reaching it is theoretically possible, but depends on accelerated action from countries and international agencies.

The correction of iodine deficiency is conceptually straightforward. People lack iodine, so they need to obtain it. A choice of good methods for providing iodine exists. Of these, iodized salt is preferred, but the alternatives are also acceptable. Iodized salt has been in use for 80 years. Some countries have adopted it with dramatic success. Why, then, does iodine deficiency continue in so much of the world?

Countries and their inhabitants are unique. Even though a country may share the same geography and ethnic mix as its neighbors, it may differ in many ways that influence the success of an iodization program. Some of the more common reasons that programs are not successful are as follows.

Difficulties in Implementing Iodized Salt

As already pointed out, some countries have numerous remote salt deposits that are easily mined and sold locally. Other countries have only a few large salt producers, but those do not comply with the law. Still others import their salt, but its iodization is not enforced, and much also enters as contraband.

The compliance and cooperation of the salt industry are crucial to successful iodization. Producers need education on its importance, assistance with technical issues, and constructive actions to make it economically attractive. They must be assured of a market for iodized salt, especially if it costs much more than the noniodized products. The consumer must learn to demand iodized salt because of its health benefits, even if the price is greater.

Lack of Awareness

Consumers, salt producers, and government officials must appreciate the damage from iodine deficiency and the importance of its correction. All levels need vigorous communication efforts.

Insufficient Data

Information about iodine nutrition is fragmentary, not only in the developing world but also in many socioeconomically advanced countries. Baseline surveys are necessary in order to plan action. Countries such as Australia and New Zealand have recognized their current iodine deficiency only recently. Other countries, such as Canada, though unlikely to be deficient, do not have recent national data. If a government is unwilling or unable to obtain such information, then other groups, such as endocrinologists, universities, or independent national coalitions, should.

Inadequate Government Support

The government is ultimately responsible for the public health of its citizens, including their iodine nutrition. Policy makers must be convinced of the importance of iodine nutrition and of the means for its correction and this effort may require extensive lobbying. The government should have specific laws and enabling regulations to support universal salt iodization and should designate responsibility to a specific unit with sufficient budget to carry out the program. Often government support is strong during periods of great publicity and activity by the unit, but this enthusiasm may taper with new personnel or budget constraints.

Poor Monitoring

Because iodine deficiency is a chronic condition, it needs regular long-term monitoring. The government must provide for follow-up surveys and respond promptly to any reports that the control program is not working. National coalitions can help to keep iodine nutrition in constant view and to prod the government when lapses in control occur.

Summary

People need iodine because it is an essential component of the thyroid hormones, which influence a variety of vital biochemical reactions in the body. Insufficient iodine, and therefore insufficient thyroid hormone production, causes pregnancy complications, neonatal and infant death, mental retardation, goiter, hypothyroidism, deaf–mutism, and low economic productivity. The recommended daily intake for an adult is 150 μg, with larger amounts recommended during pregnancy and lactation. The best measure of iodine nutrition is the urinary concentration of iodine.

Salt is the most effective vehicle for delivering iodine to a deficient population and can be iodized by simple inexpensive techniques. Other delivery systems are iodized vegetable oil, iodized water, and iodine tablets. Success in achieving iodine sufficiency depends on an effective program, usually the responsibility of the Ministry of Health and supported by many other sectors, both public and private, especially health providers and the salt industry. Key components in the program are communication, education, and monitoring of both iodine nutrition and salt iodine content.

Approximately half of the world's population lives in countries with iodine deficiency and risks its consequences. Most of these individuals are in the developing world, but many in Western Europe also continue to be deficient. Approximately 70% of households in the developing world use adequately iodized salt. The United Nations and heads of states have pledged virtual elimination of iodine deficiency by the year 2005, but achieving this goal requires an intensified effort.

Ralf Paschke, University of Calgary, Calgary, AB, Canada

Glossary

Nontoxic goiter A diffuse or nodular enlargement of the thyroid gland that is not associated with hyperfunctioning of the thyroid and that does not result from an autoimmune or inflammatory process. Also known as "euthyroid goiter."

Radioiodine treatment Administration of radioactive iodine to humans with the aim of inhibiting the function of thyroid follicular cells or destroying them.

Recombinant TSH Recombinant thyroid stimulating hormone used to stimulate thyroid follicular cells prior to treatment with radioactive iodine.

Thyroidectomy Surgical removal of the thyroid gland.

Thyroxine treatment Synthetic thyroid hormone given to patients with thyroid hormone deficiency to normalize their thyroid function. Thyroid hormone replacement is typically administered in the form of an oral tablet containing thyroxine (T4).

Definition

Nontoxic goiter is defined as a diffuse or nodular enlargement of the thyroid gland that is not associated with hyperthyroidism and that does not result from an autoimmune or inflammatory process. Endemic goiters are those present in greater than 10% of the population due to chronic iodine deficiency. By contrast, sporadic goiters develop in areas of normal iodine intake, and typically occur in younger individuals. This article will focus on the evaluation and management of patients with sporadic, nontoxic goiters.

Introduction

Iodine deficiency is the most important risk factor for goitrogenesis, and even modest levels of iodine deficiency may contribute to goiter formation. Additional risk factors for goitrogenesis include female gender, increasing age, history of smoking, and various dietary and environmental factors (Hegedus *et al.*, 2016). Moreover, twin and family studies suggest a hereditary contribution to the development of nontoxic goiter. Although the responsible genetic mechanisms are incompletely understood, linkage studies have identified several candidate genes (Krohn *et al.*, 2005; Paschke, 2011). *MNG1* is a candidate locus on chromosome 14q31 that was first identified in a large Canadian family and later confirmed in a kindred from Germany (Paschke, 2011). An extended genome wide linkage analysis identified four novel candidate loci on chromosomes 2q, 3p, 7q, and 8p. The 3p locus was of particular relevance as it was identified in 20% of families with nontoxic goiter and appears to have an autosomal dominant pattern of inheritance, thus representing a plausible genetic mechanism for goitrogenesis (Bayer *et al.*, 2004). Weaker genetic defects, or combinations of genetic variations in different genomic regions may also contribute to goiter predisposition, which may not be detected by linkage studies. Thus, development of nontoxic goiter is likely driven by the interaction of environmental risk factors and individual genetic susceptibility (Paschke, 2011).

Nontoxic goiter is often a precursor of toxic multinodular goiter. The natural history of nontoxic goiter includes an average increase in thyroid volume by 4.5% per year accompanied by increasing nodularity and autonomy of the thyroid gland (Berghout *et al.*, 1990). If goiter volume increases significantly, nontoxic goiters may result in compression of surrounding structures leading to dyspnea, dysphagia, or globus sensation, necessitating treatment. However, most nontoxic goiters exhibit slow growth, and can be managed conservatively (Hegedus *et al.*, 2003).

Diagnosis

The clinical presentation of nontoxic goiter can vary depending on the size, nodularity, location, and functional status of the thyroid gland. Patients may be asymptomatic and present only due to the incidental finding of gland enlargement or nodularity on

☆*Change History*: March 2018. Sana Ghaznavi, Kirstie Lithgow, Veena Agrawal, and Ralf Paschke introduced Abstract, updated/expanded the history and physical section, and investigations and management sections, introduced a References section, and updated the Further Reading list. Fig. 1 was deleted.

This article is an update of A.R.M.M. Hermus and D.A.K.C. Huysmans, Nontoxic Goiter, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 367–370.

 doi:10.1016/B978-0-12-801238-3.96012-4

diagnostic imaging done for other reasons. Alternatively, they may present due to detection of an enlarging neck mass, or symptoms of compression of surrounding structures, as discussed below.

The general approach to a patient with goiter includes a detailed history and physical examination, serum thyroid-stimulating hormone (TSH) evaluation, and ultrasound (US) examination of the thyroid. Additional evaluation may include thyroid scintigraphy, primarily in the setting of low serum TSH, fine needle aspiration biopsy of suspicious nodules, or cross-sectional imaging of suspected substernal goiter.

History and Physical Examination

The history for a patient with nontoxic goiter should focus on assessment of thyroid gland enlargement, compressive symptoms, thyroid dysfunction, and risk factors for thyroid cancer. Clinicians should inquire about the discovery of the goiter, rate of change or growth, and associated pain or tenderness. Enlarged goiters may cause compression of surrounding structures such as the trachea, esophagus, recurrent laryngeal nerve, or thoracic cavity. Mild tracheal compression does not cause any symptoms; however, as the trachea becomes narrower, patients may complain of exertional or positional dyspnea, stridor, choking sensation, or cough. Dyspnea is typically exacerbated in the recumbent position. Occasionally, patients complain of acute worsening of symptoms of tracheal compression, which can be seen with bleeding into a thyroid nodule or cyst. Compression of the esophagus is rare due to its posterior location, but when present, leads to dysphagia. Compression of the recurrent laryngeal nerve may result in hoarseness of voice. A goiter that extends inferiorly into the mediastinum (i.e., substernal goiter) may manifest symptoms of thoracic outlet obstruction, such as facial plethora or dilated neck veins.

The history should include assessment of symptoms associated with hyperthyroidism, which are not present in patients with nontoxic goiters, and would therefore point to an alternative diagnosis. These symptoms are discussed elsewhere. Patients should also be assessed for risk factors for thyroid cancer, such as history of head and neck irradiation, and previous personal or family history of thyroid cancer.

General inspection of the patient includes listening for dyspnea, stridor, or hoarseness of voice. Palpation of the goiter should focus on assessment of its size, nodularity, position, texture, mobility, tenderness, and the presence or absence of cervical lymphadenopathy. If it is not possible to palpate the lower edge of the goiter, the goiter may extend into the thoracic cavity. Suspected substernal goiters should be evaluated by percussion over the sternum listening for dullness, and special maneuvers such as Pemberton's sign. This maneuver is conducted by having the patient elevate both arms above their head for one minute. A positive sign is the finding of facial plethora, facial swelling, or dilatation of neck veins, and is indicative of thoracic outlet obstruction. Rare complications of enlarged goiter include paralysis of the phrenic nerve, potentially resulting in elevated diaphragm or dyspnea, or paralysis of sympathetic nerve chains, resulting in Horner syndrome. Horner syndrome is characterized by unilateral miosis, ptosis, and anhidrosis.

Investigations

Assessment of Thyroid Function

The serum TSH level should be measured for all patients with diffuse or nodular goiter. If the TSH concentration is below the lower limit of normal, it is necessary to measure the level of free thyroxine (T4) to distinguish between subclinical or overt hyperthyroidism. As the name implies, "nontoxic" goiters are typically not associated with suppressed serum TSH levels. However, the progression of nontoxic goiter to toxic multinodular goiter represents a continuum of disease, and therefore, patients with nontoxic goiter may present with euthyroidism or subclinical hyperthyroidism. In patients with a subnormal TSH, thyroid scintigraphy (in the form of ^{99m}Tc pertechnetate or ^{123}I) should be performed to determine the functional status of the nodules. The scintigraphy images should be compared to thyroid ultrasound images to map the location of hyper- or hypo-functioning nodules. Thyroid scintigraphy can also help determine whether a substernal mass represents functioning thyroid tissue. Furthermore, if radioactive iodine (RAI) treatment is being considered to reduce thyroid volume (see below), measurement of the radioiodine uptake (%) helps to guide radioactive iodine dosing and the decision of whether or not to use recombinant TSH. If the serum TSH is above the upper limit of normal and the concentration of free T4 is low, chronic autoimmune thyroiditis should be considered as a possible cause of the thyroid enlargement. This diagnosis can be confirmed by measurement of serum thyroid peroxidase (TPO) antibodies.

Assessment of Thyroid Nodules

Thyroid ultrasonography is recommended for all patients with suspected thyroid nodules (Haugen *et al.*, 2016; Gharib *et al.*, 2016). Thyroid ultrasonography gives detailed information about thyroid gland size, presence of thyroid nodules, and characterization of malignancy risk within each nodule. Nodules should be evaluated in the manner outlined by clinical practice guidelines (Haugen *et al.*, 2016; Gharib *et al.*, 2016). Broadly speaking, this includes selective use of fine needle aspiration biopsy based on a nodule's sonographic features of malignancy, size, and rate of growth over time.

Assessment of Compression of Surrounding Structures

If local obstruction is suspected, contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) of the neck and chest should be performed to assess the exact size and anatomic location of the goiter and its relationship to surrounding structures in the neck and mediastinum. In addition, the smallest cross sectional area of the trachea should be measured (Bahn and Castro, 2011). Cross sectional imaging is also helpful to assess for substernal extension of the goiter and to rule out thoracic outlet obstruction. It should be noted that iodine-containing contrast agents may lead to hyperthyroidism in patients with autonomously functioning thyroid tissue, and therefore should be used with caution in patients at high risk of cardiac decompensation from thyrotoxicosis. Clinicians may consider pretreatment with antithyroidal medications (including perchlorate) or beta-blockers as needed.

If tracheal compression is suspected based on clinical features or imaging, pulmonary function tests should be obtained to assess the degree of upper airway obstruction. It should be noted that tracheal compression affects inspiratory flow more than expiratory flow. Measurement of forced expiratory volume in one second/peak expiratory flow ratio over 8 mL/L/min has a high sensitivity and specificity for upper airway obstruction, while measurement of forced expiratory flow at 50% of vital capacity ($FEF_{50\%}$)/forced inspiratory flow at 50% of vital capacity ($FIF_{50\%}$) has a high sensitivity but poorer specificity for upper airway obstruction (Sorenson *et al.*, 2014). The smallest cross sectional area of the trachea ("SCAT") has been shown to significantly positively correlate with the $FIF_{50\%}$ (Bonnema *et al.*, 2008).

Treatment of Nontoxic Goiter

The presence of a diffuse or multinodular goiter is not an indication for treatment on its own. The most important indications for treatment are compression of surrounding structures or presence of a suspicious nodule. There is no thyroid volume threshold beyond which treatment is deemed necessary, as there is poor correlation between goiter volume and presence of compressive symptoms. Treatment should also be considered in the case of progressive growth where development of compression is likely to occur, if even mild compression would be poorly tolerated, or if there is significant intrathoracic growth. Occasionally, treatment is considered for cosmetic reasons and patient preference.

Choice of Treatment

There are three traditional modalities for treatment of nontoxic goiter: thyroidectomy, radioiodine, and levothyroxine suppressive therapy. Clinicians should assess the most appropriate modality for their patients based on treatment risks and benefits, availability, and patient factors such age, comorbidity, and personal preference. Thyroidectomy is the standard treatment, especially for young and otherwise healthy patients, and when prompt decompression of vital structures is required. Radioiodine treatment with or without recombinant TSH is an alternative to surgery for older patients and for those who are poor surgical candidates, as well as in the case of recurrent goiters. Levothyroxine suppressive therapy is rarely efficacious for treatment of nontoxic goiter.

Thyroidectomy

Surgery is the first-line therapy for the treatment of nontoxic goiter, as it results in fast decompression of vital structures with alleviation of obstructive symptoms, and provides tissue material for pathological examination. The most common procedure is a subtotal or total thyroidectomy performed with an open approach (Dralle *et al.*, 2014). When performed by experienced surgeons, thyroidectomy is a safe and effective procedure. Potential complications of thyroid surgery include voice changes or vocal cord paralysis resulting from damage to the recurrent laryngeal nerve, or surgical hypoparathyroidism. Rarely, bilateral recurrent laryngeal nerve damage may result in tracheomalacia or tracheal obstruction requiring intubation. Surgical morbidity is greater in patients with very large goiters or those undergoing repeat neck surgery. The incidence of postsurgical hypothyroidism occurs in 100% of patients with total thyroidectomy necessitating lifelong levothyroxine supplementation.

Radioactive Iodine

RAI treatment has emerged as an attractive alternative to thyroidectomy in patients who are either poor surgical candidates or those who have declined surgery. RAI treatment of nontoxic goiter typically involves a single orally administered dose of 3–5 MBq/g thyroid mass of radioactive iodine (^{131}I) (Bonnema and Hegedus, 2012). Goiter volume reduction varies from 30% to 50% by five years after administration of therapy (Bonnema and Hegedus, 2012). In addition to the reduction in thyroid volume, the treatment also reduces compressive symptoms for a majority of patients. Recurrent goiter growth after 3–5 years occurs in approximately 10% of patients. A second RAI treatment can be considered in these cases.

The degree of thyroid volume reduction depends on three factors: the baseline thyroid volume, the amount of radioiodine uptake of the gland (RAIU), and the administered dose of ^{131}I. Most patients with nontoxic goiter have normal or low RAIU in the gland. Therefore, in larger goiters or those with low RAIU, higher doses of ^{131}I are needed to achieve adequate goiter volume

reduction. Most studies looking at RAI therapy for nontoxic goiter thus used a dosing algorithm that takes into account both thyroid weight and 24-h RAIU; an absorbed dose of 100 Gy is usually targeted, although the superiority of calculated versus fixed dosing is controversial (Gharib *et al.*, 2016). Another strategy to overcome the relatively low RAIU in nontoxic goiters is the use of recombinant TSH (rhTSH) prior to ^{131}I administration. Low dose rhTSH given 24 h prior to RAI therapy has been shown to increase the 24 and 96 h RAIU, thus allowing lower doses of applied radiation to result in equivalent thyroid volume reduction (Fast *et al.*, 2010a). Moreover, the use of rhTSH with RAI leads to an additional 15%–20% thyroid volume reduction, when compared to the same dose of applied radiation alone (Lee *et al.*, 2015). Several studies have tried to delineate the optimal dose and timing of rhTSH. Theoretically, the optimal dose of rhTSH would be the lowest dose that achieves a satisfactory increase in RAIU, timed such that the RAIU peaks at the same time as RAI administration. Such a dose would maximize the intended effects of RAI while minimizing the risk of thyroid swelling and thyrotoxicosis. Although there is no universally accepted dose, the optimal dose is likely between 0.03 and 0.1 mg, and the optimal timing is likely 24 h prior to RAI administration (Fast *et al.*, 2010b; Nielsen *et al.*, 2005).

Early side effects of RAI therapy include transient radiation thyroiditis (tenderness and swelling of the thyroid gland) and hyperthyroidism, both of which are usually self-limited. Although rhTSH may slightly increase the degree of radiation thyroiditis and hyperthyroidism, this is a dose-dependent effect, and can be minimized by using low dose rhTSH (0.03–0.1 mg) (Bonnema and Hegedus, 2012; Fast *et al.*, 2010b). Moreover, several studies have shown the safety of RAI with or without rhTSH, even in the setting of very large goiters (volume > 150 mL) (Lee *et al.*, 2015; Albino *et al.*, 2010; Bonnema *et al.*, 1999). Notably, there have been no reported cases of respiratory compromise induced by this therapy. Nevertheless, transient swelling caused by RAI therapy may in theory temporarily worsen tracheal compression, and thus caution should be used when treating high risk patients. High-risk patients include those with very large goiter, very small cross-sectional area of the trachea, or significant upper airway obstruction detected by flow-volume loops. Pretreatment of these patients with glucocorticoids can be considered, although the evidence for this practice is limited. A rare consequence of RAI therapy is the onset of Graves' disease induced by elevation of TSH receptor antibodies (Nygaard *et al.*, 1997). A late side effect of RAI therapy is the development of hypothyroidism necessitating levothyroxine supplementation, which occurs in 20%–50% of cases after 5 years (Le Moli *et al.*, 1999). Treatment with high doses of radioactive iodine is potentially carcinogenic, however, such high doses are rarely required in this setting.

All patients receiving RAI for the treatment of nontoxic goiter should be followed for alleviation of obstructive symptoms, thyroid function tests, and thyroid volume as assessed by neck ultrasonography. Although RAI is an appealing treatment for patients with nontoxic goiter unable or unwilling to undergo surgery, its universal adoption will require more data showing its safety and efficacy in various populations, where the ambient iodine levels may differ from those of previously studied European cohorts.

Levothyroxine Suppressive Therapy

TSH is the most important growth stimulator of normal thyroid tissue. Treatment of patients with levothyroxine is based on the hypothesis that the growth of a goiter is also TSH-dependent and that suppression of TSH secretion will result in the reduction of thyroid volume or at least prevent further growth of the goiter. However, this assumption has not been borne out in the literature. In a randomized clinical trial by Wesche *et al.* (2001) comparing levothyroxine to radioactive iodine therapy for sporadic nontoxic goiter, levothyroxine failed to shrink goiter volume after two years of therapy (median goiter size reduction − 1%). Other studies have shown a very modest reduction in thyroid volume in small goiters, but negligible thyroid volume reduction in large goiters (Shimaoka and Sokal, 1974). In addition, the subclinical hyperthyroidism induced by levothyroxine suppressive therapy has been associated with an increased risk of atrial fibrillation, increase in bone turnover markers, and significant decline of bone mineral density particularly in postmenopausal women (Wesche *et al.*, 2001; Knudsen *et al.*, 1998). Most patients are not suitable candidates for levothyroxine suppressive therapy for the treatment of nontoxic goiter (Fast *et al.*, 2008). Given the lack of efficacy and potential detrimental impact on cardiovascular and bone health, this past therapy should be abandoned.

Thyroid Nodule☆

Laszlo Hegedüs, Odense University Hospital, Odense, Denmark

Introduction

A thyroid nodule is characterized by excessive growth and structural and/or functional transformation of an area within the normal thyroid tissue (**Fig. 1**). In the absence of thyroid dysfunction, autoimmune thyroid disease, thyroiditis, and thyroid malignancy, it can be described as a simple nodule. The main concern of patients and physicians is to diagnose the few cancers (approximately 5%) as rapidly and cost-effectively as possible and reduce superfluous thyroid surgery (Hegedüs, 2004; Burman and Wartofsky, 2015).

Although important, the clinical evaluation of nodule size, morphology, and function is highly inaccurate. Thus, up to 50% of subjects with a solitary palpable thyroid nodule are found to have multiple nodules when investigated by ultrasound. Additionally, up to 50% of subjects with a normal gland by palpation have thyroid nodules when investigated by ultrasound. This is one of the reasons for the increasing use of imaging in such patients (Hegedüs, 2004).

Almost any thyroid disease can appear as a thyroid nodule. The spectrum ranges from the incidental finding in a normal gland to diffuse, uni- or multinodular and cystic enlargement of the thyroid gland. The manifestations are related to those of growth and functional autonomy, leading to cosmetic and pressure symptoms, and that of hypersecretion of thyroid hormones. A number of diagnostic and therapeutic aspects are unresolved and recent European and North American investigations and guidelines have disclosed some differences in the management (Paschke *et al.*, 2011).

Etiology

It is well accepted that nodular thyroid diseases belong to the group of diseases referred to as complex diseases. Such diseases are common, vary in severity, and are multifactorial. Thus, the clinical entity is the net effect of all the contributing genetic and environmental factors (Hegedüs *et al.*, 2003).

Although iodine deficiency is the major environmental factor, other factors are clearly important since nodular thyroid disease also exists when there is abundant iodine intake (Carlé *et al.*, 2014). Constitutional factors such as gender are implicated, as illustrated by a 5–10:1 ratio of affected females to males. Other risk factors include cigarette smoking, naturally occurring goitrogens, emotional stress, irradiation, and infection.

Evidence of a genetic effect is provided by twin studies demonstrating that concordance rates for nodular thyroid disease are much higher in monozygotic twins than in dizygotic twins. The heritability has been estimated to be 82% in a non'iodine deficient goiter area. The remaining 18% is the result of individual specific environmental factors not shared by the twins (e.g., cigarette smoking). Studies assessing the role of specific candidate genes in the etiology of nodular thyroid disease have not provided a clear picture, mostly because too small and too few families have been studied. Although single genes may play a role in certain families, it is thought that genetic heterogeneity (i.e., no single gene is either necessary or sufficient for disease development) is highly likely (Hegedüs *et al.*, 2003).

The following sequence of events appears to lead to the development of nodular thyroid disease: First, iodine deficiency or other goitrogenic factors induce thyroid hyperplasia. Second, due to increased proliferation during this stage, mutagenesis is increased. In the case of hot or toxic nodules, these mutations confer constitutive activation of the cyclic AMP cascade (e.g., thyroid-stimulating hormone receptor and $G_s\alpha$ protein mutations). This eventually leads to stimulation of iodine uptake and metabolism, thyroid hormone synthesis and release, and hyperthyroidism. In the case of cold thyroid nodules, a similar mechanism, but with mutations in genes that favor dedifferentiation (e.g., *ras* oncogene), is suggested. These latter mutations initiate growth but not function of the affected thyroid cells (Eszlinger *et al.*, 2017).

Epidemiology

Unfortunately, our knowledge is somewhat hampered by a lack of population-based longitudinal studies using sensitive diagnostic imaging (e.g., ultrasound) allowing distinction between uninodular and multinodular disease and morphologic as well as functional characterization. Despite these shortcomings, there is a clear pattern of increased thyroid nodularity with decreasing

☆*Change History*: December 2017. Laszlo Hegedüs updated the article throughout.

This chapter is an update of Laszlo Hegedüs, Thyroid Nodule, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 521–529.

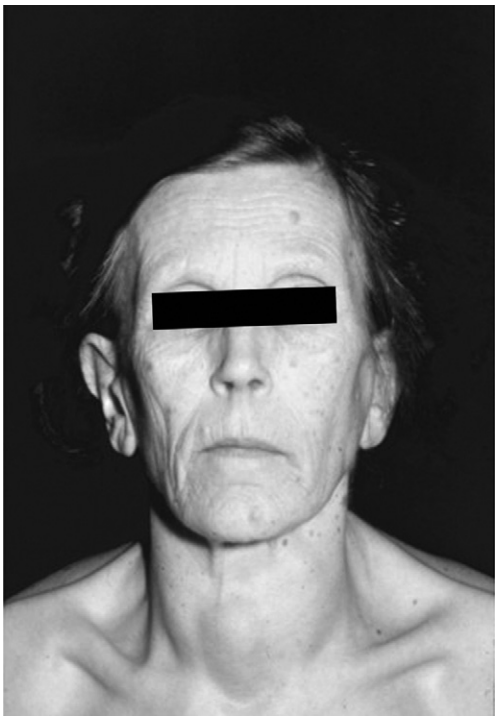

Fig. 1 Patient with a clinically solitary thyroid nodule located in the midline of the anterior neck.

iodine intake. The fact that nodules exist in the face of iodine sufficiency and even iodine excess emphasizes the importance of other environmental etiologic factors acting in concert with genetic factors (Carlé *et al.*, 2014).

In the Whickham survey (United Kingdom), a solitary thyroid nodule was present in 5.3% of women and 0.8% of men (6.6:1 ratio). Size and function of the nodules were not indicated. In the Framingham, Massachusetts, study, a solitary thyroid nodule was present in 6.4% of women and 1.6% of men. Both investigations used clinical evaluation (palpation) and were performed in an iodine-sufficient area. If ultrasound is used, the prevalence of thyroid nodules >10 mm is usually 20%–30%, increasing with age and in areas with insufficient iodine intake (Carlé *et al.*, 2014). In autopsy studies, 50% or more have either single or multiple thyroid nodules. If investigated using isotope scintigraphy, approximately 10%–15% of all nodules are autonomously functioning (taking up the isotope, hot or toxic), whereas 85%–90% are nonfunctioning (cold, no isotope uptake). The incidence of clinical disease is estimated to be 0.1% by palpation, corresponding to a lifetime risk of 5%–10%.

Natural History

The natural history with respect to growth and function varies and is difficult to predict in a given patient since no specific growth parameters exist. Therefore, it is difficult to decide whether a patient can be monitored without treatment or should be offered treatment before the nodule grows any more.

In the Framingham survey, new nodules appeared with an incidence of 1 per 1000 individuals per year, resulting in an estimated lifetime risk for developing a nodule of 5%–10%. After exclusion of the minority of patients who have rapid growth and symptoms and clinical suspicion of malignancy, and who are therefore offered treatment, nodules on average do not change significantly over time. Nodules that increase in size are predominantly solid and carry a higher risk of harboring thyroid malignancy than those predominantly cystic, which are more prone to decrease in size or even disappear. In many patients, ultrasound will identify additional nodules not evident at clinical investigation. Given time, many patients will be classified as having multinodular goiter.

In the subgroup of hot nodules, the rate of evolution into a toxic nodule is approximately 4% annually. The risk is closely related to nodule size. If the nodule is >3 cm, the risk is 20% within 6 years, whereas the risk is only 2%–5% if nodule size is <2.5 cm.

Diagnosis

Clinical Evaluation

There is no clear-cut relation between thyroid nodule size, morphology, and function, on the one hand, and the complaints, quality of life and treatment effects in the individual patient, on the other hand (Sørensen *et al.*, 2014; Cramon *et al.*, 2015). The

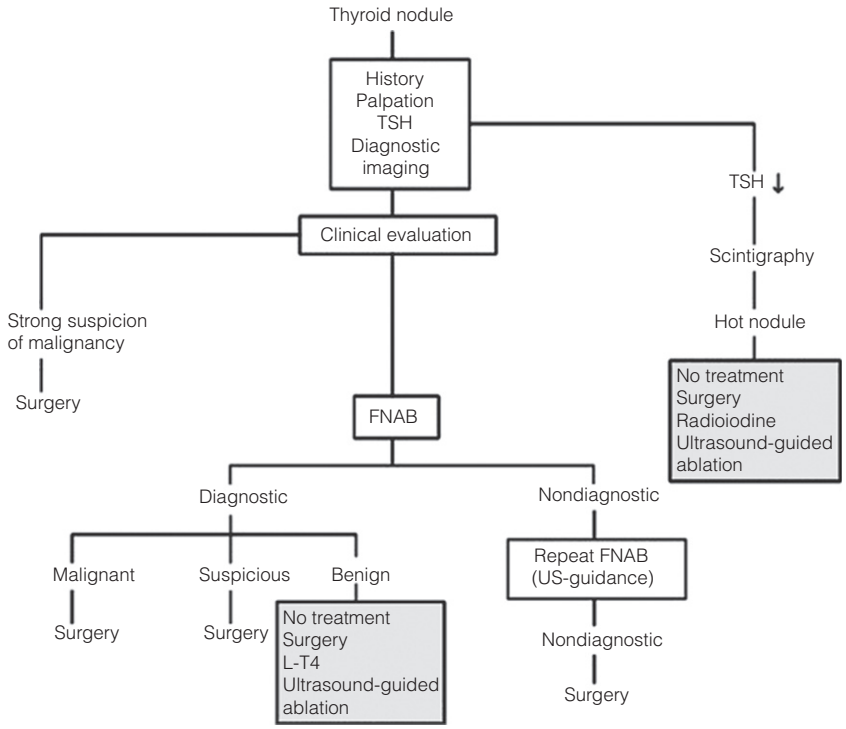

Fig. 2 Management algorithm outlining a cost-effective evaluation and treatment of the solitary thyroid nodule. In case of strong suspicion of malignancy, surgery is advised irrespective of fine needle aspiration biopsy (FNAB) results. In case of a nondiagnostic result, repeat FNAB yields a satisfactory aspirate in 50% of patients. FNAB guided by ultrasonography (US-guidance) allows sampling from the periphery of a solid nodule or solid part of a mixed solid–cystic nodule, increasing the sufficiency rate. The options in case of a diagnostic FNAB include those for both solid and cystic nodules. In case of recurrent cysts, the possibilities are reaspiration, surgery, or ethanol injection. The *shaded boxes* indicate treatment options. Ultrasound-guided ablation covers: Ethanol sclerotherapy as well as thermal ablation by laser, radiofrequency, high frequency ultrasound, or microwaves (Gharib et al., 2013).

majority of patients have few or no clinical symptoms. Therefore, given normal thyroid function and exclusion of malignancy, many need no treatment. A rough management algorithm for the majority of patients with a thyroid nodule is shown in **Fig. 2**.

Manifestations

When present, the most important symptoms and signs are caused by compression of structures in the neck or, rarely, in the upper thoracic cavity. In addition to various degrees of neck disfigurement, which by itself can merit treatment, the symptoms are related to compression of the trachea or esophagus. The symptoms of tracheal compression are dyspnea, stridor, cough, and choking sensation, but respiratory distress is rare unless the nodule extends into the thoracic cavity (Hegedüs *et al.*, 2003; Sørensen *et al.*, 2014). An acute exacerbation may be caused by hemorrhage into a nodule or by upper respiratory infections causing endotracheal swelling. Complaints due to esophageal compression are less common, as is vocal cord paralysis caused by stretching and/or compression of the recurrent laryngeal nerves.

A high proportion of functioning nodules cause slight or overt hyperthyroidism due to excessive secretion of thyroid hormones. This condition, with or without pressure symptoms or cosmetic complaints, may by itself merit treatment.

Clinical Examination

The evaluation of a patient with a thyroid nodule comprises a careful history and physical examination focusing on inspection of the neck, including regional lymph nodes, the upper thorax, and palpation of the thyroid. This clinical evaluation should preferably be done with the patient swallowing gulps of water and the head tilted slightly backward. Observer variation is very high, and the specificity and sensitivity of the diagnosis of a thyroid nodule are low. Detection of nodules depends on their size, morphology, and location within the thyroid parenchyma; the anatomy of the patients neck; and, most important, the training of the physician. The patient is usually unaware of the presence of a nodule smaller than 1.5–2 cm in diameter, and a nodule of 1.0 cm or less usually escapes detection by the physician (Hegedüs, 2004; Burman and Wartofsky, 2015).

Table 1 The most important clinical factors increasing the likelihood of thyroid malignancy in a patient with normal thyroid function and a solitary thyroid nodule

Family history of thyroid malignancy
Rapid nodule growth (especially during levothyroxine therapy)
Very firm or hard nodule
Fixation to adjacent structures
Vocal cord paralysis (evidenced by laryngoscopy)
Regional lymphadenopathy (enlarged regional lymphnodules)
Detection of distant metastases
Age <20 or >60 years
Male sex
History of head and neck irradiation
Diameter of nodule >4 cm and partially cystic
Compression symptoms (dysphagia, hoarseness, dyspnea)

Assessment of Risk of Malignancy

A family history of benign goiter suggests a benign disorder but is not proof thereof. Medullary thyroid carcinoma or even papillary or follicular thyroid carcinoma in the family should raise suspicion. The risk of harboring cancer is highest in the young and the old, and the risk is higher in men than in women. Head or neck irradiation during childhood for a number of benign conditions leads to clinically evident thyroid abnormality in 10%–40% of these individuals 5–40 years later. Thyroid carcinomas, mainly papillary carcinomas, are seen in 30% of those with thyroid abnormality. The importance of fallout radiation is tragically evidenced by the epidemic of childhood papillary thyroid cancer seen in Belarus and Ukraine after the Chernobyl nuclear accident. Rapid nodule growth (weeks to months) and symptoms of local invasion, such as pain, dysphagia, hoarseness, or dyspnea, suggest a carcinoma; however, only a minority of patients have these symptoms. Growth during thyroid hormone therapy is particularly worrisome. Sudden growth is most likely a thyroid cyst or hemorrhage into a previously undetected nodule. A hard and immobile nodule is suggestive of thyroid carcinoma, as is same-sided lymphadenopathy. Virtually all patients with thyroid carcinoma have normal thyroid function, as do most patients with benign thyroid nodules. On the other hand, thyroid hyperfunction normally rules out thyroid malignancy. In case of a high clinical suspicion of malignancy (**Table 1**), thyroid surgery should be recommended, irrespective of a benign needle biopsy, since the likelihood of malignancy is very high.

Laboratory Investigations

The only relevant biochemical test that is routinely needed is serum thyrotropin (TSH), which if normal indicates normal thyroid function. Subnormal serum TSH values should lead to determination of free thyroxine (T_4) and free triiodothyronine (T_3) in serum. If serum TSH is decreased on repeat examination, treatment of this hypermetabolic state should be offered independent of whether free T_4 and/or free T_3 are elevated, especially in the elderly, since this condition is associated with increased morbidity and mortality (Lillevang-Johansen *et al.*, 2017). Isotope scintigraphy is recommended and will most likely demonstrate a functioning nodule. Most patients have normal serum TSH, including those with thyroid malignancy. Elevated serum TSH with or without decreased serum free T_4 suggests that the patient has chronic autoimmune thyroiditis (Hashimoto's thyroiditis). This can be verified by demonstrating thyroid autoantibodies in serum. The latter condition may be an independent risk factor for thyroid malignancy.

Thyroid autoantibodies against thyroid peroxidase or thyroglobulin do not aid in the differentiation between malignant and benign nodules. However, they are markers of an increased risk of developing hypothyroidism (Hashimoto's thyroiditis) and hyperthyroidism (Graves' disease) spontaneously or secondary to surgery or treatment with radioactive iodine.

Calcitonin, a hormone produced by the parafollicular C cells of the thyroid gland, is the only clinically relevant biochemical marker of medullary thyroid carcinoma, which accounts for approximately 5% of all thyroid carcinomas. Basal or pentagastrin-stimulated serum calcitonin measurement is more sensitive than thyroid biopsy in detecting medullary thyroid carcinoma. However, there is no consensus on its routine use in patients with thyroid nodules (Paschke *et al.*, 2011).

Diagnostic Imaging

Neck palpation is very imprecise with regard to the determination of thyroid nodule morphology and size. For this reason, imaging methods are increasingly used, although no imaging method can accurately differentiate benign and malignant nodules.

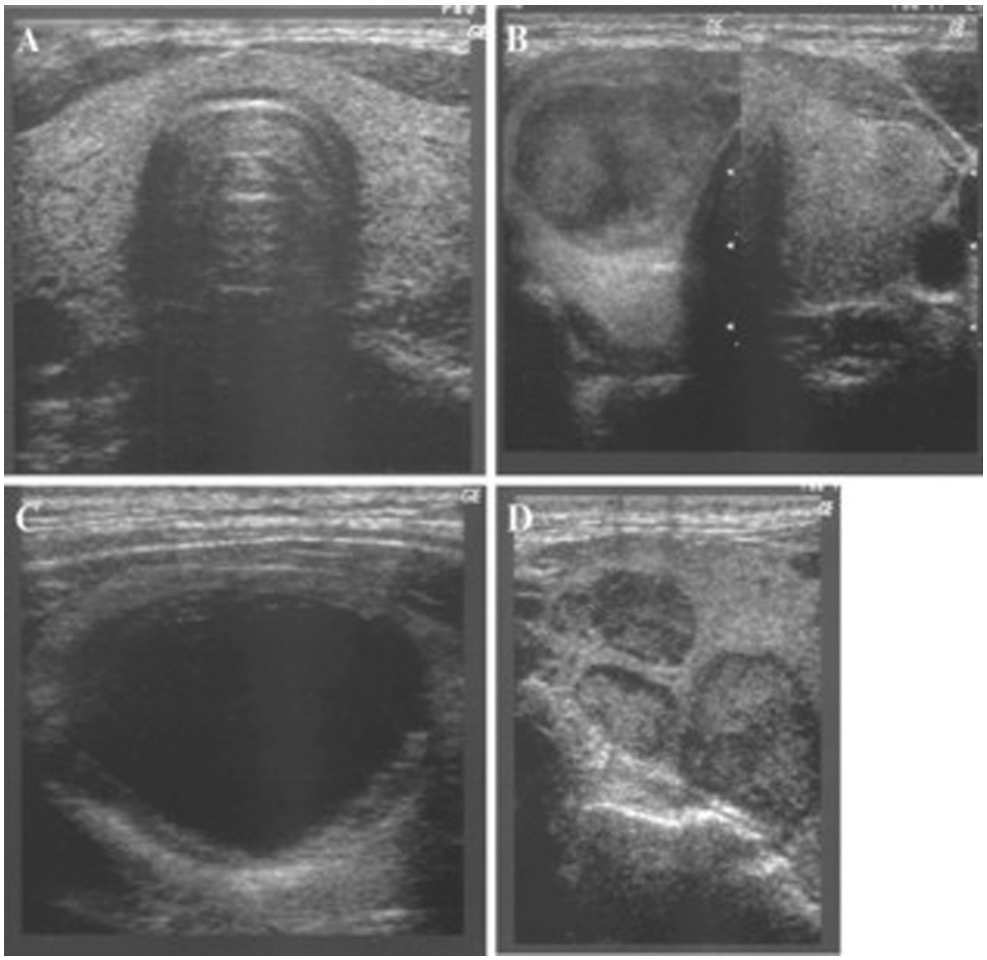

Fig. 3 Various appearances (morphological patterns) of a thyroid nodule using ultrasonography. (A) Normal thyroid tissue. (B) Solitary solid hypoecchoic (*dark*) thyroid nodule in the right thyroid lobe (left) surrounded by normal thyroid tissue (medium *gray*). (C) Solitary cyst (*black area*) surrounded by normal thyroid tissue. (D) Multiple nodules with varying ecchogenicity (multinodular gland).

Ultrasonography

This very sensitive technique with a high resolution has had a dramatic impact on clinical practice. When used in patients with a goiter, it has been shown to alter management in more than half of these patients. The increasing and widespread use, whether initially or during follow-up, is related to high availability, low cost, little discomfort to the patient, and its nonionizing nature. It allows determination of total thyroid volume, individual nodule size and echogenicity, and morphology of extranodular tissue and the evaluation of regional lymph nodes. Color-flow Doppler provides additional information regarding regional blood flow and nodule vascularity (**Fig. 3**). It distinguishes solid from cystic lesions and aids in the performance of accurate biopsies, punctures, and therapeutic procedures, such as percutaneous ethanol injection and thermal ablation procedures (Gharib *et al.*, 2013). Although there is no ultrasonographic pattern, alone or in combination with other techniques that may be considered specific for thyroid malignancy, characteristics such as hypoechogenicity, microcalcifications, increased nodular flow, and decreased elasticity are all predictive of malignancy to some extent. However, fine needle aspiration biopsy, preferably guided by ultrasonography, is far more accurate for this distinction (Gharib *et al.*, 2016; Haugen *et al.*, 2016).

Scintigraphy

Although the resolution of isotope imaging can be enhanced to 5–10 mm by tomography, this resolution is still far below that of ultrasonography. Therefore, scintigraphy is not so much used for evaluation of morphology as for evaluation of the regional uptake of the isotope and thereby the determination of functionality of the thyroid nodules (**Fig. 4**). Nodules with uptake by scintigraphy (hot or toxic) almost never harbor clinically important malignancy, although rare exceptions do exist. In an unselected population of patients with a thyroid nodule, 80%–90% of the nodules were nonfunctioning (cold). The a priori risk of malignancy is probably no higher than 5% for such a nodule. Scintigraphy is inaccurate in estimating thyroid and nodule size as well as in diagnosing malignancy.

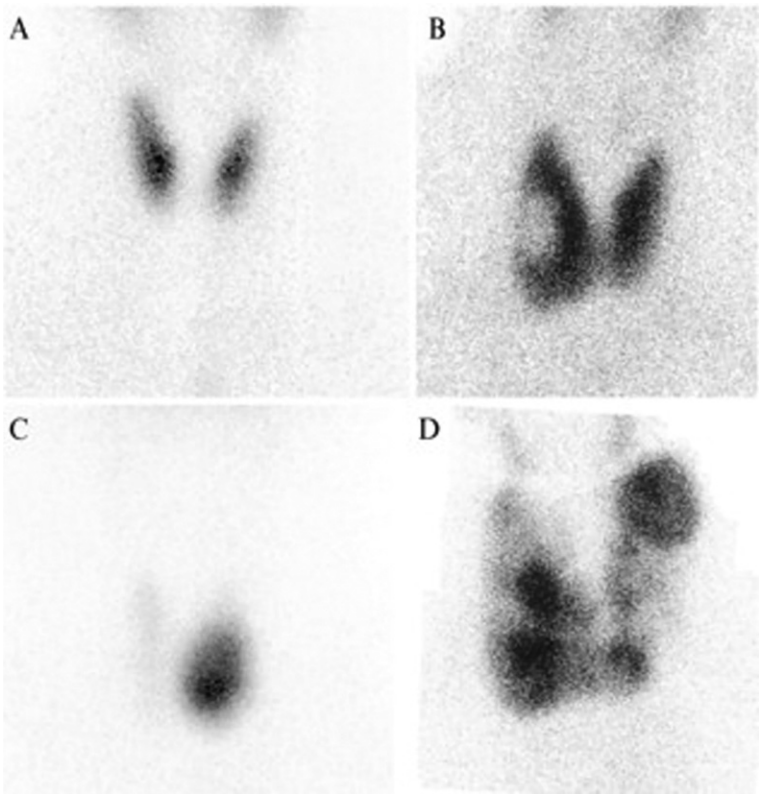

Fig. 4 Various appearances (morphological patterns) of a thyroid nodule using scintigraphy. (A) Normal uptake in two thyroid lobes. (B) Solitary nonfunctioning (cold) nodule in the right thyroid lobe (left). (C) Solitary functioning (hot or toxic) nodule in the left thyroid lobe (right). (D) Multiple nodules with varying degrees of isotope uptake (multinodular gland).

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are expensive, time-consuming, and not readily available for imaging thyroid nodules. Their major strength is their ability to diagnose and assess the extent of substernal/intrathoracic thyroid tissue much more precisely than any other method. Both methods are well suited for visualizing the trachea and demonstrating narrowing of the tracheal area or a decrease in its volume. However, this measure correlates poorly with lung function.

Importantly, the increasing use of ^{18}F-fluorodeoxyglucose positron emission tomography (PET), for non-thyroid indications, has led to the incidental detection of focal uptake in the thyroid in around 2%–3% of cases. Approximately one in three of such patients harbor thyroid malignancy, predominantly papillary thyroid cancer (Soelberg *et al.*, 2012).

Fine Needle Aspiration Biopsy

Fine needle aspiration biopsy (FNAB) provides the most direct and specific information about a thyroid nodule and is used by virtually all thyroid specialists in the initial evaluation of a patient with a solitary thyroid nodule or a dominant nodule in a multinodular goiter (Gharib *et al.*, 2016; Haugen *et al.*, 2016). It is without complications, inexpensive, and easy to learn to perform. Use of FNAB has reduced the number of thyroid surgeries by approximately 50%, doubled the surgical yield of thyroid cancer, and reduced the overall cost of medical care for these patients by 25%.

The technique involves the use of a 5- to 20-mL plastic syringe with a 22- to 27-gauge needle. The skin is cleaned with alcohol, and sometimes skin infiltration with 1 or 2 mL of 1% lidocain is used. The needle attached to the syringe is inserted perpendicular to the anterior surface of the neck. Negative pressure is applied, and as soon as bloody fluid in the hub of the needle appears, pressure is released and the needle withdrawn. No fluid should enter the syringe. If the nodule is a cyst, or partly cystic, the aspiration should be followed by FNAB of any residual solid component. Investigation of the cyst sediment rarely aids in the diagnosis of malignancy. After withdrawal, the needle is detached and the specimen is evacuated onto a slide. The specimen should be smeared immediately. Often, air drying is used and a number of staining methods are available.

Diagnostically useful FNAB specimens are obtained in approximately 80% of the cases and rebiopsy typically reduces the number of insufficient samples by half. The number of sufficient samples increases with operator experience, use of ultrasound guidance, the number of aspirations, when the nodule is solid, and with increasing cytopathologist experience, but it is highly dependent on the criteria used for adequacy of a sample. The relative distribution of FNAB results is given in **Table 2**.

Table 2 Etiology of thyroid nodules and the relative distribution of fine needle aspiration biopsy results[a]

Etiology	*Distribution (%)*
Benign (no evidence of malignancy)	70
Colloid nodule	
Cyst	
Thyroiditis (acute, subacute, or chronic)	
Suspicious	10
Follicular neoplasia	
Malignant	4
Follicular carcinoma	
Papillary carcinoma	
Medullary carcinoma (C-cell carcinoma)	
Undifferentiated carcinoma (anaplastic)	
Lymphoma	
Metastasis	
Nondiagnostic (insufficient)	16[b]

[a]Data are representative of the author's institution.
[b]The number of nondiagnostic results can be halved by rebiopsy.

Diagnostic accuracy of FNAB at large depends on the classification of the 10%–15% of suspicious lesions, of which 15%–25% are malignant. If regarded negative, sensitivity will decrease and specificity will increase. If regarded positive, the converse is true. Patients with suspicious, malignant, and nondiagnostic FNAB results (after reaspiration) should be operated on (**Fig. 2**). If this strategy is followed, the risk of postponing the diagnosis of malignancy in the approximately 70% of cases in which nonsurgical therapy is an option can be reduced to 1%. Repeat FNAB during follow-up of nodules left untreated will virtually eliminate the risk of overlooking thyroid malignancy. Neither elaborate classification systems for suspicious FNAB findings nor the use of large-needle biopsy increase diagnostic accuracy considerably. Attempts to include biochemical analysis of thyroid cyst fluid or immunodetection of various candidate molecules, such as thyroid peroxidase or lectin-related molecules, in the evaluation of thyroid cytology are still in the experimental stage. Current focus on increasing diagnostic accuracy is very much on molecular tests. Thus a "rule in" approach employing the detection of BRAF, NRAS, HRAS, and KRAS and PAX8/PPARG- and RET/PTC rearrangements is increasingly used on cytology material for cytologically indeterminate samples. A "rule out" approach, using gene expression classifiers, has been adopted by many, especially in case of follicular tumors. However, dependent on the clinical setting, the risk of overlooking malignancy is still around 3%–5%, which precludes its clinical use in many organizations and lack of consensus on their routine implementation from the thyroid specialty societies (Burman and Wartofsky, 2015; Eszlinger *et al.*, 2017; Gharib *et al.*, 2016; Haugen *et al.*, 2016).

Treatment

There is no ideal treatment for the thyroid nodule. Furthermore, despite availability of thyroid specific quality of life instruments, e.g. the ThyPRO (Watt *et al.*, 2014), little information is available regarding influence on quality of life of any of these therapy options (Cramon *et al.*, 2015). Neither are there large-scale studies comparing, head-to-head, the available therapies. The optimal therapy varies depending on the size and morphology of the nodule and whether it is functioning (**Fig. 2**; **Table 3**). Although nodules 1–1.5 cm or larger should undergo FNAB, treatment is often not necessary once malignancy has been ruled out. In the subcentimetric nodule, FNAB need not routinely be performed and treatment is rarely indicated. However, there is a continuous debate on not overlooking clinically significant malignancy on the one hand, and avoiding superfluously diagnosing and treating microcarcinomas, most of which will never become clinically significant, on the other hand (Gharib *et al.*, 2016; Haugen *et al.*, 2016; Burman and Wartofsky, 2015).

Levothyroxine Therapy

Although on the decline, some still use thyroid suppression with levothyroxine (L-T4) in the management of solid thyroid nodules in the euthyroid patient. The aim is to shrink existing nodules, considered to be a favorable sign indicating that the nodule is benign. TSH suppression seems most beneficial in the subgroup of patients with small, solid nodules. Approximately 20% of solitary solid nodules actually regress as a result of L-T4 therapy, and cessation of therapy leads to rapid regrowth. On average, long-term therapy is without significant nodule-reducing effect. Growth can be suppressed or slowed, and the formation of new nodules may be prevented. However, this necessitates that serum TSH is suppressed to subnormal values, which may have adverse effects. This degree of TSH suppression, called mild or subclinical hyperthyroidism, is associated with an increased risk of atrial fibrillation, other cardiac side effects, and reduced bone density, potentially leading to osteoporosis. Even more grave is the recently shown TSH-suppression related time-dependent increase in mortality (Lillevang-Johansen *et al.*, 2017) L-T4 is without effect in the cystic nodule and in patients with spontaneously low serum TSH

Table 3 Advantages and disadvantages of the treatment options for the solitary thyroid nodule

Treatment	*Advantages*	*Disadvantages*
Levothyroxine	Outpatient Low cost May slow nodule growth Possibly prevents new nodule formation	Low efficacy Lifelong treatment Regrowth after cessation Adverse effects (bone and heart) Not feasible with TSH suppressed
Surgery[a]	Prompt relief of symptoms Nodule ablation Definite diagnosis	Inpatient High cost Anesthesiological risk Surgical risk Vocal cord paralysis Hypoparathyroidism Hypothyroidism Bleeding and infection Scar
Radioiodine[b]	Outpatient Low cost	40% size reduction Contraceptives needed in fertile women Side effects Radiation thyroiditis Graves' disease Hypothyroidism Long-term cancer risk unknown
Ethanol injection and ultrasound-guided thermal ablation techniques (laser, radiofrequency, high-frequency ultrasound and microwave therapy)	Outpatient Relatively low cost compared to surgery Thyroid function preserved	Repeat treatment may be needed Low efficacy in large nodules Operator dependency Side effects[c] Pain Transient dysphonia Thyroiditis Extranodular fibrosis Complicates subsequent cytological interpretation

[a]In this case, unilateral operation limiting the risk of side effects.
[b]It can only be used in the nodule with uptake, whether thyroid function is increased or not.
[c]Except for various degrees of pain, side effects are rare.

with or without elevated thyroid hormone levels. For these reasons, its use is questionable; at most, it can be used for a limited time period in younger patients with small nodules, in whom treatment is in fact least necessary.

Surgery

When there is malignant or suspicious cytologic features and/or symptoms due to the nodule, surgery is often recommended, especially for younger patients and in cases in which there are large nodules (Gharib *et al.*, 2016; Haugen *et al.*, 2016). The preferred operation is a unilateral removal of the affected lobe. The frequency of complications decreases with increasing experience and specialist training and is generally low. Complications include temporary and permanent unilateral vocal cord paralysis (1%–2% and 0.5%–1.0%, respectively), temporary and permanent hypocalcemia (1.0% and 0.5%, respectively), and wound hematomas and infections (0.5% and 0.3%, respectively). The risk of complications increases with the extent of operation. In the patient with normal thyroid function postoperatively, there is no indication for routine L-T4 treatment since this does not seem to hinder thyroid growth in the long term, at least in iodine-sufficient regions.

Although an option, surgery is rarely used in the hyperthyroid patient with a toxic nodule. In this situation, radioactive iodine treatment is the preferred treatment, although there are no comparative studies (Bonnema and Hegedüs, 2012).

Radioactive Iodine

If the patient has hyperthyroidism (toxic nodule), antithyroid drugs (methimazole or propylthiouracil) can normalize thyroid function but disease recurrence is the rule when medication is stopped. With the exception of a few patients who have a large nodule, in which case surgery may be indicated, radioactive iodine is the treatment of choice (Bonnema and Hegedüs, 2012). This is also the case for the clinically euthyroid patient with a functioning (hot) nodule without hyperthyroidism, in whom treatment

may be dictated by the nodule size, which may cause compression or cosmetic disturbances. In addition, radioactive iodine treatment is used to prevent hyperthyroidism (annual risk of approximately 4%).

A cure rate (i.e., normalization of thyroid function and the appearance on a thyroid isotope scintigram) of 75% is seen, and the nodule shrinks 30%–40% following a single dose of radioactive iodine. Side effects are few, with rare cases of radiation thyroiditis and transition to Graves' disease. The risk of hypothyroidism is approximately 10% after 5 years and poorly related to the dose of radioactivity. The long-term risk of malignancy is unknown but considered negligible.

Radioactive iodine has no effect in the nonfunctioning (cold) thyroid nodule, whether solid or cystic. In the future, the possibility of stimulation with recombinant human TSH before radioactive iodine treatment may lead to an increased iodine uptake and also an effect in the solid, cold nodule.

Ethanol Injection and Thermal Ablation Techniques

Ethanol (70%–100%) causes local small vessel thrombosis and coagulative necrosis, leading to fibrosis and permanent tissue ablation. It has been used in both autonomously functioning thyroid nodules and nonfunctioning thyroid nodules, whether solid or cystic. If multiple injections are used, complete cure (normal serum TSH and isotope scintigraphy) can be achieved in 60%–70% of patients with toxic nodules and 70%–80% with hot nodules. A single ethanol instillation (after aspiration) in thyroid cysts reduces recurrence to approximately 20% compared to approximately 50% after aspiration alone. In solitary solid, nonfunctioning thyroid nodules, approximately 50% of patients are relieved of their clinical symptoms based on a 50% nodule volume reduction. Additional injections have little effect. It is an option for patients who do not wish to undergo radioiodine treatment or surgery. However, it often necessitates repeat treatment to obtain complete cure. The long-term effects are unknown, and the treatment is not devoid of side effects. The procedure requires the special technical skill that can be obtained only at a center familiar with interventional ultrasound. While recommended for benign recurrent thyroid cysts, specialty societies do not recommend it for routine therapy of solid thyroid nodules due to the risk of side-effects. In such nodules, current studies focus on thermal ablation techniques, which are only available in a limited number of centers.

Ultrasound-guided thermal ablation, whether with laser, radiofrequency, high-frequency ultrasound or microwaves, have been introduced for solid and cystic solitary, benign, nonfunctioning thyroid nodules. Most experience is available for laser and radiofrequency therapy (Gharib *et al.*, 2013; Papini *et al.*, 2014; Ha *et al.*, 2015). One treatment session results in a nodule reduction of 50%–70% or more. It may be repeated and significantly reduces pressure symptoms and cosmetic complaints. These results are similar to those obtained using ethanol therapy. The fact that the spread of energy with thermal destruction can be better controlled, as opposed to chemical destruction by injection of ethanol, may favor these techniques in the long term. Controlled studies with surgery as the gold standard, and comparison of not only efficacy and side-effects but also quality of life and cost are awaited and may promote routine use.

Thyroid and Irradiation☆

Barbara Jarzab, Daria Handkiewicz-Junak, and Jolanta Krajewska, Maria Skłodowska-Curie Memorial Institute - Cancer Center, Gliwice, Poland

Glossary

Chernobyl accident The explosion of the nuclear power plant in Chernobyl, Ukraine, on 26 April 26, 1986.

Differentiated thyroid carcinoma An endocrine malignant neoplasm arising from the follicular thyroid cell, which exhibits thyroid differentiation features.

External irradiation The delivery of radiation to the human body by any external source of radiation.

Effective radiation dose It is the tissue-weighted sum of the equivalent doses in all specified tissues and organs of the human body and represents the stochastic health risk (the probability of cancer induction and genetic effect) to the whole body. It is used to assess the potential for long-term effects that might be related to radiation exposure; it takes into account: (1) radiation dose, (2) the relative harm level of the radiation used (not all radiation is the same), (3) the sensitivities of each organ to radiation (e.g., bone marrow is more sensitive than bone); the SI unit for effective radiation dose is the sievert (Sv).

Fukushima accident The accident of the nuclear power plant in Fukushima, Japan, on March 11, 2011.

Internal irradiation The delivery of radiation to the body by ingested or inhaled radioactive isotopes.

Radiation dose Amount of energy deposited in tissue as a result of an exposure to ionizing radiation. It is used to calculate the dose uptake in living tissue in radiation protection and radiology. The unit of measurement for absorbed dose is the gray (Gy).

Introduction

Radiation exposure of the thyroid gland, like in many organs of the body, may result in DNA damage. Depending on the modality and severity of irradiation, the damage to the thyroid may cause cell death or may be less severe leading to specific genetic abnormalities. The thyroid is particularly vulnerable to the effect of ionizing radiation with the pediatric population being the most sensitive. Diagnostic and therapeutic medical radiation represents the largest source of man-made radiation exposure. However, the most striking increase in the incidence of thyroid cancer has occurred after Chernobyl nuclear plant accident, among children and adolescents who lived in the most contaminated areas of Belarus, the Russian Federation, and Ukraine.

This article reviews the sources of thyroid radiation, radiation risk to the thyroid gland and the most relevant health consequences on the thyroid after external and internal irradiation.

Source of Radiation Exposure

People are exposed to natural radiation sources (background radiation) as well as human-made sources on a daily basis. Natural radiation comes from naturally occurring radioactive materials found in soil, water, and air. The average background radiation is about 3.0 mSv/year, but is some regions can be as high as 6 mSv/year (e.g., Ramsar, Iran—the annual radiation ranges between 0.7 and 131 mSv). The average exposure to medical X-rays, estimated to be about 2.2 mSv, is related mostly to computer tomography imaging, nuclear medicine procedures or external beam radiation treatment. Beyond medical radiation nuclear accidents and nuclear bomb testing can be a source of high radiation dose in some regions.

Both external radiation (therapeutic or accidental) and internal radiation (caused by therapeutic or accidental irradiation due to radioactive isotopes of iodine) have been associated with thyroid diseases in vitro as well as in vivo (Sinnott *et al.*, 2010).

Factors Affecting Sensitivity to Develop Radiation-Induced Thyroid Cancer

Age and Sex

Young age at the time of radiation exposure is a major risk factor with a strong inverse relationship between age at exposure and the risk of thyroid cancer development. According to a pooled analysis of 12 studies including 970 thyroid cancer patients exposed

☆*Change History*: March 2018. Barbara Jarzab, Daria Handkiewicz-Junak and Jolanta Krajewska. Updated for Thyroid damage after radiation; age and sex; genetic predisposition; post-Chernobyl thyroid cancer, biology of post-Chernobyl thyroid cancer, glossary, and further reading and added the section for source of radiation exposure; Fukushima nuclear power plant accident; Prevention of thyroid cancer after internal contamination with radioactive iodine; Table 1.

This article is an update of Furio Pacini, Irradiation, Thyroid and, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 108–113.

to radiation in childhood (before age of 20), recently published, patients exposed to external radiation before the age of four demonstrated a fivefold greater risk per Gy of developing thyroid carcinoma comparing to those aged 10–14 years (Veiga *et al.*, 2016). The excess risks (ERs) of thyroid cancer among the Japanese atomic bomb survivors were 9.5, 3.0, 0.3, and 0.2 in the age categories of 0–9, 10–19, 20–39, and over 40 years of age at the time of the bombing, respectively (Pacini, 2004). However, above the age of 15 the risk was not longer statistically significant (Sinnott *et al.*, 2010).

Another question is related to in utero exposure of the thyroid. Accidental fetal exposure occurred after the Chernobyl accident. The data coming from a screening study of thyroid cancer prevalence among individuals exposed in utero to iodine isotopes suggested that such exposition may lead to an increased risk of thyroid cancer approximately 20 years later (Sinnott *et al.*, 2010). Among other effects of in utero radiation exposure, observed after Chernobyl, were dose dependent and significant reductions in head and chest circumference without any significant effect of birth weight (Hatch *et al.*, 2017). The effects of accidental medical exposure in pregnant women depend on gestational age and how much is taken up by mother's thyroid gland. The carcinogenic potential of such exposure is not known (Sinnott *et al.*, 2010).

The risk of thyroid cancer after exposure to external radiation was believed to be two- to threefold higher in females than in males, but this gender effect was not confirmed in the recent pooled analysis of 12 studies, mentioned above, and was not found in contaminated children after the Chernobyl accident (Veiga *et al.*, 2016; Iglesias *et al.*, 2017). Thus, gender does not seem to influence the risk of developing radiation-induced thyroid cancer.

Genetic Predisposition

There are some data suggesting that genetic predisposition, such as defects in the DNA repair mechanisms, may play a role in developing radiation-induced thyroid cancer. It was reported that in some families several irradiated individuals developed thyroid cancer more often, that could be expected by chance (Iglesias *et al.*, 2017). Patients who experience one radiation-related cancer are more likely to develop a second radiation-related cancer (Pacini, 2004). A higher risk was demonstrated in children irradiated for neuroblastoma and Hodgkin disease than in those, who underwent radiation treatment due to other reason (Rubino *et al.*, 2002). However, studies available so far have not identified genetic determinants that modify individual predisposition to radiation-induced childhood thyroid cancer. Genome-wide association studies using adult sporadic thyroid cancers and Belarusian cases aged 0–18 years at the time of the accident pointed out that a common single nucleotide polymorphism marker, rs965513, located in the FOXE1 vicinity at chromosome 9q22.33 showed a strong correlation with both sporadic and radiation-related thyroid cancer (Takahashi *et al.*, 2010).

Thyroid Damage After External Irradiation (Pacini, 2004)

Irradiation to the head and neck for the treatment of distinct benign conditions (e.g., enlargement of the thymus, tonsils, adenoids, or neck lymph nodes; skin angioma; acne; otitis; tinea capitis) used to be a common procedure applied in children since 1920. The relationship between irradiation and thyroid carcinoma for the first time was reported in 1950 (Duffy and Fitzgerald, 1950) and subsequently confirmed in numerous studies (Hanford *et al.*, 1962; Albright and Allday, 1967; DeGroot and Paloyan, 1973). In 1970 in the United States up to 76% of children diagnosed with thyroid carcinoma had a history of previous radiation exposure (Pacini, 2004). Therefore, since 1970 external radiation for benign diseases has been totally abandoned in nearly all countries (Pacini, 2004). In Europe the incidence of radiation-induced thyroid carcinoma in children and adolescent was substantially lower: 10% in France and 7% in Italy (Pacini *et al.*, 1997).

Based on the data of the National Council on Radiation Protection (NCRP), the risk estimate (EAR) for radiation-induced thyroid cancer is 2.5×10^{-4}/Gy/year for persons exposed under 18 years of age, whereas for adults the risk per year is assumed to be half of this value. Because of their smaller number of years at risk, the lifetime risk for adults is about one-fourth the risk for children. In a pooled analysis of five cohorts, the EAR is 4.4×10^{-4}/Gy/year for persons exposed before 15 years of age—the highest risk group. Little risk concerns persons after 20 years of age, and it is close to zero in persons after 40 years of age (Pacini, 2004).

In a recent study, which included 12 large cohorts with 927 thyroid cancers after radiation exposure, the risk of thyroid cancer significantly increased after a mean dose to the thyroid during childhood as low as 0.05–0.1 Gy (50–100 mGy). The relative risk increased supralinearly through 2–4 Gy, leveled off between 10 and 30 Gy and declined thereafter, probably because of cell killing, but the overall risk remained significantly elevated above 50 Gy (Veiga *et al.*, 2016).

In children exposed to a dose of 1 Gy to the thyroid, the relative risk of thyroid carcinoma ranges among series from 5.1 to 8.5. It was estimated that 88% of the thyroid cancers in this group of patients are attributable to radiation exposure (Sinnott *et al.*, 2010). Although radiation-induced differentiated thyroid cancer (DTC) used to be considered as more aggressive the recently published data discredited this opinion. A retrospective analysis, evaluating 257 DTC patients treated in the United States between 1951 and 1987 with median follow up of 27 years, showed significantly longer overall survival in patients with DTC developed after radiation exposure comparing to DTC without previous radiation exposure, 43 versus 38 years, respectively. However, regarding the percentage of recurrences and DTC-specific mortality the differences between the groups were not significant (White *et al.*, 2016).

In most studies, the minimal latency period between the time of radiation exposure and the development of thyroid cancer ranges between 5 and 10 years. A shorter interval was noticed after the Chernobyl accident probably due to the large number of contaminated children among whom thyroid cancer was diagnosed earlier (Iglesias *et al.*, 2017). The risk peaks at 20–35 years and decreases thereafter remaining still elevated even 45–60 years after exposure (Iglesias *et al.*, 2017; Lubin *et al.*, 2017).

The specific effect of diagnostic radiation exposure on thyroid cancer risk, previously believed to be controversial, has been unequivocally demonstrated by a meta-analysis of nine studies, just published. The overall diagnostic radiation exposure significantly increased the risk of thyroid cancer (the odds ratio [OR] = 1.52). Considering a particular radiological examination both computed tomography and dental X-ray were associated with increased odds of thyroid cancer, 1.46 and 1.69, respectively, whereas chest X-ray and mammography not. Both head/neck and chest diagnostic exposure increased the risk of thyroid cancer, OR 1.31 and 1.71, respectively. Conversely, the other body site exposure did not (Han and Kim, 2017).

High-dose radiation therapy to the neck (>20 Gy) results in a high rate of hypothyroidism but also in an increased risk of thyroid cancer with OR of 9.8 (Sigurdson *et al.*, 2005; Hancock *et al.*, 1991). The thyroid damage is probably related to the distance between the thyroid gland and the radiation field. If this is far from the thyroid, as in the case of thoracic or abdominal radiation fields in children, the thyroid gland may receive minimal radiation doses of some 100 mGy, not enough to cause hypothyroidism but sufficient to trigger thyroid cancer (Pacini, 2004). Interestingly, the meta-analysis of 13 studies evaluating the risk of thyroid cancer in individuals living near nuclear power plants did not demonstrate any significant increase in thyroid cancer incidence and mortality. The pooled estimates did not show different risk patterns by sex, exposure definition, or reference population (Kim *et al.*, 2016).

Thyroid Disorders After Exposure to Radioactive Iodine

Radioiodine (^{131}I) is commonly used in the treatment of benign thyroid conditions as well as in differentiated thyroid cancer. Nowadays, the use of RAI in the diagnostics of benign thyroid disease plays a minor role due to widely accessible thyroid sonography.

Radioiodine administration leads to direct and indirect radiobiological effects on affected tissues. The direct effect is related to ionization of the thyroid cell and results in DNA damage, whereas indirect effect leads to the production of free radicals that react with the critical macromolecules. Beta decay is responsible for causing DNA mutation and death in affected cells and other cells up to several millimeters away. For this reason, lower doses of ^{131}I may be more dangerous than higher doses, since they do not kill thyroid cells and may lead to carcinogenesis as a result of the irradiation. Therefore ^{131}I administration, particularly its lower activity in children is disputable.

Swedish analysis that involved 34,104 patients exposed to ^{131}I diagnostic activities with a mean estimated thyroid dose of 110 cGy demonstrated a small increase in the number of observed thyroid cancer in comparison to the expected number, 67 versus 50 cases respectively. It has to be emphasized that this increase was confined to subjects in whom thyroid scan was performed due to suspicion of thyroid cancer. These differences disappeared if the analysis was carried out in patients tested for other reasons. The authors concluded that the diagnostic ^{131}I administration showed no health effect on thyroid. However, one should be cautious as only a minority of patients in Swedish cohort were children (Hall and Holm, 1997).

Thyroid Effects of the Chernobyl Nuclear Accident (Pacini, 2004)

The accident at the nuclear power plant in Chernobyl, Ukraine, occurred on 26 April 1986 and dispersed large quantities of radioactive isotopes into the atmosphere, including ^{131}I, ^{133}I, ^{132}Te rapidly decaying to ^{132}I, ^{134}Ce, and ^{90}Sr. Among the most contaminated territories were southern Belarus, northern Ukraine, and adjacent oblasts of Russian Federation (Pacini, 2004).

Volatile radioactive isotopes could be first inhaled or later ingested. The time at which ingestion occurred varied considerably, but the milk chain, particularly in children, played the major role. Several factors contributed to the high radiation exposure of the population, in particular: the lack of or delay in protective procedures such as advising and evacuating the people at risk and distributing iodine prophylaxis, and moderate iodine deficiency of the most contaminated regions leading to increased iodine uptake. The thyroid is the only tissue in the body able both to take up and store iodine. Its contamination depends on amounts of uptaken radioiodine, thyroid mass itself and the magnitude of contamination. In addition, regardless of the level of contamination, the thyroid dose is always higher in children than in adults, and the uptake in children is similar to that observed in adults but the thyroid mass is smaller and the thyroid dose per gram of tissue is greater and extremely high in newborns and very young children (Pacini, 2004). These entire factors resulted in increased incidence rate of childhood thyroid cancer following the Chernobyl accident.

Post-Chernobyl Thyroid Cancer

The first information of any increase in malignancy rate among individuals exposed to fallout was reported in 1990, only 4 years after the accident, when growing incidence of thyroid cancer was noticed in Minsk and Kiev (Williams, 2008). The magnitude of

this increase and the geographical and temporal distribution of the cases strongly suggest that thyroid cancer was due to the reactor explosion and particularly to the huge amount of iodine radioisotopes released (Pacini, 2004). It is estimated that 7000 thyroid cancer cases occurred among the 2 million highly contaminated subjects, who were younger than 18 years at the time of the accident. In the most contaminated area of Belarus, the Gomel region, thyroid cancer incidence following the accident, between 1986 and 1996 was the highest—13 per 100,000 children per year, whereas a baseline incidence was lower than 1 per 100,000 children per year. However, the questions why only some people exposed to the same radiation dose develop cancer, whether it is just chance or depends on genetic or environmental factors remain open (Thomas *et al.*, 2011).

According to dosimetric data the mean estimated thyroid dose was nearly 700 mSv in Belarus. In Ukraine, 79.0% of children received a thyroid dose less than or equal to 300 mSv, 10.5% received between 300 mSv and 1 Sv, and 10.5% received more than 1 Sv. In most of the children, who developed thyroid cancer, the estimated thyroid dose has been less than or equal to 300 mGy. However, an excess thyroid cancer incidence has been observed even in areas where the mean thyroid dose in children was significantly lower; 50–100 mGy (Pacini, 2004).

Biology of Post-Chernobyl Thyroid Cancer

In earlier cases after Chernobyl accident, nearly virtually all thyroid cancers were papillary of the solid subtype, which was the unique characteristic observed after the Chernobyl accident. Subsequently, the proportion shifted to the classic subtype, which is less aggressive and metastatic, and is the common subtype in sporadic childhood PTC. Diffuse sclerosing variant, cribriform type and Warthin-like variant were rare, whereas tall cell and columnar cell variants were absent (LiVolsi *et al.*, 2011).

Rearrangements of the *RET* proto-oncogene (mostly *RET/PTC1*) are found in nearly 30%–70% of the childhood PTC. Molecular studies of the early Chernobyl-related tumors found that a very high proportion showed a RET rearrangement (Elisei *et al.*, 2001), and almost all were *RET/PTC3*. It was speculated that this rearrangement might be a marker for radiation-induced tumors. Over time, the proportion of tumors with RET rearrangement has declined. Radiation exposure is an efficient inducer of DNA double-strand breaks, therefore it is highly expected to cause gains or losses of DNA. A variety of copy number alterations (CNAs) have been identified in childhood thyroid cancers after the Chernobyl accident, mostly gains of DNA, and these were compared with CNAs in sporadic cases, in which losses were more frequent than gains. Ricarte-Filho and coworkers identified kinase fusion oncogenes aberrantly activated MAPK signaling pathway in post-Chernobyl radiation-induced thyroid cancers (Ricarte-Filho *et al.*, 2013). However, most studies have failed to demonstrate specific CNAs associated with radiation exposure except one study that described a unique gain of chromosome 7q11, which was absent in all unexposed cases (Hess *et al.*, 2011).

Several studies have been carried out and some of them reported gene expression changes unique to radiation-induced childhood PTCs, whereas others have failed to identify the signatures (Maenhaut *et al.*, 2011). Importantly, the identified genes substantially varied between the studies, with few recurrent genes. More recently, gene expression profiles in normal thyroid tissues and tumor tissues obtained from exposed and unexposed children after the Chernobyl accident were compared (Handkiewicz-Junak *et al.*, 2016). These studies that managed to eliminate most of confounding factors (e.g., environment) identified a significant, but subtle, differences in gene expression that are associated with low-dose radiation exposure.

Fukushima Nuclear Power Plant Accident

Twenty-five years after Chernobyl accident, on March 11, 2011, large amounts of radioactive isotopes, including 131-I, were released after Fukushima Daiichi (Japan) nuclear power plant accident. In terms of severity, the accident at the Fukushima was rated at level 7 on the International Nuclear and Radiological Event Scale, which matches the rating to the Chernobyl accident in 1986. However, the radiation dose to the thyroid gland was much lower because the authorities ordered shielding, evacuation from the most contaminated territories, and food restriction. Furthermore, the thyroid uptake of iodine was low in relation to the high iodine alimentary intake. Doses of less than 15 mSv were reported in 99% of children aged 0–14 years and the average thyroid dose was <1 mSv (maximal 33 mSv) (Nagataki *et al.*, 2013). Soon after the accident thyroid ultrasound screening began for those who were from the areas, where the radiation doses were the highest. In total, more than 300,000 subjects aged 18 years or younger at the time of the disaster were screened between 2011 and 2014. One hundred and one cases of thyroid cancer were found in the screened population (preliminary baseline screening), and a similar incidence was found in a Japanese control population of nonexposed children and adolescents (Suzuki, 2016; Yamashita *et al.*, 2017). Since these cases were discovered soon after the accident, there is no clear evidence related these cases to radiation exposure after the accident. The second round (the first full-scale survey), completed between 2014 and 2016, revealed another 71 cases with malignant or suspicious for malignancy fine needle aspiration biopsy results. Among 44 individuals, who underwent surgery, thyroid cancer was confirmed in all cases (Yamashita *et al.*, 2017).

Further follow-up of the exposed population is essential in obtaining the full picture of the long-term thyroid cancer risk at a very low radiation doses. Fukushima Health Management Survey is the largest health-monitoring project, currently ongoing. It involves the Basic Survey to estimate the external radiation dose received during first 4 months following the accident, when the airborne activity was at peak, and four detailed surveys: thyroid ultrasound examination, comprehensive health check-up, mental health and life-style survey, and survey of expectant and nursing mothers (Yamashita *et al.*, 2016).

Table 1 World Health Organization Guidelines for potassium iodide prophylaxis following a nuclear accident

Issue	*Details*
Potassium iodide dosage	Age dependent: Neonate (<1 month): 16 mg/day 1 months to 3 years: 32 mg/day 3–12 years: 65 mg/day >12 years of age and adults: 130 mg/day
Preparation form	Potassium iodine tablets Lugol solution (130 mg = 1 mL)
How long	A single dose of KI is usually sufficient for adequate protection for 24 h In the event of prolonged or repeated exposure, public health authorities may advise taking KI tablets more than once
Who should receive	The first group to get prophylaxis (most sensitive): Pregnant and breastfeeding women infants and children <18 years of age
Avertable radiation dose to thyroid to start prophylaxis	10 mGy (most sensitive group)

Other Thyroid Consequences of Radiation Exposure (Pacini, 2004)

Radiation exposure of the thyroid gland may also cause other thyroid abnormalities including hypothyroidism, acute thyroiditis, and the possibility of developing of autoimmune thyroid disorders. Thyroid cancer and benign thyroid nodules after radiation exposure represent the stochastic effects, whereas hypothyroidism and acute thyroiditis depend on the radiation dose.

Hypothyroidism was reported in 34% of 1677 patients treated with radiation therapy due to Hodgkin disease (Hancock *et al.*, 1991). Hypothyroidism was diagnosed in 43 among 2587 atomic bomb survivors in Nagasaki. Twenty-seven of these individuals were thyroid antibody positive and 16—thyroid antibody negative, without sex differences. There was an association noticed between thyroid dose and the prevalence of antibody positive but not antibody negative hypothyroidism, what might suggest an underlying autoimmune thyroid disorder (Nagataki *et al.*, 1994). Hypothyroidism is also a frequent consequence of internal radiation as observed in patients treated with radioiodine.

External irradiation to the head and neck may result in the development of thyroid autoimmunity. A significant increase in thyroid autoimmunity in exposed children comparing to nonexposed individuals was noticed 6–8 years after the Chernobyl accident, 19.5% versus 3.8% respectively (Pacini *et al.*, 1998). Similarly, an increased incidence of thyroid antibodies was observed in children who underwent radiation for benign disorders. More than two-thirds of irradiated patients demonstrated variable degrees of thyroid lymphocytic infiltration several years before thyroidectomy for nodular thyroid lesions. In patients who received radiation of the neck for Hodgkin's disease, 3% or more developed Graves' disease (a 7- to 20-fold excess risk) and 1% developed thyroiditis. The possible pathomechanism is related to the release of thyroid antigen from damaged thyroid cells, regardless of the modality of thyroid exposure (Pacini, 2004).

Prevention of Thyroid Cancer After Internal Contamination With Radioactive Iodine

Stable iodine, administered as potassium iodide (KI), inhibits the thyroid uptake of radioactive iodine by more than 98% if it is administered several hours before contamination, by 90% at the time of the contamination, and by 50% if it is given 6 h after the accident. Uptake will be low during 48–72 h and then will re-increase. Stable iodine does not protect against any other radioactive substances. The Guidelines proposed by World Health Organization for potassium iodide prophylaxis following a nuclear disaster are summarized in **Table 1**.

Polish experiences after the Chernobyl accident strongly support the necessity of stable iodine administration to prevent thyroid gland damage. KI administration, implemented in Poland within the first 4 days following the start of exposure, led to a reduction in committed thyroid dose between 40% and 60%. It has been estimated that about 90% of children under the age of 16 showed thyroid radiation dose below the predicted mean maximal burden (<50 mSv) (Nauman and Wolff, 1993).

Thyroid Imaging

Luca Giovanella, Giorgio Treglia, and Pierpaolo Trimboli, Cantonal Hospital Agency, Bellinzona, Switzerland and Oncology Institute of Southern Switzerland, Bellinzona, Switzerland

Introduction

The thyroid gland may be affected by different diseases with variable outcome and prognosis. A crucial step for the correct management of these disorders is the early diagnosis, the proper differential diagnosis, and, when appropriate, an accurate disease staging. Beyond clinical and laboratory data, different imaging modalities are available to evaluate thyroid disorders. These imaging modalities include both morphological and functional imaging methods, sometimes combined by using hybrid devices. The aim of this chapter is to provide a comprehensive overview on the thyroid imaging of thyroid moving from the basic characteristics of the different imaging methods and ancillary techniques used for evaluation and diagnosis to their applications in a wide range of thyroid disorders encompassing Graves' disease, toxic multinodular goiter, toxic adenoma, thyroiditis, nontoxic goiter, benign thyroid nodules, and the different forms of thyroid carcinoma.

Thyroid Ultrasonography

Since 1990s ultrasonography (US) has become the most diffused thyroid imaging tool. In fact, US allows to estimate thyroid size and evaluate its morphology (Haugen *et al.*, 2016; Gharib *et al.*, 2016). Also, a main power of US is the detection of thyroid lesions which may be not evident at palpation or other imaging techniques (Haugen *et al.*, 2016; Gharib *et al.*, 2016). **Table 1** details the main strengths of thyroid US. The procedure is safe, takes few time (i.e. 10–15 min), is relatively cheap, and does not require specific preparation of patient.

Assessment of Diffuse Thyroid Diseases

The thyroid gland is more echo-dense than the adjacent structures. Thyroid volume can be estimated by ellipsoid volume formula applied to each lobe, and a size between 7 and 20 mL can be considered as the normal reference in adult population (Rago *et al.*, 2006; Shapiro, 2003; Lyshchik *et al.*, 2004; Deveci *et al.*, 2007; Vejbjerg *et al.*, 2006; Trimboli *et al.*, 2008). As a general rule, the normal cells/colloid ratio gives homogeneous and normoechoic thyroid presentation at US, while higher cells/colloid ratio determines hypoechogenicity. Then, normal thyroid appearance at US (i.e. normoechoic and homogeneous echostructure combined with normal size) theoretically correlates with normal thyroid function and negative thyroid antibodies (Trimboli *et al.*, 2010, 2012); on the contrary, hypoechoic and inhomogeneous thyroid structure is associated with thyroid dysfunction and is highly suspicious for autoimmune diseases (i.e., Hashimoto or Graves' disease) (Marcocci *et al.*, 1991; Rago *et al.*, 2001). The presence of nodules within the gland does not influence the global thyroid function with the exception of autonomously functioning nodules which can be detected by scintigraphy. **Fig. 1** illustrates the normal thyroid US presentation, while **Figs. 2** and **3** show two cases of Hashimoto thyroiditis and Basedow disease.

Assessment of Thyroid Nodules

The role of US to identify thyroid nodules at risk has become the most relevant in clinical practice. In this context, it is well known that some US specific features can help to discriminate nodules at higher risk from those with no need to be further investigated. Overall, based on the US risk stratification, up to 80% of thyroid cancers are correctly identified (Haugen *et al.*, 2016; Gharib *et al.*, 2016). However, specificity of US in this context was reported as low. In fact, thyroid nodules are very common (their prevalence achieves 70% of European adult population) and US can detect a lot of clinically non-relevant nodules. As a consequence, performing US in patients with no specific risk factors (i.e. previous neck irradiation) or clinical indications is strongly discouraged. **Table 2** illustrates the reliability of the US characteristics useful to discriminate nodules suspicious for malignancy from those with low/very-low suspicious.

Remarkably, none of these features is accurate alone and the combination of all features achieves relevance to identify malignant nodules. As the most relevant novelty over the recent years in the field of thyroid US, several international societies have been published multi-points score systems to assess the risk of thyroid lesions. The major aim of these US systems was to cover the potential limitation of using each US parameter as a single predictor of malignancy. Firstly the so called TIRADS (Thyroid Imaging Reporting and Data System) was proposed by radiologists (Horvath *et al.*, 2009); there was a 6-points system. Following, the American Thyroid Association (ATA) proposed a 5-score scale (Haugen *et al.*, 2016) and, more recently the American Association Clinical Endocrinologists/American College of Endocrinologists and Associazione Medici Endocrinologi (AACE/ACE/AME)

Table 1 Main goals of thyroid US examination

What thyroid US can evaluate	*How*	*When is useful*
To verify the presence of gland in the correct position and its correct development	Localizing the entire gland and its shape	To exclude thyroid agenesia
To estimate thyroid size	Applying the ellipsoid volume formula to each thyroid lobe	In the initial evaluation of all patients and during their follow-up
To assess the presence of and risk for autoimmune thyroid disease	Evaluating the ecogenicity ed. echostructure of the gland	In presence of thyroid dysfunction
To assess the relationship between thyroid and other cervical organs	Examining if trachea and esophagus are damaged by increased thyroid size	In presence of cervical compressive symptoms (i.e. dysphagia and dyspnea)
To detect thyroid nodules	During thyroid evaluation	In all patients undergoing thyroid US
To discriminate nodules suspicious for malignancy from those with poor risk	Searching for the presence of suspicious US features in each one nodule	In each one patient with nodular disease
To follow-up nodules	Assessing change in size and echostructure of nodules over the time	In each one patient with nodular disease
To identify cervical lymph nodes suspected to be thyroid metastases	Examining neck levels (II to VI)	In each one patient with nodular disease or followed-up for thyroid cancer
To guide thyroid interventions	Performing the procedures under real time US-guide	During biopsy, percutaneous ethanol injection, or thermal therapy

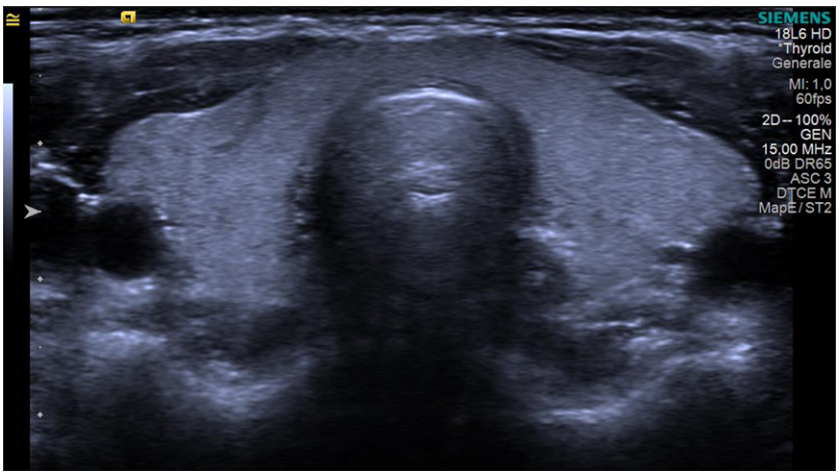

Fig. 1 Normal thyroid presentation at ultrasonography (bilobar transaxial section).

(Gharib *et al.*, 2016), and British Thyroid Association (BTA) (Perros *et al.*, 2014) systems were reported. Despite of different interpretation of the specific US parameters of the experts boards, these four US systems seem to furnish similar performance. **Table 3** summarizes and compares these four US systems. To date, a few papers have investigated the performance of these US systems in clinical cohorts of patients, and the results should suggest that ATA guidelines (Haugen *et al.*, 2016) have good sensitivity and in thyroid nodules (Yoon *et al.*, 2016; Xu *et al.*, 2017) and in the selected category of nodules with previous indeterminate cytology (Trimboli *et al.*, 2017; Grani *et al.*, 2016). However, these papers reported retrospective series, and further studies with prospective design are required. **Figs. 4** and **5**. Illustrate the presentation of one non-suspicious nodule and one nodule at risk for malignancy. In **Fig. 6** is shown an inelastic lesion at elastographic assessment.

Ultrasound-Guided Thyroid Interventions

US is pivotal in assisting fine-needle aspiration cytology (FNAC) of thyroid nodules and neck lymph nodes. Until the 1990s FNAC was performed without US guidance and its accuracy was suboptimal. In the last years US-guided FNAC has been worldwide diffused with improvement of cytologic diagnosis. Moreover, complications are very rare and FNAC can be performed in ambulatory office (Haugen *et al.*, 2016; Gharib *et al.*, 2016). Cytologic evaluation is essential to assess thyroid nodules with suspicious US presentation: the larger part of nodules are assessed at FNAC, while a rate of 15–25% of thyroid cytology is inconclusive due to inadequate material (Thy 1, Category I) or indeterminate diagnosis (Thy 3, Category III or IV). Nodules with Thy 1 or Category I need to repeat FNAC, and those lesions with repeated inadequate sample should be addressed to diagnostic

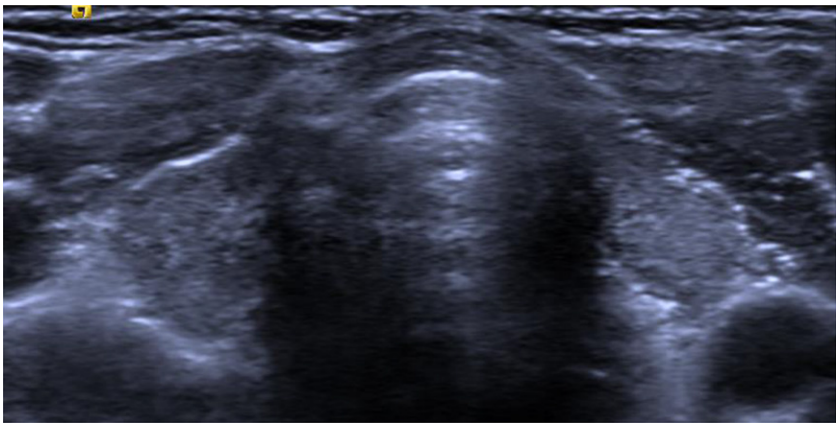

Fig. 2 Hashimoto's thyroiditis: thyroid size is markedly reduced, echogenicity is reduced with inhomogeneous echostructure (bilobar transaxial section).

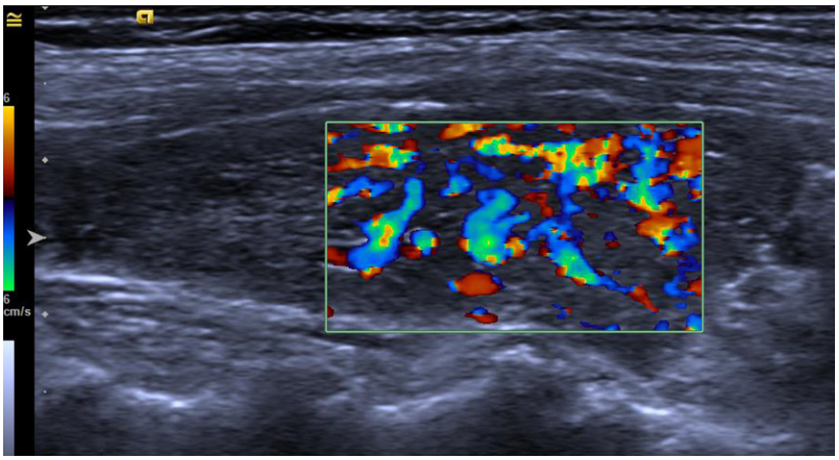

Fig. 3 Graves' disease: echogenicity is reduced with irregular echostructure. A diffuse increase of parenchymal vascularization is observed at color-Doppler evaluation (right lobe, sagittal section).

surgery or other biopsy (see below) (Haugen *et al.*, 2016; Gharib *et al.*, 2016). Generally, a 23–27 gauge needle attached to a syringe is used. Several fashions can be adopted for thyroid FNAC, being the free-hand mode the most popular. In a parallel approach the needle is inserted parallel to the probe or at an angle of that: the needle can be viewed as it traverses the nodule. A perpendicular approach is also largely used due to its simplicity.

As above mentioned, US is accurate in identifying suspected recurrence of thyroid cancer in enlarged lymph nodes. Also in these cases, US-guided FNAC has been reported as highly accurate.

Finally, US is highly useful also for guidance of core needle biopsy (CNB). In the last decade, several papers described the use of CNB as a second-line approach to assess those thyroid nodules with prior indeterminate or inadequate FNAC report (Trimboli and Crescenzi, 2015). This biopsy has been included in AACE/AME/ETA guidelines (Gharib *et al.*, 2016). In **Fig. 7** is shown a US scan during thyroid FNAC.

The "Problem" of Small Non-palpable Thyroid Nodules

Thyroid micro-nodules (i.e. nodules with larger diameter below 1 cm) may be detected at US in up to 70% of adult European population and the large majority of these are detected during US of other neck structures (i.e., carotid, jugular veins, etc.) (Horvath *et al.*, 2009) Rarely, one micro-nodule harbors a cancer, and this is generally a well-differentiated papillary micro-carcinoma with indolent behavior. It is recognized that US has poor accuracy in lesions with size <1 cm, and the above mentioned US risk factors are difficult to assess due to the small size of the nodule. Also, FNAC may be not practicable, and cytologic sample often is unsatisfactory to achieve a diagnosis. Remarkably, there is no consensus in this context between international US systems (Haugen *et al.*, 2016; Gharib *et al.*, 2016; Horvath *et al.*, 2009; Perros *et al.*, 2014).

Table 2 Performance of US features in detecting thyroid cancer

Feature	*Accuracy*	*To be considered*
Echogenicity	Has high sensitivity: thyroid cancers are often solid and hypoechoic because of their high cells/colloid ratio	Some cancers (i.e., medullary carcinoma) may manifest as mixed or spongiform. Rarely, papillary cancer has a cystic presentation
Microcalcifications	Is the most specific feature	They may be detected in up to 20% of thyroid cancers. Macrocalcifications do not raise the risk for cancer
Hypoechoic halo	Is the most accurate feature to identify a benign nodule	Rarely, papillary cancers have a halo.
Shape	Nodules with taller than wide shape should be viewed as at higher risk	There is no a fixed cut-off to define a nodule taller than wide
Vascularization	A few cancers (up to 20%) have intranodular vascularization. The color Doppler evaluation may be performed during conventional US assessment	The enthusiastic studies of 1990s have not been confirmed. This feature has low accuracy
Elastography	Theoretically, thyroid cancer is hard. The elastographic examination may be useful to increase the sensitivity of conventional US	Different color scales and elastographic methods have been reported and future studies have to be performed before to routinely introduce thyroid elastography
Margins	Up to 30% of thyroid cancers appear with irregular, spiculated, or blurred borders	The identification of these feature requires expert US examiners

Table 3 Nodule's ultrasound features included in current classification systems

	ATA	*AACE/ACE/AME*	*BTA*	*TIRADS*
Echostructure	Yes	Yes	Yes	Yes
Echogenicity	Yes	Yes	Yes	Yes
Margins/halo	Yes	Yes	Yes	Yes
Shape	Yes	Yes	Yes	Yes
Calcifications	Yes	Yes	Yes	Yes
Vascularization	No	Yes	Yes	Yes
Elastography	No	Yes	No	No
Size cut-off to select for FNA	Yes	Yes	No	No
>1.0 cm	High or intermediate suspicion	high risk		
>1.5 cm	Low suspicion			
>2.0 cm	Very low suspicion	intermediate or low risk		

Cervical Ultrasonography in the Follow-Up of Thyroid Cancer

After initial treatment, i.e. surgery and iodine-131 ablation, differentiated thyroid carcinomas (DTC) recur in about 20%. In the vast majority of these cases the relapse of disease occurs in the neck, being frequently discovered in cervical lymph nodes and rarely in the thyroid bed (Haugen *et al.*, 2016; Gharib *et al.*, 2016). Then, US is essential to be performed routinely during the follow-up of these patients. In 2013 the European Thyroid Association (ETA) task force on US in thyroid cancer follow-up has assessed a sort of guidelines on this topic. There, sensitivity and specificity of several US signs were reported. Of very high utility for clinical practice, the authors described the rate of non-metastatic lymph nodes with specific US signs; as the most relevant annotation, microcalcifications and cystic changes are never recordable in normal nodes, while round shape, peripheral vascularization, and hyperechogenicity are rarely present in these nodes. Thus, these have to be taken into account as major risk factors (Leenhardt *et al.*, 2013).

In addition to the in-office work, US should be useful in the operating room during surgery; this intraoperative US examination can significantly improve the localization of metastases to be excised reducing the risk of further operations. In **Fig. 8** is illustrated a metastatic cervical lymph node detected at US.

Thyroid Scintigraphy

Radioactive iodine was first employed for the diagnosis and therapy of thyroid diseases in the 1950s and thyroid scintigraphy with either iodine or iodine-analogue isotopes remains the only method able to characterize autonomously

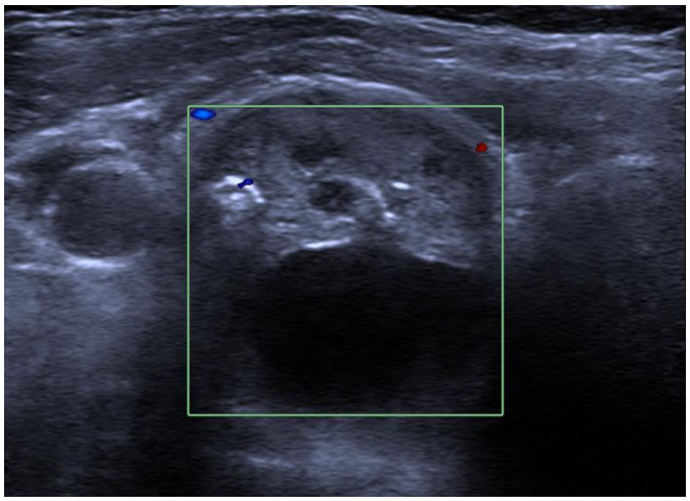

Fig. 4 A spongiform nodule with anechoic area of the right thyroid lobe: this lesion can be assessed as not suspicious for malignancy.

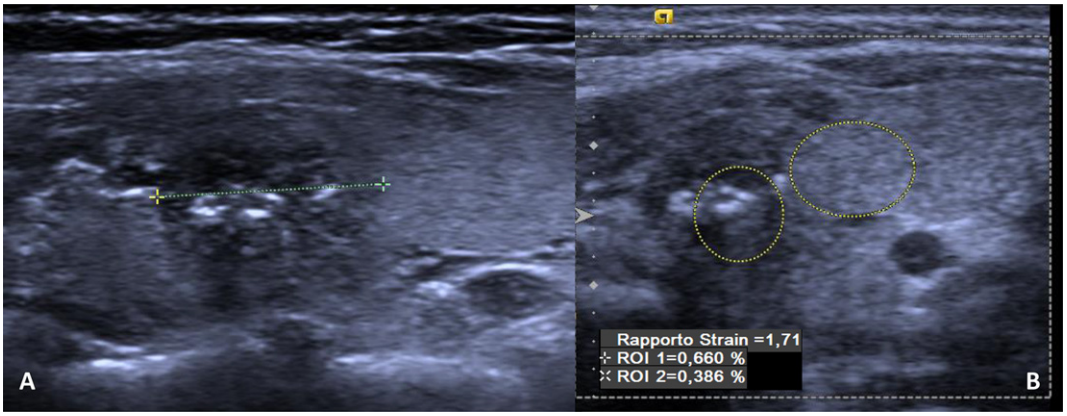

Fig. 5 Suspicious thyroid nodule at ultrasonography: the lesion is solid, hypoechoic, with microcalcifications and blurred margins (A); at elastography a high strain ratio between normal parenchyma and nodule is observed (B).

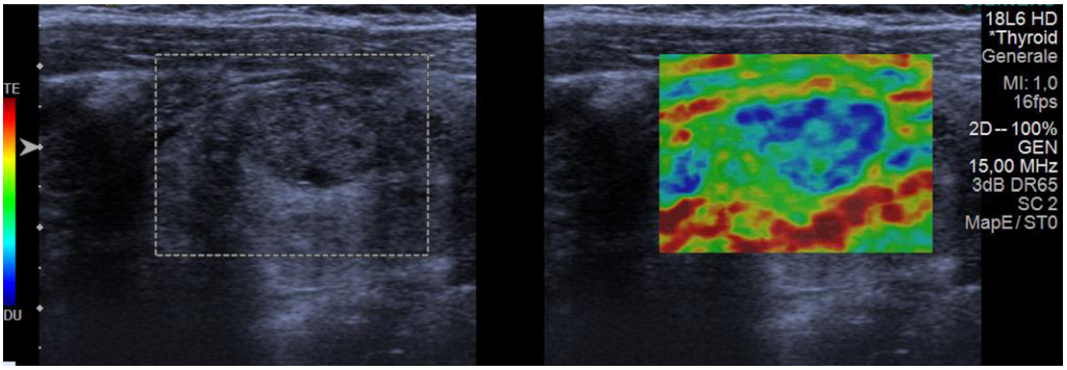

Fig. 6 Sonoelastography: the inelastic thyroid nodule appears as blue (hard) while the surrounding tissue is green (soft).

functioning nodules (Haugen *et al.*, 2016). Additionally, whole body scan (WBS) is pivotal in patients (to be) treated with radioiodine for DTC. Recently, tracers to evaluate the proliferation rate of the thyroid cells became also available. Finally, novel imaging technologies such as single-photon emission computed tomography (SPECT) and hybrid SPECT/computed tomography (SPECT/CT) consistently increased the quality of nuclear medicine images allowing sophisticated quantification procedures (Gharib *et al.*, 2016). Basically, thyroid scintigraphy may performed by using radiotracers describing the function of follicular cells and radiotracers mapping the proliferative activity of follicular cells, respectively.

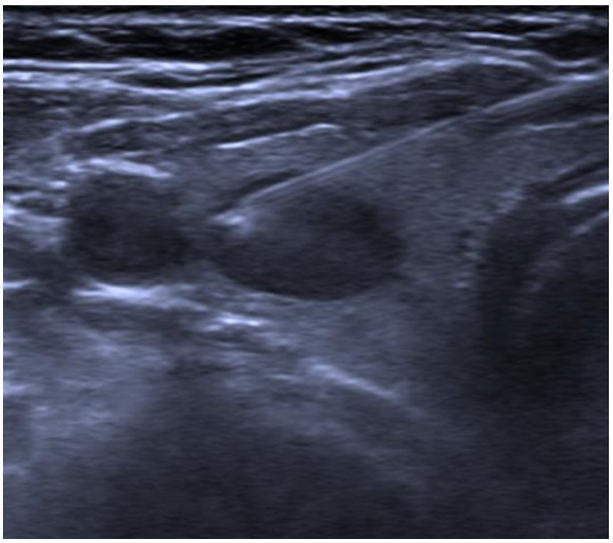

Fig. 7 Ultrasound-guided FNAC: the tip of the needle is placed inside the lesion assuring the optimal cytologic sampling.

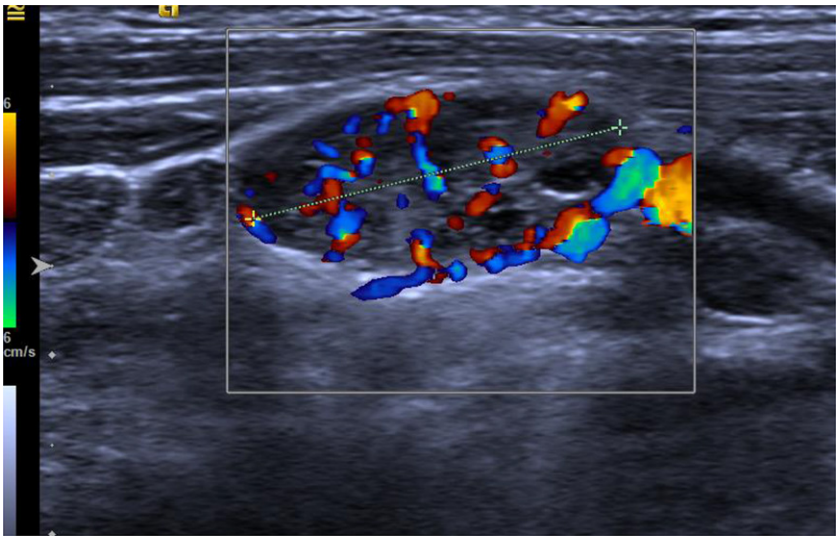

Fig. 8 Ultrasound presentation of a neck lymph node metastasis: the node is hypoechoic with cystic areas and increased and irregular vascular signal.

Tracers Mapping the Function of Follicular Thyroid Cells

Normal thyroid tissue is characterized by the unique capability of its follicular cells to trap and to process stable iodine (I) which is subsequently incorporated in thyroglobulin (Tg) in order to form thyroid hormones. The I uptake into the follicular cells is regulated by the sodium-iodide symporter (NIS), a transmembrane protein that carries sodium and iodine from the blood into the follicular cells (Dohán *et al.*, 2003). The NIS allows the thyroid trapping of different radioactive thyroid tracers. Iodine-123 (^{123}I) is an ideal thyroid radiopharmaceutical due to low radiation burden and optimal imaging quality, as opposed to the use of iodine-131 (^{131}I), which is strongly discouraged for routine diagnostic use (excepted thyroid cancer management) because of its much higher radiation burden to the thyroid. The thyroid uptake of a different tracer, ^{99m}Tc-pertechnetate, is also related to NIS expression. Importantly, it is not a substrate for any metabolic pathways and a complete washout from thyroid cells occurs in about 30 min. However, although the thyroid does not organify ^{99m}Tc-pertechnetate, in the majority of cases the uptake and imaging data provide all the information needed for accurate diagnosis (Giovanella *et al.*, 2014). ^{99m}Tc-pertechnetate has a shorter half-life and a preferred energy for scintigraphic imaging compared to ^{123}I. Additionally, it is cheaper and readily available in nuclear medicine departments. As a consequence, it has generally been adopted as the primarily used thyroid tracer in clinical practice (Meller and Becker, 2002).

Tracers Mapping the Proliferation of Follicular Thyroid Cells

The ^{99m}Tc-MIBI is a lipophilic cation that crosses the cell membrane and penetrates reversibly into the cytoplasm via thermodynamic driving forces and then irreversibly passes the mitochondrial membrane using a different electrical gradient regulated by a high negative inner membrane potential (Heston and Wahl, 2010). The cancer cells, with their greater metabolic turnover, are characterized by a higher electrical gradient of mitochondrial membrane, thus determining an increased accumulation of ^{99m}Tc-MIBI compared to normal cells. The characteristics of various nuclides used for the visualization of the thyroid gland are shown in **Table 4**.

Instrumentations and Methodology

Thyroid scans are obtained by a gamma-camera equipped with a parallel-hole collimator. Sometimes dedicated "pin-hole" collimators are employed to increase focal resolution but a significant geometric distortion should be taken into account in this case. Planar images, acquired in the anterior view for some minutes, provide a reliable map of thyroid function and metabolism. Whole-body scans are obtained by double-head gamma camera to obtain simultaneously anterior and posterior images covering the entire body. Additional SPECT and SPECT/CT images may be very useful in case of intra-thoracic goiter, ectopic thyroid tissue and thyroid cancer metastases. **Table 4**.

In addition to qualitative evaluation of thyroid maps, tracer uptake can be measured by semi-quantitative indexes (i.e. TcTU: ^{99m}Tc-pertechnetate thyroid uptake, RAIU: Radioactive Iodine Uptake). Remarkably, the uptake of these tracers is strictly related to the stable I in plasma and any overload of I [due to dietary intake (i.e. kelp), drugs (i.e. amiodarone), or iodinated radiological contrast media] causes a competitive interference with the radioactive tracer uptake by the NIS (Reinhardt *et al.*, 1998). In addition, medication such as thyroid hormones and anti-thyroid drugs affect the pituitary-thyroid axis and, thereby, the tracer uptake by the thyroid gland. Therefore, a thorough medical history should be obtained prior to administration of the radiopharmaceutical, and interfering drugs should be discontinued for an appropriate period of time (i.e. T3: 2 weeks, T4: 4 weeks, anti-thyroid drugs: 3–7 days) and, if necessary, the investigation should be delayed correspondingly.

Clinical Applications of Thyroid Scintigraphy

Thyroid Imaging with ^{99m}Tc-Pertechnetate and ^{123}I-Iodide

Thyroid scintigraphy, with both ^{99m}Tc-pertechnetate and ^{123}I, reflects the metabolic rate of thyroid cells and are mainly employed to distinguish different causes of hyperthyroidsm and to assess the functional activity of thyroid nodules. In addition it is also performed to detect and locate ectopic thyroid tissue (including the differential diagnosis of congenital hyperthyroidism).

Hyperthyroidism

The etiology of hyperthyroidism should be determined in order to correctly address the treatment. Thyroid uptake measurements are indicated when the diagnosis is in question (except during pregnancy and usually during lactation) and distinguishes causes of hyperthyroidism having elevated uptake over the thyroid gland (i.e. true hyperfunction) from those with near-absent uptake (i.e. thyrotoxicosis due to destructive thyroiditis or exogenous interferences) (**Fig. 9**). Radioactive iodine uptake (RAIU) test was traditionally indicated in such cases, especially by US thyroidologist; however it may be easily substituted by ^{99m}Tc-pertechnetate scan that is immediately available in any nuclear medicine laboratory, cheap and fast (i.e. a diagnosis is obtained in 15–20 min). Notably, a ^{99m}Tc-pertechnetate or ^{123}I-iodide scan, mapping the distribution of thyroid activity, should be always obtained when the clinical presentation suggests nodular Graves' disease, thyroid autonomy or multinodular toxic goiter.

Assessment of the functional activity of thyroid nodules

Thyroid autonomy appears as one (unifocal autonomy) or more (multifocal autonomy) hyperactive areas (i.e. hot nodules) while the tracer uptake is variably reduced in normal, TSH-dependent, thyroid tissue (**Fig. 10**). A timely diagnosis of thyroid autonomy

Table 4 Thyroid scintigraphy: tracers and procedures

	$^{99m}TcO_4$-	^{123}I	^{131}I	^{99m}Tc-MIBI
Administration	i.v.	o.a.	o.a.	i.v.
Activity (adults)	74–111 MBq	7.4–14.8 MBq	74–200 MBq	185–370 MBq
Technique	Planar (ev SPET or SPET/CT)	Planar (ev SPET or SPET/CT)	Planar whole body (ev SPET or SPET/CT)	Planar (ev SPET or SPET/CT)

allows early treatment avoiding progression toward manifest hyperthyroidism (Meller and Becker, 2002; Giovanella et al., 2016a, b). Of even higher importance, autonomous nodules extremely rarely harbor malignancy and current clinical guidelines suggest refraining from FNA of hyperactive nodules (Haugen *et al.*, 2016; Perros *et al.*, 2014). Importantly, although almost all thyroid cancers are nonfunctioning (i.e. cold nodules), the majority of these nodules are benign (i.e. 90–95%) which greatly reduces the specificity of a thyroid scan. Accordingly, a thyroid scan is generally performed when nodules occur in patients with low or low-normal TSH levels. However, the relationship between thyroid autonomy and TSH levels is affected by the degree of iodine sufficiency and varies widely regionally (Treglia and Giovanella, 2015; Treglia *et al.*, 2015). In summary, while autonomous nodules are almost invariably accompanied by decreased TSH levels (i.e. <0.1–0.4 mUI/L) when iodine supply is adequate, the bulk of autonomous tissue may be insufficient to suppress the TSH level in iodine-depleted thyroids, especially in the early phases of autonomy. As a consequence, different indications are given in current clinical guidelines (Haugen *et al.*, 2016; Gharib *et al.*, 2016; Paschke *et al.*, 2010; **Table 5**).

Independently from the iodine status and the TSH levels, a thyroid scan is also recommended in patients with a large multinodular goiter in order to select suspicious nodules for fine needle aspiration and/or to identify a benign compensated functioning adenoma. Thyroid scintigraphy may also help when evaluating nodules with indeterminate cytology readings (i.e. follicular proliferation) as diagnostic surgery can be safely omitted when hot nodules are demonstrated. As in very rare cases the appearance of a thyroid nodule may be discordant on radioiodine and pertechnetate scans due to iodide organification defects in the nodule that results in a rapid washout of radioiodine (i.e. so-called "trapping only nodule"), ^{123}I is recommended (Giovanella, 2009).

Table 5 Indications for ^{99m}Tc-pertechnetate and ^{123}I thyroid scintigraphy in different clinical guidelines

ATA (United States)	*AACE/AME/ETA (US and Europe)*	*DGN/DGE (Germany)*
Nodules >10–15 mm and subnormal TSH	Nodules and TSH level below the lower limit of reference range *Iodine-deficient regions*: consider performing scintigraphy to exclude autonomy for thyroid nodules even if TSH is normal.	Thyroid nodules >10 mm

Congenital hypothyroidism and ectopic thyroid tissue

^{99m}Tc-pertechnetate scan remains the most accurate test for the detection of ectopic thyroid tissue (Noussios *et al.*, 2011; **Fig. 11**). Despite new molecular genetic insight into congenital hypothyroidism the ^{123}I or, preferably, ^{99m}Tc-pertechnetate scan remains the most accurate test for the detection of ectopic thyroid tissue and the differential diagnosis between thyroid dysgenesis (60–70% of cases), athyreosis (10–30% of cases) and inherited disorders of thyroid metabolism (10–20% of cases) (Meller and Becker, 2002). In particular, thyroid scan is the highly accurate for the detection and location of thyroid dysgenesia while neck ultrasound miss the correct diagnosis in about 50% of cases (De Bruyn *et al.*, 1990; **Fig. 12**).

Thyroid Imaging with ^{99m}Tc-MIBI

^{99m}Tc-MIBI uptake within the nodule reflects its abundance of actively functioning mitochondria and therefore its oxidative burden. ^{99m}Tc-MIBI scan has been used by several authors to investigate thyroid nodules, in order to differentiate between benign and malignant nodules. This can be based on the intensity of uptake of ^{99m}Tc-MIBI within the nodule and/or by assessing an eventual increase in uptake within the nodule over time, in comparison with radiotracer wash-out from normal thyroid tissue (Theissen *et al.*, 2009). A meta-analysis (Treglia et al., 2013a, 2013b, 2013c), including twenty-one studies, demonstrated that ^{99m}Tc-MIBI scan is a sensitive diagnostic tool in predicting malignancy of thyroid nodules in which malignancy is suspected on the basis of conventional diagnostic techniques. Of note, only hypofunctioning thyroid nodules (i.e. "cold" nodules) should be evaluated by ^{99m}Tc-MIBI scan. In fact, an increased metabolic rate in hyperfunctioning thyroid nodules (i.e. "hot" nodules) is responsible for the higher ^{99m}Tc-MIBI uptake within autonomously functioning thyroid tissue. In this setting, as a second-line investigation, ^{99m}Tc-MIBI scan was found to be significantly more accurate than mutation analysis (i.e. mutations for *KRAS*, *HRAS* and *NRAS* and for *BRAF* and translocations of PAX8/PPARγ, RET/PTC1 and RET/PTC3) in patients with a cytological diagnosis of follicular neoplasm (Saggiorato *et al.*, 2009; Giovanella et al., 2016a, 2016b; Campennì *et al.*, 2016; **Figs. 13** and **14**). Therefore, combined FNA/^{99m}Tc-MIBI scan strategies are potentially cost-effective in the management of solitary or dominant thyroid nodules leading to a lower rate of unnecessary thyroidectomies (Verburg *et al.*, 2014; Wale *et al.*, 2014). Then, in patients with a thyroid nodule cytologically diagnosed as a follicular proliferation, semiquantitative analysis of ^{99m}Tc-MIBI scintigraphy should be the considered for differentiating benign from malignant nodules.

Whole Body Imaging with $^{131/123}$I-Iodide

Post-treatment whole body scan

For many years, postoperative management of thyroid cancer patients included radioiodine administration, followed by a post-therapy whole body scan (PT-WBS) obtained 2–10 days after radioiodine administration (1.1–7.4 GBq) (Luster *et al.*, 2008; Haugen *et al.*, 2016). The PT-WBS is highly accurate to show the degree of radioiodine uptake, determine the extension of the disease, identify situation at risk (requiring additional actions) and predict prognosis. Currently, SPECT/CT is added to conventional WBS: the synergistic combination of functional and anatomic information has been found to have many advantages over traditional planar imaging in different clinical settings (Avram, 2012). Advantages of SPECT/CT include accurate anatomic localization of radioiodine uptake foci and clear discrimination between normal thyroid remnant and neck lymph node metastases (**Fig. 15**). Due to CT-based attenuation correction, SPECT/CT can reveal more foci of pathologic activity as compared to planar studies, solve difficult diagnostic interpretations and reveal metastatic lesions to unexpected sites or tissues. The size and iodine avidity of metastatic lesions can be assessed on the CT and SPECT components, respectively, providing information about the likelihood of response to ^{131}I therapy properly addressing clinical decisions on alternative therapeutic options (i.e. surgical excision or external-beam radiation therapy for large lesions or targeted drugs for diffuse non–iodine-avid metastatic disease) (Chen *et al.*, 2008; **Fig. 16**). Finally, when a physiologic mimic of disease is suspected on planar images, SPECT/CT clarifies their interpretation, thereby avoiding false-positive diagnoses (Kohlfuerst *et al.*, 2009; Glazer *et al.*, 2013).Therefore, performing a PT-WBS is recommended in all patients receiving radioiodine ablation after surgery (Luster *et al.*, 2008; Haugen *et al.*, 2016). However, the current American Thyroid Association (ATA) Practice Guidelines for Thyroid Cancer Management, published in 2016 emphasize postoperative management according to stage and risk stratification based on clinical-pathologic criteria to assess the prognosis for an individual patient, decide on the use of ^{131}I therapy, decide the frequency and intensity of follow-up (Haugen *et al.*, 2016). Consequently, staging with PT-WBS cannot be performed when ^{131}I therapy is omitted with the potential to underestimate the recurrence risk in non-ablated patients.

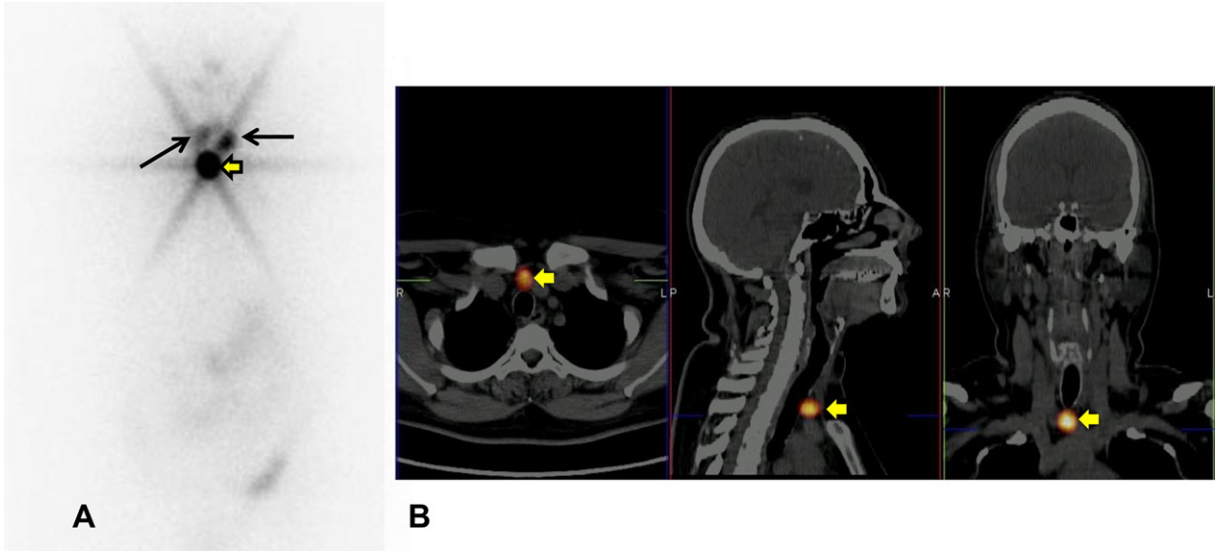

Fig. 15 Post-ablation ^{131}I WBS (A) and SPECT/CT (B) in a young female affected by papillary thyroid carcinoma (pT2 Nx) showing remnant tissue within the thyroid bed (arrows) and a central neck lymph-node metastases (yellow arrow head).

Diagnostic whole body scan (post-surgery)

When ^{131}I therapy is omitted (*see the previous paragraph*) valuable information on disease status, remnant uptake, and the presence of residual radioiodine-avid disease may be obtained by performing a diagnostic radioiodine WBS (DxWBS). This test could alter management and potentially benefit outcome as it provides the opportunity of identifying patients with unsuspected regional and distant metastases. Particularly, DxWBS can detect metastases in normal-sized cervical lymph nodes (frequently not visible on neck ultrasonography), pulmonary micrometastases (that may remain undetected on X-ray and CT scans), and bone metastases before cortical disruption is visible on bone radiographs (Avram et al., 2013, 2015). Questions regarding the potentially negative impact of DxWBS with ^{131}I on radioiodine therapeutic efficacy for successful remnant ablation (i.e. "stunning") may be mitigated or avoided by the use of either low-activity ^{131}I (74–111 MBq) or alternative isotopes such as ^{123}I (7.4–14 MBq) (Yap and Murby, 2014; Barwick *et al.*, 2010; **Fig. 17**).

The role of diagnostic whole body scan in follow-up of DTC patients

Measuring serum Tg and performing a diagnostic whole body scan (DxWBS) was for a long time the standard for follow-up of patients with DTC. More recently, however, the role of DxWBS was questioned as many studies demonstrated that PT-WBS with additional SPECT/CT is superior in terms of diagnostic accuracy to DxWBS. Accordingly, the DxWBS usually is no longer necessary in low and intermediate risk patients with negative PT-WBS scan, if complete response to therapy is achieved (Pirich and Schweighofer-Zwink, 2017). In contrast, the DxWBS may have a role in the follow-up of patients with high or intermediate risk of persistent disease especially in patients with abnormal uptake outside the thyroid bed on PT-WBS or poorly informative PT-WBS due to extensive thyroid remnants, and patients with circulating anti-Tg antibodies and associated risk of false-negative Tg measurements (Haugen *et al.*, 2016).

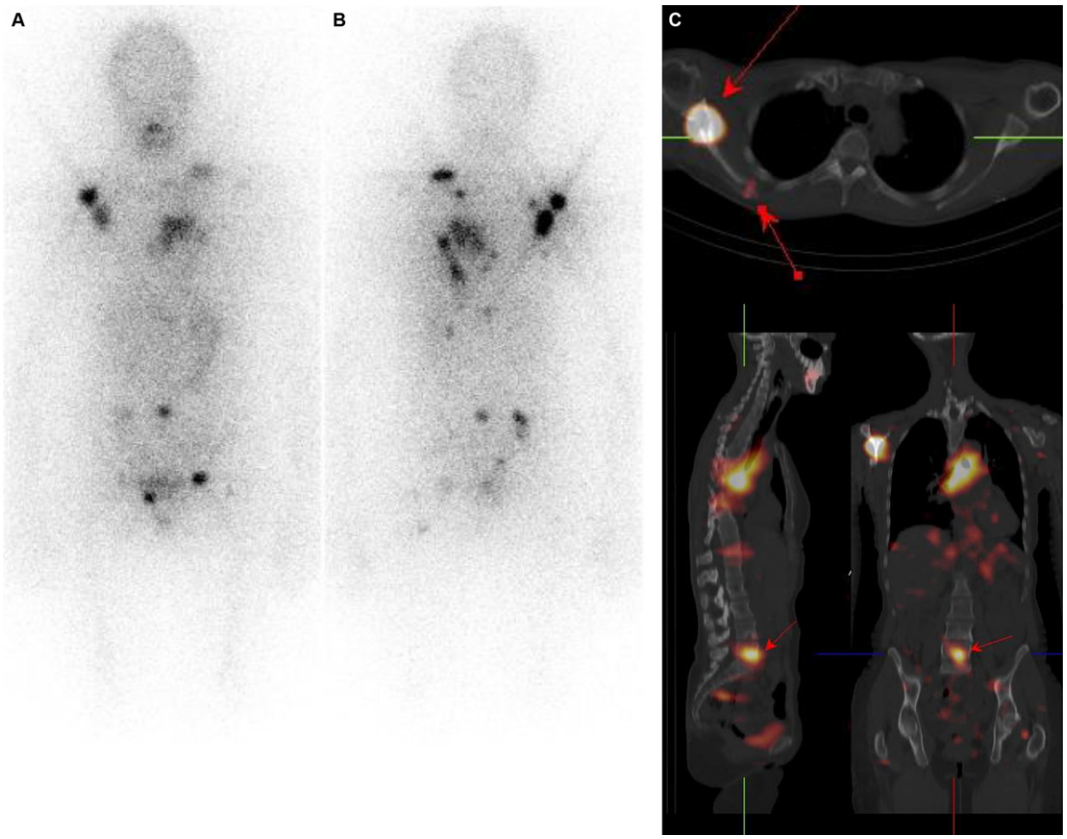

Fig. 16 Post-therapy ^{131}I WBS (A, anterior; B, posterior views) and SPECT/CT (C) in a 50 years old female affected by papillary thyroid carcinoma (pT2 N1b) showing multiple visceral and skeletal radioiodine-avid metastases.

Computed Tomography and Magnetic Resonance Imaging

Because of its high iodine content, the thyroid gland attenuates more than nearby soft tissues, appearing slightly hyperdense at CT imaging. If possible, CT should be performed without contrast media in patients with thyroid disorders and when a scintigraphy for thyroid disease is planned because the iodine load received may delay treatment with radioiodine and may also lead to thyrotoxicosis (i.e. Jod-Basedow). The normal thyroid gland has homogeneous MRI signal intensity slightly greater than neck musculature in T1-weighted images. Normal thyroid glands appear as hyperintense in T2-weighted images. Thyroid carcinomas are isointense or slightly hypointense lesions on T1-weighted images and hyperintense lesions on T2-weighted images compared with normal thyroid tissue (Hoanga *et al.*, 2013). Overall, computed tomography (CT) and magnetic resonance imaging (MRI) is not as sensitive as ultrasonography for the evaluation of intrathyroid lesions (i.e. nodules) (Loevner *et al.*, 2008). Consequently, the role of CT in thyroid disorders is mainly limited to presurgical evaluation to assess the extent of the disease, substernal components, or relationship with extrathyroidal structures, i.e., the trachea, esophagus, or vascular structures by both benign (i.e. substernal multinodular goiter) and malignant thyroid tumors (**Fig. 18**; Loevner *et al.*, 2008).

Furthermore CT/MRI scans are also be used to evaluate extrathyroidal manifestations of thyroid disorders (i.e. Graves' orbitopathy). Thyroid nodal metastases commonly occur in the central compartment (level VI) and the lateral nodal groups (levels II-IV). While US is highly sensitive in evaluating lateral neck compartments, its accuracy greatly decrease in central compartment and retropharyngeal and retroesophageal lymph node groups cannot be assessed. The presence of superior mediastinal nodes may preclude surgery for curative intent so CT or MRI may be indicated if there are predictors of mediastinal disease such as lateral nodes or large and/or invasive primary tumor. Indeed, cross-sectional imaging is pivotal if local invasion is suspected with a similar accuracy for MRI and CT in predicting local invasion of the esophagus, trachea/larynx and recurrent laryngeal nerve, the prevertebral space posteriorly and the mediastinum inferiorly (Hoanga *et al.*, 2013). The main sign for tracheal and esophageal invasion on both MRI and CT is a mass contacting the circumference of these organs. Other findings suggesting tracheal invasion are deformity of the lumen, focal mucosal irregularity or thickening, and intraluminal mass. The esophageal wall is more difficult to evaluate than the trachea because it is usually not distended with air (**Fig. 19**).

On MRI, the most suspicious finding for esophageal invasion is a focal T2 signal in the outer layer of the esophageal wall. On CT, the radiologist should look for loss of the normal esophageal wall and lumen. Invasion of the RLN can be predicted on MRI and CT by effaced fatty tissue in the tracheoesophageal groove where the nerve courses. Other imaging features of RLN invasion are signs of vocal cord dysfunction and 25% or more of the circumference of the primary tumor abutting the capsule at the posterior

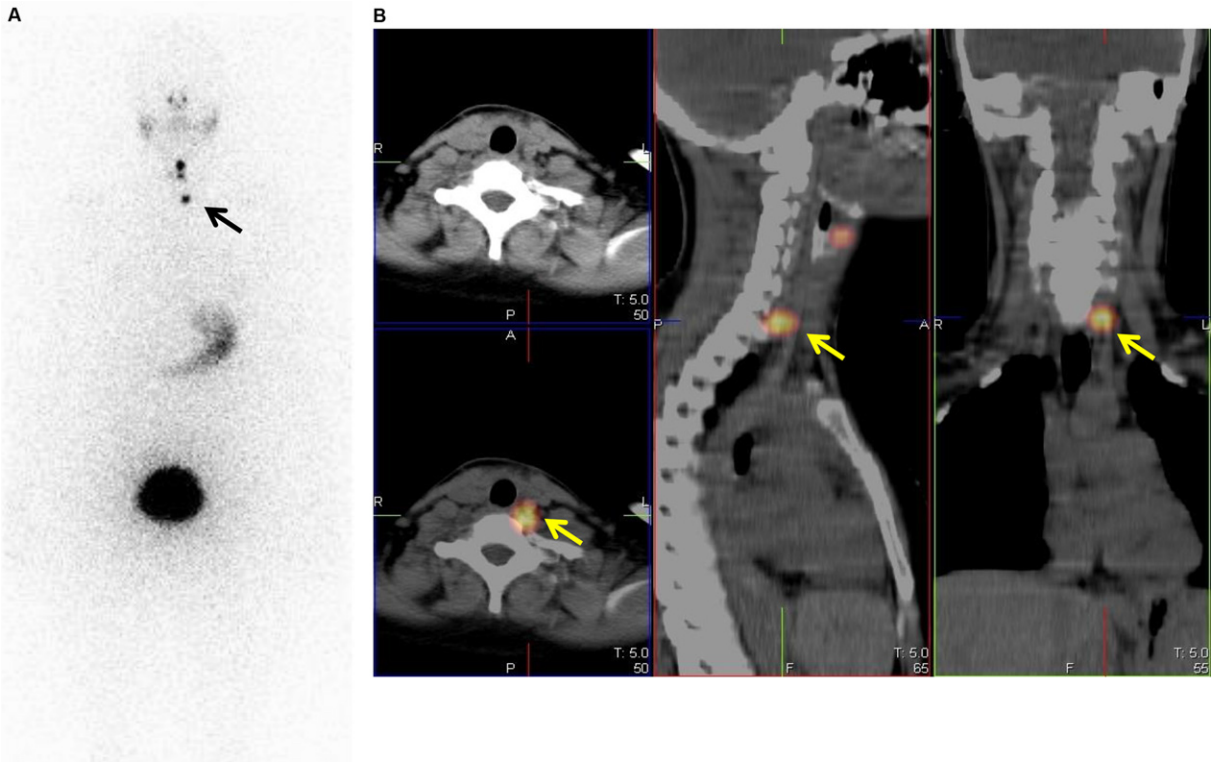

Fig. 17 Post-surgery ^{123}I WBS (A, anterior view) and SPECT/CT (B) in a 34 years old female affected by papillary thyroid carcinoma (p1b Nx) showing residual thyroglossal duct and a radioiodine-avid lymph node metastases (arrow).

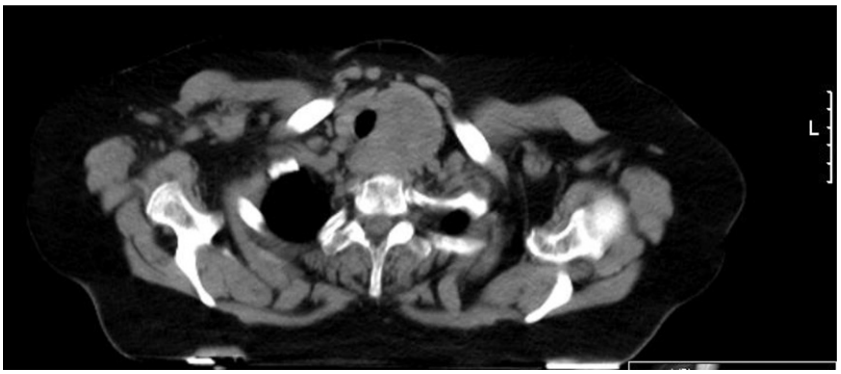

Fig. 18 Large goiter, mainly affecting the left thyroid lobe, with lateral deviation and compression of the trachea.

portion of the thyroid (sign of posterior extracapsular invasion) (Seo *et al.*, 2010). Finally, that more accurate findings for arterial involvement on CT/MRI were arterial compression/deformation or fat/fascial plane deletion. In general, these invasive findings preclude the patient from curative surgery and treatment regimen may be changed to a palliative approach (Hoanga *et al.*, 2013). After primary treatment CT/MRI can be readily performed for assessment of thyroid recurrence, even if it is not dedifferentiated or retropharyngeal nodal groups involvement is suspected (Kaplan *et al.*, 2009; **Fig. 20**).

Currently, however, ^{18}F-fluorodeoxyglucose (^{18}F-FDG) positron emission tomography/computed tomography (PET/CT) is generally performed in these case providing more accurate combined metabolic and morphologic data (*see the paragraph below*).

Positron Emission Tomography (PET)

PET is an established diagnostic imaging method in oncology. PET/CT is a hybrid technique which combines morphological information obtained by CT with functional data provided by PET. In the last years PET/MRI has emerged as another useful hybrid imaging technique in oncology (Treglia and Sadeghi, 2014).

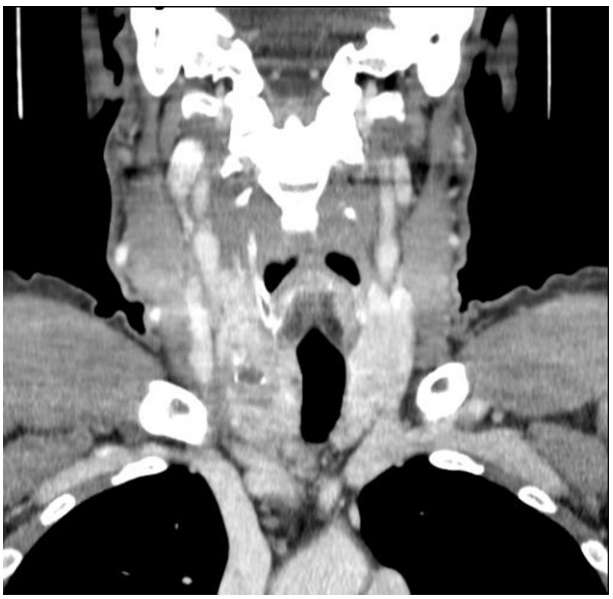

Fig. 19 Poorly differentiated thyroid carcinoma diffusely involving the thyroid gland: inhomogeneous contrast-enhancement, especially within the right thyroid lobe (also containing macrocalcifications). Mediastinal dislocation of the lower portions of the thyroid gland with mild tracheal deviation.

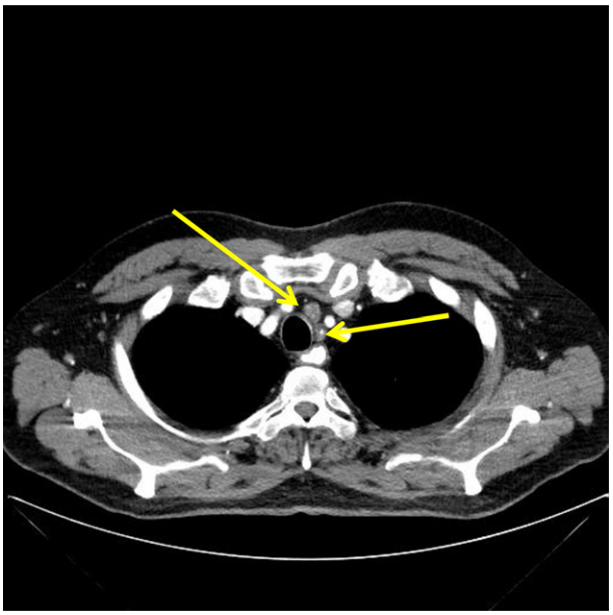

Fig. 20 Differentiated thyroid carcinoma: left paratracheal lymph node metastases (arrows) containing microcalcifications.

Table 6 The most used PET radiopharmaceuticals for thyroid tumors

Radiopharmaceutical	*Function evaluated*	*Thyroid tumors evaluated*
Fluorine-18-fluorodeoxyglucose (^{18}F-FDG)	Glucose metabolism	More aggressive thyroid tumors
Iodine-124 (^{124}I)	Iodine metabolism	Well differentiated thyroid tumors
Fluorine-18-dihydroxyphenylalanine (^{18}F-DOPA)	Amino acid uptake, decarboxylation and storage	Medullary thyroid carcinoma
Somatostatin analogues labeled with Gallium-68 (^{68}Ga-SSA)	Somatostatin receptor expression	Medullary thyroid carcinoma

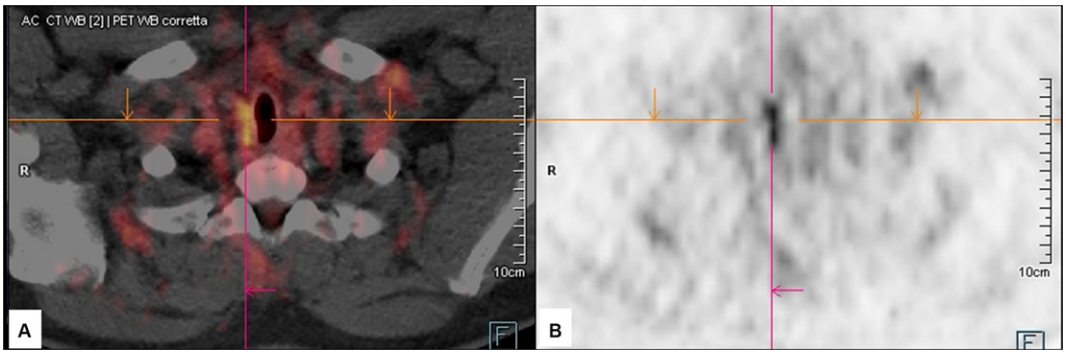

Fig. 21 Axial ^{18}F-FDG PET/CT (A) and PET (B) images in a differentiated thyroid carcinoma patient with increasing serum thyroglobulin levels after thyroidectomy and negative radioiodine whole-body scan. PET/CT showed an area of increased radiopharmaceutical uptake corresponding to a tissue located in the right thyroid bed and corresponding to DTC relapse.

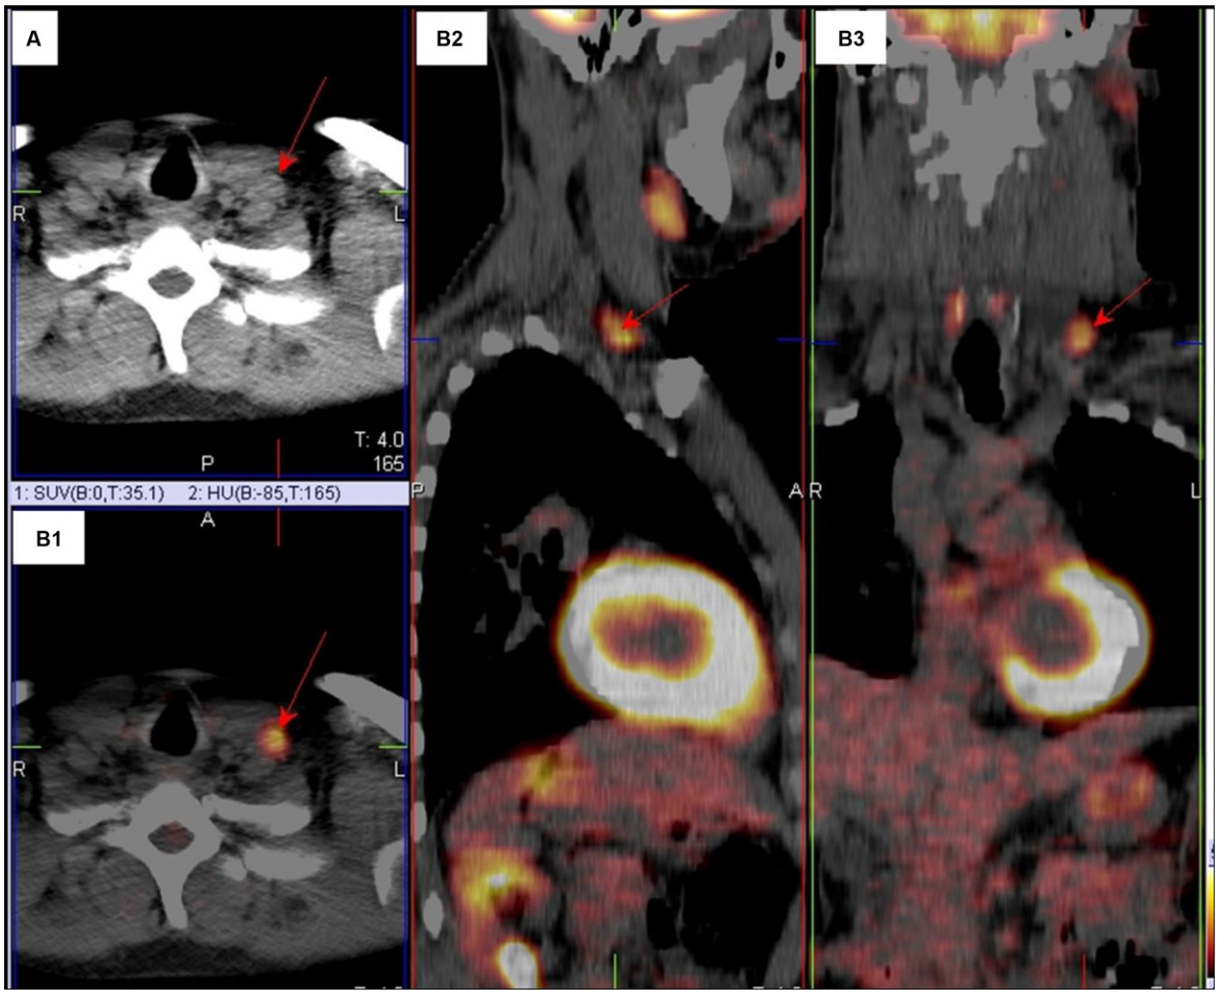

Fig. 22 Axial CT (A) and ^{18}F-FDG PET/CT images in axial (B1), sagittal (B2) and coronal (B3) projection in a differentiated thyroid carcinoma patient with increasing serum thyroglobulin levels after thyroidectomy and negative radioiodine whole-body scan. PET/CT showed an area of focal increased radiopharmaceutical uptake corresponding to a left laterocervical lymph node (arrow) suspicious for tumor relapse (diagnosis confirmed by surgery).

^{18}F-FDG is the most frequently used PET radiopharmaceutical for oncological diseases, including thyroid tumors. This glucose analogue is trapped by tumor cells via the glucose transporters (GLUTs) which are overexpressed in aggressive tumors; in addition, overexpression of hexokinase-1 promotes ^{18}F-FDG uptake in cancer cells (Giovanella *et al.*, 2013). Beyond ^{18}F-FDG, other PET radiopharmaceuticals evaluating different metabolic pathways are available to evaluate thyroid tumors (**Table 6**).

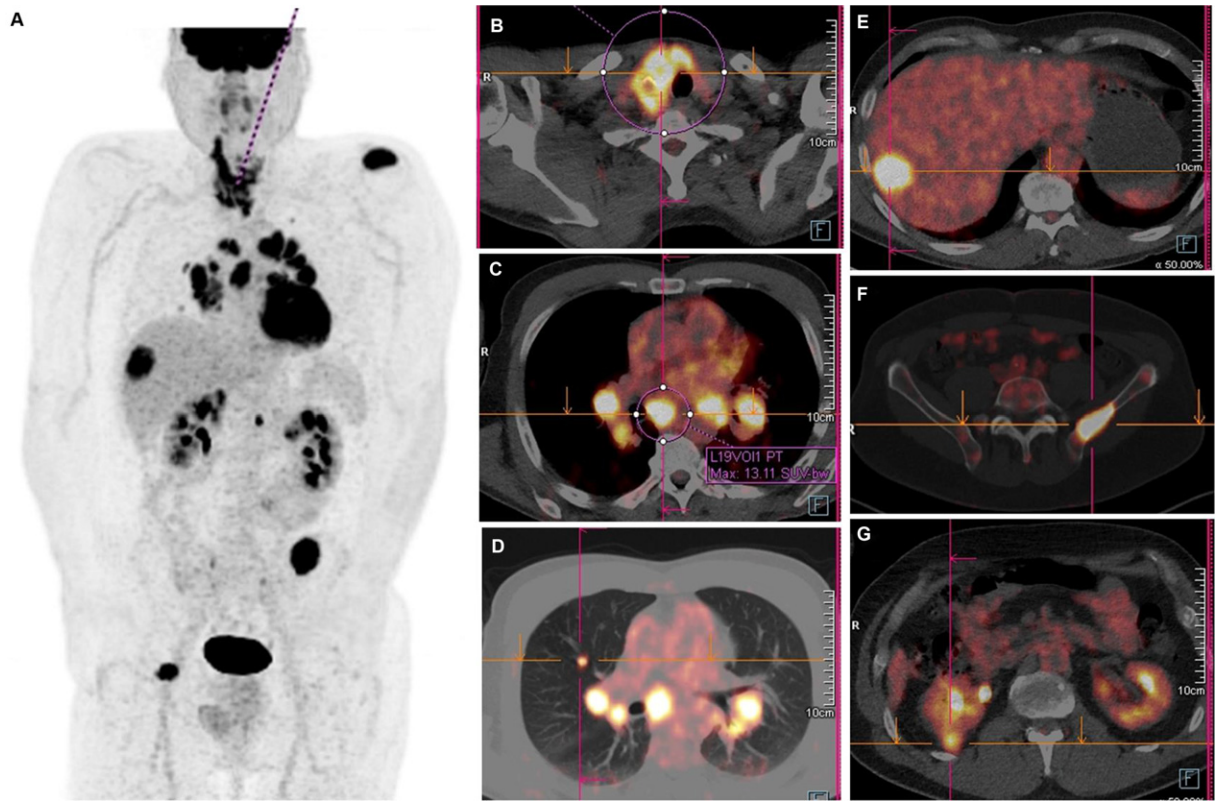

Fig. 23 ^{18}F-FDG PET maximum intensity projection image (A) and axial ^{18}F-FDG PET/CT images (B-G) in a patient with poorly differentiated thyroid carcinoma showing increasing radiopharmaceutical uptake in the thyroid (B) corresponding to the primary tumor site. Furthermore multiple lymph nodal (C), lung (D), liver (E), bone (F) and renal (G) metastases were detected by ^{18}F-FDG PET/CT.

Iodine-124 (^{124}I) has been used to evaluate the iodine metabolism in DTC. Fluorine-18-dihydroxyphenylalanine (^{18}F-DOPA), which assesses the amino acid uptake, decarboxylation and storage, and somatostatin analogues labeled with Gallium-68 (^{68}Ga-SSA), which evaluate the somatostatin receptor status, are PET radiopharmaceuticals useful for diagnosis of recurrent medullary thyroid carcinoma (MTC) (Treglia et al., 2013a, 2013b, 2013c).

During the last decades PET/CT and PET/MRI using different radiopharmaceuticals have been increasingly used in patients with thyroid tumors. Furthermore the usefulness of ^{18}F-FDG PET in assessing indeterminate thyroid nodules at fine needle aspiration biopsy (FNAB) and the clinical relevance of thyroid incidental ^{18}F-FDG uptake at PET imaging have been evaluated (Treglia et al., 2013a, 2013b, 2013c).

Role of PET in DTC

DTC cells expressing the sodium'iodine symporter take up radioiodine. In a small percentage of DTC the tumor cells are less differentiated and the radioiodine uptake capacity is reduced; these cells multiply more rapidly, their glucose metabolism is increased and consequently their ability to take up ^{18}F-FDG is higher (Giovanella *et al.*, 2013).

According to international guidelines routine preoperative ^{18}F-FDG PET is not recommended in the majority of DTC patients. In fact the sensitivity of ^{18}F-FDG PET for the detection of cervical lymph node metastases in the pre-operative setting is relatively low (30%–40%) in DTC. ^{18}F-FDG PET can also detect inflammatory lymph nodes, which reduces the specificity of this imaging method in many patients with DTC (Haugen *et al.*, 2016). Invasive DTC has been reported to occur in 10%–15% of patients at the time of diagnosis. In this group of DTC ^{18}F-FDG PET may be sensitive in some patients for neck or mediastinal involvement and may reveal distant metastases as well (Haugen *et al.*, 2016).

Currently, the most valuable role of ^{18}F-FDG PET in the work-up of DTC is in the post-operative setting, in particular in high-risk DTC patients with increasing serum Tg levels and a negative DxWBS (**Figs. 21** and **22**; Haugen *et al.*, 2016). If no disease sites are identified on conventional imaging or DxWBS or serum Tg levels are elevated out of proportion to minor disease found on conventional imaging, ^{18}F-FDG PET should be performed to detect recurrent or metastatic disease (Treglia et al., 2013a, 2013b, 2013c). In this setting ^{18}F-FDG PET/CT showed a good diagnostic accuracy with pooled sensitivity and specificity of 83% and 84%, respectively. Factors influencing ^{18}F-FDG PET/CT sensitivity included tumor dedifferentiation, larger tumor burden, and TSH stimulation (Haugen *et al.*, 2016). In patients with a TSH-stimulated serum Tg < 10 ng/mL, the sensitivity of ^{18}F-FDG PET is lower. Nevertheless it should be taken into account that in case of aggressive pathological variant of thyroid cancer low amounts of serum Tg

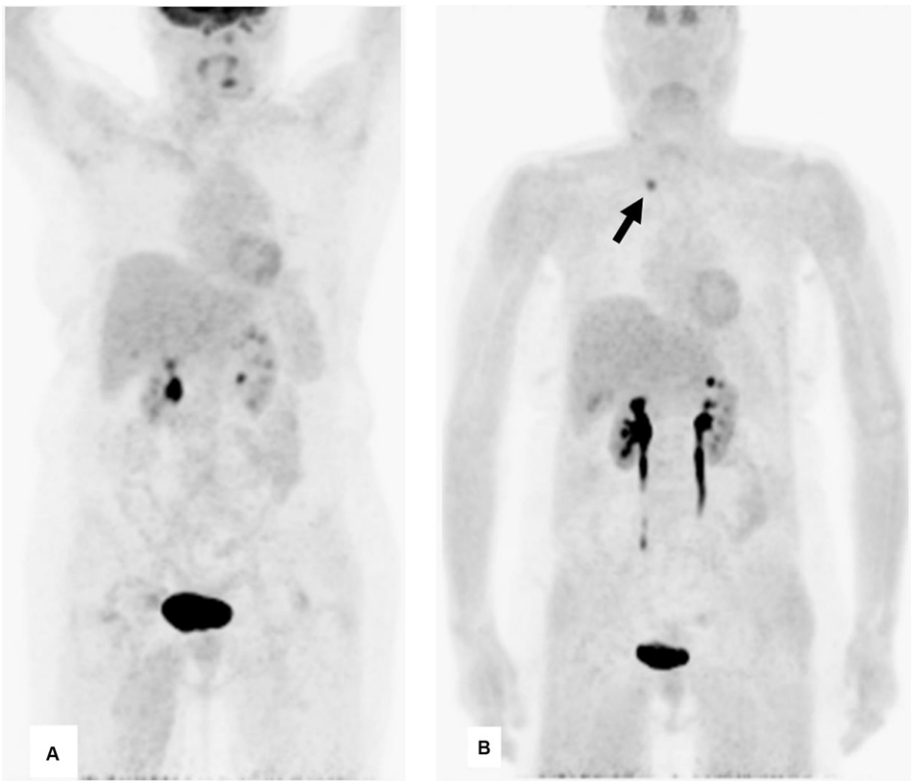

Fig. 24 ^{18}F-FDG PET (A) and ^{18}F-DOPA PET (B) maximum intensity projection images in a patient with recurrent medullary thyroid carcinoma based on increased serum calcitonin levels. ^{18}F-FDG PET was negative whereas ^{18}F-DOPA PET showed an area of increased radiopharmaceutical uptake corresponding to a right laterocervical lymph node (arrow) suspicious for tumor relapse (diagnosis confirmed by surgery).

can be produced. Furthermore, in patients with undetectable serum Tg levels but with persistent Tg antibodies the level of serum Tg cannot be reliably assessed and ^{18}F-FDG PET may localize disease in some of these patients (Haugen *et al.*, 2016). Lastly the accuracy of ^{18}F-FDG PET significantly improves when the Tg doubling time is less than 1 year, independently of the absolute serum Tg value (Giovanella *et al.*, 2013). When indicated ^{18}F-FDG PET findings might alter the indications for ^{131}I treatment or the decision for surgical removal of small tumor foci with ^{18}F-FDG uptake in some DTC patients (Haugen *et al.*, 2016).

^{18}F-FDG PET may be also useful in DTC as prognostic tool in patients with metastatic disease to identify lesions and patients at highest risk for rapid disease progression and disease-specific mortality (Treglia and Giovanella, 2015; Treglia *et al.*, 2015) and in the evaluation of post-treatment response following systemic or local therapy of metastatic or locally invasive disease (Haugen *et al.*, 2016).

About ^{124}I PET, it is used as a dosimetric and also as a diagnostic tool to localize recurrent disease in DTC (Haugen *et al.*, 2016). ^{124}I PET provides images of higher spatial resolution and lesion contrast than either planar or tomographic imaging with ^{131}I, although the impact of this improved lesion detection compared to ^{131}I imaging in DTC remains to be proven. The combination of ^{18}F-FDG and ^{124}I PET allows detection of non'iodine-avid lesions and discrimination from simultaneously occurring iodine-positive lesions, thus improving restaging in recurrent DTC. The pre-treatment dosimetry by using ^{124}I-PET may result in a significant alteration in the therapeutic procedure compared to standard therapy with fixed activities of ^{131}I (Treglia et al., 2013a, 2013b, 2013c).

Role of PET in Aggressive Histological Subtypes of Thyroid Cancer

Aggressive histological subtypes of thyroid cancer are rare and have a poor prognosis. The most important aggressive subtypes of thyroid cancer are Hürthle cell carcinoma, anaplastic and poorly differentiated thyroid carcinomas. Aggressive histological subtypes of thyroid cancer show aggressive clinical behavior with high glucose metabolism and intense ^{18}F-FDG uptake at PET. In these patients ^{18}F-FDG PET may be indicated for staging and for prognostic purposes and, in selected cases, for evaluating the efficacy of therapy (**Fig. 23**; Treglia et al., 2013a, 2013b, 2013c).

Role of PET in MTC

PET imaging with different radiopharmaceuticals is not recommended for routine initial screening of patients with a FNAB and/or serum calcitonin levels suggestive for MTC, but it may have a role in the post-operative setting in detecting recurrent MTC based on increased serum calcitonin levels. In fact, MTC recurrences are often difficult to detect using conventional morphological imaging

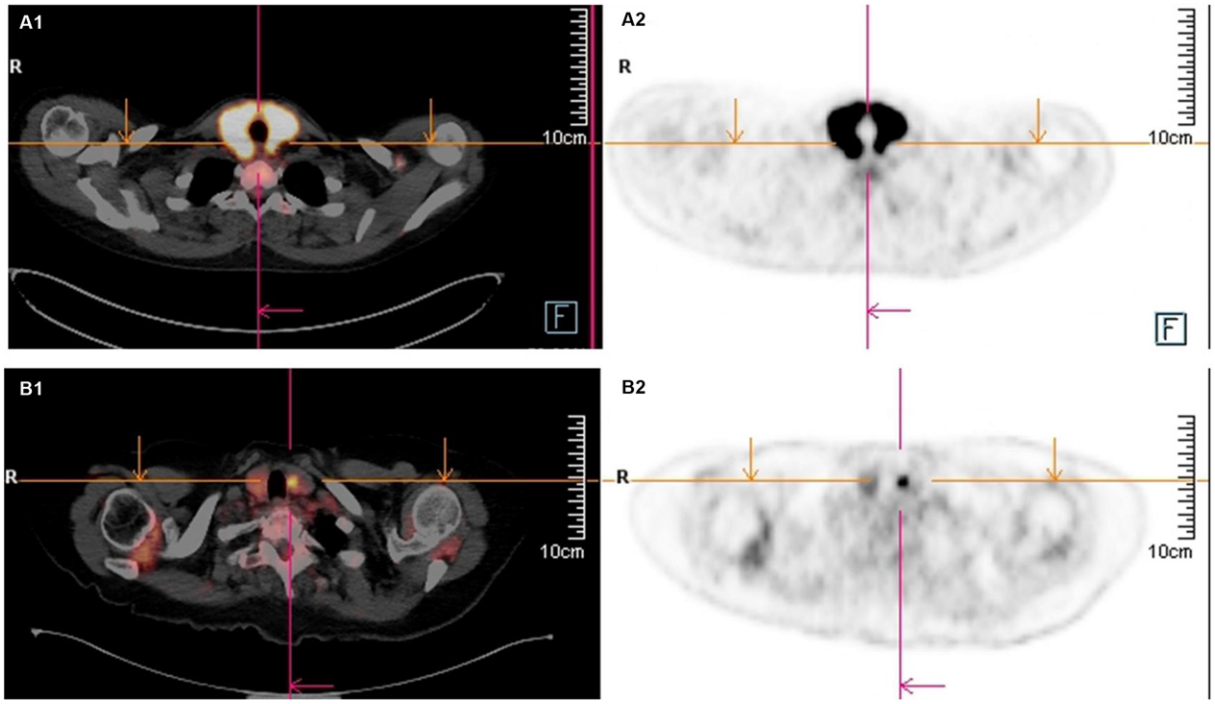

Fig. 25 Axial ^{18}F-FDG PET/CT (A1, B1) and PET (A2, B2) images showing diffuse (A1, A2) and focal (B1, B2) patterns of incidental ^{18}F-FDG uptake in the thyroid gland in two oncological patients evaluated by ^{18}F-FDG PET/CT for non-thyroid tumors.

and traditional scintigraphic methods (Treglia *et al.*, 2016). ^{18}F-FDG PET could be very helpful in detecting MTC recurrences in those patients in whom a more aggressive disease is suspected. To date, ^{18}F-DOPA seems to be the most useful PET radiopharmaceutical in detecting recurrent MTC based on rising levels of calcitonin (**Fig. 24**). ^{68}Ga-SSA PET may be useful to select patients who could benefit from therapy with radiolabeled somatostatin analogues. Anyway, the different PET radiopharmaceuticals reflecting different metabolic pathways seem to show a complementary role in detecting recurrent MTC (Slavikova *et al.*, 2013).

Role of ^{18}F-FDG PET in Thyroid Nodules with Indeterminate FNAB and Significance of Thyroid Incidental ^{18}F-FDG Uptake

According to international guidelines ^{18}F-FDG PET is not routinely recommended for the evaluation of thyroid nodules with indeterminate cytology. False-negative findings of ^{18}F-FDG PET in this setting is low; conversely, a positive ^{18}F-FDG-PET result does not identify cancer because approximately 50% of these patients had benign nodules (Haugen *et al.*, 2016).

Sometimes ^{18}F-FDG PET reveal thyroid incidental uptake (TIU) of the radiopharmaceutical which may have a focal or a diffuse pattern (**Fig. 25**). Diffuse TIU at ^{18}F-FDG PET can be considered at low risk of malignancy, being more likely associated with thyroiditis or diffuse thyroid autonomy. Conversely, focal TIU at ^{18}F-FDG PET may represent both benign and malignant lesions with a risk of malignancy of about 35%. Therefore, a complete work-up including laboratory examinations, ultrasonography and FNAB should usually be obtained to exclude malignant lesions in focal TIU detected by ^{18}F-FDG PET (Bertagna *et al.*, 2012).

Thyroid Fine Needle Aspiration Cytology☆

Ivana Kholová, Tampere University, Tampere, Finland
Camilla Schalin-Jäntti, Endocrinology, Helsinki University and Helsinki University Hospital, Helsinki, Finland

Introduction

The fine needle aspiration (FNA) biopsy of the thyroid gland was developed at Karolinska Hospital in Stockholm, Sweden in the 1950s. A preliminary report by Söderström was published in Acta Medica Scandinavica in 1952. Thyroid nodule FNA cytology has since been recognized as the most accurate way of diagnosing thyroid cancer. However, thyroid nodules are a common clinical problem and FNA is not indicated for all thyroid nodules. The prevalence of palpable thyroid nodules in iodine-sufficient areas is estimated to 5% in women and 1% in men. When thyroid ultrasound is performed in randomly selected persons, nodules are found in as many as 19%–68%. The frequency is highest in women and the elderly. The aim should be to identify clinically relevant cancers in persons who would benefit from intervention, while avoiding excessive diagnostic procedures in persons who would not benefit from it. All patients must undergo careful clinical examination. Clinical signs and symptoms of hypo- or hyperthyroidism should be registered, as well as possible patient reports of rapid growth of the thyroid/nodule, as well as family history of thyroid disease. Palpation of the thyroid should include an estimate of the size of the thyroid, prevalence of multiple or a single nodules as well as their consistence. Serum TSH should be measured. Patients with nodules or goiter causing compression symptoms in the neck should be referred for surgery. Neck ultrasound in combination with FNA, when adequate, should be performed preoperatively. FNA should not be performed if the patient anyway is unlikely to be referred for surgery because of comorbidities and advanced age. In general, small, nonpalpable (<1 cm), incidentally found nodules can often be followed up conservatively while larger nodules (>1 cm) and those with suspicious sonographic features should undergo FNA. The Bethesda system for reporting thyroid cytopathology (TBSRTC) should be used for reporting the FNA findings.

FNA Techniques

A wide variety of needles of varying diameters and lengths are available for FNA use with 27- to 22-gauge needles used for thyroid FNA. The Zajdela technique using a bare needle without syringe or a variety of syringe holders for suction technique are used (Table 1). Cellular material is obtained by the cutting action of the trailing edge of the needle and is retained in the needle core by forward motion and capillary tension.

Most patients only experience complications similar to those of a blood draw as bleeding, bruising and local pain during the procedure. Occasionally hematoma appears after FNA of vascular lesions. Severe complications are rare.

According to the local practice, samples can be triaged for various stainings and ancillary techniques. Air dried direct smears are stained by May-Grunwald-Giemsa of Diff-Quick stains. Polychrome Papanicolaou stain requires wet fixed smears. The material can also be fixed by 95% ethyl alcohol and cytocentrifuged on slides. Liquid-based preparations concentrate cells into monolayer removing obscuring blood. Interpretation requires a learning curve.

Cell block refers to the processing of sediment, blood clots, or grossly visible pieces of tissue from cytologic specimens that are processed into paraffin block and stained by hematoxylin-eosin. Cell blocks can be prepared by various techniques, such as plasma-thrombin, agar or histogel techniques.

The Bethesda System for Reporting Thyroid Cytopathology (TBSRTC)

TBSRTC was introduced to thyroid gland FNA diagnostics in 2007 and it has become the most widely used reporting system for thyroid cytopathology in the world. Use of the TBSRTC terminology has been endorsed by the revised 2015 ATA guidelines and 2016 AACE/ACE/AME guidelines. In addition, national endocrine and cytopathology societies all around the world recommend TBSRTC in daily practice. A second edition of TBSRTC is currently being prepared and will be available by 2018.

Introduction

TBSRTC diagnostic categories are shown in Table 2. Each category has an implied risk of malignancy and evidence-based clinical management guidelines. For some of the general categories, subcategorization is recommended.

☆Change History: February 2018. Camilla Schalin-Jantti updated the text in the chapter.

This article replaces the one by Armando Bartolazzi, Thyroid Fine Needle Aspiration Cytology, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 430-441.

Table 1 FNA techniques

Technique	*Zajdela/French technique*	*Swedish technique*
Description	Without suction, nonaspiration, capillary method	With suction
Pros	Less blood dilution	Quantitatively more material
	More concentrated specimen	Possible to drain cystic lesion
	Needle easy to conceal	
	Better fine motor control	
Cons	Quantitatively less material	More blood dilution
	Impossible to drain cystic lesion	Less concentrated specimen
		Syringe holder hard to conceal
		Worse fine motor control

Table 2 The Bethesda system for reporting thyroid cytopathology

Diagnostic category	*Risk of malignancy*	*Management*
Nondiagnostic/unsatisfactory	N.D.	Repeat FNA
Benign	0–3	Clinical follow-up
Atypia of undetermined Significance/Follicular Lesion of Undetermined Significance (AUS/FLUS)	5–15	Repeat FNA
Follicular neoplasm	15–30	Surgical lobectomy
Suspicious for malignancy	60–75	Total thyroidectomy or lobectomy
Malignant	97–99	Total thyroidectomy

N.D. not determined.

Nondiagnostic/Unsatisfactory

TBSRTC introduced criteria for adequacy as other terminology systems also did. Unsatisfactory smears contain less than six groups of follicular cells with fewer than 10 cells per group. Not preserved or poorly preserved and obscured follicular cells also belong to this category. Approximately 5%–20% of thyroid FNAs are nondiagnostic. Inflammation rich specimen are an exception to the adequacy rule: thyroid FNA with abundant inflammatory cells only can be placed in the benign category. The nondiagnostic rate can be reduced by ultrasound-guided FNA, rapid on site evaluation (ROSE) and use of liquid-based preparations. Thyroid cysts can lead to false positive and false negative results. In TBSRTC, cysts aspirates lacking follicular cells belong to the nondiagnostic category (**Fig. 1**).

Benign

A benign result is the most common thyroid FNA interpretation: 60%–70% of thyroid FNAs belong to the benign category. This category is associated with a very low risk of malignancy. Benign category results are further sub-classified as benign follicular nodules, thyroiditis, or other less common entities such as acute infection-related inflammation, amyloid goiter, and minocycline-related changes.

Benign follicular nodule

All follicular lesions are a mixture of micro- and macrofollicles. The predominant pattern should be focused. Benign follicular nodule specimen are composed of predominantly macrofollicles, honeycomb clusters and sheets and colloid. Degenerative background with macrophages and hemosiderin and oncocytic metaplasia may occur (**Figs. 2** and **3**). Benign FNAs originates from multinodular goiter, adenomatous nodule or macrofollicular follicular adenoma. Micro:macrofollicular lesions (50:50) are diagnostic pitfalls. The reason is mixed nature of the lesion or contamination by normal thyroid macrofollicles.

Thyroiditis

Chronic lymphocytic thyroiditis (Hashimoto thyroiditis) is the most common form of thyroiditis. The cytologic features include cytoplasm-rich oncocytic cells with possible atypia. On background lymphocytes/plasma cells are revealed. There may be germinal center fragments. Colloid is usually scant or absent (**Fig. 4**).

Subacute (de Quervain) thyroiditis cytologic features include granulomatous inflammation with multinucleated giant cells and lymphoid cells.

Riedel thyroiditis aspirates are hypocellular or acellular due to dense fibrosis. There may be mixed inflammation with myofibroblasts and fragments of fibrosis.

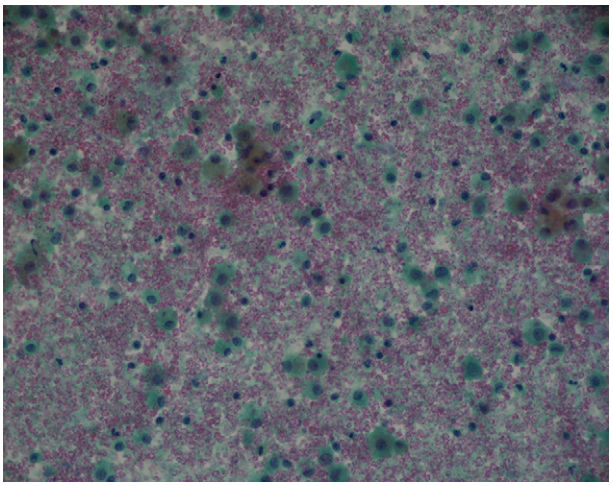

Fig. 1 Numerous macrophages and siderophages in bloody background. Cyst material only is diagnosed in TBSRTC as nondiagnostic sample. Papanicolaou stained cytospin, 400 × magnification.

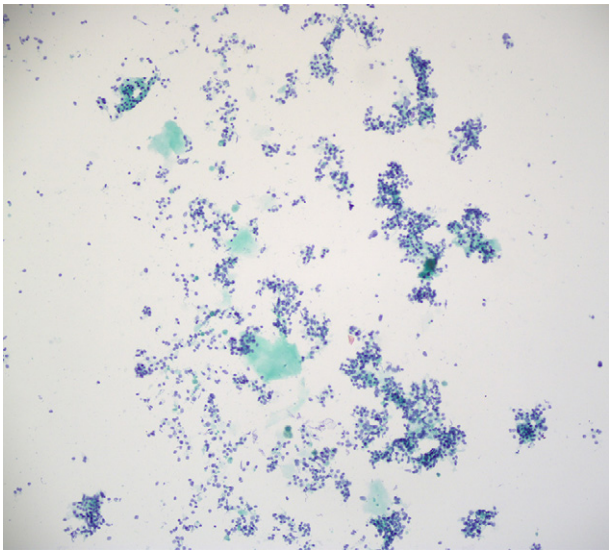

Fig. 2 Thyroid follicular cells with monotonous nuclei in variously sized groups and fragments in goiter. Notice focal oncocytic metaplasia. Colloid detected on background. TBSRTC benign category. Papanicolaou stained cytospin, 100 × magnification.

Atypia of Undetermined Significance/Follicular Lesion of Undetermined Significance (AUS/FLUS)

AUS/FLUS category is a heterogeneous and partially controversial group. Generally, samples contain architectural or nuclear atypia that is more than would be expected in benign lesions but that falls short of being suspicious for follicular neoplasm or malignancy. A specimen is often compromised by low cellularity or from artifacts such as blood contamination or air-drying.

Different scenarios for AUS/FLUS can be divided into three main categories: nuclear atypia, architectural atypia and compromised specimen. The most common different scenarios are listed in Table 3.

The risk of malignancy for AUS/FLUS in the original Bethesda system is estimated to be 5%–15%, however, the results in resected cases were reported to be on average 34%, with 6%–97% range. The reason behind this is the heterogeneity of the AUS/FLUS category. Unfortunately, not all AUS/FLUS cases are submitted to histopathological examination and a 100% cyto-histopathological correlation is rare. In the majority of the studies, less than half of AUS/FLUS cases are histopathologically verified.

Recommended management after AUS/FLUS is repeated FNA. Two AUS/FLUS result in lobectomy. Molecular markers are recommended in AUS/FLUS category in 2nd TBSRTC edition.

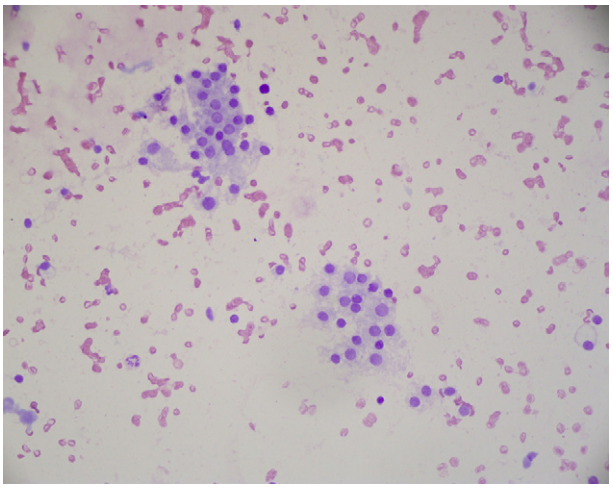

Fig. 3 Benign follicular cells in two groups in goiter. TBSRTC benign category. May-Grunwald-Giemsa stained imprint, 400 × magnification.

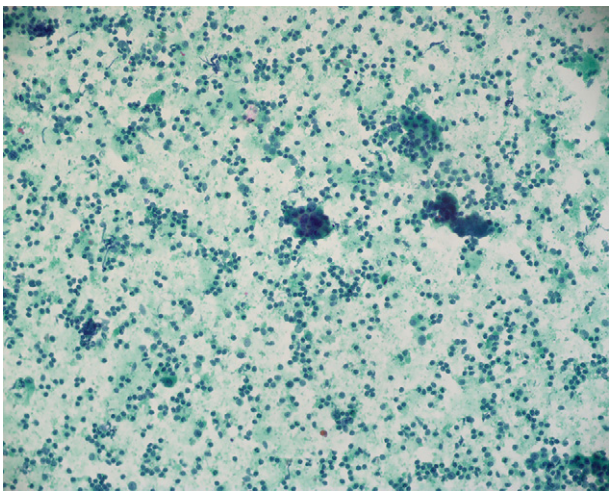

Fig. 4 Rich lymphocytes/plasma cells inflammatory background with sparse follicular oncocytic cells in lymphocytic thyroiditis. TBSRTC benign category. Papanicolaou stained cytospin, 200 × magnification.

Follicular Neoplasm/Suspicious for Follicular Neoplasm

It is not possible to distinguish between follicular adenoma and follicular carcinoma based upon cytologic material. Cytologically, cellular aspirate consists of follicular cells arranged in microfollicular or, rarely, trabecular pattern. Cells are uniform in size, significantly crowded. Nuclei are round and mildly hyperchromatic (Fig. 5). If the aspirate is composed almost entirely of oncocytes (Hürthle cells), the nodule represents oncocytic variant of follicular neoplasm and this fact should be reported.

The recommended management is surgical lobectomy. Cytology–histology correlation usually reveals cellular adenomatous nodule, follicular adenoma, follicular carcinoma, and follicular variant of papillary carcinoma.

Suspicious for Malignancy

The majority of primary thyroid malignancies have distinctive cytologic features and are easily diagnosed by FNA. The aim of separating the suspicious category from the malignant category is to preserve the very high positive predictive value of the malignant category without compromising the overall thyroid FNA sensitivity.

A suspicious for malignancy interpretation is rendered when some of the diagnostic features are either absent or equivocal. The diagnosis is an indication for surgery. Perioperative frozen section is recommended.

Table 3 Most common AUS/FLUS scenarios

Prominent microfollicular architecture
Predominance of oncocytes and oncocytes only
Nuclear features suggestive of papillary carcinoma
Focally enlarged nuclei
Atypical cyst-lining cells
Atypical lymphoid infiltrate
Clotting and air-drying artifacts

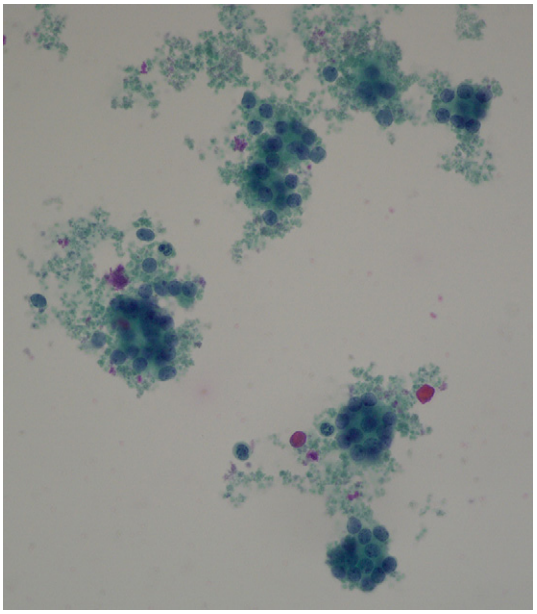

Fig. 5 Follicular cells arranged in microfollicle in follicular proliferation. TBSRTC follicular neoplasm category. Papanicolaou stained cytospin, 400 × magnification.

Malignant

A malignant thyroid FNA diagnosis accounts for 4%–8% of all thyroid FNAs and the majority of them represent papillary carcinoma. The recommended management is total thyroidectomy.

Papillary carcinoma

Papillary carcinoma is the most common endocrine malignancy with excellent prognosis for the majority of its variants. Smears are usually very cellular. Follicular cells are arranged in groups, syncytial sheets, papillary fragments and fronds. Follicular cells are cuboidal, columnar, polygonal, flattened or hobnailed. Cells are larger than normal follicular cells with increased nuclear: cytoplasmic ratio. Large usually oval or elongated nuclei have irregular membrane and are overlapping. Intranuclear pseudoinclusions, nuclear grooves and prominent nucleoli are present (Figs. 6 and 7).

Poorly differentiated carcinoma

Prognosis is intermediate between well- and undifferentiated thyroid carcinomas. Definite diagnosis requires histologic examination. Aspirates are highly cellular with monotonous, small to intermediate-sized cells containing bland nuclei. Cells in microfollicles are arranged in nests ("insulae"), trabecular, solid clusters, and as single discohesive cells. Colloid is scant, necrosis and mitoses are common.

Anaplastic (undifferentiated) carcinoma

Anaplastic carcinoma is an aggressive malignancy with rapidly progressive disease course. Isolated cells in highly cellular aspirates have marked nuclear polymorphism, prominent nucleoli and abundant cytoplasm. Dirty background contains necrotic debris, inflammatory cells and scant to absent colloid. Mitoses and apoptotic bodies are common (Fig. 8).

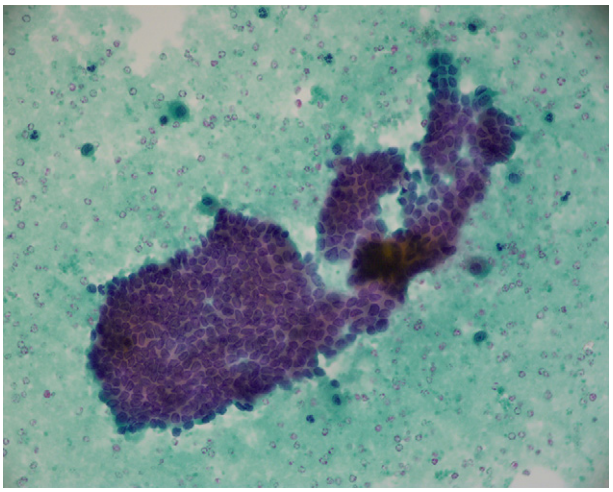

Fig. 6 Papillary fragment with enlarged cells with overlapped nuclei with irregular membrane. Notice cystic background in papillary carcinoma. TBSRTC malignant category. Papanicolaou stained cytospin, 400 × magnification.

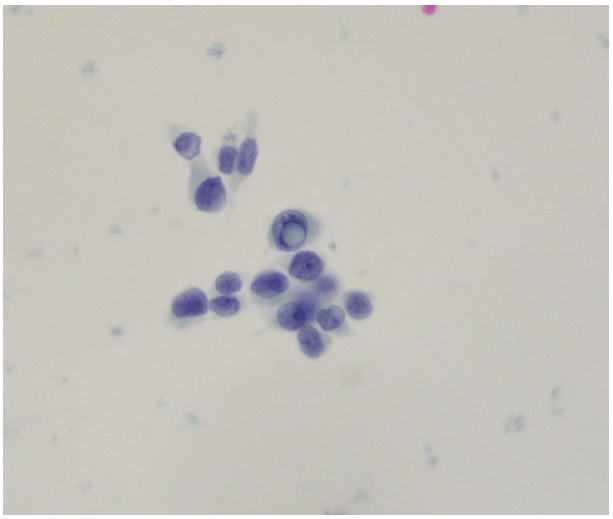

Fig. 7 Nuclear pseudoinclusion in papillary carcinoma. TBSRTC malignant category. Papanicolaou stained cytospin, 400 × magnification.

Medullary carcinoma

Medullary thyroid carcinoma arises from C-cells and comprises 5%–10% of all thyroid malignancies. Hypercellular aspirates contain loosely cohesive to noncohesive cells. In addition to single cells, small clusters are papillary-, trabecular-, microfollicular-, or syncytially patterned. Variably sized and shaped cells are spindle, polygonal, oncocytic, or bipolar with common binucleated and multinucleated cells. Amyloid can be detected on background, colloid is absent. Differential diagnosis regards other tumors, such as anaplastic carcinoma and oncocytic neoplasms may be difficult based on cytology only. However, positivity for calcitonin and other neuroendocrine markers is diagnostic. Increased serum calcitonin and CEA concentrations are hallmarks of medullary thyroid carcinoma.

Lymphoma

Malignant lymphomas can arise in the thyroid gland as primary malignancies or involvement can be part of systemic disease. The most common type is diffuse large B-cell lymphoma (60%–80%). Lymphoma is almost always associated with lymphocytic thyroiditis. Hypercellular aspirates contain monotypic lymphoid cells in noncohesive sheets of single cells. Nuclear chromatin is relatively fine. Background karyorrhexis is often extensive.

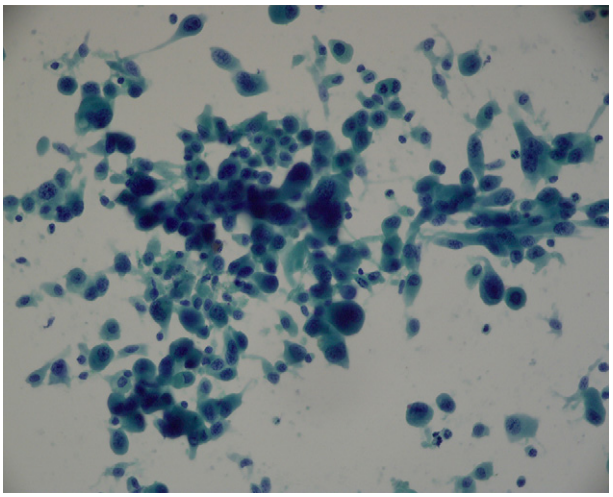

Fig. 8 Atypical cells with abundant cytoplasm with enlarged pleomorphic nuclei with prominent nucleoli in anaplastic carcinoma. TBSRTC malignant category. Papanicolaou stained cytospin, 400 × magnification.

Secondary tumors

Tumors secondarily involving the thyroid gland are metastases from distant organs or direct extension of tumors from adjacent organs. The thyroid gland is a vascular organ and therefore predisposed to metastases. The incidence varies in surgical versus autopsy study series. The incidence depends on the incidence of the underlying tumor. The involvement can form three different patterns: (1) solitary large nodules, (2) multiple small discrete nodules and, (3) diffuse involvement. The cytologic picture depends on the primary malignancy. Aspirates are cellular with two distinct cell populations. Background necrosis and mitotic figures are common. Immunocytochemistry and clinical history are of great importance.

Indeterminate Categories

The term is used for three categories: AUS/FLUS, Follicular Neoplasm and Suspicious for Malignancy. The indeterminate thyroid FNA comprises 15%–30% of all thyroid FNAs and continues to present a challenge for clinical management.

Non-Invasive Follicular Thyroid Neoplasm With Papillary-Like Nuclear Features (NIFTP)

The recently described new thyroid gland low-risk neoplasm redefines a group of follicular encapsulated or well demarcated tumors, with predominant follicular growth pattern without vascular or capsular invasion, tumor necrosis and high mitotic activity. This subset of tumors was before classified as follicular variant of papillary carcinoma. The new entity should be managed as follicular adenomas, that is, lobectomy is indicated. Cytologically, NIFTP is follicular-patterned. Nuclei are enlarged, pallor, grooved and overlapped. Pseudoinclusions are rare. Papillae and psammoma bodies are absent. As a consequence, risk of malignancy in several TBSRTC categories has changed. It has modified the cytologic criteria for classifying follicular-patterned FNAs. An optional note about possible NIFTP on selected cases is warranted.

Immunohistochemistry

Most of the thyroid lesions are relatively easy to interpret on FNA. Immunocytochemistry is the method to detect tissue antigens by utilizing specific antibodies and visualize antigen-antibody reaction by microscopically visible chromogen. Immunocytochemistry can be performed on cytological cell blocks or on cytological smears as well as on liquid-based specimens.

In thyroid FNA, immunocytochemistry can be used to differentiate follicular-derived cells from C-cells. Parathyroid lesions can be also distinguished from follicular lesions by immunocytochemistry. Poorly differentiated, anaplastic and secondary carcinoma can be distinguished from malignant lymphoma by specific antibodies. Furthermore, prognostic markers can be detected by immunocytochemistry (Table 4).

Molecular Cytology

Common genetic alterations detected in differentiated thyroid carcinomas are BRAF and RAS mutations and RET/PTC and PAX8/PPARγ rearrangements, respectively. A panel of the listed molecular alterations was successfully tested in indeterminate cytology

Table 4 Common immunohistochemical diagnostic markers used in immunocytochemistry

Follicular cells	Thyroglobulin, thyroid transcription factor-1 (TTF-1)
C-cells, medullary carcinoma	Calcitonin
Parathyroid gland	Parathyroid hormone
Papillary and follicular carcinoma	Cytokeratin-19, HBME-1, galectin-3, thyroid peroxidase (TPO)

specimens. Larger commercially available tests such as Afirma, ThyroSeq, ThyGenX-ThyraMIR and RosettaGX are available for FNA thyroid ancillary diagnostics. They are convenient in bringing objective results and in avoiding waiting for repeat FNA. Nevertheless, they increase the overall diagnostic costs.

Recently, an aberrant microRNA (miRNA) profile was described in thyroid carcinomas as compared to normal thyroid tissue. Both downregulation and upregulation of numerous miRNAs was found. miRNA-222, miRNA-221 and miRNA-146b are upregulated in papillary carcinoma. Currently, miRNA testing is not recommended as clinical routine in indeterminate cytology nodules due to overlapping profiles. Several studies demonstrated discrepancy between miRNA profiles in surgically resected tissues and FNA material.

Quality Control and Assurance

The specimen- should be monitored from the moment it arrives in the laboratory until the clinician receives the report. Turnaround time should be determined in the laboratory. Cytology–histology correlations should be systematically monitored. AUS: malignant ratio can be calculated for the individual pathologist and the whole laboratory. This can be used as a performance measure for thyroid FNA.

Thyroid Carcinoma☆

Rossella Elisei, University of Pisa, Pisa, Italy

Introduction

Thyroid carcinoma (TC) is the most frequent malignant neoplasm of the endocrine system, representing about 4% of all human malignant neoplasms (National-Cancer-Institute Surveillance, n.d.) and is considered a rare disease. Different histotypes are distinguished on the basis of the morphological features, degree of differentiation and cell origin (**Fig. 1**). Some of these histotypes are really very rare and require to be managed in referral center by expert endocrinologists.

Epidemiology

The TC incidence has been increased from 2.4/100.000 subjects in the 50s, up to 10.2/100,000 in the recent years (Burke *et al.*, 2005). This increase of incidence was likely due to the increase in the diagnosis of small papillary microcarcinoma (mPTC) (Davies and Welch, 2014; McLeod *et al.*, 2013) likely related to the progressive and widely use of the neck ultrasound (US) in the clinical practice. Nevertheless, recently an increase of bigger tumors and more advanced cases have also been observed, thus raising the question of whether we are facing a true increase of TC incidence (Morris and Myssiorek, 2010).

The male:female ratio is 1:3, resulting in a different incidence of 5.2/100.000 in males and 15.5/100.000 in females. The mean age at diagnosis is around 45 years but recently an increase of the mean age has been also observed with a plateau around 50 years (National-Cancer-Institute Surveillance, n.d.). Age at diagnosis is also an important prognostic factor, with a worse prognosis if the onset of the disease is >55 years (UICC, 2016). Children are very rarely affected and, although a more aggressive phenotype is observed at diagnosis, the prognosis is usually good with a very low rate of death (Sassolas *et al.*, 2013).

Cancer related death is relatively low, with a risk of death of 0.5/100,000 subjects per year in both men and women; during the last 20 years, mortality remained stable despite the increase in incidence (Davies and Welch, 2014).

Pathological Features and Classification

As shown in **Table 1**, the classification of TC is based on the degree of differentiation, on their cellular origin and morphology. Well differentiated thyroid cancer (DTC) are so defined because the tumor cells maintain the typical features of normal follicular cells such as the production and secretion of thyroglobulin (Tg), the ability to take up iodine and to respond the thyrotropin stimulus (TSH). Papillary (PTC) histotype is the most frequent representing the majority of all TC followed by follicular (FTC) and then medullary (MTC) thyroid cancer. Several variants of PTC are nowadays well recognized (**Fig. 2**) and demonstrated to have different biological behavior (Shi *et al.*, 2016). Poorly differentiated thyroid cancer (PDTC) and anaplastic thyroid cancer (ATC) are both rare representing 5%–8% and 2%–3% of all TC, respectively. Other tumors can be present in the thyroid such as lymphomas and sarcomas or metastases of other human malignancy (Wood *et al.*, 2004) (**Table 1**). They are all very rare but they must be taken into consideration for a differential diagnosis when an undifferentiated tumor is diagnosed.

Risk Factors

The main risk factor of DTC is represented by the exposure to ionizing radiations, especially during the period of infancy, childhood and adolescence (Veiga *et al.*, 2012). Several studies evaluated the consequences of the external radiation therapy on pediatric subjects suffering from benign diseases of the head and neck, such as tinea capitis, acne, chronic tonsillitis, skin angiomas, thymic hyperplasia. They showed a significantly higher incidence of thyroid nodules and then thyroid cancer compared to nonirradiated subjects (Brooks, 1973). Moreover, after the explosion of the Chernobyl nuclear power plant in 1986, a few years later the incidence of the DTC increased dramatically in children of Belarus and Ukraine and, to a lesser extent, in those of Russia, affected by the radioactive fallout (Kazakov *et al.*, 1992; Baverstock *et al.*, 1992).

Other risk factors are represented by the presence of a concomitant thyroid disease (e.g., chronic autoimmune thyroiditis) in the family; deficient food intake of iodine (Belfiore *et al.*, 1992); hormonal factors and pregnancy (ratio females/males close to 1 before puberty and after menopause, between 2 and 4 in the average age of life).

Living close to active volcanoes has been also reported as a risk factor to develop TC. In several volcanic island the incidence of TC is greater than in other regions and in particular in Sicily, the population living in the areas close to the ETNA volcano has a higher prevalence of TC than those living in the same region but far from the volcano (Pellegriti *et al.*, 2009).

☆*Change History:* March 2018. Rossella Elisei has updated the text of the article.

This article is an update of Martin Jean Schlumberger and Sophie Leboulleux, Thyroid Carcinoma, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 385–394.

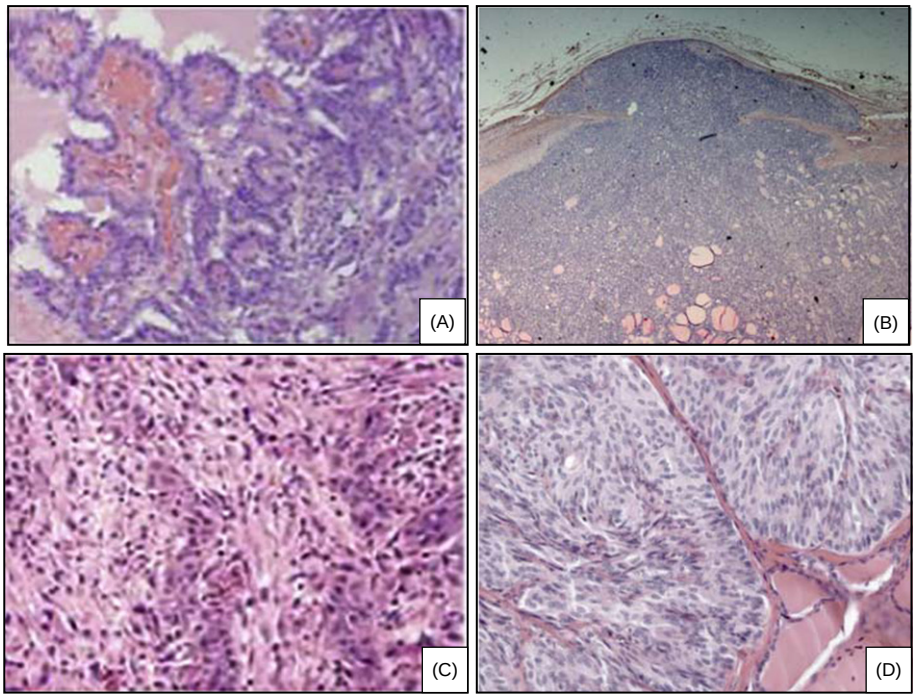

Fig. 1 Different histotypes of thyroid cancer. Panel (A) Papillary thyroid cancer; panel (B) Follicular thyroid cancer; panel (C) Anaplastic thyroid cancer; panel (D) Medullary thyroid cancer.

Table 1 Classification of thyroid cancers according with their origin, degree of differentiation and morphology

Cell origin	*Degree of differentiation*	*Histotypes, variants and prevalence (% of all TC)*
Thyroid cancers originating from follicular cells	Well differentiated thyroid cancers	- Papillary thyroid cancer (PTC), (80–85%): - Classic variant; - Follicular variant; - Diffuse sclerosing variant; - Hobnail variant; - Solid variant; - Tall cell variant; - Columnar cell variant - Hürthle cell variant (oncocytic)
		- Follicular thyroid cancer (FTC) (5%–10%): - Minimally invasive; - Widely invasive; - Hürthle cell (oncocytic) carcinoma;
	Poorly and undifferentiated thyroid cancer	- Poorly differentiated (PDTC) (5%) - Anaplastic thyroid cancer (ATC) (2%)
Thyroid cancers originating from parafollicular C -cells		- Medullary thyroid cancer (MTC), (5%): (a) Sporadic form (75% of all MTC) (b) Hereditary form (25% of all MTC): - Multiple endocrine neoplasia type 2A (MEN2A) - Multiple endocrine neoplasia type 2B (MEN2B) - Familial medullary thyroid cancer (FMTC)
Other cancer with different cellular origin but localized in the thyroid		Lymphomas Sarcomas Hemangiosarcomas Metastases from other human tumors (mainly kidney, lung, breast and colon malignancies)

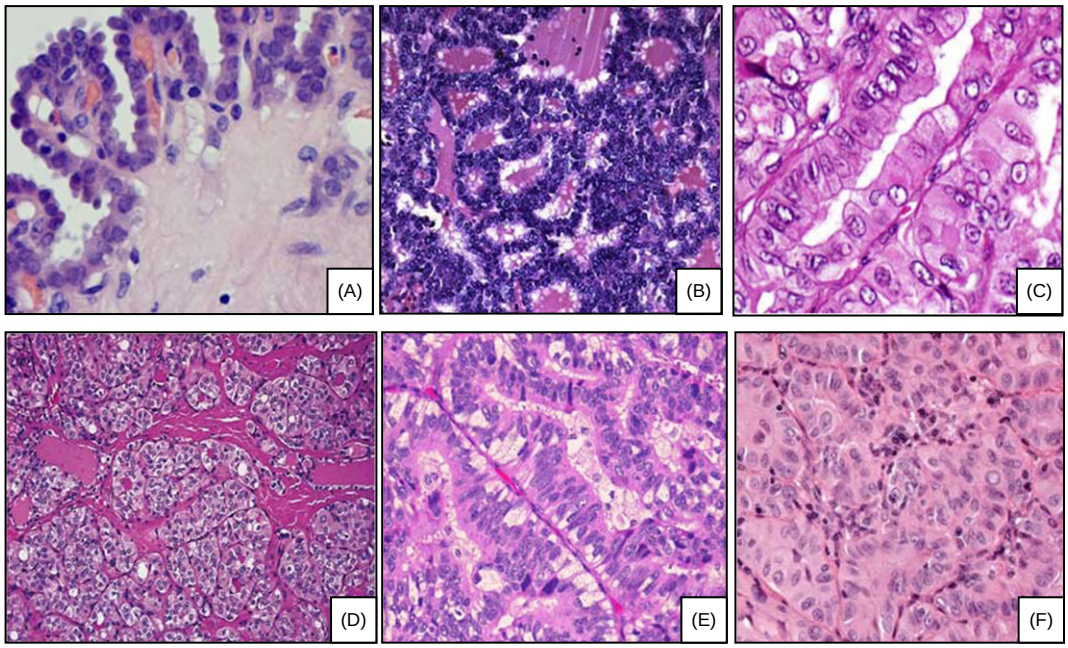

Fig. 2 Different histological variants of papillary thyroid cancer. Panel (A) Classical variant; panel (B) Follicular variant; panel (C) Tall cell variant; panel (D) Solid variant; panel (E) Columnar variant; panel (F) Hürthle (oncocytic) variant.

Obesity and several human cancers appear to be correlated (Strong *et al.*, 2017; Colditz and Peterson, 2018). As far as a relationship between TC and obesity is concerned, several controversial studies have been reported so far and this issue is still not well defined (Pappa and Alevizaki, 2014).

Recently, a few studies have shown a direct causal relationship between elevated serum TSH levels and a higher prevalence of DTC (Fiore and Vitti, 2012). On this regard, it is worth noting that elevated TSH is necessary to develop TC in mouse models transfected with oncogenes, thus suggesting a promoting role of TSH (Franco *et al.*, 2011). However, a true causative role of TSH in thyroid tumorigenesis has not been demonstrated yet.

No risk factors are known for MTC as well as for PDTC and ATC. For these latter a longstanding goiter can be considered a risk factor since in many cases they are discovered in patients with a medical history of goiter (Molinaro *et al.*, 2017). Nevertheless, there are cases of ATC rapidly developing from an apparent normal thyroid without any history and type of risk exposure.

Clinical Manifestations

The most frequent clinical manifestation of TC is a thyroid nodule, isolated or in the context of a multinodular goiter. Sometimes, a lump in the laterocervical region(s) of the neck can be the first appearance, especially in children. Only advanced cases or ATC can show up with a local symptom such as swallowing difficulties or change of the voice tone. Rarely, very advanced MTC can arrive at clinical observation for general symptoms such as diarrhea or flushing that are likely due to the elevated levels of serum calcitonin (Ct) and other peptides produced by this tumor.

PTC usually remains localized in the thyroid gland, has a rather slow growing rate and in the majority of cases the surgical treatment alone can cure the patient. In about 25% of cases, and in particular in young patients, it can metastasize through the lymphatic vessels to the lymph nodes, in particular to the cervical ones and the upper mediastinum. At variance, FTC has a more aggressive clinical behavior (Grani *et al.*, 2017). Unlike PTC, metastases occur mainly by blood vessels and are located in lungs and bones. Although more rarely, the brain and the liver parenchyma can also be sites of metastases. Frequently, bone metastases, particular in the vertebrae, can be the first clinical manifestation of FTC, especially in older patients (**Fig. 3**).

From a prognostic point of view an advanced stage and an advanced age at diagnosis are the most important poor prognostic factors for survival in all TC (Elisei and Pinchera, 2012). However, as previously said, with the exception of ATC that is almost invariably lethal, both PTC and FTC mortality is rather low and the major concern is the risk of recurrence that can happen in 15%–20% of PTC and/or FTC also several years after the initial treatment. For this reason, in 2009, the American thyroid association experts developed a new classification related to the risk of structural recurrence by defining three levels of risk: low, intermediate and high (Cooper *et al.*, 2009). This classification is very important to plan the therapeutic and follow up strategies (**Table 2**).

As far as MTC prognostic factors are concerned, also in this case an advanced stage at diagnosis and in particular the presence of distant metastases represent a high risk for death within 10 years, while the presence of lymph nodes in the absence of distant

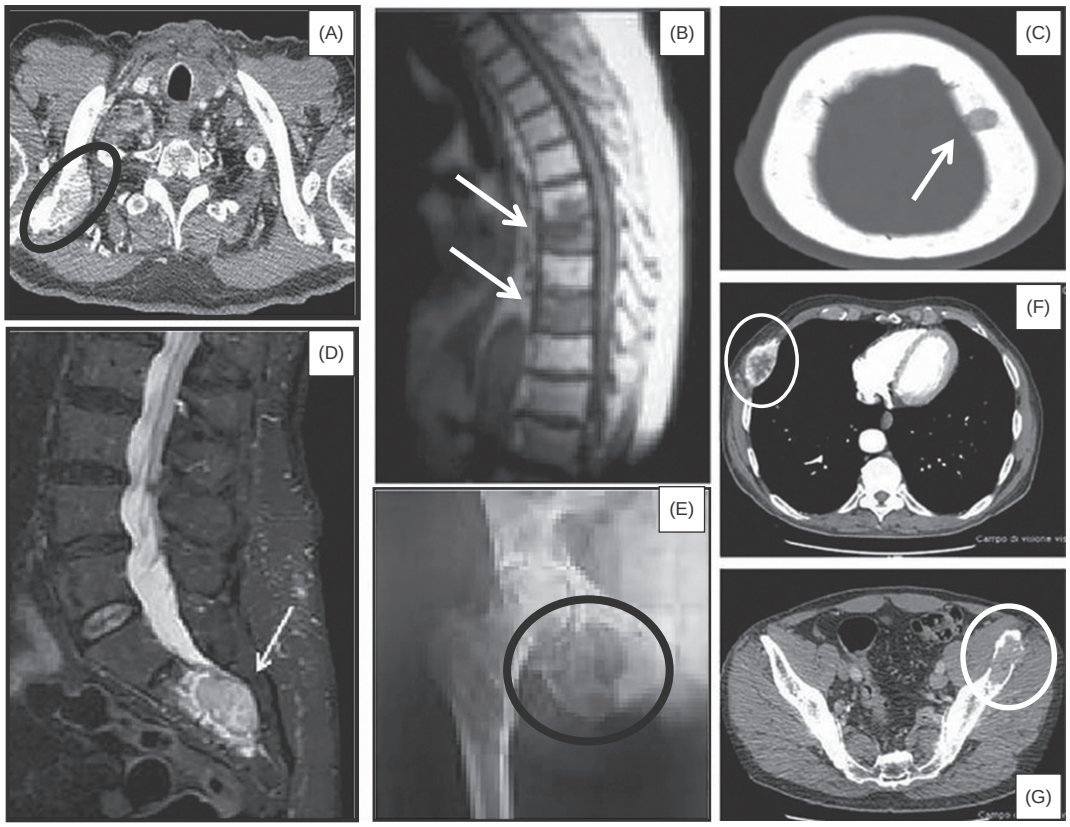

Fig. 3 Typical cases of bone metastases of follicular thyroid cancer indicated by *arrows* or *circles*. Panel (A) left clavicular lesion; panel (B) lytic vertebral lesions; panel (C) skull lesion; panel (D) sacral lesion; panel (E) right ischiatic lesion; panel (F) big lesion of the VI left rib; panel (G) left iliac crest lesion with extension in the gluteus.

metastases represents a high risk of disease persistence with a very low probability to obtain a definitive cure with the initial treatment.

Initial Treatment

Once the diagnosis of TC has been done, usually by cytology, the first therapeutic approach is surgery. A complete resection of the disease is the intent of this procedure but, since TC have different biological behaviors depending on their pathological features and particularly on the extension of the disease, a more tailored surgical approach is nowadays recommended. A similar concept has been developed for the radioiodine (131-I) treatment and, at variance with the past decades, nowadays a more personalized therapy is required thus confining the use of 131-I for the ablation of the postsurgical remnant to selected cases. This new therapeutic approach is described below.

Surgery

For many years, total thyroidectomy (TTx) and radioiodine remnant ablation (RRA) represented the initial treatment of all patients with PTC and FTC (Mazzaferri and Jhiang, 1994; Molinaro *et al.*, 2013). Although most of the DTC have a slow evolution and a favorable prognosis, they can be potentially lethal neoplasms, especially those cases, representing 20% of all DTC, that lose both the ability to produce Tg and to take up 131-I thus becoming de-differentiated and radioiodine refractory (RAR). Therefore, the initial treatment, which represents the most important step, should aim to reach a complete surgical removal of the tumor but avoiding iatrogenic complications which are more frequent when the surgery is more extended (Chen *et al.*, 2017).

Until a few years ago the surgical treatment of PTC and FTC, usually consisted in TTx in all cases. At variance, the most recent international consensus guidelines suggest that when tumors are smaller than 4 cm, unifocal, without a history of previous head and neck irradiation or familiarity for TC and the neck US can exclude the presence of cervical lymph node metastases, lobectomy alone can be sufficient and preferred for a lower risk of surgical complication (Haugen *et al.*, 2016).

When TTx is planned the question to perform also a central neck node dissection must be taken into consideration. A lot of controversial opinions and evidence have been reported about the need to add this procedure prophylactically. The higher risk to

Table 2 ATA 2009 risk stratification system with proposed modifications in ATA 2016 guidelines: indication for radioiodine postsurgical remnant ablation

Risk of structural disease recurrence	*Histological features*	*Radioiodine remnant ablation (RRA)*
Low risk (LR)	*Papillary thyroid cancer (with all of the following):* ● No local or distant metastasis; ● All macroscopic tumor has been resected ● No tumor invasion of loco-regional tissues or structures ● The tumor does not have aggressive histology (e.g., tall cell, hobnail variant, columnar cell carcinoma) ● If ^{131}I is given, there are no RAI-avid metastatic foci outside the thyroid bed on the first posttreatment whole-body RAI scan ● No vascular invasion ● Clinical N0 or $\leq$ 5 pathologic N1 micrometastasis ($<$0.2 cm in largest dimension) ● Intrathyroidal, encapsulated follicular variant of papillary thyroid cancer (NIFTP)* ● Intrathyroidal, well differentiated follicular thyroid cancer with capsular invasion and no or minimal ($<$4 foci) vascular invasion ● Intrathyroidal, papillary microcarcinoma, unifocal or multifocal, including BRAFV600E mutated (if known) *Follicular thyroid cancer minimally invasive $<$ 4 cm*	Not recommended
Intermediate risk (IR)	● Microscopic invasion of tumor into the perithyroidal soft tissues (mETE) ● RAI-avid metastatic foci in the neck on the first posttreatment whole-body RAI scan ● Aggressive histology (e.g., tall cell, hobnail variant, columnar cell carcinoma) ● Papillary thyroid cancer with vascular invasion ● Clinical N1 or $>$ 5 pathologic N1 with all involved lymph nodes $<$3 cm in largest dimension ● Multifocal papillary microcarcinoma with ETE and BRAFV600E mutated (if known)	Recommended in selected cases
High risk (HR)	● Macroscopic invasion of tumor into the perithyroidal soft tissues (gross ETE) ● Incomplete tumor resection ● Distant metastasis ● Postoperative serum thyroglobulin suggestive of distant metastasis ● Pathologic N1 with any metastatic lymph node $\geq$3 cm in largest dimension ● Follicular thyroid cancer with extensive vascular invasion ($>$4 foci of vascular invasion)	Usually recommended

have surgical complications, and in particular hypoparathyroidism, against a modest reduction of risk of recurrence makes this procedure very unpopular (Viola *et al.*, 2015). At variance, the central neck node dissection is at the present mandatory when an MTC is diagnosed. The only exception is when a prophylactic thyroidectomy is performed in children carrying a *RET* oncogene mutation without any evidence of disease and undetectable levels of serum Ct (Wells *et al.*, 2015).

The lymph node dissection of the latero-cervical compartment(s), on the other hand, is still a matter of discussion. Usually, in DTC it is performed only in case of laterocervical lymph node metastases already evident at neck US before the surgical treatment and this approach has been approved by all experts involved in the preparation of the DTC guidelines (Haugen *et al.*, 2016). At variance, no unanimous consensus was reached by the experts involved in the preparation of guidelines for MTC management (Wells *et al.*, 2015) since some of them suggested to perform laterocervical dissection based on the levels of preoperative serum Ct and independently from neck US evidences (Machens and Dralle, 2010). Sometimes echographic features of laterocervical lymph nodes are not clear enough to decide if a lymph node is metastatic or inflammatory. In these cases a fine needle aspiration cytology (FNAC) and the measurement of either Tg or Ct in the washout of the needle used for FNA will reveal the correct diagnosis (Pacini *et al.*, 1992; Boi *et al.*, 2007).

In advanced cases and in particular in ATC the TTX can be not feasible for the infiltration of other local structures such as trachea, esophagus, laryngeal nerves, and blood vessels. In these cases the surgeon should envisage if a good debulking (i.e., R1) can be obtained and in this case it is always convenient to proceed. However, if this would not be the case and just a biopsy of the tumor can be the best surgical option, it is better to decline the surgical treatment and start with other therapeutic strategies (Haddad *et al.*, 2015).

Radioiodine Therapy

Radioiodine (131-I) therapy can be used both for post surgical thyroid remnant ablation and for the treatment of distant metastases. While it is still the gold standard therapy for the treatment of distant metastases in well differentiate thyroid cancer, both PTC and FTC, its role for remnant ablation has been recently revised and limited to all high risk and some selected intermediate risk cases.

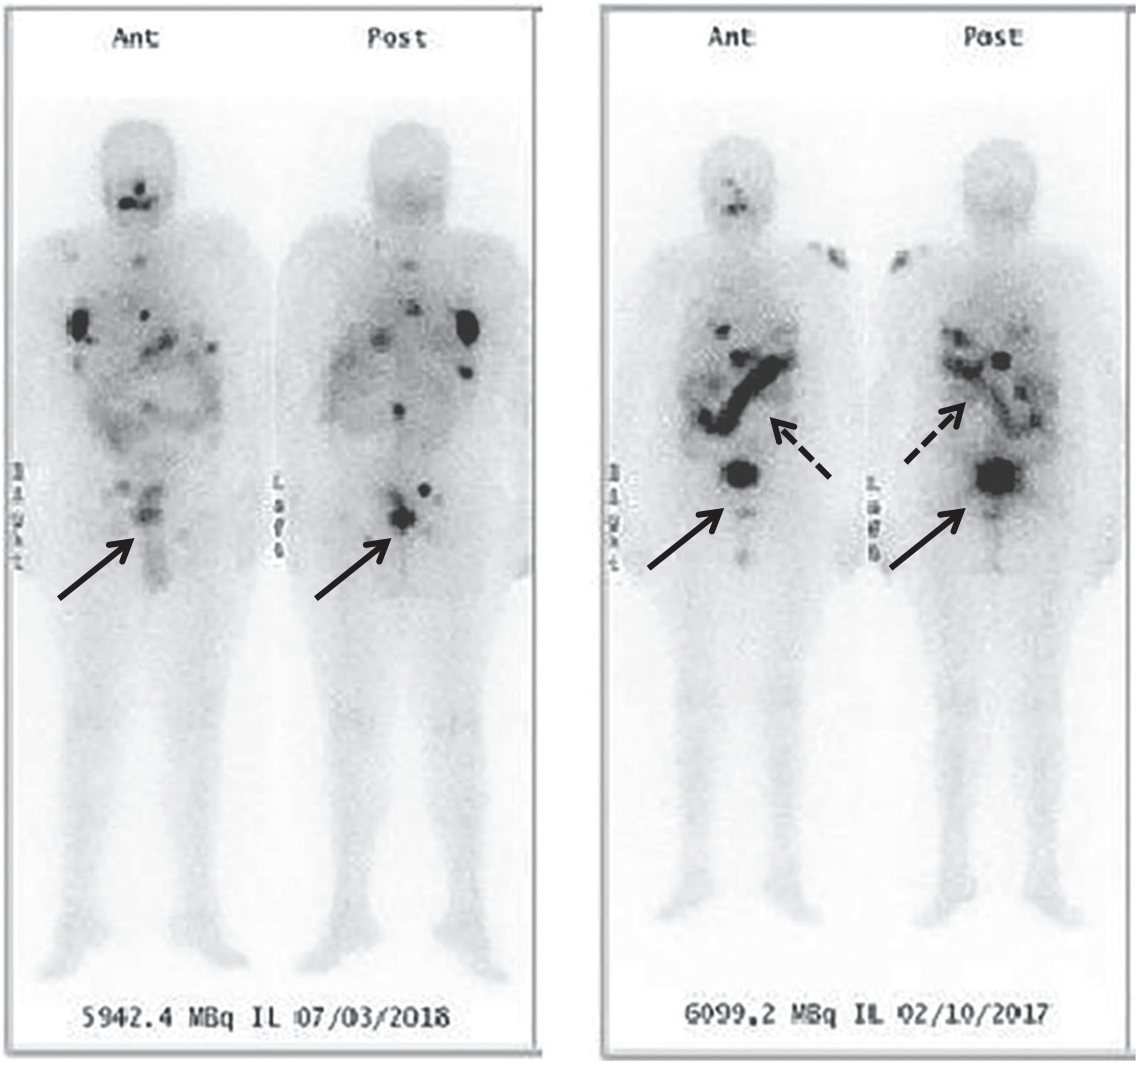

Fig. 4 Typical examples of post therapeutic whole body scans (WBS) showing several lesions still able to take up 131-I. The interpretation of the WBS must take into consideration also the physiological areas of uptake or iodine accumulation that should not be confused with metastatic lesions such as bladder (*continuous line arrows*) and colon (*dot line arrows*).

Radioiodine for remnant ablation (RRA)

The rationale of the RRA is represented by two major concerns:

1) Ablation of the normal thyroid remnant that can produce Tg which can reduce its specificity as tumor marker.
2) Adjuvant therapy of microscopic residual disease a/o RAI-avid metastatic foci, particularly in PTC which is multifocal in 40%–50% of cases.

It is well recognized that this approach facilitates the follow up of DTC, but there is currently much debate surrounding the real clinical impact of not only TTx, but especially RRA on both recurrence and survival-specific rates (Sacks *et al.*, 2010; Mazzaferri and Jhiang, 1994), particularly in low (LR) and intermediate (IR) risk DTC (Sawka *et al.*, 2008; Schvartz *et al.*, 2012; Cooper *et al.*, 2009; Haugen *et al.*, 2016). For this reason, the international referral guidelines (Haugen *et al.*, 2016; Cooper *et al.*, 2009), proposed an initial risk classification based on the histological features of DTC, to better identify the patients, mainly those with a high or intermediate-high risk tumor, who could really benefit from RRA (**Table 2**).

Usually the decision making to perform or not RRA is based on the presence of aggressive histopathological features (i.e., severe extrathyroidal extension, aggressive variants of PTC, vascular invasion, lymph node metastasis, distant metastasis). At the moment, there are no stratification analyses to determine the real efficacy of RRA on the recurrence rate during the time. Furthermore, cancer related death (CRD) is almost negligible in the LR group and very rare in the IR group thus the real clinical challenge nowadays in the management of DTC is to identify and treat the recurrences as soon as possible but avoiding the overtreatment of all the other non recurrent cases (Haugen *et al.*, 2016).

An important decision making role in the opportunity to perform RRA has been recently recognized for both serum Tg and neck US performed 3 months after the TTx (Rosario *et al.*, 2016). If neck US is negative and postsurgical Tg is already <0.2 μg/L the disease can already be considered in clinical remission and patients can avoid RRA, independently from the level of risk (Matrone *et al.*, 2017a).

Once the decision to perform RRA is taken, remnant ablation should be performed with the lowest but efficacy activity of 131-I and after stimulation with recombinant TSH (rhTSH) to avoid hypothyroidism that is very demanding for patients. Several uncontroversial studies demonstrated that low activities as 30 mCi of 131-I combined with the rhTSH stimulation will display the same results as higher amount of activities either after LT4 withdrawal or rhTSH stimulation (Mallick *et al.*, 2012; Schlumberger *et al.*, 2012). Higher activities of 131-I must be reserved to advanced cases with incomplete surgical treatment or cases with already known distant metastases.

RRA is not indicated in MTC since C cells are unable to take up 131-I although in the past some evidences of effectiveness was demonstrated for a "by-stander" effect due to 131-I entered in adjacent follicular cells (Nusynowitz *et al.*, 1982). Nowadays this practice is not recommended. Thus MTC can be either cured or not by the first surgery after which few other therapeutic options are available (Orlandi *et al.*, 2001). Even less effective is 131-I in ATC and should not be used. High activities can be used in PDTC with the hope that at least a minimal ability to take up iodine is persisting.

Radioiodine for metastatic lesions

Almost 2/3 of DTC metastatic lesions are able to take up iodine (**Fig. 4**) and 131-I can be used with subsequent administrations until the evidence of clinical benefit (Durante *et al.*, 2006; Pitoia *et al.*, 2014). No limits of cumulative dose have been identify and courses of high activities of $^{131\text{-}I}$ can be repeated several times if renal and/or liver and/or lung functions are not yet compromised. From a clinical point of view it is indicated not to repeat 131-I courses in less than 6 months especially if lung lesions are present where the risk of pulmonary fibrosis can become a life treating event (Hebestreit *et al.*, 2011). Although 131-I courses can be repeated many times without a real cumulative dose limitation, it is known that after a total of 600 mCi of 131-I it is very difficult to definitively cure the patient only with this type of treatment (Martins-Filho *et al.*, 2010).

The Follow Up of Thyroid Cancer Patients

About 80% of DTC and 30% of MTC can show an excellent response to initial treatment and patients can be considered in clinical remission with a risk of recurrence of 1%–3% in both cases (Tuttle *et al.*, 2010; Pellegriti *et al.*, 2003). About 50% of the recurrences usually show up within 5 years from the diagnosis while the others are commonly spread during the rest of the patients' life (Leung *et al.*, 2011). The other 20% of DTC and 70% of MTC usually have persistent disease that can be either biochemical, when only the specific biochemical marker is detectable without any evidence of metastases, or structural when imaging procedures show the presence of local or distant metastases (Tuttle *et al.*, 2010).

It is evident that the follow up of both the cured and not cured patients is fundamental for the benefit of the patients. The two specific and sensitive markers of DTC and MTC are serum Tg and Ct, respectively. Patients with an excellent response to initial therapy have undetectable levels of these markers and their de novo detected positivity is expression of recurrence as well as the persistence of detectable levels is expression of persistent disease (Tuttle *et al.*, 2010). Patients must be submitted to periodical controls whose schedule is very much dependent from the disease status. When the disease is apparently cured, patients can be monitored every 12 months with the measurement of serum Tg or Ct and neck US since, both in DTC and MTC, the most frequent site of recurrence is in the neck with lymph node metastases. Whenever the serum marker, either Tg or Ct in DTC and MTC respectively, turns out to be detectable other imaging procedures must be used to search for metastases especially if the neck US is negative. In cases with biochemical persistent disease the trend of increase of the serum marker becomes more relevant than the absolute value per se. In particular the doubling time (DT) of both the serum Tg and Ct can predict the outcome of the disease with a higher risk of death when the DT is <0.5–1 year (Miyauchi *et al.*, 2011; Meijer *et al.*, 2010). In these cases imaging procedures such as computerized tomography scan (CT), magnetic resonance (MRI), bone scintigraphy or positron emission tomography (PET) should be performed to find the sites of the metastatic lesions and evaluate their rate of growth. As far as the radiopharmaceutical to be used in PET imaging is concerned, 18 Fluoro deoxyglucose (18FDG) is useful for metastatic DTC while 18 Fuoro-di idrossi-fenil-alanina (18DOPA) is preferred in metastatic MTC for a higher specificity. Nevertheless, both in DTC and MTC imaging techniques, and particular PET scan, are usually positive only when the disease is rather advanced and serum markers are significantly elevated (i.e., >10 ng/mL in DTC and >150 pg/mL in MTC) (Agate *et al.*, 2014; Haugen *et al.*, 2016). A preferential use of some imaging techniques is usually recommended according to the anatomical district to be analyzed (Giraudet *et al.*, 2007).

It is well known that approximately 25%–30% of patients with DTC have serum Tg antibodies (TgAb) (Pacini *et al.*, 1988; Fiore *et al.*, 2011), which interfere with Tg measurement, causing either false negative or false positive results depending on the type of assay used (Latrofa *et al.*, 2016; Spencer *et al.*, 2014). TgAb are the expression of an associated lymphocytic thyroiditis (LT) or the expression of an immune reaction to DTC (Latrofa *et al.*, 2012). In these cases, serum Tg loses its function as tumor marker, but the change of the serum TgAb levels over the time can be used as a "Tg surrogate" since it has been demonstrated that in cured DTC patients, the TgAb levels decline to reach negativization (Verburg *et al.*, 2013; Chiovato *et al.*, 2003). At the same time, the persistence of stable levels of TgAb for a long period of time or the increase of TgAb levels after TTx plus/minus RRA represent an alert about the possibility of persistence or recurrence of DTC (Kim *et al.*, 2008; Tsushima *et al.*, 2013; Yamada *et al.*, 2014).

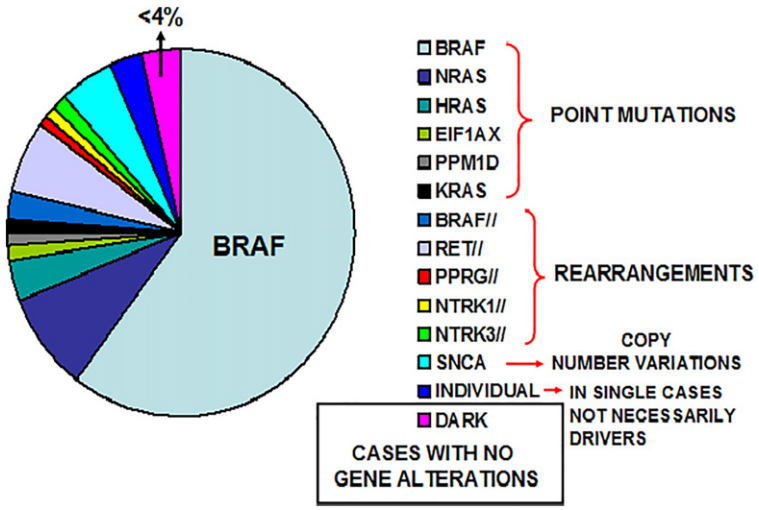

Fig. 5 Schematic representation of the prevalence and types of differentiated thyroid cancer oncogenes according to the data obtained by the TCGA (Cancer-Genome-Atlas-Research-Network, 2014): only a 4% of cases are still orphan of driver mutations.

Currently, this concept is so well established that the new international referral guidelines for the management of DTC include the TgAb evaluation after initial treatment as essential to assess the ongoing risk stratification (Haugen *et al.*, 2016).

Serum Tg becomes less significant as tumor marker in PDTC and even less in ATC. In fact because of the lost of differentiation features they produce less or null amount of Tg. In a few cases of dedifferentiated MTC also serum Ct production can be reduced and serum Ct levels be improperly low with respect to the tumor burden. In these latter cases serum carcinoembrionic antigen (CEA) levels can be useful to monitor the progression of the disease (Giovanella *et al.*, 2008).

Therapy of Advanced Cases

Radiorefractory metastatic DTC cannot be further treated with 131-I and other therapies must be considered when the disease becomes progressive. However, until recently, no effective therapeutic options were available for patients with any type of advanced thyroid cancer. In fact, classical cytotoxic chemotherapies have shown only a transient and poor response rate (10%–20%), with no prolongation of survival in response to the use of either a single therapeutic agent or in combination (Orlandi *et al.*, 1994; De Besi *et al.*, 1991). The significant improving of our knowledge of the molecular mechanisms underlying thyroid carcinogenesis and the description of drugs able to inhibit the catalytic activity of tyrosine kinases (TK) involved in the tumor process has opened up an era of targeted cancer therapies that represent new and important therapeutic options (Viola *et al.*, 2016).

The Rationale of Target Therapy

Since 1986, when the first activated oncogene (i.e., *RET/PTC*) was found in the DNA extracted from an irradiated PTC tumor and transfected into a cell line (Fusco *et al.*, 1995) up to 2014, when the genomic landscape of DTC has been fully revealed (Cancer-Genome-Atlas-Research-Network, 2014), a lot of interest has been growing for the possibility to use these oncogene alterations as targets of the new tyrosine kinase inhibitors (TKI) (Bible and Ryder, 2016).

The most common activated oncogenes in the different types of TC are reported in **Fig. 5**. Somatic activating point mutations of BRAF (i.e., V600E) and RET/PTC rearrangements are the most frequent altered oncogene in DTC. They are usually mutually exclusive but in advanced cases and especially in PDTC and ATC the presence of several alterations in the same tumor tissue has been observed and correlated to a greater aggressiveness and poor prognosis. A high prevalence of both *P53* and *TERT* promoter mutations are found in these cases (Landa *et al.*, 2016; Giordano, 2018; Yoo *et al.*, 2016).

RET oncogene is the most important driver in MTC tumorigenesis and somatic mutations are present in about 90% of sporadic advanced cases (Romei *et al.*, 2016). *RAS* oncogene is also altered but in a lower percentage of cases, usually in about 20% of *RET* negative cases (Ciampi *et al.*, 2013). Germline mutations are present in the hereditary forms of MTC that represent about 25% of all MTC. The genetic screening of *RET* mutations is nowadays recognized as the most important tool to early identification of gene carriers and plan the best therapeutic strategy (Elisei *et al.*, 2013a).

In the majority of cases, the activated oncogenes involved in thyroid tumorigenesis induce cell proliferation and tumor-transformation via the mitogen-activated protein kinase (MAPK) pathway, also known as the Ras-Raf-MEK-ERK pathway, and/or PI3K/AKT/mTOR pathway that is the other most important signaling mechanism in thyroid tumor-transformation. TKI can stop

Table 3 Major adverse events (AE) and their prevalence (%) in the four phase III studies

AE	*Sorafenib*	*Lenvatinib*	*Vandetanib*[a]	*Cabozantinib*

[a]Vandetanib has some peculiar cutaneous AE such as eritrodermia and photosensitisation likely due to its anti epidermal growth factor receptor; nd = not determined.

Table 4 Local treatments to take into consideration before starting a systemic therapy

Different types of local treatments
a) Other surgeries
b) Thermoablation
c) Alcohol ablation
d) Laser ablation
e) Transarterial chemoembolization (TACE)
f) Transarterial radioembolization (TARE)
g) External radiotherapy (conventional or stereotaxic)
h) Endotracheal stent

the tumor cell growth by blocking these activated pathways and exerting a cytostatic action thus significantly slowing down the tumor progression (Bible and Ryder, 2016).

Tyrosine Kinase Inhibitors

Although several TKIs have been tested in advanced and progressive TC only four drugs, two for RAR-DTC and PDTC and two for MTC, have been approved by both FDA and EMA for the therapy of these patients (Viola *et al.*, 2016). Sorafenib and lenvatinib are the TKI for the treatment of advanced and progressive RAR-DTC and PDTC (Brose *et al.*, 2014; Schlumberger *et al.*, 2015). Vandetanib and cabozantinib are those for the treatment of advanced and progressive MTC (Wells *et al.*, 2012; Elisei *et al.*, 2013b) but vandetanib can also be used for symptomatic patients and in children with metastatic MTC (Fox *et al.*, 2013). They have been tested in phase III clinical trials and a significant increase of the progression free survival (PFS) has been demonstrated in all these studies. Similar adverse events (AE), but with different prevalence and degree of severity, have been shown for all the four drugs (**Table 3**). However, a good knowledge of these AE, their prevention whenever possible, the early report of their appearance from patients and the possibility to reduce the daily dose of the TKI without losing their cytostatic activity, allow to find a good compromise between continuing the therapy and maintaining a good quality life (QoL) (Matrone *et al.*, 2017b).

The major concern is "when" to start the TKI therapy that should be not too late but also not too early because of the AE of the drugs that can impair the QoL of TC patients, which is usually rather good despite the presence of a metastatic disease. Moreover, TC, particularly de-differentiated cases, are slowly growing and a long interval of time will be required to become clinically significant (Kwong *et al.*, 2014). For this reason there is a general consensus that TKI must be started when the metastases are affecting several organs, are at least 1.5–2 cm in their bigger diameter and are progressing according to radiological criteria (i.e., RECIST) (Schlumberger *et al.*, 2014). Moreover, to be considered relevant to start TKI, the progression should involve several lesions simultaneously and the possibility to use a local treatment must be considered anytime the growth is regarding a single lesion (**Table 4**).

No TKI have been approved for ATC so far. Several phase II studies have been performed with good results (Sosa *et al.*, 2014; Smallridge *et al.*, 2013; Savvides *et al.*, 2013; Bible *et al.*, 2012; Copland *et al.*, 2006) but not enough to start phase III studies and

TKI may be used only as "off label" drugs or "compassionate use." ATC still remains a lethal tumor with a median survival of 6–8 months and the therapy should be addressed to avoid suffocation whenever possible (Molinaro *et al.*, 2017).

Conclusions

Thyroid carcinoma is represented by a variety of histotypes characterized by different biological behaviors. The majority of them, particularly those well differentiated, are cancers that have a good prognosis and a lifelong survival. For this group of patients the risk of an overtreatment is the most important risk since they are frequently cured with the initial treatment represented by TTx and RRA, if indicated. However, a not negligible subset, particularly those that lose the ability to take up iodine and those that are undifferentiated from the beginning, require the application of therapeutic procedures varying from further surgeries, external radiotherapy, thermoablation, chemoembolization and/or systemic therapies. For these reasons and for the rarity of the disease TC should be managed and treated in referral centers and by multidisciplinary teams.

Medullary Thyroid Carcinoma☆

Maria Alevizaki, Katerina Saltiki, and Theodora Pappa, National and Kapodistrian University, Athens, Greece

Introduction

MTC is derived from the parafollicular cells (C-cells) of the thyroid gland, which are of neural origin. Although they reside in the thyroid, C-cells do not play a role in thyroid function; they secrete amines, polypeptides and prostaglandins. Calcitonin is the main secretory product of C-cells and is widely used for the diagnosis of this tumor. Importantly, CT is also a useful marker after thyroidectomy for the follow-up of these patients and the identification of relapse or progression of disease (Wells *et al.*, 2015; Elisei *et al.*, 2004). Carcinoembryonic antigen (CEA) is another, non-specific, marker of the disease.

The clinical presentation includes enlargement of the thyroid and quite frequently palpable cervical lymph nodes. Approximately 10% of patients may have distant metastases already at the time of diagnosis (Kebebew *et al.*, 2000; Modigliani *et al.*, 1998). Postoperatively, the diagnosis of MTC raises some important questions involving disease staging, further therapeutic management in case of disease persistence as well as the identification of familial disease.

MTC is inherited in 25% of cases, frequently in the context of multiple endocrine neoplasia (MEN) syndromes which comprise familial MTC (FMTC), MEN 2A and MEN 2B variants. Mutations in the "rearranged during transfection" (*RET*) proto-oncogene are responsible for the transmission of familial disease. Genetic screening is performed in all patients diagnosed with MTC in order to identify familial disease within the group of apparently sporadic cases; early intervention may be performed in gene carriers. The time of prophylactic thyroidectomy is planned according to the risk level for aggressive disease associated with the identified affected *RET* codon (Wells *et al.*, 2015). Investigation for the coexistence of other tumors such as pheochromocytoma and primary hyperparathyroidism in MEN 2 cases is mandatory.

Thyroidectomy with or without lymph node dissection is the standard treatment for MTC in the majority of cases. The completeness of the initial surgery is of great importance for cure of the disease. Stage at diagnosis, tumor size, lymph node metastases and postoperative CT levels are important predictors of disease free survival and disease progression (Kebebew *et al.*, 2000; Verbeek *et al.*, 2015; Saltiki *et al.*, 2014; Roman *et al.*, 2006).

The majority of MTC cases with undetectable postoperative CT levels does not relapse and can achieve very high cure rates. In cases with elevated postoperative CT levels the clinical course varies. Estimation of CT and CEA doubling time helps predict progression and outcome. Locoregional therapies for metastatic lesions are of value as well as palliative or adjuvant therapy depending on the site. Two tyrosine kinase inhibitors (TKIs), vandetanib and cabozantinib, have been recently approved for the treatment of metastatic MTC; these agents can induce clinical response and disease stabilization (Wells Jr *et al.*, 2012; Elisei *et al.*, 2013b). An overview of the recent developments in the presentation, diagnosis, clinical course and management of both sporadic and inherited MTC are presented in this article.

Epidemiology

Sporadic MTC may present at any age but is most frequently encountered in the 4th–6th decade of life. Recent studies have shown that its incidence may be higher than previously believed as it has been found that 0.5%–1.3% of multinodular goiters may harbor unsuspected small MTCs. Small MTCs are being discovered more frequently due to the routine CT measurement in nodular disease, as well as to the increased use of high resolution ultrasound. However, the clinical significance of these may be different from the classical MTC (Alevizaki *et al.*, 2012; Elisei *et al.*, 2004; Valle and Kloos, 2011; Scheuba *et al.*, 2007). Moreover, incidental MTCs may be found in 0.2%–0.8% of autopsies; the majority of these are microcarcinomas (Baudin *et al.*, 1998; Beressi *et al.*, 1998; Valle and Kloos, 2011). Interestingly, in 10%–15% of MTCs the diagnosis is made only postoperatively (Ahmed and Ball, 2011; Valle and Kloos, 2011).

Histology

In 75% of MTCs there is amyloid deposition in the stroma which has a characteristic appearance. Immunohistochemistry is positive for CT and CEA staining. In the majority of cases with familial disease C-cell hyperplasia is also seen. This is considered a pre-malignant condition in cases of familial disease. It should be noted that C-cell hyperplasia can also occur in 20% of thyroid

☆*Change History*: March 2018. Maria. Alevizaki, Katerina. Saltiki, and Theodora. Pappa have updated all figures (except for Fig. 1) and all tables have been changed.

This article is an update of Cornelis J. M. Lips, Jo W. M. Höppener, Rob B. van der Luijt, Medullary Thyroid Carcinoma, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 218-227.

 doi:10.1016/B978-0-12-801238-3.90367-2

samples, in the absence of malignancy, frequently in the context of Hashimoto's thyroiditis (Albores-Saavedra and Krueger, 2001). In case of familial disease the tumors are multicentric more frequently compared to sporadic disease (Leboulleux *et al.*, 2004).

Clinical Picture: Diagnosis

MTC patients usually present with a single firm hard nodule in the upper middle region of thyroid lobes or less frequently with palpable lymph nodes. Thyroid ultrasound may show features of malignancy such as microcalcifications and hypoechogenicity with irregular margins and occasionally infiltrated lymph nodes. Fine needle aspiration (FNA) cytology is diagnostic in only 50% of the cases (Trimboli *et al.*, 2014). It may be false negative, may indicate papillary thyroid cancer or unspecified malignancy. Serum CT measurement along with FNA-calcitonin may improve the diagnostic accuracy in patients at risk for MTC and avoid false negative or inconclusive results from cytology (Wells *et al.*, 2015; Trimboli *et al.*, 2016).

The clinical picture of MTC may vary and patients are frequently asymptomatic. In 20% of the cases diarrhea may be the presenting symptom due to prostaglandin release by the tumor. Rarely, Cushing syndrome may be present due to ectopic ACTH secretion by MTC cells as well as flushing due to the release of biogenic amides from the tumor. In familial cases of MEN 2 syndrome the symptoms of pheochromocytoma may appear first (10%–50% of cases). Pheochromocytoma is bilateral in 60%–80% of cases and is usually benign although malignant pheochromocytomas have also been reported. Pheochromocytoma symptoms depend on the degree of catecholamine release; when diagnosed early, it may be asymptomatic. Hyperparathyroidism may appear in the 3rd decade of life in 10%–25% of MEN 2A patients and is usually mild and slow-progressing.

Cervical lymph node involvement may be detected at diagnosis and may be present in up to 20%–30% of MTC patients with tumors ≤ 1 cm. This percentage increases to 50% in cases with tumors >1–4 cm and up to 90% in larger tumors (De Groot *et al.*, 2006b; Scollo *et al.*, 2003). Lymph node metastases usually involve the central and lateral compartments. However, contralateral and upper mediastinal involvement may occur in locally invasive tumors, in which case the prognosis is worse (Machens *et al.*, 2005; Scollo *et al.*, 2003). Distant metastases may involve the lung, liver, bones and less frequently the brain and skin. Occasionally, in 10% of cases, distant metastases may be present already at diagnosis (Roman *et al.*, 2006).

Serum CT measurement is valuable in the preoperative evaluation (Machens and Dralle, 2010). Practically all patients have elevated CT levels. In recent years it has been suggested that CT measurements should be included in the laboratory assessment of multinodular goiter (Costante *et al.*, 2007; Alevizaki *et al.*, 2012; Elisei *et al.*, 2004). The European Thyroid Association (ETA) recommends one measurement of CT levels in all cases while the American Thyroid Association (ATA) guidelines are more reluctant to generalize this recommendation (Daniels, 2011; Wells *et al.*, 2015; Elisei *et al.*, 2013a). It should be noted that measurement of CT is a preventive action that leads to the earlier diagnosis, earlier intervention and higher cure disease rates (Alevizaki *et al.*, 2012, Elisei *et al.*, 2004). It should however be recognized that in a small percentage of cases CT may be slightly elevated in the absence of MTC; such cases are chronic renal failure, smoking, proton pump inhibitors intake, neuroendocrine tumors or Hashimoto's thyroiditis (Gibelin *et al.*, 2005). Another cause of falsely elevated CT may be the presence of heterophilic antibodies (Preissner *et al.*, 2005). It has been reported that up to 50% of patients who have been operated for multinodular goiter on the basis of elevated CT levels did not have MTC in the final histology (Hahm *et al.*, 2001).

In a recent study a cut-off value of 65 pg/mL for basal CT levels has been proposed as a threshold for detecting MTCs larger than 1 cm. However, microMTCs or even C-cell hyperplasia cannot always be discriminated (Kwon *et al.*, 2015). For investigation of marginally elevated CT levels stimulation tests either with intravenous calcium or pentagastrin administration may be useful (Mian *et al.*, 2014, Fugazzola, 2013, Machens *et al.*, 2009). In both familial and sporadic MTCs a threefold increase of CT levels or an absolute level of >100 pg/mL after stimulation is considered abnormal. Gender-specific CT thresholds may better differentiate between C-cell hyperplasia and MTC cases (Mian *et al.*, 2014; Machens *et al.*, 2009; Fugazzola, 2013). It is recommended that laboratories determine their own reference levels for stimulated CT.

Serum CT levels in MTC patients are usually associated with tumor size (Machens *et al.*, 2005; Cohen *et al.*, 2000). Rarely a "hook effect" may occur and give erroneously low levels due to very high serum CT levels interfering with the immunoassay. This should be examined when inappropriately low serum CT levels are found in a patient with large tumor burden. Furthermore, rarely calcitonin-negative or low-calcitonin tumors have been reported; in such cases MTC cells are poorly differentiated and may have aggressive biological behavior (Trimboli and Giovanella, 2015). In these cases other markers such as procalcitonin and CEA may be useful (Trimboli *et al.*, 2015; Karagiannis *et al.*, 2016; Giovanella *et al.*, 2008). CEA is a useful, although non-specific, marker which is produced from the cancerous cells (Barbet *et al.*, 2005). When CEA levels are >100 at diagnosis, lymph node involvement and also distant metastases are usually present.

In cases with familial disease, catecholamines and metanephrines should be measured in plasma or 24 h urine. In the presence of a positive result, adrenal imaging should be performed. In case a pheochromocytoma is diagnosed, this should be surgically removed before the operation for MTC. Furthermore, calcium measurements should be performed to exclude the presence of hyperparathyroidism. Serum chromogranin A may be elevated only in case of large tumor burden. Elevated chromogranin A levels in a patient with moderately elevated CT levels may indicate the presence of pheochromocytoma or other neuroendocrine tumor (De Groot *et al.*, 2006a). MTC is a neuroendocrine tumor and thus other hormones, bioactive amines and neuropeptides may be ectopically produced; these include ACTH, calcitonin gene-related peptide, histaminase, neuron specific enolase, prostaglandins, serotonin, somatostatin, vasoactive intestinal peptide, gastric inhibitory peptide, etc.

Familial Disease

In about 25%–30% of MTC the disease is inherited in the context of the multiple endocrine neoplasia (MEN) 2A or 2B syndromes or as familial MTC (FMTC). In MEN 2A, practically all patients develop MTC, which is accompanied by pheochromocytoma in 50% and primary hyperparathyroidism in 25%–30% of the cases. Rarely, cutaneous lichen amyloidosis and Hirschsprung disease may also be present in MEN 2A patients. In the rare MEN 2B syndrome, MTC may be associated with 50% lifetime risk of pheochromocytoma, mucosal neuromas, ganglioneuromatosis of the intestinal tract, medullated corneal nerves, musculoskeletal abnormalities and a characteristic phenotype with Marfanoid habitus. FMTC is a clinical variant of MEN 2A characterized by the isolated existence of MTC not accompanied by any other endocrine neoplasia. It is interesting that cases initially considered as FMTC have been subsequently re-classified as MEN 2 as pheochromocytomas developed at later generations (Moers *et al.*, 1996). Compared to sporadic MTC, hereditary MTC is usually, but not always, bilateral, multicentric and associated with C-cell hyperplasia. The distribution of familial cases is shown in **Fig. 1**.

The gene responsible for the transmission of the predisposition for hereditary MTC is the *RET* (Rearranged during Transfection) proto-oncogene. The characterization of the *ret.* mutation in a family allows the genetic screening of relatives allowing diagnosis of the disease at early stages; the disease outcome has thus significantly improved, because preventive rather than curative thyroidectomy can be performed (Spinelli *et al.*, 2010). The wide application of genetic testing has also resulted in the recognition of previously undiagnosed hereditary disease in cases among those initially considered as sporadic. The widespread application of molecular testing has resulted in an increase in the incidence of hereditary MTC (Machens *et al.*, 2013). Interestingly, in sporadic cases of MTC, somatic *RET* mutations are present in tumor cells in approximately 50% of cases; some studies have correlated these somatic mutations with higher proliferation rate and adverse prognosis (Elisei *et al.*, 2008; Mian *et al.*, 2011).

The *RET* Gene

The *RET* gene is located in chromosome 10q11.2, spans 21 exons and encodes a tyrosine kinase transmembrane receptor; it was first described by Takahashi *et al.* in 1985 (Takahashi *et al.*, 1985). It has three distinct domains: an extra-cellular ligand-binding segment with a cadherin-like region, a calcium-binding site and a juxtamembrane cysteine-rich region critical for receptor dimerization, a hydrophobic transmembrane domain and an intra-cellular part with two tyrosine kinase subdomains that mediate the downstream signaling pathways. The structure of the gene is shown in (**Fig. 2**).

In the physiologic state, *ret.* dimerization is required for autophosphorylation of the intracellular tyrosine residues and, subsequently, for receptor activation to ensue. Ligands binding *ret.* include the glial cell-line derived neurotrophic factor, neurturin, persepin, and artemin. The physiologic role of RET during development is to transmit signals in cells of neural origin. In hereditary MTC, germline gain-of-function mutations, present in 95%–98% of cases, lead to ligand-independent dimerization of mutant *ret.* proteins and constitutive activation of the tyrosine kinase domain and its downstream transduction pathways (Santoro *et al.*, 1995). These molecular abnormalities result in proliferation of tissues derived from neural crest cells, including C-cells and adrenal medulla cells.

Mutations in the cysteine-rich extra-cellular ligand-binding segment lead to ligand–independent receptor dimerization, whereas mutations in the transmembrane domain augment noncovalent interactions and closer proximity between the RET monomers. Regarding the intra-cellular part, mutations in the tyrosine kinase domain induce access of ATP to its binding site, whereas mutations in the intracellular catalytic core (such as M918T) result in preferential binding of the substrate and activation of the downstream signaling pathway (Santoro *et al.*, 1995).

The majority of recognized mutations are located in exons 5, 8, 10, 11, and 13–16; this information is important in the planning of the panel that has to be screened for hereditary MTC in all patients presenting with MTC (Elisei *et al.*, 2013a; Machens *et al.*, 2013). Novel *RET* mutations are continuously recognized. >150 germline *RET* mutations, accessible in electronic databases

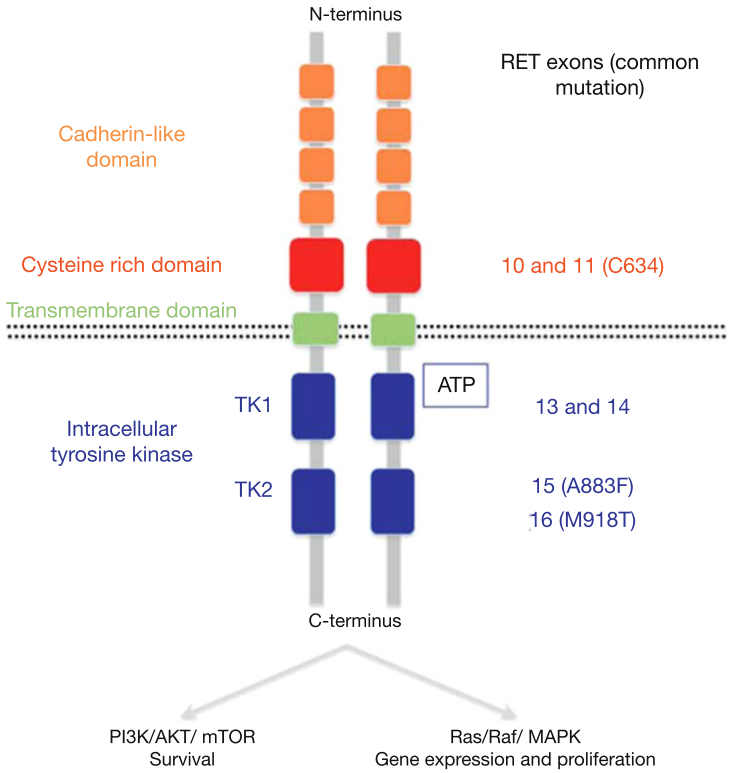

Fig. 2 Schematic representation of the RET tyrosine kinase receptor (TK: tyrosine kinase domain).

(e.g., www.arup.utah.edu/database/MEN2) have been identified to date. A list of confirmed pathogenic *RET* mutations associated with MEN 2 syndromes is presented in **Table 1**.

During *RET* genetic analysis polymorphisms may be found, the significance of which is unclear. The European Thyroid Association suggests validating the oncogenicity of novel *RET* mutations with in silico and in vitro testing (Elisei *et al.*, 2013a; Machens *et al.*, 2012). An appropriate population should serve as a control to exclude gene polymorphisms lacking any functional relevance (Elisei *et al.*, 2013a, Machens *et al.*, 2012).The term unclassified is used to describe mutations reported in families or individuals with suspected or known hereditary MEN 2 disease, who do not however meet the clinical criteria of a specific MEN 2 syndrome.

Genotype-Phenotype Correlation

In MEN 2 syndromes a genotype-phenotype correlation has been recognized (Elisei *et al.*, 2013a; Eng *et al.*, 1996). Most typical MEN 2A cases harbor mutations in the cysteine-rich region of the extra-cellular ligand-binding segment, specifically in exon 10 (codons 609, 611, 618, 620) and exon 11 (630 and 634) (Romei *et al.*, 2010). In a large multicenter Italian study, the most prevalent mutations in MEN 2A syndrome were Cys634Arg (35.3%) and Cys634Tyr (24.7%) (Romei *et al.*, 2010); in pedigrees with codon 634 mutations the prevalence of pheochromocytoma and primary hyperparathyroidism is significantly higher (Frank-Raue *et al.*, 1996; Machens *et al.*, 2001). A few European large-scale studies have investigated the distribution of *RET* mutations (Raue and Frank-Raue, 2009; Elisei *et al.*, 2007; Jindrichova *et al.*, 2004; Paszko *et al.*, 2007; Sarika *et al.*, 2015; Saltiki *et al.*, 2017) and have shown slightly different mutation spectra. Raue *et al.* reported that the distribution of the detected mutations has changed over the last decades. Earlier, mutations involving codon 634 in exon 11 were the most frequent, while recently mutations in exons 8, 10, 13, 14, and 15 are increasingly recognized (Raue and Frank-Raue, 2009). This change may be attributed to the different ethnic origin of the study populations, the wider testing including more than just the hot spot region, as well as to the extent of genetic screening now performed in apparently sporadic MTCs, which may potentially be re-classified as hereditary MTCs.

Regarding MEN 2B, in >95% of cases the mutation is localized in codon 918 of exon 16 (ATG to ACG) and rarely in codon 883 of exon 15 (Wells *et al.*, 2015). The course of MTC in MEN 2B syndrome caused by the M918T mutation is more aggressive, with cancer development as early as in the first year of life; this can be explained from the structure of the protein; Met918 is an important element of the substrate recognition pocket in the intracellular catalytic core of RET and is closely related to the conformational change of the kinase and constitutive RET activation in a monomeric form of RET.

FMTC has a more indolent course and the distribution of the mutations concerns a wider region of the *RET* gene; the most frequently affected sites include exons 10 (codons 609, 611, 618, and 620) and more rarely exon 11 (codon 634); mutations in the

non-cysteine regions of *RET* have also been described, such as exon 14 (codon 804), exon 15 (codon 891), exon 16 (codon 912), exon 8 (codons 532 and 533), and exon 13 (codons 768, 790 and 791) (Figlioli *et al.*, 2013).

Genetic Screening and Clinical Applications

All scientific societies now recommend genetic testing in patients with MTC. According to the European Thyroid Association (ETA) guidelines, analysis of the *RET* gene should be performed in all patients with apparently sporadic or familial MTC with the following order for testing *RET* gene exons (based on the frequency they appear): 10, 11, 14, 15, 13, 8, 5, and 16 (Elisei *et al.*, 2013a). The clinical features should also be taken into account; if there is suspicion of MEN 2B syndrome, exon 16 should be analyzed first (Elisei *et al.*, 2013a). In the large study of Romei *et al.* with 729 MTC patients, sequencing eight exons of the *RET* gene led to the re-classification of 6.5% of MTCs to hereditary and the identification of 41.1% of gene carriers within the MTC kindreds; 50% of them underwent total thyroidectomy and 90% remained disease-free after a 6-year follow up (Romei *et al.*, 2011). These cases would have remained undiagnosed using only conventional genetic testing. In the same line, one study from Greece recently reported an appreciable prevalence (7.75%) of the G533C exon 8 mutation in apparently sporadic MTCs and suggested that this site should be routinely screened in MTC patients presenting without any obvious family history (Sarika *et al.*, 2012; Saltiki *et al.*, 2017).

The widespread application of genetic screening has revolutionized the management of MTC patients and the counseling of family members carrying the mutated *RET* gene. Early identification of gene carriers allows timely prophylactic thyroidectomy at an early stage before lymph node involvement (Spinelli *et al.*, 2010). This approach significantly decreases the incidence of

persistent or recurrent disease (Machens *et al.*, 2003; Skinner *et al.*, 2005). Several studies have evaluated the beneficial role of prophylactic thyroidectomy in asymptomatic carriers; the site of the mutation, patient's age and basal CT levels are important parameters that have direct impact on the long-term outcome (Pappa and Alevizaki, 2016).

In the recent ATA guidelines *RET* mutations have been classified according to risk level and aggressiveness of MTC in three groups: moderate (ATA-MOD), high (ATA-H), highest (ATA-HST) risk level of aggressiveness (Wells *et al.*, 2015) (**Tables 1** and **2**). The ATA-HST category includes patients with MEN 2B (mutation in *RET* codon M918T), the ATA-H category includes MEN 2A patients with a C634 *RET* mutation and the category ATA-MOD includes the rest of familial MTC patients (Wells *et al.*, 2015). ATA-HST mutation harbors the highest risk for MTC developing very early in life with increased metastatic potential and prompts for total thyroidectomy within the first year of life. For ATA-H mutation it is advised that gene carriers undergo surgery within the first 5 years of life. Concerning the third class, ATA-MOD, the risk of MTC developing at a young age is lower, and although thyroidectomy before age 5 is advocated, it is suggested that it could be postponed if CT values (baseline and stimulated), and neck ultrasound are still normal (**Table 2**). Age-appropriate prophylactic thyroidectomy according to the risk classification of the mutations may improve disease-free survival (Shepet *et al.*, 2013). Recent studies demonstrated that stimulated CT values could represent a safe and reliable tool to personalize timing of thyroidectomy independent of the *RET* mutation and the gene carrier age (Elisei *et al.*, 2012).

Treatment

The primary treatment of MTC is surgical. Total thyroidectomy is recommended for both familial as well as for sporadic disease, as C-cells are distributed in both lobes and multifocality may be observed in sporadic cases as well. Preoperative levels of CT and CEA are also valuable to determine the extent of the initial surgery as these markers have been strongly correlated with the extent of lymph node metastases (Machens and Dralle, 2010; Machens *et al.*, 2007; Wells *et al.*, 2015).The decision for lymph node dissection is based on ultrasound findings, preoperative CT levels as well as the specific *RET* mutation in familial cases, according to the ATA guidelines risk stratification for each mutation (Wells *et al.*, 2015). Patients without lymph node involvement in the preoperative ultrasound and no evidence of distant metastases should undergo central compartment dissection at the initial surgery as lymph node invasion is frequently present at diagnosis (Wells *et al.*, 2015). In patients with preoperatively confirmed cervical lymph node involvement, lateral and central compartment dissection should be performed (Scollo *et al.*, 2003). In those with basal preoperative CT >200 pg/mL and positive ipsilateral lymph nodes a contralateral neck dissection should be considered; however, such a procedure is not curative in most cases (Wells *et al.*, 2015; Miyauchi *et al.*, 2002). In case of locally advanced disease debulking with removal of as much tissue as possible is recommended, however in many cases surgical resection is not feasible. Thoracic surgery may be needed for infiltrated upper-mediastinum lymph nodes (Wells *et al.*, 2015).

The prognosis is better in familial disease presumably because of earlier diagnosis and treatment. In young gene carriers with familial MTC and normal CT levels the necessity for prophylactic lymph node dissection is questionable. Pheochromocytoma should be excluded before thyroidectomy is performed. In case of a single pheochromocytoma, this should be removed. The probability of a second contra-lateral tumor within the next 10 years is 60%–80%. Adrenal cortex sparing surgery has been advocated in some centers (Castinetti *et al.*, 2014). In case of primary hyperparathyroidism the surgical procedure may vary according to the findings: either a single adenoma or 3.5 parathyroids may be removed, while in some centers total

Table 2 Overview of the American Thyroid Association (ATA) recommendations regarding prophylactic thyroidectomy for *RET* mutation carriers

ATA risk category	*Mutation*	*Thyroidectomy*	*Rationale for central neck dissection*	*Annual cervical ultrasound and serum basal CT*
Highest (ATA-HST)	M918T	– First year of life	– Suspicious lymph nodes present – Aim to preserve parathyroid glands	
High (ATA-H)	C634 A883F	– By5 years of age or sooner if CT high	– CT levels >40 pg/mL – Positive imaging – Suspicious lymph nodes during surgery	– Start at age 3 years
Moderate (ATA-MOD)	G533C C609,611,618,620,630 D631Y K666E E768D L790F V804 S891A R912P	– CT elevated or $\approx$ age 5 years if long term follow up difficult	– CT elevated	– Start at age 5 years

parathyroidectomy and a parathyroid implant in the forearm are performed (Alevizaki and Saltiki, 2015).The evaluation and management algorithm for MTC patients is shown in **Fig. 3**.

Disease Course and Prognosis

The detection of disease at earlier stages and the optimized surgical techniques are of paramount importance for the survival of MTC patients and for the possibility of cure (Cupisti *et al.*, 2007). The best outcome and highest 10 year survival rates are achieved with a successful first operation (Scollo *et al.*, 2003). Important prognostic factors are tumor size, lymph node invasion, disease stage, pre- and post-operative CT levels and age at diagnosis.

The overall 10-year survival rate is 65% but depends on the stage at diagnosis. In stage I it is 95%, stage II 93%, stage II 71%, and 20%–40% in stage IV patients. Of patients with no lymph nodes at diagnosis, biochemical and clinical cure may be achieved in 75%–90% of the cases while, of those with lymph node metastases at diagnosis only 20%–30% will have remission. The 10 year survival rate is 75% (Scollo *et al.*, 2003; Kebebew *et al.*, 2005; Modigliani *et al.*, 1998; Bergholm *et al.*, 1997). In cases with over 10 positive lymph nodes, this remission rate decreases to 4% (Scollo *et al.*, 2003; Pelizzo *et al.*, 2007). Compliance to ATA guidelines results in fewer local reoperations and more frequent biochemical cure of the disease (Verbeek *et al.*, 2015).

During follow-up, CT measurement appears to be the most sensitive marker for the evaluation of disease persistence and progression (Barbet *et al.*, 2005; De Groot *et al.*, 2006a; Kebebew *et al.*, 2005; Siironen *et al.*, 2016; Cho *et al.*, 2016). CT and CEA measurement are performed 3 months postoperatively (since both have long half-lives). When postoperative CT is undetectable the probability of relapse decreases to 0%–5% (Kebebew *et al.*, 2005; Modigliani *et al.*, 1998).

In a substantial proportion of patients postoperative CT may be detectable, indicating persistent disease. Many patients with lymph node metastases and/or elevated postoperative CT will have a long survival (Siironen *et al.*, 2016). In patients with persistent disease and postoperative CT > 100–200 pg/mL it is important to localize the disease and select the appropriate therapeutic approach. For disease localization various imaging methods are available depending on the organ that needs to be explored. Thus neck ultrasound, computed tomography of the thorax, magnetic resonance imaging (MRI) of the liver and bone MRI may be performed (Giraudet *et al.*, 2007). Positron emission tomography–computed tomography (FDG-PET/CT and F-DOPA-PET/CT) have poor sensitivity unless the tumor progresses rapidly (Wells *et al.*, 2015; Giraudet *et al.*, 2007; Skoura *et al.*, 2012).

CT and CEA levels are monitored every 6–12 months at follow-up. Short doubling time of CT and CEA has been proposed as the best indicator of disease progression (Meijer *et al.*, 2010; Laure Giraudet *et al.*, 2008). Specifically, CT doubling time shorter than 2 years correlates with structural disease progression (Barbet *et al.*, 2005; Laure Giraudet *et al.*, 2008). Fluctuations in

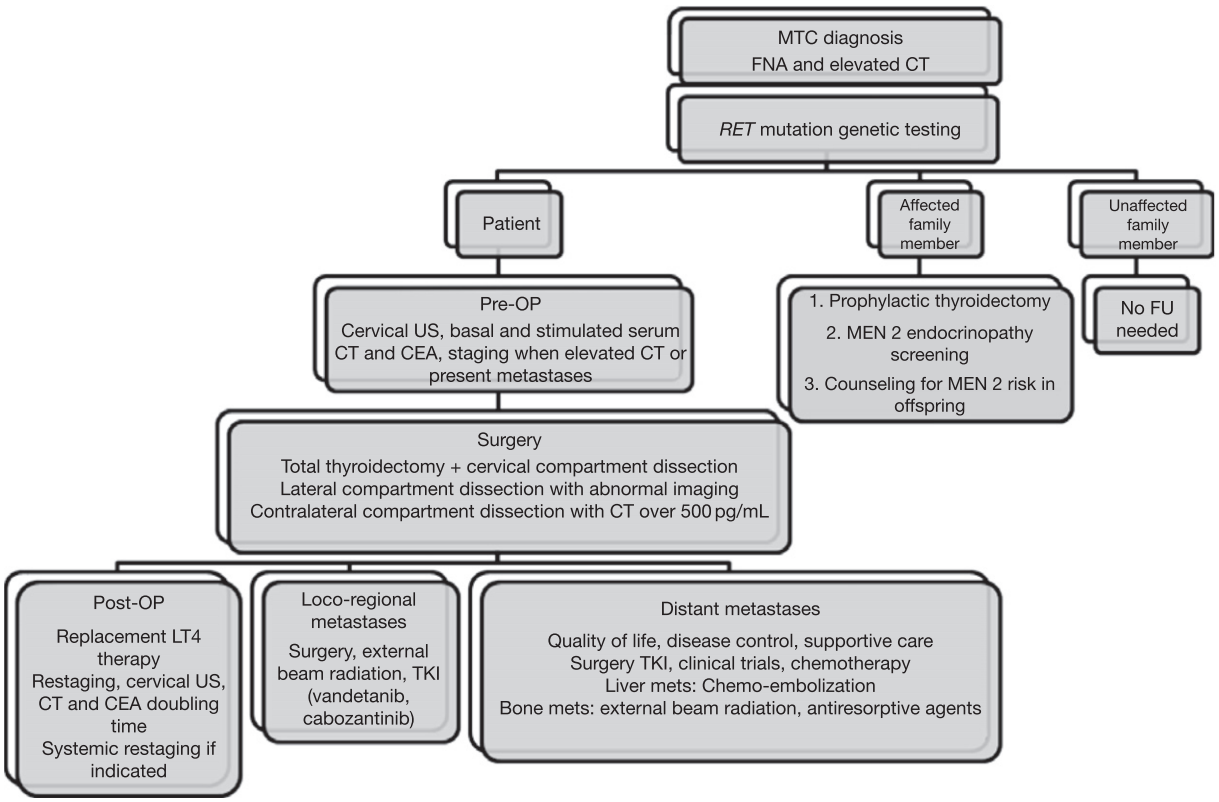

Fig. 3 Evaluation and management algorithm for MTC patients.

successive measurements of CT levels (20%–30%) do not indicate disease progression. A short CEA doubling time also indicates tumor progression. Increasing CEA levels in case of declining CT levels postoperatively may be a marker of dedifferentiation (Mendelsohn *et al.*, 1984). Tumor progression needs to be validated with imaging techniques, similar to those used preoperatively. The RECIST criteria (response evaluation criteria in solid tumors) are used to evaluate the structural disease progression before and during systemic treatment.

Patients with persistent disease with measurable CT but negative imaging need close follow-up as the location of the disease may eventually be identified in 40% within the following 10 years. In these patients the 10-year survival is 86% (Yip *et al.*, 2011). Patients with postoperative CT levels >400–500 pg/mL are likely to have distant metastases. When present, the 10-year survival is 20%–40%. However identifying the metastasis site is not always successful. MTC metastases are found in the liver, lungs, bones, and rarely in other organs. The lung metastases are usually small in size or micronodular. Liver metastases are usually small and mimic hemangiomas; therefore MRI is needed for the differential diagnosis. Bone metastases are either osteolytic or osteoblastic and will show-up in the bone MRI or the bone scan. It should be noted that MTC has a slow progression even in the case of distant metastases; occasionally, no disease progression is observed over a long period even without any systemic treatment.

Management of Metastatic Disease

In patients with local and regional recurrence of disease the main treatment is surgery, before which the extent of the tumor as well as the presence of distant metastases must be taken into consideration. In cases of locally invasive tumors endangering aero-digestive structures external radiation is proposed. In distant metastases palliative locoregional therapies may provide local control. For hepatic metastases chemoembolism may be used to decrease tumor mass and symptoms or to stabilize sizeable lesions. Chemoembolization is effective in lesions <3 cm and with limited liver involvement. External radiation in bone metastases may offer pain relief, protect from fractures and preserve motility. Surgery and/or stereotactic irradiation for brain metastases and radiofrequency ablation in lung, bone and liver metastases have been used (Baere De *et al.*, 2015; Wells *et al.*, 2015) (**Fig. 3**). Local interventions should preferably be performed before the initiation of systemic therapy. They may also stabilize the disease in patients with slow progression and thus delay the initiation of systemic therapy. For diarrhea control, loperamide is administered, whereas analgesic medication is administered for painful metastases. Somatostatin analogs may help in the control of diarrhea but have no other place in the management of metastatic MTC.

Classical chemotherapy is not currently used as it does not prolong survival. Radioiodine has no place in the management of MTC (Wells *et al.*, 2015).

The recent progress in the understanding of the oncogenic pathways in MTC and the identification of specific molecular alterations has played a crucial role in the development of molecular targeted therapies, mainly tyrosine kinase inhibitors (TKIs) (**Table 3**). Their main targets are the RET kinase, the vascular endothelial growth factor receptor (VEGFR), the epidermal growth factor receptor (EGFR), and other factors participating in signaling downstream pathways involved in tumorigenesis, such as the mesenchymal-epithelial transition (MET) pathway, mutations in MET gene with activation in c-MET/hepatocyte growth factor (HGF), as well as the activation of RAS and mTOR factors in RET-mutated tumors. Receptors for fibroblast growth factor (FGFR)

Table 3 Tyrosine kinase inhibitors used in patients with metastatic MTC

Tyrosine kinase inhibitors (references)	*Molecular targets*	*PFS (vs. placebo) in months (% increase)*	*ORR (%)*	*Major adverse events*
Vandetanib (Wells *et al.*, 2012)	RET, VEGFR2, VEGFR3, EGFR, PDGFR	30.5 (19.3) 58%	45	Fatigue, rash, dry skin, photosensitivity, folliculitis, diarrhea, anorexia, weight loss, nausea, asthenia, hypertension, QT prolongation
Cabozantinib (Elisei *et al.*, 2013b)	VEGFR2, RET, c-MET, KIT, AXL, FLT3, Tie2	11.2 (4) 180%	28	Diarrhea, abdominal discomfort, fatigue, hypertension, mucositis, hand-foot syndrome, anorexia, weight loss, GI perforation, hemorrhage, fistula formation
Sorafenib	RET, VEGFR, PDGFR, RAF, c-KIT, FLT3	17.9	21	Hand-foot syndrome, hypertension, diarrhea, infection, leukopenia, musculoskeletal pain, alopecia, rash, anorexia, fatigue
Sunitinib	RET, VEGFR1-3, PDGFR, c-KIT, FLT3, CSF1R		32	Leukopenia, fatigue, diarrhea, hand-foot syndrome, musculoskeletal pain
Pazopanib (Bible *et al.*, 2014)	VEGFR1-3, c-KIT, FGFR, PDGFR	9.4	14	Fatigue, anorexia, diarrhea, abnormal liver tests, hypertension
Lenvatinib (Schlumberger *et al.*, 2016)	VEGFR1-3 FGFR1-4 PDGFRα, c-KIT, RET	12.6	50	Weight loss, hypertension, fatigue, diarrhea, dehydration, anorexia, nausea, stomatitis, proteinuria

PFS, progression free survival; *ORR*, objective response rate; *AE*, adverse events; *GI*, gastrointestinal.

and for platelet-derived growth factor (PDGFR) may also participate in tumor angiogenesis (Papotti *et al.*, 2000; Plaza-Menacho *et al.*, 2014).

The rare cases with symptomatic or rapidly progressive metastatic disease are candidates for receiving molecular targeted therapy (Wells *et al.*, 2015; Links *et al.*, 2015; Hadoux *et al.*, 2016) which aims to stabilize disease and to potentially prolong survival. Such therapy should not be used in patients with only biochemical disease progression without structural disease or in asymptomatic patients with small metastatic lesions and no evidence of progression (Wells *et al.*, 2015; Hadoux *et al.*, 2016).

Two multikinase inhibitors, vandetanib and cabozantinib have been approved by FDA (Food and Drug Administration) and EMA (European Medicines Agency) for use in progressive metastatic MTC. Vandetanib inhibits VEGFR2, VEGFR3, RET, EGFR. In a large randomized controlled phase-3 trial vandetanib showed, compared to control group, increased progression-free survival (30.5 vs. 19.3 months) and objective imaging response (45% vs. 13%), irrespective of various factors such as *RET* mutation status, progression rate, disease location and disease extent at baseline (Wells Jr *et al.*, 2010). Cabozantinib inhibits RET kinases, VEGFR2 and c-met. Its efficacy was documented in a large randomized controlled phase-3 clinical trial where improved progression-free survival (11.2 vs. 4 months) and objective imaging response (28% vs. 0%) was found compared to placebo, irrespective of age, tumor burden and location, progression rate or prior TKI treatment (Elisei *et al.*, 2013b) (**Table 3**). Both drugs have been associated with disease stabilization in 30% and partial regression in 35% of cases (Elisei *et al.*, 2013b; Schlumberger *et al.*, 2012). However, the estimation of the effect of these agents on overall survival is difficult because the majority of patients have a relatively long life expectancy. The presence of either germline or somatic *RET* mutation may predict response to TKI treatment (Verbeek *et al.*, 2011; Fox *et al.*, 2013). In sporadic tumors the most common somatic mutation is *RET* M918T (85%) and its presence is associated with higher proliferation rate and more aggressive disease. RAS mutations, usually without coexisting *RET* mutations, are also present in 0%–43% of intermediate risk MTC tumors (Moura *et al.*, 2015).

Treatment with TKIs should be discontinued in cases with disease progression. A switch to another TKI may be helpful in maintaining disease control. TKIs have substantial adverse effects in 30%–60% of patients (**Table 3**). General not specific symptoms, cutaneous adverse events, gastrointestinal symptoms as well as hypertension, hypocalcemia and TSH increases are frequent but they can usually be treated symptomatically. Serious adverse events occur in 2% of patients. The most serious of these are the prolongation of QT interval in the electrocardiogram caused by vandetanib and the development of gastrointestinal fistulas and life threatening bleeding resulting from the use of cabozantinib. Dose reductions are required in 35% of patients treated with Vandetanib and 79% of those under cabozantinib. Discontinuation of treatment has been reported in 12% for Vandetanib and 16% for cabozantinib.

Other multikinase inhibitors (pazopanib, lenvatinib) are currently being studied and show promising response (Bible *et al.*, 2014; Schlumberger *et al.*, 2016) (**Table 3**). Novel drug molecules as well as combined targeted therapies may prove efficient. Finally, other treatments (labeled antiCEA-antibodies and DTPA, octreotide analogs labeled with Yttrium-90) have shown some response, however they present significant toxicity (Wells *et al.*, 2015).

Conclusions

MTC prognosis has significantly improved in recent years because of the timely diagnosis through routine CT screening in nodular disease, the availability of better quality ultrasound, the wide application of genetic screening and improved surgical procedures. Overall the most important advancement in the field has been the wide availability of genetic testing which allows screening and early intervention in familial disease. This should be performed in all MTC patients, those with positive family history as well as those with the apparently sporadic form. The course of disease may vary but is generally of slow progression. Tyrosine kinase inhibitors represent another important advancement in the management of patients with distant metastases and progressive disease.

Causes of Hypothyroidism☆

Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen, Copenhagen University Hospital, Copenhagen, Denmark

Glossary

Congenital hypothyroidism Hypothyroidism present at birth.

Craniopharyngiomas Tumors arising from Rathke's pouch.

Dysgerminomas Germ cell tumors.

Hashimoto's thyroiditis Chronic goitrous autoimmune thyroiditis

Hemangiomas Tumors composed of blood vessels; the most common tumors of infancy, characterized by rapid growth during the first year of life, followed by involution and gradual regression by adolescence.

Pituitary adenomas Benign tumors arising in adenohypophyseal cells.

Rathke's pouch Invagination of part of the roof of the primitive nasopharynx; transforms later in the development into the adenohypophysis.

Thyroid agenesis Absent thyroid gland due to developmental disorder during embryogenesis.

Thyroid ectopia Thyroid gland located at aberrant position.

Wolff–Chaikoff effect Obstruction of the organic binding of iodine and its incorporation into hormone, caused by large doses of iodine; usually transient, but in large doses in susceptible people, the effect can be prolonged and cause iodine myxedema.

Introduction

Hypothyroidism, a syndrome characterized by the clinical and biochemical manifestations of thyroid hormone deficiency in the target tissues of thyroid hormone, may be caused by an abnormality in the thyroid gland itself (primary hypothyroidism) or by an abnormality in the pituitary or hypothalamus causing insufficient stimulation of the thyroid gland by thyroid-stimulating hormone (TSH) (central hypothyroidism). In rare cases, the abnormality is located in the target tissues of thyroid hormone ("peripheral" hypothyroidism) (Wiersinga, 2017). Within each of these, some of the disorders are genetic. Occurrence of central hypothyroidism is often related to hypothalamo-pituitary disease, and thus often associated with other pituitary hormone dysfunctions. The primary causes of hypothyroidism are very dependent on environmental factors, and the global distribution is therefore very variable. In areas with iodine deficiency, this is the main cause of hypothyroidism, while autoimmunity accounts for most cases in iodine sufficient areas (**Table 1**).

Central Hypothyroidism

The reduced secretion of thyroxine (T_4) due to deficient TSH secretion by the pituitary can be caused directly by lesions in the pituitary (secondary hypothyroidism) or indirectly by lesions in the hypothalamus via diminished secretion of TSH-releasing hormone (TRH) (tertiary hypothyroidism). The term central hypothyroidism is preferred because some lesions involve both sides, preventing a clear-cut distinction between secondary and tertiary hypothyroidism.

One would expect decreased serum TSH concentrations in central hypothyroidism, but normal or even slightly elevated TSH concentrations are not infrequently observed. This apparent paradox is explained by an aberrant glycosylation of TSH in these patients resulting in reduced biological activity of the TSH molecule while maintaining its immunoreactivity in conventional TSH immunometric assays (Beck-Peccoz and Persani, 1994; Persani *et al.*, 2000). Central hypothyroidism is also associated with a decrease in the nocturnal surge of TSH that may contribute to insufficient thyroid stimulation (Feldt-Rasmussen and Klose, 2016; Persani, 2012).

The incidence of central hypothyroidism in the general population is generally assumed to be very low: 1–2 cases per 100,000 persons per year (Feldt-Rasmussen and Klose, 2016). However, several studies have indicated that it might not be so rare after all (Beckett and Toft, 2003; Feldt-Rasmussen and Klose, 2016; Preiss *et al.*, 2008). The main reason for overlooking cases is the current screening strategy for hypothyroidism based on only TSH measurement (Beckett and Toft, 2003; Feldt-Rasmussen and Klose, 2016; Preiss *et al.*, 2008), while inclusion of free T4 in the programme might increase the diagnostic sensitivity (Beckett and Toft, 2003; Preiss *et al.*, 2008). This is not generally advocated for financial reasons and lack of good evidence (Dayan, 2001; Stockigt, 2011; Weetman, 1997). The gender distribution of central hypothyroidism is nearly equal. The occurrence of central

 doi:10.1016/B978-0-12-801238-3.96006-9

Table 1 Causes of hypothyroidism

Central (hypothalamic/pituitary) hypothyroidism
Loss of functional tissue
Tumors (pituitary adenoma, craniopharyngioma, meningioma, germinoma, glioma, metastases)
Trauma (surgery, irradiation, head injury)
Vascular (ischemic necrosis, hemorrhage, stalk interruption, aneurysm of internal carotid artery)
Infections (abscess, tuberculosis, syphilis, toxoplasmosis)
Infiltrative (sarcoidosis, histiocytosis, hemochromatosis, lymphocytic, immunoglobulin G4 hypophysitis, hypophysitis after treatment with monoclonal antibodies and granulomatous hypophysitis)
Congential (pituitary hypoplasia, septo-optic dysplasia, basal encephalocele)
Functional defect in TSH biosynthesis and release
Mutations in genes encoding for TRH receptor, TSH-β, or Pit-1 (pituitary-specific positive transcription factor 1)
Drugs: dopamine, glucocorticoids, L-thyroxine withdrawal, somatostatin analogues, interferons, RXR-selective ligands
Recovery after hyperthyroidism with sustained or temporary suppressed TSH
Primary (thyroidal) hypothyroidism
Loss of functional thyroid tissue
Chronic autoimmune thyroiditis e.g. Hashimoto's thyroiditis
Reversible autoimmune hypothyroidism (silent and postpartum thyroiditis, cytokine-induced thyroiditis, immune therapy (antibodies against cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) or programmed cell death protein (PD-1) and its ligand PD-L1))
Surgery and irradiation (^{131}I or external irradiation)
Infiltrative and infectious diseases, subacute thyroiditis
Thyroid dysgenesis/agenesis
Functional defects in thyroid hormone biosynthesis and release
Congenital defects in thyroid hormone biosynthesis
Iodine deficiency and iodine excess
Drugs: antithyroid agents, lithium, Amiodarone, natural and synthetic goitrogenic chemicals/agents, mitotane
"Peripheral" (extrathyroidal) hypothyroidism
Thyroid hormone resistance
Infantile hemangioma

hypothyroidism peaks during childhood and in adults 30 to 60 years of age. TSH deficiency caused by loss of functional tissue usually becomes manifest after the development of growth hormone and gonadotropin deficiency, and before loss of corticotropin and prolactin production (Feldt-Rasmussen and Klose, 2016).

Childhood

Congenital cases are due to pituitary hypoplasia, midline defects such as septo-optic dysplasia (TSH deficiency in 20% of patients), Rathke's pouch cyst, or rare "loss-of-function" mutations in genes encoding for the TRH receptor, the TSH-β-subunit, or Pit-1. Pit-1 is a pituitary-specific transcription factor confined to nuclei of somatotropes, lactotropes, and thyrotropes in the anterior pituitary, and Pit-1 deficiency results in growth hormone and prolactin deficiency and sometimes also in TSH deficiency. However, most childhood cases of central hypothyroidism are caused by craniopharyngiomas (TSH deficiency in 53% of patients) or cranial irradiation (e.g., for dysgerminoma or hematological malignancies) (Beck-Peccoz *et al.*, 2017; Feldt-Rasmussen and Klose, 2016; Lando *et al.*, 2001; Persani, 2012).

Adulthood

Adult cases of central hypothyroidism are most frequently due to pituitary macroadenomas (TSH deficiency in 10%–25% of patients), pituitary surgery, or irradiation (Feldt-Rasmussen and Klose, 2016; Persani, 2012; Schmiegelow *et al.*, 2003). TSH deficiency sometimes disappears after selective removal of a pituitary adenoma. Cranial radiotherapy for brain tumors causes hypothyroidism in 65% of patients, depending on the radiation dose, and its onset varies between 1 and 26 years after the irradiation. Radiotherapy for pituitary tumors is followed by hypothyroidism in at least 15% of patients (up to 55% when combined with surgery). Less common causes are severe head trauma, ischemic necrosis of the pituitary from postpartum hemorrhage (syndrome of Sheehan) or severe shock, pituitary apoplexy (hemorrhage in a pituitary adenoma), and immune therapy-induced hypophysitis, immunoglobulin G4 hypophysitis or lymphocytic hypophysitis. Lymphocytic hypophysitis is likely an autoimmune disease, presenting as a pituitary mass with hypopituitarism predominantly in women during pregnancy and the postpartum period.

Dopamine infusions in critically ill patients may cause central hypothyroidism by inhibition of pituitary TSH secretion. A huge excess of glucocorticoids (e.g., in Cushing syndrome) also dampens TSH secretion. Removal of the dopamine or steroid excess restores TSH release. A transient inhibition of TSH release is observed after withdrawal of long-term T_4 treatment in TSH-

suppressive doses, lasting for about 6 weeks, but can be longer in cases of very long-term treatment at very high dosages. Due to the same mechanism, TSH release can be inhibited for a very long time during recovery after hyperthyroidism.

Primary Hypothyroidism

The hallmark of primary hypothyroidism is an elevated serum TSH. The pituitary senses the lower plasma concentrations of T_4 and responds by increasing the release of TSH. Primary hypothyroidism is a very prevalent disease worldwide, especially in iodine-deficient regions. The incidence in the adult population is 4.1 cases per 1000 women per year and 0.6 cases per 1000 men per year. Thus, the most frequent causes of primary hypothyroidism in any given population depend very much on environmental factors, of which iodine intake is the most important (Zimmermann and Boelaert, 2015). Primary hypothyroidism is therefore mainly caused by iodine deficiency in areas of low iodine intake of the population (Zimmermann, 2009), but it is also very common in iodine-sufficient regions. In those areas, however, the cause is mainly due to chronic autoimmune thyroiditis such as Hashimoto's thyroiditis, followed by thyroidectomy and ^{131}I treatment. The incidence of congenital hypothyroidism is approximately 1 in 3500 newborns.

In a Danish epidemiological study from the DanThyr cohorts, Carle *et al.* (2006) described during a 4-year period from 1997 to 2000 (2,027,208 person-years) 685 new diagnosed cases of overt hypothyroidism; the incidence rate was 32.8 per 100,000 person-years (standardized to the Danish population). Nosological types of hypothyroidism were: spontaneous (presumably autoimmune) 84.4%, post-partum 4.7%, amiodarone-associated 4.0%, subacute thyroiditis 1.8%, previous radiation or surgery 1.8%, congenital 1.6% and lithium-associated 1.6%. Crude incidence rates were 29.0 around Aalborg and 40.6 in an area of Copenhagen. The higher incidence rate of hypothyroidism in the area with higher iodine intake was caused solely by more cases of spontaneous (presumably autoimmune) hypothyroidism, whereas the incidence of non-spontaneous hypothyroidism (all types combined) was significantly lower in the area with higher iodine intake.

Childhood

Congenital primary hypothyroidism can be caused by structural loss of thyroid tissue due to thyroid agenesis or an ectopic thyroid gland or by functional defects in thyroid hormone biosynthesis due to loss-of-function mutations in genes encoding the TSH receptor, the sodium iodide symporter, thyroglobulin, or thyroid peroxidase (Hannoush and Weiss, 2017; Persani and Bonomi, 2017). Neonatal mass screening programs will detect nearly all cases of congenital primary hypothyroidism. Chronic autoimmune thyroiditis is rare during childhood.

Adulthood

Hypothyroidism secondary to chronic autoimmune thyroiditis is caused mainly by destruction of thyrocytes. Its atropic variant is much more common than the goitrous variant, which is the original definition of Hashimoto's thyroiditis. Hashimoto's thyroiditis is, however, now often used synonymous with chronic autoimmune thyroiditis. The incidence is higher in women than in men and increases with advancing age. Still other variants are silent or painless thyroiditis and postpartum thyroiditis (occurring in 4%–6% of women during the first year after delivery and in up to 25% of women with type 1 diabetes mellitus), which are mostly self-limiting diseases with spontaneous recovery. Another type of reversible autoimmune hypothyroidism is induced by treatment with cytokines such as interleukin-2 and interferon-α, associated with the occurrence of thyroid peroxidase antibodies.

Hypothyroidism after subtotal thyroidectomy is less common after surgery for nontoxic or toxic nodular goiter (15% of patients) than after surgery for Graves' hyperthyroidism (40% of patients after 10 years). Most patients become hypothyroid during the first year after surgery. Likewise, hypothyroidism after ^{131}I therapy is less common in patients with toxic nodular goiter (6%–13%) than in patients with Graves' hyperthyroidism (up to 70% after 10 years). External radiotherapy of the neck for lymphomas or head and neck cancer causes hypothyroidism in 25%–50% of patients, depending on pretreatment with iodine-containing radiographic contrast agents, radiation dose, and duration of follow-up.

Hypothyroidism is very rarely caused by thyroid infections or thyroidal infiltration during the course of invasive fibrosis, cystinosis, or amyloidosis. In contrast, hypothyroidism during the recovery phase of subacute thyroiditis or postpartum thyroiditis is not uncommon. Iodine excess may induce hypothyroidism by failure to escape from the Wolff–Chaikoff effect. Sources of iodine excess include an iodine-rich diet (e.g., seaweed) and iodine-containing medications such as potassium iodide, kelp, topical antiseptics, radiographical contrast agents, and amiodarone.

Lithium inhibits thyroidal iodide transport and release of thyroid hormones. Long-term lithium treatment results in goiter (up to 50% of patients) and hypothyroidism (20% of patients), usually occurring during the first 2 years of treatment and particularly in patients with preexisting thyroid peroxidase antibodies. Furthermore the newly developed immune therapeutical drugs may induce thyroiditis as a side effect.

"Peripheral" Hypothyroidism

Hypothyroidism due to abnormalities outside the hypothalamus, pituitary, and thyroid is rare. Impaired sensitivity to thyroid describes a process that interferes with the effectiveness of thyroid hormone and includes defects in thyroid hormone action, transport, or metabolism. Several genomic causes have been described and the field has expanded immensely over the past years (Hannoush and Weiss, 2017; Persani and Bonomi, 2017). The most common cause of thyroid hormone resistance is a genomic mutation of the thyroid hormone receptor TRβ_1 fails to transmit the proper signal, causing symptoms and signs of thyroid hormone deficiency in certain target tissues. Serum TSH and serum T_4 and triiodothyronine (T_3) are increased - a remarkable combination of test results. The disease is frequently detected only during adulthood. Three cases of infants with massive hepatic hemangioma and hypothyroidism with markedly elevated serum TSH have been described (Huang *et al.*, 2000). The hypothyroidism was caused by high levels of type 3 iodothyronine deiodinase activity in the hemangioma tissue, which catalyzes the degradation of T_4 into the inactive reverse T_3 and the degradation of T_3 into the inactive 3,3′-T_2.

Diagnosis of Hypothyroidism☆

Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen, Copenhagen University Hospital, Copenhagen, Denmark

Glossary

Accuracy The proportion of all test results, both positive and negative, that are correct.

Hypothyroidism Syndrome characterized by the clinical and biochemical manifestations of thyroid hormone deficiency in the target tissues of thyroid hormones.

Negative predictive value The probability of not having the disease when the test result is negative (normal).

Nosology The systematic classification of diseases.

Positive predictive value The probability of disease in a patient with a positive (abnormal) test result.

Sensitivity The proportion of people with the disease who have a positive test for the disease.

Specificity The proportion of people without the disease who have a negative test for the disease.

Syndrome A group of manifestations that together are characteristic of a specific disease.

Introduction

The diagnosis of hypothyroidism can be divided into two phases. During the first phase, it should be ascertained whether thyroid hormone deficiency exists (diagnosis of the hypothyroid syndrome). If so, the second phase is aimed to establish which disease is causing the lack of thyroid hormone (nosologic diagnosis) (Stockigt, 2016).

Diagnosis of the hypothyroid syndrome starts with the history and physical examination of the patient, followed by laboratory tests in case of sufficient and appropriate clinical suspicion. The rationale for history, including family history, and for clinical examination is to increase the pretest likelihood of hypothyroidism so that fewer patients need hormone tests, thereby increasing the diagnostic accuracy of the laboratory test results. In some cases, however, a diagnostic laboratory screening strategy may be used for example, in relation to investigations for infertility (Baloch *et al.*, 2003; Feldt-Rasmussen *et al.*, 2011; Stockigt, 2016). The rationale for a nosologic diagnosis is to detect possible cases of reversible hypothyroidism and to increase awareness of the possible existence of conditions associated with a specific cause. In all situations it is important to exclude confounders (e.g. drug and assay interference) that can distort conclusions of diagnoses (Baloch *et al.*, 2003; Feldt-Rasmussen *et al.*, 2011; Esfandiari and Papaleontiou, 2017).

Syndromal Diagnosis

Clinical Assessment

None of the symptoms and signs of hypothyroid patients is specific for the syndrome, but the simultaneous occurrence of a number of symptoms and signs adds to the specificity. Consequently, statistical methods have been applied based on the relative frequency of symptoms and signs in hypothyroid patients and in controls. A simple score is derived awarding 1 point each for the presence of 12 symptoms and signs; correction for age is done by adding 1 point for individuals below 55 years of age (**Table 1**). The positive predictive value for hypothyroidism is 96.9% with a score of 6 points or more; the negative predictive value for exclusion of hypothyroidism is 94.2% with a score of 2 points or less. Approximately 62% of overt hypothyroid patients and 24% of subclinical hypothyroid patients are classified as clinically hypothyroid by this score (Seshadri *et al.*, 1989; Zulewski *et al.*, 1997).

Biochemical Assessment

The ideal test would be one that accurately measures the consequence of thyroid hormone deficiency in target tissues. However, tissue function tests such as serum cholesterol lack sufficient sensitivity and specificity to be of much use. Without doubt, serum thyroid-stimulating hormone (TSH) is currently the best single assay for detection of hypothyroidism (Wiersinga, 1989; Baloch *et al.*, 2003; Esfandiari and Papaleontiou, 2017), although presence of TSH isoforms may compromise results (Estrada *et al.*, 2014). Test characteristics of the serum TSH assay for the diagnosis of abnormal thyroid function are 98.8% sensitivity, 94.3%

☆*Change History*: November 2017. U Feldt-Rasmussen, M Klose, and Å K Rasmussen updated extensively all sections of the chapter, and extended and updated the references. Table 1 has been unaltered.

Delayed ankle reflex	77	94	92	80
Coarse skin	60	81	76	67
Cold skin	50	80	71	62

Note: Hypothyroid, $\geq$6 points; intermediate, 3–5 points; euthyroid, $\leq$2 points.

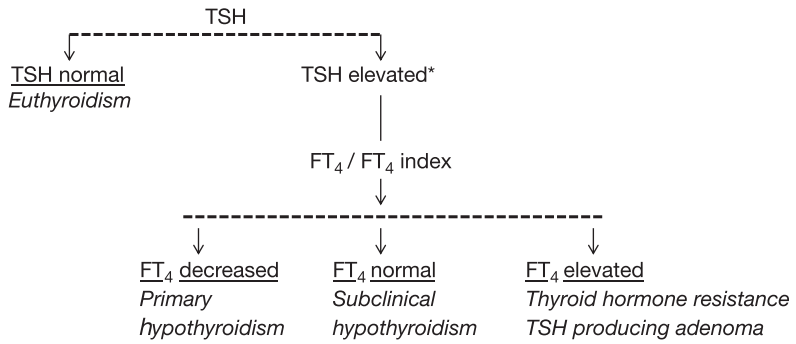

Fig. 1 Flow diagram for the biochemical diagnosis of hypothyroidism. *, if TSH is elevated it is important to exclude confounders for TSH elevation such as recovery after nonthyroidal illness, heterophilic antibodies or other interfering factors in the patient's serum, or transitory high TSH. FT4: Serum free thyroxine; FT4 index: measure of the total serum thyroxine concentration corrected for binding proteins = free thyroxine estimate.

specificity, 83.9% positive predictive value, and 99.7% negative predictive value. The high diagnostic accuracy of the TSH assay is caused by the exquisite sensitivity of the pituitary for small changes in serum thyroid hormone concentrations, displaying a log-linear relationship (Baloch *et al.*, 2003). Because of the negative feedback of thyroid hormone on the TSH release from the pituitary, a fall in serum thyroxine will result in elevated TSH levels in serum, and a rise in serum thyroid hormone concentrations will suppress serum TSH. This, however, requires an intact and stable hypothalamo–pituitary–thyroid axis (Baloch *et al.*, 2003), which is probably the only situation where the relationship between serum TSH and serum free thyroxine (fT4) has been reported to be log-linear (Baloch *et al.*, 2003; Esfandiari and Papaleontiou, 2017).

Fig. 1 depicts a flow diagram for the biochemical diagnosis of primary hypothyroidism. If TSH is normal, euthyroidism is nearly certain, and no further tests are necessary. However, central hypothyroidism (due to TSH deficiency) may be overlooked because serum TSH in this condition is usually normal or decreased. Fortunately, clinical examination often provides sufficient clues to suspect hypothalamic or pituitary disease such as symptoms arising from space-occupying lesions in the sella or from overproduction of pituitary hormones. As a rule, lack of gonadotropins occurs before the onset of TSH deficiency; therefore, the presence of regular menstrual periods in women or normal potency in men renders central hypothyroidism unlikely (Feldt-Rasmussen and Klose, 2016). The low incidence of central hypothyroidism (1–3 per 100,000 persons per year) does not warrant routine free thyroxine (FT_4) measurements after a normal TSH test result, although the possibility is being discussed (Waise and Belihetz, 2000; Beckett and Toft, 2003; Preiss *et al.*, 2008; Beck-Peccoz, 2017).

If TSH is elevated, a decreased serum FT_4 value indicates overt hypothyroidism and a normal FT_4 points to subclinical hypothyroidism. In both instances, the thyroid gland itself is at fault (primary hypothyroidism). The very rare combination of elevated TSH and elevated FT_4 allows the diagnosis of thyroid hormone resistance or TSH-producing adenoma (Feldt-Rasmussen and Klose, 2016; Beck-Peccoz, 2017).

It is important to recognize possible confounders in the assays for thyroid function tests or the pathophysiology of other situations that carry the risk for false interpretation. Estimates of FT_4 concentrations are globally widely measured on different platforms in Clinical Biochemical Laboratories, and they display a huge interlaboratory variability (Baloch *et al.*, 2003; Welsh and Soldin, 2016). Furthermore, changes in thyroid hormone binding proteins and use of many drugs may distort the results and their

interpretation. In such cases a total T4 measurement combined with an assessment of binding proteins (free T4 index) gives more information and more reliable results (Baloch *et al.*, 2003; Feldt-Rasmussen *et al.*, 2011; Welsh and Soldin, 2016; Esfandiari and Papaleontiou, 2017). If TSH is elevated it is important to exclude confounders for TSH elevation such as during recovery after nonthyroidal illnesss, heterophilic antibodies or other interfering factors in the patient's serum, or transitory high TSH (Baloch *et al.*, 2003; Stockigt, 2016; Esfandiari and Papaleontiou, 2017). Reversibility is verified by repeat serum TSH after 3–6 months, where serum TSH then will be normalized.

Nosologic Diagnosis

The cause of the hypothyroidism may reveal itself in many instances from the history (e.g., recent delivery, exposure to iodine excess, presence of other autoimmune diseases (Hollowell *et al.*, 2002; Feldt-Rasmussen, 2015; Bliddal *et al.*, 2017a,b; Kahaly and Frommer, 2017), family members with autoimmune thyroid disease or other autoimmune diseases, use of antithyroid drugs, thyroid surgery or ^{131}I therapy, intake of certain other drugs, hypothalamo–pituitary disease) and physical examination (although many patients will have no goiter), and clinical scoring (Seshadri *et al.*, 1989; Zulewski *et al.*, 1997). In iodine deficient areas, this deficiency as cause should be suspected.

The presence of thyroid peroxidase antibodies (and/or thyroglobulin antibodies) (Baloch *et al.*, 2003; Bliddal *et al.*, 2017a,b) in serum indicates chronic autoimmune thyroiditis, which is the most prevalent cause of hypothyroidism in the Western world (Carlé *et al.*, 2006). Serum TSH measurement is therefore paramount in the differential diagnosis, sometimes supplemented with measurement of serum thyroglobulin antibodies. Thyroid scans usually show low and inhomogenous uptake of the radioisotope in chronic autoimmune thyroiditis. Preserved thyroidal radioiodine uptake and homogenous distribution of the tracer increases the likelihood of reversible hypothyroidism (due to iodine excess).

Aberrant thyroid tissue (e.g., lingual thyroid, ovarian goiter) can be detected by a thyroid scintiscan, while hypothyroidism due to subtle enzyme and other abnormalities can be more challenging, as in for example, Pendred syndrome where genetic testing for a mutation in the pendrin gene may be required. This will be dealt with in other articles (Baloch *et al.*, 2003).

Spontaneous recovery of hypothyroidism occurs in the course of subacute and postpartum thyroiditis and sometimes during the first 6 months after subtotal thyroidectomy or ^{131}I therapy. It is unlikely in the final stages of chronic autoimmune thyroiditis, but may be present during the initial phases of autoimmune thyroiditis with fluctuating hyperthyroidism (autoimmune destructive release of thyroid hormone from the gland) alternating with hypothyroidism or stimulating thyroid hormone receptor antibodies alternating with blocking ones (Kraiem *et al.*, 1992; Diez *et al.*, 2005).

Glossary

Thyrotopin (TSH) Pituitary heterodimeric molecule belonging to the glycoprotein hormone family, including also gonadotropins (FSH, LH, CG) and the recently identified thyrostimulin. TSH and gonadotropins are constituted by a common alpha subunit and a beta subunit which confers the specific hormone properties to the heterodimer. TSH synthesis and secretion occur in specific pituitary cells (thyrotropes), are negatively regulated by thyroid hormone feedback mechanism and positively influenced by hypothalamic Thyrotropin-Releasing Hormone. TSH is the major stimulator of thyroid function and postnatal growth. It binds to a specific G protein-coupled receptor, which consists of seven membrane-spanning domains and preferentially coupled to Gs. TSH binding is mainly associated with the activation of adenylate cyclase and cAMP pathway. However, recent evidences support a relevant functional role also to Gq coupling and consequent activation phospholipase C and the inositol-phosphate/diacylglycerol pathway.

Thyrotropin-Releasing Hormone (TRH) Tripeptide (L-pyroglutamyl-histidyl-prolineamide) secreted by hypothalamic neurons. Cell bodies are located in the medial parvocellular portion of the paraventricular nucleus, and project neuronal endings to the median eminence, where TRH is secreted. The neuro-hormone reaches pituitary target cells through the portal system and the pituitary stalk. TRH synthesis and secretion are mainly under the control of negative thyroid hormone feedback mechanism and are influenced by several other hypothalamic factors. TRH is the major positive regulating factor of thyrotropin synthesis and secretion and also stimulates prolactin secretion. TRH binds to a specific G-protein coupled receptor, which is preferentially coupled to a Gq. TRH binding is associated with the activation of phospholipase C and the inositol-phosphate/diacylglycerol pathway.

Definition

Central hypothyroidism (CeH) is a rare form of hypothyroidism, representing about 1 out of 1000 hypothyroid subjects (Nebesio *et al.*, 2010; Kempers *et al.*, 2006; Price and Weetman, 2001). It is the consequence of defects in thyrotropin (TSH) secretion, finally resulting in an insufficient stimulation of an otherwise normal thyroid gland. In central hypothyroid cases, a combined hypothalamic-pituitary impairment is usually found (Persani and Bonomi, 2017; Schoenmakers *et al.*, 2015; Persani, 2012).

Diagnosis

The missed diagnosis of CeH represents the main drawback of the reflex-TSH strategy for the screening of thyroid function (Persani, 2012; LaFranchi, 2010; Miyai *et al.*, 1971; Kempers *et al.*, 2006). The serum concentrations of immunoreactive TSH and free thyroxine (FT4) in a series of CeH patients clearly indicate that the diagnosis of these patients cannot be reached by using single TSH measurements. Indeed, FT4 is the parameter with the highest sensitivity and specificity for the diagnosis of hypothyroidism in a population of patients with hypothalamic-pituitary lesions (Persani, 2012; Koulouri *et al.*, 2011; Yamada and Mori, 2008; Alexopoulou *et al.*, 2004; Ferretti *et al.*, 1999). As in primary hypothyroidism, total T4 allows only the recognition of patients with severe impairment of thyroid function. The finding of low FT4, measured by reliable immunoassays, in the presence of low/normal/or even elevated immunoreactive TSH concentrations is consistent with the diagnosis of CeH (**Fig. 1**). Free thyroxine index is a valid alternative parameter for the diagnosis and management. Nevertheless, TSH concentrations in the range of mild primary hypothyroidism can be found also among patients with CeH with prevalent hypothalamic damage and could lead to misdiagnosis (Persani and Bonomi, 2017; Persani, 2012). The exclusion of primary thyroid failure and of interference in TSH measurement retains a fundamental role in confirming the central origin of the thyroid dysfunction (Persani, 2012). Exclusion of primary hypothyroidism should be documented by the absence of any sign of direct thyroid lesion (negative antithyroid antibodies, gland of small/normal size and normal structure at ultrasound). Interference possibly leading to false decrease of TSH concentrations in noncompetitive modern immunoassays includes anti-TSH autoantibodies: exclusion of interference in TSH measure may be obtained by dilution or recovery tests. Indeed, the existence of concomitant or preexisting hypothalamic-pituitary disease, such as combined pituitary hormone deficiencies or

☆*Change History:* March 2018. Marco Bonomi contributed the update. Table 1 was updated.

 doi:10.1016/B978-0-12-801238-3.04094-0

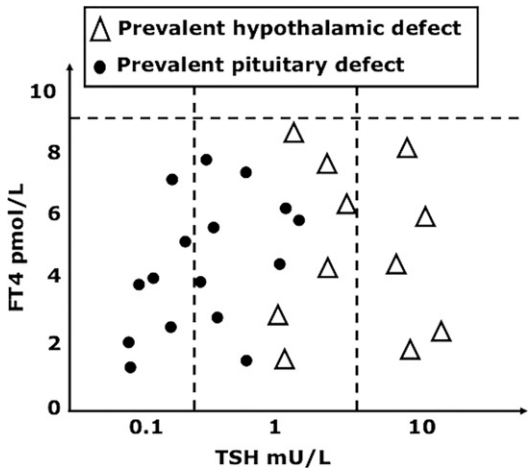

Fig. 1 Serum levels of FT4 and TSH in patients with central hypothyroidism. *Dotted lines* indicate the lower or upper limits of the normal ranges. The evident lack of correlation between TSH and FreeT4 demonstrates that quantitative impairment of TSH secretion does not completely explain the pathogenesis of CeH, and indicates the involvement of qualitative alterations of hypothalamic regulation in a large portion of CeH patients and in particular in those with prevalent hypothalamic defects.

alterations at imaging of sella region, strongly supports the diagnosis of CeH. The history of previous traumatic brain injury or vascular accidents can also support a CeH diagnosis.

Confirmation of CeH can be obtained by TRH testing, in the settings where this test is still currently available (Persani, 2012; van Tijn *et al.*, 2008; Darzy and Shalet, 2005; Mehta *et al.*, 2003; Rose *et al.*, 1999; Faglia, 1998). The finding of blunted or delayed/prolonged responses of immunoreactive TSH after intravenous TRH injections confirm a prevalent pituitary or hypothalamic defect, respectively. Others have not found the test more useful than measurement of basal serum TSH (Hartoft-Nielsen *et al.*, 2004; Yamakita *et al.*, 2001). Another characteristic of CeH is the blunting of nocturnal TSH surge (Darzy and Shalet, 2005; Yamakita *et al.*, 2001; Rose *et al.*, 1999). Both of these anomalies can become useful to support a hidden CeH diagnosis that may be suspected in the presence of FT4 levels in the lower part of the normal range, as in mild primary thyroid failure.

Transient or reversible forms of CeH can be associated with drugs able to inhibit TSH secretion or during recovery from thyrotoxicosis (Persani, 2012; Haugen, 2009).

Finally, before giving the diagnosis of CeH, one should exclude the presence of the so-called "nonthyroidal illnesses" (NTIs) leading to the biochemical picture of the "low T3 syndromes" (Persani, 2012). These conditions include acute (e.g., myocardial infarction, severe infections, extended burns) or chronic (e.g., liver or kidney insufficiency) diseases, or fasting (as in anorexia nervosa), or recovery from general surgery and occur also in patients with intact hypothalamic-pituitary-thyroid axis. NTIs are generally associated with low T3, but normal TSH and FT4, and fall of circulating TSH and FT4 can be seen only in prolonged and manifest disease states as the likely consequence of the suppression of hypothalamic TRH gene expression.

Clinical Presentation

Depending on the cause of CeH, some characteristics of the disease may vary greatly. Genetic CeH can be either isolated or combined with other pituitary hormone deficiencies (CPHD) and can be associated with growth retardation, delayed puberty and/or neurological defects (Persani, 2012; Castinetti *et al.*, 2016; Schoenmakers *et al.*, 2015; Raivio *et al.*, 2012; Pfäffle and Klammt, 2011). Neonatal forms of CeH are not recognized by the screening programs for congenital hypothyroidism based on primary TSH evaluation on dried blood spots (Persani, 2012; LaFranchi, 2010; Bonomi *et al.*, 2009; van Tijn *et al.*, 2008; Miyai, 2007; Kempers *et al.*, 2006), and neurological defects may be particularly severe in patients with TSHβ defects (Persani and Bonomi, 2017; Libri *et al.*, 2013; Ramos *et al.*, 2010; Bonomi *et al.*, 2001; Dacou-Voutetakis *et al.*, 1990; Hayashizaki *et al.*, 1989; Miyai *et al.*, 1971). Nevertheless, several genetic forms generate a mild and/or progressive onset of hypothyroidism beyond the vulnerable period of central nervous system development during infancy (Persani and Bonomi, 2017; Schoenmakers *et al.*, 2015; Bonomi *et al.*, 2009; Collu *et al.*, 1997). Some genetic forms should also be suspected in adolescents or adults with the biochemical features of CeH but lacking a plausible cause of acquired CeH. Some particular clinical features are indicative of specific gene defects (such as macrorchidism for *IGSF1*, or audiometric defects for *TBL1X* defects) (Joustra *et al.*, 2013, 2016; Heinen *et al.*, 2016; Sun *et al.*, 2012).

Nongenetic CeH is typically sporadic and acquired in most cases as the consequence of large sella tumors (Schoenmakers *et al.*, 2015; Persani, 2012). Among the lesions potentially leading to CeH, those that are more frequently associated with hypothalamic defects include large pituitary macroadenomas with suprasellar extension, craniopharyngiomas and suprasellar tumors, cranial irradiation, vascular accidents, and head traumas. In these situations, defects of posterior pituitary function with diabetes insipidus as well as visual field defects, due to compression of the optic nerves, may be concomitant. These lesions generally affect both pituitary and hypothalamic functions to various extent leading to hypothyroidism, always combined with defects of other anterior pituitary hormones and frequently associated with high prolactin levels due to stalk resection or compression. The association with signs and symptoms secondary to the altered secretion of other pituitary hormones (e.g., menstrual disorders, decreased libido, hair loss, galactorrhea, pallor, altered lipid metabolism, etc.) or to local compression (visual defects, headache, etc.) may cover the specific hypothyroid manifestations in several cases. Therefore, the evaluation of TSH and FT4 should always be included in the biochemical evaluation of patients with hypothalamic-pituitary diseases (Feldt-Rasmussen and Klose, 2016), and mild CeH should be suspected also in cases presenting with significant decrements of FT4 levels toward the lower limits of normal.

Pathogenesis

The pathogenesis of typical CeH is due to defects affecting the TRH/TSH function. These defects occur in various pathological conditions including large pituitary macroadenomas with suprasellar extension, craniopharyngiomas and suprasellar tumors (such as meningiomas or gliomas), cranial irradiation, vascular accidents (including Sheehan syndrome), head traumas (including traumatic delivery), infiltrative diseases (such as sarcoidosis) (Schoenmakers *et al.*, 2015; Persani, 2012; Barbesino *et al.*, 2012). As shown also in **Fig. 1**, quantitative impairment of pituitary TSH reserve does not completely explain the pathogenesis of CeH, and indicates the involvement of qualitative alterations in a large portion of CeH patients and in particular in those with prevalent hypothalamic defects. Several patients with CeH of hypothalamic origin have normal or even elevated circulating TSH levels. The lack of any signs of primary thyroid insufficiency (absent antithyroid autoantibodies and normal response to exogenous TSH injection) suggested that hypothyroidism in these patients could result from the secretion of biologically inactive TSH molecules (Persani, 2012). This hypothesis was indirectly supported by the blunted thyroid hormone response to endogenous TRH-stimulated TSH, despite exaggerated and prolonged responses of endogenous TSH to the tripeptide. The very low bioactivity of TSH molecules circulating in several patients with CeH of various origins (idiopathic, secondary to pituitary or hypothalamic tumors, or due to cranial irradiation or Sheehan syndrome) was obtained by means of different bioassays. The reduced bioactivity was due to an impaired binding of circulating TSH to its specific thyroid receptor. Chronic TRH treatment restored both TSH receptor binding and bioactivity, indicating that this hypothalamic factor is necessary for the secretion of TSH molecules with structural features essential for appropriate thyroid stimulation. Lectin affinity chromatography showed that the oligosaccharide structure of TSH molecules circulating in CeH is altered.

Genetic defects associated with CeH in humans and the relative clinical features are reported in **Table 1**.

Table 1 List of genes known to be involved in the pathogenesis of CeH and the corresponding phenotypes

Genes (OMIM #)	*Phenotypes (OMIM #)*	*Inheritance*
TSHβ (188540)	Severe isolated CeH of neonatal onset with high α-GSU, pituitary hyperplasia (275100)	Recessive
TRHR (188545)	Isolated CeH with blunted TSH/PRL response to TRH and apparently uneventful infantile development, and with childhood (growth retardation) to adulthood onset	Recessive
IGSF1 (300137)	CeH associated with low PRL, partial GH deficiency, and macro-orchidism	X-linked
TBL1X (300196)	Mild isolated CeH, normal TRH test, audiometric defects	X-linked
POU1F1 (173110)	Moderate/severe CeH of neonatal to childhood onset combined with GH and PRL defects, prominent forehead, mid-face hypoplasia, depressed nose (613038)	Dominant or recessive
PROP1 (601538)	Moderate/severe CeH of neonatal to childhood onset, combined with GH, PRL, LH/FSH defects, and ACTH deficiency, pituitary hypo – /hyperplasia (262600)	Recessive
HESX1 (601802)	Severe panhypopituitarism associated with septo-optical dysplasia (SOD), supernumerary/hypoplastic digits (182230)	Dominant or recessive
SOX3 (313430)	Hypopituitarism with pituitary hypoplasia, variable ectopic posterior pituitary, persistent cranio-pharyngeal canal and mental retardation (312000)	X-linked
OTX2 (600037)	Hypopituitarism with pituitary hypoplasia, ectopic posterior pituitary, ano/microphtalmia, retinal dystrophy (610125)	Dominant
LHX3 (600577)	Hypopituitarism with conserved ACTH function and associated with pituitary hypo- or hyperplasia, short/rigid cervical spine and variable deafness (221750)	Recessive
LHX4 (602146)	Combined anterior pituitary defects associated with abnormalities of cerebellum and small sella turcica (262700)	Dominant
LEPR (601007)	Severe obesity and hyperphagia combined with delayed puberty and mild thyrotropin defect	Recessive

Treatment

As in primary hypothyroidism, treatment of CeH is based on the administration of L-thyroxine (Persani, 2012; Wiersinga *et al.*, 2012; Beck-Peccoz, 2011). In this condition, particular attention should be paid to the recognition of possible concomitant corticotropin (ACTH) defects leading to partial adrenal insufficiency before starting L-thyroxine therapy. Failure to recognize this concomitant defect may lead to acute adrenal insufficiency during initial days of therapy. Therefore, if a combined corticotrope deficiency is suspected, the screening for adrenal insufficiency is recommended. Alternatively, cautionary treatment with corticosteroids may be advised before starting L-thyroxine.

L-thyroxine replacement therapy should be tailored for each patient, as in primary hypothyroidism (Persani, 2012; Koulouri *et al.*, 2011; Klose *et al.*, 2013; Feldt-Rasmussen and Klose, 2016). Nevertheless, this goal is not easily reached in CeH patients because TSH measurement loses its value as monitoring index. Therapy should be tailored in order to maintain FT4 (and FT3) concentrations in the middle of the reference range, provided that blood for hormone measurement is withdrawn before the morning administration of L-Thyroxine (Persani, 2012; Koulouri *et al.*, 2011). Evaluation of parameters of thyroid hormone action (such as cholesterol, bone markers or sex hormone-binding globulin) could be helpful in cases of doubt. Replacement doses range 1.1–1.7 $\mu g\,kg^{-1}$ per day in the large majority of adult patients, and are generally lower in those over 65 years. Inappropriate treatment should be suspected on the basis of the following conditions: (a) careful clinical evaluation uncovering manifestations of under- or overtreatment regimens; (b) circulating FT4 values in the lower or upper tertile of normal range suggesting under- or overtreatment, respectively; (c) circulating TSH values >0.5 mU L^{-1} generally suggesting undertreatment; (d) addition or removal of replacement therapies for multiple pituitary hormone deficiencies, such as growth hormone or gonadotropin deficiencies.

Hashimoto's Thyroiditis☆

Grigoris Effraimidis and Ulla Feldt-Rasmussen, Rigshospitalet, Copenhagen, Denmark

Glossary

Autoimmunity The condition in which the immune system of an organism attacks its own healthy cells, tissues, or organs, resulting in their damage.

Iodine and the thyroid Iodine is an essential element for the production of thyroid hormone. Thyroid antibodies and autoimmune hypothyroidism are more common in iodine-sufficient areas than in iodine-deficient areas.

Euthyroid Relating to or characterized by normal thyroid function.

Goitrous Affected with goiter; that is, having an enlargement of the thyroid gland.

Hypothyroidism A pathological condition due to insufficient production of thyroid hormones; diminished activity of the thyroid gland.

Thyroglobulin antibodies Auto-antibodies against the protein thyroglobulin, a substrate for the synthesis of the thyroid hormones and a storage of the inactive forms of thyroid hormone and iodine.

Thyroid antibodies Antibodies targeting against components on the thyroid tissues. Clinically relevant thyroid autoantibodies are the antithyroid peroxidase antibodies (TPOAb), thyrotropin receptor antibodies (TRAbs) and thyroglobulin antibodies (TgAb).

Thyroperoxidase antibodies Auto-antibodies against the thyroperoxidase (TPO), an essential enzyme involved in thyroid hormone synthesis.

Hashimoto's thyroiditis is a common, lifelong, organ-specific autoimmune disease. Hashimoto's thyroiditis is associated with hypothyroidism and represents the one end of the clinical-pathological spectrum of the different phenotypes of autoimmune thyroid disease, with its counterpart being Graves' disease associated with hyperthyroidism.

Introduction

In his original article published in 1912 (Hashimoto, 1912), Hakaru Hashimoto described four goitrous patients with a typical histological pattern: diffuse lymphocytic infiltration and fibrosis of the thyroid gland, with a variable degree of atrophy and eosinophilic changes of the thyroid follicular cells. In 1956, Roitt *et al.* (1956) and Rose and Witebsky (1956) detected antibodies against thyroid microsomes (later identified as thyroid peroxidase antibodies Czarnocka *et al.*, 1985) in the serum of patients with Hashimoto's goiter.

Nowadays, the term Hashimoto's disease or Hashimoto's thyroiditis is widely used as a synonym for chronic lymphocytic thyroiditis, chronic autoimmune thyroiditis or autoimmune hypothyroidism, an organ-specific autoimmune disease characterized by lymphocytic infiltration of the thyroid gland and thyroid peroxidase antibodies in serum. Two main clinical types of chronic autoimmune thyroiditis exist marked by the presence or absence of a goiter but in any case, there are no serological markers that can distinguish between them. Purists might argue that the term Hashimoto's disease should be reserved for the less common goitrous variant of chronic autoimmune thyroiditis as originally described by Hashimoto.

Epidemiology

The presence of thyroid peroxidase antibodies (TPOAb) in serum correlates with the presence of focal thyroiditis in biopsy and postmortem material (Yoshida *et al.*, 1978) and is thus a reliable marker of chronic autoimmune thyroiditis. More than 90% of the patients with Hashimoto's thyroiditis are positive for TPOAb and it has been proposed that TPOAb have superior diagnostic value than the thyroglobulin antibodies (TgAb). Therefore, for many physicians TPOAb positivity suffices for the confirmation of Hashimoto's thyroiditis. Although this is true for the vast majority of Hashimoto's thyroiditis patients, there are patients where TgAb positivity is the only serological marker of thyroid autoimmunity (Pedersen *et al.*, 2011).

The prevalence of serum TPO-Ab in women rises from 15% at ages 18–24 years to 24% at ages 55–64 years, whereas the prevalence in men is much lower (~3%) with no age trend. The prevalence of subclinical hypothyroidism, is very high

☆*Change History*: February 2018. Grigoris Effraimidis and Ulla Feldt-Rasmussen updated the text, tables, further reading and glossary to the entire "Hashimoto's Disease" chapter.

This article is an update of Wilmar M. Wiersinga, Hashimoto's Disease, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 434–435.

(75 per 1000 women and 28 per 1000 men) in the general adult population (Tunbridge *et al.*, 1977; Vanderpump *et al.*, 1995) and increases with advancing age. The prevalence of overt hypothyroidism in adults is 18 per 1000 women and 1 per 1000 men. It has been estimated that 90% of noniatrogenic hypothyroidism in iodine sufficient areas is due to thyroid autoimmunity.

Clinics

Most patients (~70%) with chronic autoimmune thyroiditis are asymptomatic and remain euthyroid. Many factors have been proposed as the determinants of the progression toward development of hypothyroidism. High iodine intake might be involved in light of a higher prevalence of autoimmune hypothyroidism in iodine-sufficient regions as compared with iodine-deficient regions (Bülow Pedersen *et al.*, 2002; Pedersen *et al.*, 2011). Overt hypothyroidism in patients on a very rich iodine diet (e.g., seaweed, kelp) can be reversible on avoiding the source of the iodine excess.

Current smoking is a known risk factor for Graves' disease but it has been showed that it is protective for Hashimoto's disease (Effraimidis and Wiersinga, 2014). Moderate alcohol consumption is associated with a reduction in the risk of Hashimoto's thyroiditis (Effraimidis *et al.*, 2012). Current studies don't allow definite conclusions regarding the use of selenium supplementation for Hashimoto's thyroiditis (van Zuuren *et al.*, 2014). Low vitamin D levels have been reported as a risk factor for various autoimmune diseases but the picture is less clear regarding Hashimoto's thyroiditis (Effraimidis and Wiersinga, 2014).

In the atrophic variant of chronic autoimmune thyroiditis (atrophic myxedema), fibrosis is the predominant feature along with lymphocytic infiltration. In the less common goitrous variant originally described by Hashimoto, the histology remains essentially unaltered after 20 years. The goiter is diffuse and has a firm "rubbery" consistence; it does not regress in 43% of patients despite T_4 treatment. Some patients have an initial transient hyperthyroid stage labeled as Hashitoxicosis. It disappears in a few months and can be caused either by autoimmune destruction with release of thyroid hormones into the circulation or to TSH receptor-stimulating antibodies, which may give way to TSH receptor-blocking antibodies (McLachlan and Rapoport, 2014).

The clinical features, the diagnosis and the treatment of the hypothyroidism of the Hashimoto's thyroiditis is discussed in the chapters Hypothyroidism, diagnosis of; Hypothyroidism, treatment of.

Overt autoimmune hypothyroidism demands in the vast majority of the cases lifelong treatment with L-thyroxine, but juvenile and adolescent Hashimoto's thyroiditis may be self limiting.

Systemic Manifestations of Hypothyroidism☆

Massimo Tonacchera, University of Pisa, Pisa, Italy
Luca Chiovato, University of Pavia, Pavia, Italy

Glossary

Autoimmune thyroid disease A disease in which clinical manifestations are due to the reaction of the immune system against thyroid antigens.

Central hypothyroidism Hypothyroidism due to deficient stimulation of an intrinsically normal thyroid gland by thyrotropin; can be the consequence of an anatomical or functional disorder of the pituitary gland, the hypothalamus, or both.

Primary hypothyroidism Hypothyroidism due to a deficient function of the thyroid gland.

Introduction

Hypothyroidism may affect persons of both sexes and all ages. The clinical expression of thyroid hormone deficiency varies considerably between individuals. It is influenced mainly by the age of the patient and the rate at which hypothyroidism develops, whereas it is largely independent of its cause. Most adult patients complain of a slowing of physical and mental activity.

Hypothyroidism may be overt or subclinical, with the latter being defined as increased serum thyrotropin (TSH) and normal free thyroxine (T4) and triiodothyronine (T3) concentrations. Even among patients with overt hypothyroidism, the severity is variable. At one extreme are patients who have few symptoms and signs of hypothyroidism, and at the other extreme are those with myxedema coma.

Clinical Aspects of Hypothyroidism at various Ages

Infantile and Juvenile Hypothyroidism

Hypothyroidism in the newborn results in severe mental deficiency, neurological impairment, and physical retardation unless treatment is initiated within weeks after birth. Early diagnosis and treatment of congenital hypothyroidism, consequent to systematic screening for this condition during the neonatal period, results in the disappearance of the clinical picture of the disease, at least in developed countries. Hypothyroidism in children is characterized mainly by retarded growth and impaired mental performance. Infantile hypothyroidism leads to sexual immaturity, and juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles in females. Precocious puberty may occur rarely.

Thyroid hormone is essential for normal growth and maturation of the skeleton. Deficient thyroid hormone production *in utero* and in the neonate retards growth and delays skeletal maturation. Deficiency during early life also leads to an abnormal stippled appearance of the epiphyseal centers of ossification (epiphyseal dysgenesis). Before puberty, thyroid hormones also play a major role in the maturation of bone. Impairment of linear growth leads to dwarfism, where the limbs are disproportionately short in relation to the trunk. Bone age is retarded in hypothyroid children.

Hypothyroidism in the Adult

In the adult, the clinical manifestations of hypothyroidism may be profound, but they are reversible. The development of spontaneous hypothyroidism is usually slow, and many patients seek medical attention for variable and nonspecific symptoms. In contrast, patients who develop hypothyroidism rapidly (i.e., when replacement therapy is discontinued in patients with primary hypothyroidism or after the gland is surgically removed) have more symptoms. In such patients, manifestations of overt hypothyroidism are present by 6 weeks. In general, older patients tend to have fewer symptoms and signs of hypothyroidism than do young adults.

In adults, common features of hypothyroidism include easy fatigability, tiredness, coldness, mild weight gain, constipation, menstrual irregularities, and muscle cramps. Drowsiness and slowing of intellectual and motor activity are often reported. Sensitivity to cold is suggested by the use of more blankets on the bed. Women frequently complain of hair loss, brittle nails, and dry skin. Periorbital puffiness may be present. Stiffness and aching of muscles may be attributed to rheumatism. Constipation may occur. Numbness and tingling of the extremities are frequent. Physical findings include cool dry skin, a puffy face and hands, a hoarse husky voice, and slow reflexes.

 doi:10.1016/B978-0-12-801238-3.99464-9

Clinical Features of Hypothyroidism in the Elderly

Hypothyroidism in the elderly is often atypical and elusive and often lacks the classic clinical features present in younger patients. This is due to a combination of several factors, including the insidious onset, the ambiguity of several signs and symptoms (e.g., fatigue, weakness, cold intolerance, dry skin, hair loss, constipation, poor appetite, depression and/or mental deterioration, hearing loss, cardiomegaly, congestive heart failure) that may be attributed to normal aging, and the frequent coexistence of several age-associated diseases.

The most relevant clinical findings that lead one to suspect hypothyroidism in the elderly are an unexplained increase in serum cholesterol, severe constipation, congestive heart failure (particularly when it presents as restrictive cardiomyopathy), and macrocytic anemia (as a consequence of folate deficiency or coexistent autoimmune gastritis and pernicious anemia).

Clinical Aspects of Hypothyroidism Due to Various Etiologies

Primary Hypothyroidism

Primary hypothyroidism in adults results mainly from autoimmune thyroiditis, is more common in women than in men, and occurs between 40 and 60 years of age. In these patients, clinical features of hypothyroidism may be accompanied by the typical goiter of Hashimoto's thyroiditis. When present, the goiter is usually firm in consistency, generally moderate in size, and often lobulated (although well-defined nodules are unusual).

Other organ-specific autoimmune diseases, such as insulin-dependent diabetes mellitus, Addison's disease, premature ovarian failure, celiac disease, hypoparathyroidism, and myasthenia gravis, may also coexist. Patients with primary hypothyroidism may also complain of vitiligo and alopecia. Primary autoimmune hypothyroidism may also occur as a component of either the type I or the type II polyglandular autoimmune syndrome. The specific association of primary hypothyroidism and primary adrenal cortical insufficiency is known as Schmidt syndrome. The rare type I syndrome consists of at least two of the triad of Addison's disease, hypoparathyroidism, and chronic mucocutaneous candidiadis; other autoimmune disorders, such as alopecia, chronic autoimmune thyroiditis, and malabsorption syndrome, may also be present. Autoimmune thyroid disease is reported in 10 to 12% of these patients. Type I polyglandular autoimmune syndrome presents more often during childhood. The type II syndrome is more common and usually presents during adulthood. Addison's disease, Hashimoto's thyroiditis, and type 1 diabetes are the most common endocrine deficiencies found in these patients, although gonadal failure, pernicious anemia, and vitiligo are observed in a significant percentage.

Central Hypothyroidism

The clinical picture of central hypothyroidism varies depending on the severity of thyroid failure, the extent of associated hormone deficiencies, the age of the patient, and the nature of the underlying lesion. Central hypothyroidism is due to TSH deficiency caused by either hypothalamic or pituitary disease. The differentiation of central hypothyroidism from primary hypothyroidism is important for the institution of the proper therapy. The clinical features of central hypothyroidism are similar to those of primary hypothyroidism, although the former are generally less pronounced. The skin is pale and cool, but it is not as coarse and dry as in primary hypothyroidism. Periorbital and peripheral edema are uncommon in patients with central hypothyroidism. Loss of axillary, pubic, and facial hair, as well as thinning of the lateral eyebrows, is more pronounced. The tongue is not enlarged, and hoarseness of the voice is not as prominent as it is in primary hypothyroidism. The heart tends to be small, and blood pressure is low. Atrophic breasts and amenorrhea are found in women. Body weight is more likely to be reduced than to be increased. Defects in growth hormone (GH) and gonadotropin secretion usually precede TSH insufficiency, and in most cases adrenocorticotropin hormone (ACTH) secretion is the last to be affected. Growth failure with delayed skeletal maturation results from GH deficiency in children. Hypoglycemia may occur. Gonadotropin insufficiency results in impotence, loss of libido, and diminished beard growth in men and results in amenhorrea, infertility, and atrophy of the breasts in women. ACTH deficiency leads to weakness, postural hypotension, and depigmentation of the areole and other normally pigmented areas of the skin. Symptoms and signs that arise directly from the hypothalamic or pituitary lesion may precede, accompany, or even obscure manifestations of pituitary failure. The manifestations of a sellar mass include headache and symptoms secondary to compression of adjacent structures with visual field disturbances and ophthalmoplegia.

Diagnostic Accuracy of the Clinical Features of Hypothyroidism

Several attempts have been made to develop a clinical score system that, based on the most frequent symptoms and signs of hypothyroidism, could accurately predict the diagnosis of thyroid failure in individual patients.

During the 1960s, Billewicz and colleagues described a diagnostic index that scored the presence or absence of various signs and symptoms of hypothyroidism. However, at that time, modern laboratory thyroid function tests were not available to validate the diagnostic accuracy of such a score. More recently, Zulewski and colleagues proposed a convenient clinical score that is both

Table 1 Sensitivity and specificity of the 14 symptoms and signs of hypothyroidism and analysis of their positive and negative predictive values (percentages)

Symptoms and signs	*Sensitivity*	*Specificity*	*Positive predictive value*	*Negative predictive value*
Ankle reflex	77	93	92	80
Dry skin	76	64	68	73
Cold intolerance	64	65	65	64
Coarse skin	60	81	76	67
Puffiness	60	96	94	71
Pulse rate	58	42	50	50
Sweating	54	86	79	65
Weight increase	54	77	70	63
Paresthesia	52	82	75	63
Cold skin	50	80	71	61
Constipation	48	85	76	62
Slow movements	36	99	96	61
Hoarseness	34	87	73	57
Hearing loss	22	97	90	53

Table 2 Scoring of symptoms and signs of hypothyroidism

	On the basis of	*Score*	
		Present	*Absent*
Symptoms			
Diminished sweating	Sweating in the warm room on a hot summer day	1	0
Hoarseness	Speaking voice, singing voice	1	0
Paresthesia	Subjective sensation	1	0
Dry skin	Dryness of skin, noticed spontaneously, requiring treatment	1	0
Constipation	Bowel habit, use of laxative	1	0
Impairment of hearing	Progressive impairment of hearing	1	0
Weight increase	Recorded weight increase, tightness of clothes	1	0
Physical signs			
Slow movements	Observe patient removing his/her clothes	1	0
Delayed ankle reflex	Observe the relaxation of the reflex	1	0
Coarse skin	Examine hands, forearms, and elbows for roughness and thickening of skin	1	0
Periorbital puffiness	This should obscure the curve of the malar bone	1	0
Cold skin	Compare temperature of hands with that of examiner	1	0

Note. For clinical judgment, add 1 point to the sum of symptoms and signs present in women under 55 years of age. Hypothyroid, more than 5 points; intermediate, 3 to 5 points; euthyroid, less than 3 points.

easy to determine and sensitive for individual assessment of the severity of thyroid failure. The frequencies of the 14 more common symptoms and signs of overt hypothyroidism are shown in **Table 1**. The most frequent features in hypothyroid patients were prolonged ankle reflex (77%) and complaints about dry skin (76%). A reduced pulse rate and cold intolerance were recorded with a high frequency in euthyroid controls and so were excluded from this score. The sensitivity and specificity of each symptom and sign of hypothyroidism, and the analysis of their positive and negative predictive values, are shown in **Table 1**. **Table 2** shows the scoring system of symptoms and signs of hypothyroidism. Because a correlation analysis revealed a significant correlation of these scores with age, a simple age-correcting factor was defined by adding 1 point to the sum of symptoms and signs in women under 55 years of age. According to this analysis, the following diagnostic ranges for the clinical judgment with the age-corrected score were defined: hypothyroid, more than 5 points; intermediate, 3 to 5 points; euthyroid, 0 to 2 points.

Organ System Manifestations of Hypothyroidism

Cutaneous Manifestations and Changes in the Connective Tissues

The cutaneous changes observed in hypothyroidism belong to the most classic and frequent findings of the disease (**Table 3**). In more than 80% of patients with primary hypothyroidism, the epidermis is dry, rough, cool, and covered with fine superficial scales. This is an expression of decreased cutaneous metabolism, reduced secretion of sweat and sebaceous glands, vasoconstriction, thinning of the epidermis, and hyperkeratosis of the stratum corneum. The face is puffy, pale, and expressionless at rest

Table 3 Cutaneous signs and symptoms of hypothyroidism (percentages)

Cutaneous manifestation	*Frequency*
Cold intolerance	50–95
Nail abnormality	90
Thickening and dryness of hair and skin	80–90
Edema of hands, face, and eyelids	70–85
Change in shape of face	70
Malar flush	50
Nonpitting edema	30
Alopecia	30–40
Pallor	25–60
Decreased sweat secretion	10–70

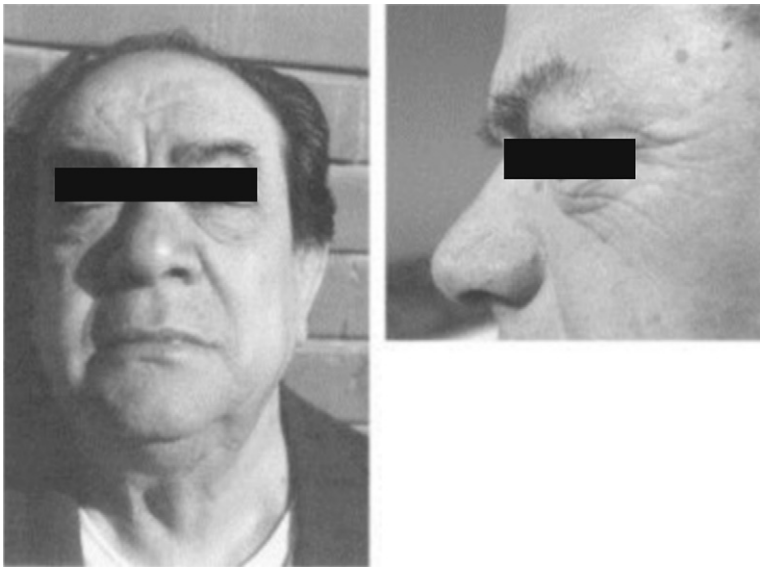

Fig. 1 Photographs of a hypothyroid patient.

(Fig. 1). The palpebral fissure may be narrowed because of blepharoptosis. The tongue is usually large, and some patients will complain of this problem. The tongue is smooth if pernicious anemia coexists. The voice is husky, low-pitched, and coarse due to the enlargement of the tongue and the thickening of the pharyngeal and laryngeal mucous membranes. The speech is deliberate and slow.

Hair Follicles and Nails

The hair is dry, dull, and coarse, and it grows slowly, becoming sparse and falling out readily. Loss of scalp, genital, and beard hair may also occur. Hair may be lost from the temporal aspects of the eyebrows (Queen Anne's sign). The nails, through retardation of growth, become thickened and brittle, striated in both transverse and longitudinal grooves, showing frequent deformities.

Cardiovascular Changes

Lack of thyroid hormones causes multiple alterations in the cardiovascular system (Table 4). Bradycardia, cardiomegaly, and low-voltage complexes on the electrocardiogram (ECG) are well-known features. The decrease in pulse rate approximately parallels the decrease in the body's metabolic rate. Myocardial contractility is reduced. The cardiac output at rest is decreased due to reduction in both stroke volume and heart rate, reflecting loss of the inotropic and chronotropic effects of thyroid hormones. Peripheral vascular resistance at rest is increased, and blood volume is reduced. These hemodynamic alterations cause narrowing of pulse pressure, prolongation of circulation time, and decreased blood flow to the tissues. Arterial blood pressure is often mildly increased. Hypertension is present in 10 to 20% of patients with hypothyroidism. Diastolic hypertension is usually restored to normal after treatment. Few symptoms associated with the cardiovascular system are referred from patients with hypothyroidism. Exertional dyspnea and exercise intolerance are probably due to skeletal muscle dysfunction.

Table 4 Cardiovascular signs and symptoms in hypothyroidism

Symptoms
Dyspnea
Decreased exercise tolerance
Angina
Signs
Low pulse rate
Increased systemic vascular resistance
Diastolic hypertension
Cardiomegaly
Pericardial effusion
Peripheral nonpitting edema
Low voltage ECG, nonspecific ST–T changes

On physical examination, certain findings can suggest hypothyroidism. The heart rate is lowered, the pulse pressure is narrowed, and the carotid upstroke and left ventricular apical impulse are diminished. The heart sounds are diminished in intensity. This finding is due largely to effusion into the pericardial sac of fluid rich in protein and glycosaminoglycans.

Electrocardiographic Changes

Electrocardiographic changes include sinus bradycardia, prolongation of the PR interval, low amplitude of the P wave and QRS complex, alterations of the ST segment, and flattened or inverted T waves. Although suggestive of myocardial ischemia, these waveform changes often disappear during T4 substitution therapy. Pericardial effusion is probably responsible for the low amplitude.

Respiratory Changes

Respiratory troubles are rarely a major complaint in hypothyroid patients. However, hypothyroidism may cause respiratory problems through (1) depression of the respiratory center in the brain, (2) disturbed neural conduction and/or neuromuscular transmission to the respiratory muscles (due to hypothyroid neuropathy), (3) diseased respiratory muscle function (due to hypothyroid myopathy), and/or (4) changes in the alveolar–capillary membranes and the surfactant lining the alveoli, leading to impaired gas exchange.

Fatigue and dyspnea on exertion are frequent symptoms. Dyspnea is a frequent complaint of myxedematous patients, but it is also a common symptom among well persons. Congestive heart failure of separate origin, pleural effusion, anemia, obesity, and/or pulmonary disease may be responsible for dyspnea.

Gastrointestinal Changes

The gastrointestinal manifestations of hypothyroidism are listed in **Table 5**. Poor appetite can be a leading symptom in hypothyroid patients. Anorexia can reasonably be interpreted as the reflection of a lowered food requirement. Although two-thirds of hypothyroid patients report weight gain, it is of modest degree and due largely to retention of fluid by the hydrophilic glycoprotein deposits in the tissues. True obesity is not a feature of hypothyroidism per se.

Constipation is frequently present and is the result of lowered food intake and decreased peristaltic activity. Atrophy of the gastric and intestinal mucosa and myxedematous infiltration of the bowel wall may be present at histological examination. Immune gastritis is often observed in hypothyroid patients with autoimmune thyroiditis. As many as 50% of patients with autoimmune hypothyroidism have achlorhydria, 25% have circulating antibodies directed against the gastric parietal cells or intrinsic factor, and 2 to 10% have pernicious anemia caused by impaired absorption of vitamin B12.

Symptoms or signs of disturbed liver or exocrine pancreatic function are usually not encountered, but biochemical tests may suggest disease. The association of liver disease and hypothyroidism is suggestive of a multisystem autoimmune disease affecting both the liver (e.g., chronic active hepatitis, primary biliary cirrhosis) and the thyroid. Structural liver damage is unusual in hypothyroidism per se. Serum glutamine–oxaloacetic transaminase (GOT), lactate dehydrogenase (LDH), and creatin–phosphokinase (CPK) levels are elevated in patients with hypothyroidism. These enzymes return to normal over 2 to 4 weeks during treatment. Urinary amylase levels may be increased.

Cerebral and Neurological Changes

Thyroid hormone is essential for the development of the central nervous system. Deficiency during fetal life or at birth causes hypoplasia of cortical neurons with poor development of cellular processes, retarded myelination, and reduced vascularity.

Table 5 Gastrointestinal manifestations of hypothyroidism

Symptoms
Anorexia
Gaseous distension
Constipation
Signs
Prolonged gastric emptying
Prolonged intestinal transit time
Slowed intestinal absorption
Ascites
Elevated liver enzymes
Gallbladder hypotonia

Table 6 Neurological and psychiatric manifestations in hypothyroidism

Neurological symptoms or signs
Somnolence, lethargy
Slow speech
Impaired cognitive functions
Headache
Paresthesias
Cerebellar ataxia
Deafness
Vertigo
Delayed relaxation of deep tendon reflexes
Psychiatric syndromes
Depression
Bipolar disorders
Affective psychosis

Deficiency of thyroid hormone beginning during adult life causes less severe manifestations that usually reverse after treatment with thyroid hormone.

Table 6 lists the numerous symptoms suggesting either neurological or psychiatric disorders in patients with moderate to severe hypothyroidism. In adult and elderly patients, mental changes may go unrecognized for a long time because of their slow development and because they may mimic cerebral atherosclerosis. However, an unusual complacency, fatigue, and pronounced somnolence or even lethargy, together with a prolonged reaction time, should suggest the possibility of hypothyroidism. All intellectual functions, including speech, are slowed. There is loss of initiative, and slow-wittedness and memory defects are common. Myxedematous dementia in the elderly patient may be mistaken for senile dementia. Memory is undoubtedly impaired, and attention and the desire to think are reduced. The emotional level seems definitely low, and irritability is decreased. Except during the terminal stage, reasoning power is preserved. Sensory phenomena are common. Numbness and tingling of the extremities are frequent. Mononeuropathies occur in hypothyroidism, as attested to by the high incidence of carpal tunnel syndrome (i.e., compression of the median nerve at the wrist). Nocturnal paresthesia and pain in the median nerve distribution in one hand or both hands is a common manifestation of this condition.

The tendon reflexes are slow, especially during the relaxation phase, producing the characteristic "hung-up reflexes." This phenomenon is due to a decrease in the rate of muscle contraction and relaxation rather than to a delay in nerve conduction.

Electroencephalographic changes include slow alpha wave activity and general loss of amplitude.

Muscle–Skeletal Changes

Muscles

In patients with hypothyroidism, disordered muscle function often is the predominating feature of the clinical syndrome. Generalized muscular hypertrophy, accompanied by easy fatigue and slowness of movements, occurs in some myxedematous children or adults.

Muscle symptoms such as myalgia, muscle weakness, stiffness, cramps, and easy fatigability are very prevalent in hypothyroid patients. The symptoms are aggravated by exposure to cold. They are also prominent during the rapid onset of hypothyroidism after surgery or 131-iodine therapy.

Skeletal system: calcium and phosphorus metabolism

In the adult skeleton, thyroid hormone deficiency decreases recruitment, maturation, and activity of bone cells, leading to decreased remodeling that is especially reflected in the impaired function of the osteoclasts. Despite this decrease in osteoclastic

Table 7 Changes in serum lipids in hypothyroidism

Total cholesterol	Increase
LDL cholesterol	Increase
HDL2 cholesterol	Modest increase
HDL3 cholesterol	No change
Triglycerides	No change or modest increase

activity, trabecular bone volume and bone mineral density appear to be comparable to those in age-matched normals, presumably because of the corresponding decrease in osteoblastic activity. The concentrations of calcium and phosphorus in serum are usually normal, but calcium may be slightly elevated. Serum alkaline phosphatase levels are often decreased, as are serum osteocalcine levels. Because the levels of parathyroid hormone are often slightly increased, some degree of resistance to its action may be present. Serum concentrations of 1,25-dihydroxycholecalciferol are also increased.

Hematological Changes

Anemia is present in as many as two-thirds of hypothyroid children and adolescents and in approximately one-third of adults with hypothyroidism. Anemia is usually mild. In two reports on a large series of patients with hypothyroidism from various causes, the incidence of anemia ranged from 32% to as high as 84%. Anemia in hypothyroidism may be a normochromic and normocytic anemia due to the diminished oxygen requirements and decreased production of erythropoietin, or it may result from a specific depression of the marrow that lacks thyroid hormone. The anemia may be macrocytic, sometimes from deficiency of vitamin B12. Folate deficiency from malabsorption or dietary inadequacy may also cause macrocytic anemia.

Granulocyte, lymphocyte, and platelet counts are usually normal in hypothyroidism. Hypothyroid patients may have bleeding symptoms such as easy bruising, menorrhagia, and prolonged bleeding after tooth extraction. The most frequent defects in hemostasis are prolonged bleeding time, decreased platelet adhesiveness, and low plasma concentrations of factor VIII and von Willebrand factor.

Changes in the Reproductive Tract

In both sexes, thyroid hormones influence sexual development and reproductive function. Infantile hypothyroidism leads to sexual immaturity, and juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles. Paradoxically, primary hypothyroidism may also cause precocious sexual development and galactorrhea.

In adult men, hypothyroidism may lead to impotence, lack of libido, and/or (rarely) testicular tubular involution. The testicles are histologically immature if hypothyroidism preceded puberty and show tubular involution if the onset of hypothyroidism was after puberty. In adult hypothyroid men, semen analysis is usually normal. In adult women, severe hypothyroidism may be associated with diminished libido and failure of ovulation. In general, hypothyroid women complain of menorrhagia as well as (occasionally) oligo and amenorrhea. Plasma gonadotropins are usually in the normal range in primary hypothyroidism, and the pulsatile gonadotropin release during the follicular phase is normal, but the ovulatory surge of luteinizing hormone (LH) might not happen. Secretion of progesterone is inadequate, and endometrial proliferation persists, resulting in excessive and irregular breakthrough menstrual bleeding. The anovulation is reflected in the frequent finding of a proliferative endometrium. These changes may be due to a deficient secretion of LH. Mild to moderate hyperprolactinemia is a frequent finding in hypothyroid women with or without galactorrhea. It is attributed to the stimulatory effect of increased thyrotropin-releasing hormone (TRH) on prolactin secretion. Fertility is reduced, and spontaneous abortion may result, although many pregnancies are successful.

The literature contains many reports of pregnancy in untreated hypothyroid women. Euthyroid neonates born to hypothyroid mothers during pregnancy have been reported to achieve lower IQs later in life. When treatment has been started during pregnancy, a normal child is usually produced, but abortion is frequent in myxedematous women. Pregnancy-induced hypertension is two to three times more common in hypothyroid women. Low birthweight may be secondary to premature delivery for gestational hypertension. The incidence of various congenital abnormalities may be increased, but recent studies do not report an increased risk of fetal death or congenital anomalies with proper treatment.

Other Endocrine Glands

Hypothyroidism decreases GH secretion, and hypothyroid children have a dramatic retardation of growth. Retarded growth caused by hypothyroidism appears to result from deficient secretion of GH as well as from impaired action of GH. Many hypothyroid children have subnormal serum GH response to insulin–induced hypoglycemia. GH secretion is decreased in hypothyroidism related to an increase in hypothalamic-somatostatinergic tone and results in low serum insulin-like growth factor-1 (IGF-1) concentrations. Serum IGF-2, IGF-binding protein-1 (IGFBP-1), and IGFBP-3 also fall, whereas IGFBP-2 rises. These changes are reversible with treatment.

Thyrotroph hyperplasia caused by primary hypothyroidism may result in sellar enlargement, particularly when the condition has remained untreated for a long period of time. Patients with severe hypothyroidism may have an increase in serum prolactin level that correlates with the level of serum TSH, and some patients develop galactorrhea.

Metabolic Changes

The decrease in energy metabolism and heat production is reflected in the low basal metabolic rate (BMR), decreased appetite, cold intolerance, and slightly lower basal body temperature. Measurement of the resting energy expenditure is rarely performed nowadays. In patients with complete athyreosis, it falls between 35 and 45% below normal. Both the synthesis and the degradation of proteins are decreased (the latter especially so), resulting in a nitrogene balance that is usually slightly positive.

In hypothyroidism, absorption of glucose from the gastrointestinal tract is slowed and peripheral glucose assimilation is retarded. At the same time, glycerol release from adipose tissue is slowed and the availability of amino acids and glycerol for gluconeogenesis is decreased. The oral glucose tolerance curve is characteristically flat, and the insulin response to glucose is delayed. Degradation of insulin is slow, so the sensitivity to exogenous insulin may be increased. Despite the easily demonstrable abnormalities in carbohydrate metabolism in hypothyroidism, clinical manifestations of these abnormalities are seldom conspicuous. A variety of abnormalities in plasma lipid concentrations occur in hypothyroidism (**Table 7**). Plasma free fatty acid concentrations are normal, whereas plasma concentrations of triglycerides, phospholipids, and low-density lipoprotein (LDL) cholesterol are well elevated. Biosynthesis of fatty acids and lipolysis is reduced. In general, the changes bear a reciprocal relationship to the level of thyroid activity.

The increased serum cholesterol may represent an alteration in the substrate steady-state level caused by a transient proportionally greater retardation in degradation than in synthesis. The increase of serum cholesterol is largely accounted for by an increase of LDL cholesterol. Interestingly, the LDL particles of hypothyroid patients are also susceptible to increased oxizability. The increase of high-density lipoprotein-2 (HDL2) cholesterol but not of HDL3 cholesterol is due to diminished activity of cholesteryl ester transfer protein and hepatic lipase (which is involved in the conversion of HDL2 to HDL3). The occasional modest increase of serum triglycerides has been related to decreased lipoprotein lipase activity in postheparin plasma.

Treatment of Hypothyroidism☆

Bernadette Biondi, University of Naples Federico II, Naples, Italy

Definition of Hypothyroidism

Primary hypothyroidism is characterized by reduced secretion of thyroid hormones by the thyroid gland. It can be overt (increased serum TSH with low thyroid hormone) or subclinical (increased serum TSH with thyroid hormone at the lower limit of their respective reference range) (Biondi and Wartofsky, 2014). Secondary hypothyroidism is due to an insufficient stimulation of a normal thyroid gland due to a deficiency in TSH as a result of hypothalamic or pituitary disease and can be diagnosed when thyroid hormone levels are low and serum TSH is inappropriately low-normal or slightly elevated (Biondi and Wartofsky, 2014). $<1\%$ of cases of hypothyroidism are due to TSH deficiency.

Iodine deficiency is the most common cause of persistent hypothyroidism in the world. Hashimoto's thyroiditis, an autoimmune disease, represents the most common cause of acquired subclinical or overt hypothyroidism in adults in areas of iodine sufficiency. Treatment with radioiodine for hyperthyroidism may induce thyroid hormone deficiency in about 82% of patients with Graves' disease and about 60% of patients with toxic adenoma and toxic multinodular goiter (Biondi and Cooper, 2008). Moreover, acquired hypothyroidism can also develop after total and partial thyroidectomy and external radiotherapy of the head and neck.

Transient hypothyroidism is characterized by a period of reduced thyroid function with elevated TSH, which is followed by recovery to a euthyroid state. Transient causes of a TSH increase in adults are frequently related to viral, autoimmune, infiltrative or infectious disorders of the thyroid gland. Postpartum thyroiditis can be developed after delivery in women with individual or personal and/or family history of autoimmune thyroid disorders, autoimmune endocrine conditions or nonendocrine autoimmune disorders.

Some drugs can interfere with thyroid function, (iodine-containing compounds, lithium carbonate, cytokines, tyrosine kinase inhibitors (TKIs), amiodarone) (Biondi and Wartofsky, 2014; Biondi and Cooper, 2008). This drugs can induce transient hypothyroidism, although a persistent thyroid hormone deficiency can be developed specially in patients with preexisting thyroid autoimmunity.

Replacement Therapy With Levothyroxine

Replacement therapy with thyroid hormone is indicated as a lifelong treatment in patients with persistent hypothyroidism (Biondi and Wartofsky, 2014; Biondi and Cooper, 2008). Synthetic levothyroxine (L-T4) has largely replaced animal thyroid extract in the treatment of hypothyroidism since 1950. Today, L-T4 represents the first-line treatment in patients with hypothyroidism because of its long half-life (about 7 days) and safe biochemical profile after once daily administration. It is generally considered well tolerated, and associated with good patient compliance.

The aim of replacement therapy with L-T4 is to restore biochemical and clinical euthyroidism.

Treatment with L-T4 is able to prevent the progression of subclinical to overt hypothyroidism avoiding a severe hypothyroid state (myxedema). L-T4 improves the symptoms, quality of life, and high risk of cardiovascular complications associated with hypothyroidism.

Two important metaanalyses provided sufficient evidence to justify treatment of patients with subclinical hypothyroidism (SHypo) and a serum TSH level above 10 mIU/L, to reduce increased risk of coronary heart disease (CHD) and heart failure (HF) (Rodondi *et al.*, 2008; Gencer *et al.*, 2012).

On this basis, L-T4 monotherapy is recommended by international guidelines in patients with overt hypothyroidism and in presence of subclinical hypothyroidism when serum TSH is above 10 mIU/L (Cooper and Biondi, 2012; Garber *et al.*, 2012; Pearce *et al.*, 2013). Treatment of patients with mild SHypo (TSH levels 4.5–9.9 mU/L) remains controversial. Evidence suggests that treatment could be indicated in patients with positive antithyroid antibody tests and a progressively rising TSH levels, new onset of symptoms or depression, goiter, or cardiovascular risk factors (Cooper and Biondi, 2012; Garber *et al.*, 2012; Pearce *et al.*, 2013).

Starting Dose of L-T4

Usually body weight is considered a good indicator for calculating an appropriate starting dose of L-T4. Most patients are well treated with a narrow dose window that varies according to body weight from 1.6 to 1.8 μg/kg/day for replacement therapy in young and middle-aged patients (Biondi and Wartofsky, 2014).

☆*Change History*: February 2018. Bernadette Biondi updated the text and references to this entire article.

This article is an update of Anthony D. Toft, Hypothyroidism, Treatment of, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 750-753.

 doi:10.1016/B978-0-12-801238-3.04164-7

The etiology and severity of hypothyroidism, age, sex, body mass index, and any underlying physiological or pathological conditions (pregnancy and comorbidities) may affect the L-T4 dose. Some conditions may be associated with increasing (e.g., pregnancy, glomerular disease, malabsorption, drugs interfering with L-T4 absorption, increased metabolism or deiodinase activity) or decreasing the L-T4 dosage (weight loss, withdrawal of drugs interfering with L-T4, and atrial arrhythmias) (Biondi and Wartofsky, 2014). Elderly patients require lower doses of L-T4 than younger patients and serum TSH should be normalized to a higher target level (>6.0 mIU/L) (Biondi and Wartofsky, 2014; Biondi and Cooper, 2008).

An initial full replacement dose is safe and effective in reversing symptoms of hypothyroidism in young adults (Biondi and Wartofsky, 2014). On the contrary, replacement therapy should be started with low doses of L-T4 (25–50 μg/d) in patients older than 50–60 years without evidence of CHD (Biondi and Wartofsky, 2014). This dosage should be titrated gradually with a progressive increase every 2–3 weeks until euthyroidism is reached. In patients with severe ischemic heart disease, the starting dose should be even lower (12.5 μg/d) with a progressive increase of 12.5 μg/d every 4–6 weeks (Biondi and Wartofsky, 2014). Some patients may need coronary revascularization before achieving euthyroidism because the progressive L-T4 may trigger severe angina or arrhythmias.

Exogenous Subclinical Hyperthyroidism

The pituitary thyrotropes is very sensitive to small changes in serum thyroid hormone concentrations, therefore, an unintentional suppressed serum TSH concentration may be developed during L-T4 replacement therapy, leading to exogenous subclinical hyperthyroidism (Biondi and Cooper, 2008). This hypermetabolic state can impair the psychological, social, and physical quality of life and can be associated with the development of some important cardiovascular risk factors (increased heart rate and left ventricular mass and enhanced risk of atrial arrhythmias) (Biondi and Wartofsky, 2014; Cooper and Biondi, 2012). Elderly patients with exogenous subclinical hyperthyroidism may be asymptomatic and the onset of atrial fibrillation may be the first symptom of overtreatment with L-T4. Current evidence supports the association of suppressed serum TSH during L-T4 therapy with an increased risk of fractures in elderly, postmenopausal women, and people with risk factors for osteoporosis.

Treatment with L-T4 should be carefully monitored, especially in elderly patients, because over-treatment can increase mortality from cardiovascular disease (Biondi and Wartofsky, 2014; Biondi and Cooper, 2008; Cooper and Biondi, 2012).

Drugs Interfering With L-T4 Administration

It is good practice to annually assess serum TSH during L-T4 therapy to ensure compliance and determine whether a change in L-T4 dose is required.

Table 1 Drugs interfering with L-T4 administration and causes of L-T4 malabsorption

Amiodarone
Glucocorticoids
Blocking drugs
Sertraline
Phenytoin
Carbamazepine
Rifampicin
Aluminum hydroxide
Antacids
Cholestyramine
Sucralfate
Aluminum hydroxide
Ferrous sulfate
Calcium carbonate
Dietary fiber supplements

Table 2 Conditions inducing L-T4 malabsorption

Lactose intolerance
Atrophic gastritis
H pylori infection
Intestinal infections
Liver cirrhosis, obstructive liver disease
Pancreatic diseases
Pancreatic insufficiency
Previous gastrointestinal surgery

Some drugs may interfere with L-T4 requirement (**Table 1**). Malabsorption can be responsible of persistent hypothyroidism despite the administration of high doses of L-T4 (**Table 2**) (Biondi and Wartofsky, 2014).

Recently, liquid formulations of L-T4 and oral soft gelatin capsules (containing L-T4 dissolved in inactive ingredients, gelatin, and glycerin) have become available in Europe and the United States (Biondi and Wartofsky, 2014). This new formulations, which are therapeutically equivalent to the same preparation in tables by pharmacokinetic analysis, have a different dissolution and absorption profile. They allow a 100% absorption from the gastrointestinal (GI) tract and can be useful in patients with malabsorption (Biondi and Wartofsky, 2014).

Combined Treatment With L-Thyroxine and L-Triiodothyronine

Levothyroxine is a pro-hormone which is periferically converted to T3, the active hormone, by type 2 deiodinase. This conversion is usually efficient in the majority of thyroidectomized patients to ensure tissue euthyroidism. Polymorphisms in the D2 gene have been detected in about 20% of the population and could explain why some hypothyroid patients continue to experience symptoms consistent with thyroid hormone deficiency despite restoration of biochemical euthyroidism (Panicker *et al.*, 2009; Biondi and Wartofsky, 2012). This minority of thyroidectomized patients continues to complain of mood changes, cognitive dysfunction, lethargy, fatigue and weight gain despite adequate L-T4 replacement doses. They have poor quality of life during monotherapy with L-T4.

The increase in L-T4 dose is usually ineffective to improve symptoms suggesting that the restoration of normal thyroid function during L-T4 does not accurately reflect euthyroidism in all tissues in some patients. Metaanalyses of intervention trials have reported no benefit of combination treatment of L-T4 and L-T3 in symptomatic patients with biochemical euthyroidism. Further prospective randomized controlled studies are required to clarify this issue. In the meantime, available guidelines suggest to prescribe combination therapy with LT4 and L-T3 in hypothyroid patients with persistent symptoms during L-T4 (Wiersinga *et al.*, 2012).

This treatment should be managed only by skilled specialists and requires a careful follow-up to detect and prevent possible adverse effects. Serum concentrations of T3, T4, and TSH should remain within their respective reference ranges during this combination regime, in particular avoiding overtreatment with suppressed TSH concentrations. T3 should ideally be given in a slow-release form but this drug is not available today.

Myxedema Coma☆

Leonard Wartofsky, MedStar Washington Hospital Center, Georgetown University School of Medicine, Washington, DC, United States

Glossary

Bradycardia Slow heart rate, generally below 60 bpm.
CNS Central nervous system, that is, brain and spinal cord.
Hypercalcemia Higher than normal blood calcium concentration.
Hypercarbia Higher than normal blood carbon dioxide content.
Hyperkalemia Higher than normal blood potassium concentration.
Hypoglycemia Low blood glucose level.
Hyponatremia Low blood sodium concentration.
Hypothermia Lower than normal body temperature.
Hypoxemia Lower than normal blood oxygen content.
Monodeiodination Refers to peripheral metabolism of thyroxine (T4) with removal of one iodine molecule to produce triiodothyronine (T3).
Myxedema Hypothyroidism, generally of a severe form.
Tachycardia Rapid heart rate, generally greater than 100 bpm.

Introduction

Myxedema coma is a state of severe life-threatening hypothyroidism that is classically associated with decreased mentation. It is a clinical diagnosis, and no one specific laboratory value can establish the diagnosis. The typical myxedema coma case presents as an elderly woman with all the features of long-standing hypothyroidism but with stupor or coma and hypothermia. This severe form of hypothyroidism is most commonly seen during the winter months, which might point to external temperature as a significant environmental factor influencing onset. Several other factors, such as hypoglycemia, hyponatremia, hypoxemia, and hypercapnia (**Table 1**), have been associated with myxedema coma. All are thought to contribute to the presentation of the disease, but in many cases it remains unclear whether these factors may reflect cause or effect of the myxedema coma. Most cases of myxedema coma are due to primary hypothyroidism, with less than 10% being related to central hypothyroidism.

Clinical Features

Usually present are all of the classic features of hypothyroidism such as dry, coarse, and scaly skin; sparse or coarse hair; nonpitting edema of the periorbital regions, hands, and feet; macroglossia; hoarseness; and delayed deep tendon reflexes (Popoveniuc *et al.*, 2014). Decreased respiratory drive can cause respiratory depression; together with decreased ventilatory response to hypercapnia, CO_2 narcosis settles in and worsens the central nervous system (CNS) depression (Wilson and Bedell, 1960; Zwillich *et al.*, 1975). Hypoventilation is also exacerbated by depressed function of the respiratory muscles. Rarely, pleural effusions or ascites can diminish respiratory function by reducing lung volumes as well as macroglossia by obstructing the upper airway.

Multiple other organ systems are typically involved in patients with myxedema coma. Hyponatremia and decreased glomerular filtration rate are seen frequently. The two most likely causes are a loss of the kidney's ability to excrete a water load because of decreased delivery of water to the distal nephron and an increased production of antidiuretic hormone. Urinary sodium is usually normal.

Decreased intestinal motility or even paralytic ileus and megacolon can be seen, with patients presenting with abdominal pain, constipation, and nausea. Cardiac enlargement, bradycardia, and decreased cardiac contractility are common features of cardiovascular involvement in myxedema coma, but congestive heart failure is rare. Nonspecific electrocardiogram changes are seen frequently. When cardiovascular collapse occurs, vasopressors and thyroid hormone replacement are required for improvement.

Routinely, these patients develop CNS depression with lethargy and then stupor or even coma. Approximately 25% of patients with myxedema coma have generalized seizures, and administration of any CNS depressants can exacerbate this.

Patients suffering from myxedema coma are susceptible to infection. What makes this aspect of their presentation more elusive is that some of classic symptoms and signs of myxedema coma, such as hypothermia (which can be seen in up to 75% of these

Acidosis
Hypercalcemia

patients) and bradycardia, may mask the classic signs of infection (e.g., fever, tachycardia). Pulmonary infections may exacerbate any respiratory dysfunction.

Laboratory Diagnosis

As in uncomplicated hypothyroidism, a significantly elevated thyroid-stimulating hormone (TSH) with very low or undetectable thyroid hormone levels is seen. The degree of TSH elevation can vary a lot between patients; a TSH level seen in a patient with mild signs and symptoms of hypothyroidism could be comparable to that seen in another patient with myxedema coma. Similarly, it is not unheard of for patients to be functional with undetectable levels of thyroid hormone (at least for some period of time).

An exception to the rule of an elevated TSH level may be the patient with central hypothyroidism due to pituitary disease in whom both low thyroid hormone and low TSH levels would be seen. However, even in this case it is possible for the TSH to be in the normal range or even somewhat elevated, possibly reflecting bioinactive TSH.

Treatment

Given the high mortality associated with myxedema coma, treatment must be instituted as soon as diagnosis is strongly suspected. Thyroid hormone therapy alone might not be enough in the presence of the multiple system organ dysfunction associated with myxedema coma. Ventilatory support is often required and helps to prevent respiratory failure, a common cause of death in these cases. An intensive care unit is always the best place in which to care for these patients. Mechanical ventilation and empirical antibiotic therapy are often indicated together maintenance of oxygenation while monitoring blood gases. It is important to realize that prolonged ventilatory support may be required despite adequate therapy of the hypothyroidism (Wilson and Bedell, 1960; Zwillich *et al.*, 1975).

Correction of hyponatremia is of equal importance. This can easily contribute to the altered mental status of these patients, especially if the serum sodium concentration is less than 120 mEq/L. Intravenous saline and dextrose are used to correct any volume depletion and to provide minimal nutritional support. If serum sodium concentration is less than 120 mEq/L, use of small amounts of hypertonic saline may be indicated; however, this requires very close monitoring of sodium concentration changes to avoid central pontine myelinolysis (Skowsky and Kikuchi, 1978). The intravenous fluids may be warmed to help correct hypothermia. Thyroid hormone will ultimately restore body temperature, and external heat with warming blankets must be used with great caution because they may act to cause vasodilation and provide too precipitous a fall in peripheral vascular resistance. Rather than external warming, it would be more prudent to use ordinary blankets or increase the ambient room temperature.

If there is any suspicion of adrenal insufficiency, stress dose corticosteroids should be given after a baseline cortisol level is drawn. The presence of signs such as hypoglycemia, hyponatremia, hyperkalemia, and hypotension is highly suggestive. This can be of extreme importance because correction of the hypothyroidism without correction of adrenal insufficiency can precipitate an adrenal crisis. Rarely, these patients require vasopressor support for hemodynamic stability.

The most important part of therapy is the replacement of the thyroid hormone deficiency. Which regimen of thyroid hormone administration to use remains controversial. Administration of levothyroxine (T4) by itself may result in insufficient levels of

triiodothyronine (T3) because of inadequate monodeiodination of T4 to T3 in sick patients. On the other hand, T4 therapy provides a steady smooth rise of the hormone level and is less likely to be associated with any adverse effects. A commonly used dosing regimen involves administration of a high dose (300–600 μg) intravenously the first day to replete the body's stores and then about 50–100 μg daily intravenously or orally after that (Holvey *et al.*, 1964).

Administration of T3 has the advantage that its onset of action is much faster than that of T4, an advantage that can be very important for patients' survival. The drawback is that there may be potential for an increased incidence of complications, especially in those patients who have primary cardiac diseases or who are at risk for arrhythmias or ischemia. Intravenous preparations of T3 are available, and common doses for myxedema coma are 10–20 μg intravenously every 4 h for the first day and then 10 μg every 6 h for 1–2 days. Oral administration is usually possible after that (Pereira *et al.*, 1982).

Another approach is to administer both T4 and T3 initially. T4 is given at a dose of 4 μg/kg lean body weight (approximately 200–300 μg) followed by 100 μg 24 h later and then 50 μg daily either intravenously or orally as tolerated. The initial T3 dose is 10 μg intravenously every 8–12 h until the patient is able to tolerate oral intake. The response to therapy can be quite variable, and close monitoring of all such patients is extremely important.

Glossary

Hypothyroidism Absolute or relative deficiency of thyroid hormones at the peripheral target tissues.

Peripheral target tissues of thyroid hormone action The effects of thyroid hormones are ubiquitous and not restricted to one target cell. Peripheral target tissues of thyroid hormone action include the brain, liver, muscle, hearth and others. Consecutively, in addition to measuring thyroid hormone and thyrotropin levels, clinical and metabolic effects of hypothyroidism are to be evaluated at the peripheral target tissues. Assessments of these tissue effects include standardized clinical scores measurement of lipid profile, or assessment of cardiac and skeletal muscle function.

Thyrotropin Thyroid-stimulating hormone (TSH) is a glycoprotein hormone released by the anterior pituitary gland that stimulates the thyroid gland to release thyroxine and triiodothyronine. The release of thyrotropin is triggered by the action of thyrotropin-releasing hormone (TRH) (or factor; TRF), a substance found in the hypothalamus of the brain. Thyroxine (T4) and its active metabolite triiodothyronine (T3) inhibit the further release of thyrotropin by a negative feedback mechanism.

Definition

Subclinical hypothyroidism or mild thyroid failure is defined by an elevated serum TSH level accompanied by normal concentrations of circulating thyroid hormones (T4 and T3), in the presence or absence of clinical signs and symptoms. Recent research has identified significant changes of thyroid hormone action at the peripheral target tissues, which are of clinical relevance and need treatment in selected patients.

Introduction and Epidemiology

An increase in the secretion of thyroid-stimulating hormone (TSH) is the earliest biochemical sign of impending thyroid failure. In this early form of hypothyroidism free thyroxine (fT4) levels are still within the laboratory reference range. However, they are below a critical individual set point, which leads to stimulation of pituitary TSH by negative feedback mechanism.

Due to the use of TSH measurement for early detection of thyroid dysfunction, subclinical hypothyroidism has been detected with increasing frequency in recent years. It occurs in 3%–16% of the general population with a particularly high prevalence observed in areas of iodine sufficiency and in women over 60 years. Recently it has been suggested that the upper limit of normal for TSH shifts to higher levels with age (Surks and Hollowell, 2007) thus the prevalence in elderly people may not be as high as previously thought and it is important to consider the age-specific reference range for TSH when establishing the diagnosis.

Etiology

The causes of subclinical hypothyroidism are the same as for those of overt hypothyroidism. Most patients have chronic autoimmune (Hashimoto's) thyroiditis with elevated serum levels of antithyroid peroxidase antibodies. According to epidemiological studies autoimmune thyroiditis is found in 40%–67% of patients with subclinical hypothyroidism. The other major causes are prior treatment for hyperthyroidism (e.g., radioiodine or surgical treatment), thyroid surgery for epidemic goiter, and drug induced subclinical hypothyroidism (e.g., lithium, amiodarone). Other causes of elevated TSH levels and normal peripheral thyroid hormone concentrations that must be included in the differential diagnosis include noncompliance with thyroxine replacement therapy in overt hypothyroid patients (up to 40% of patients), recovery from severe nonthyroidal illness, and mutations causing inactivation of the thyrotropin receptor.

Natural Course and Prognostic Factors

Hypothyroidism is a graded phenomenon and therefore some patients with subclinical hypothyroidism will progress to overt disease over time. Based on epidemiological studies progression to overt thyroid failure has been reported to occur in 3%–18% of affected patients per year. In an epidemiological study, the "Whickham survey," nearly 1900 survivors of a normal population evaluated in 1972 were re-examined 20 years later, in 1992. In this survey 97 females with subclinical or overt hypothyroidism have been detected with a prevalence of 9.3% and a calculated incidence of 0.41% per year. The risk factors for the development of hypothyroidism were a raised TSH level and/or positive antithyroid antibodies. For females with a raised serum TSH a mean annual risk for developing hypothyroidism of 26% over 10 years could be calculated.

In a prospective study of 82 female patients with known subclinical hypothyroidism we investigated the natural course of this syndrome with regular evaluations at yearly intervals. Over a mean period of 9.2 years 28% of the patients progressed to overt hypothyroidism, 68% remained in the subclinical state, and 4% reverted to a normal TSH. The incidence of overt hypothyroidism was correlated with the initial serum TSH concentrations. The calculated 10 years rate of overt hypothyroidism was 0% for TSH levels of 4–6 mU L^{-1}, but 43% for values of 6–12 mU L^{-1} and 77% for TSH levels above 12 mU L^{-1} (**Fig. 1**).

Clinical Manifestations and Benefits of Treatment

Symptoms

One of the most controversial aspects concerning subclinical hypothyroidism is whether affected patients are symptomatic and, therefore, may benefit from thyroid hormone replacement. Based on case–control studies, nearly 30% of patients with subclinical hypothyroidism have symptoms that are suggestive of thyroid hormone deficiency. Symptoms and signs of hypothyroidism may be very vague and non-specific, and hence are easily overlooked in an individual patient. This limitation can be overcome by a systematic assessment of clinical signs and symptoms of hypothyroidism with an easy scoring system (Zulewski *et al.*, 1997). Some but not all studies reported significant improvement in symptoms of hypothyroidism after thyroxine replacement assessed by different clinical scores. A meta-analysis of 12 clinical trials and a subsequent systematic review found no benefit of thyroxine therapy compared to placebo, especially if the TSH level was below 10 mIU L^{-1} (Villar *et al.*, 2007; Rugge *et al.*, 2015). This might particularly be true for the older population: a recent randomized controlled trial evaluating whether thyroxine treatment provides clinical benefits in 737 patients of at least 65 years of age and persisting TSH levels between 4.6 and 19.99 mIU L^{-1} showed negative results (Stott *et al.*, 2017).

Prospective study of the spontaneous course of subclinical hypothyroidism: prognostic value of thyrotropin, thyroid reserve, and thyroid antibodies. *Journal of Clinical Endocrinology and Metabolism* 87(7), 3221–3226, with permission.

Table 1 Indications to screen for hypothyroidism

Signs and symptoms
Symptoms suggestive of hypothyroidism
Goiter
Endocrine ophthalmopathy
Dyslipidemia
Infertility
Risk factors for hypothyroidism
Personal history of autoimmune diseases
Thyroidectomy
Neck surgery
Radioactive iodine therapy
External radiotherapy of the neck
Family history of autoimmune thyroid disease
Comorbidities
Pituitary or hypothalamic lesions
Infiltrative disorders (e.g., amyloidosis, sarcoidosis, hemochromatosis, AIDS)
Down syndrome
Turner syndrome
Drugs
Iodine-containing drugs (e.g., amiodarone, radiographic contrast agents)
Lithium carbonate
Cytokine (e.g., interferone a)
Tyrosine-kinase inhibitor

Cognitive Function and Neuropsychiatric Dysfunction

Several reports suggest that subclinical hypothyroidism is associated with neuropsychiatric disease with higher scores on scales of depression and anxiety in affected patients. Neuropsychiatric parameters (i.e., reaction time and figure identification) as well as memory scores were significantly improved in some intervention trials assessing the effect of thyroxine treatment in patients with subclinical hypothyroidism (mean TSH levels at baseline: 7–12 mU L^{-1}). However other studies including a recent meta-analysis do not support the association of subclinical hypothyroidism and neuropsychiatric diseases (Pasqualetti *et al.*, 2015).

Atherosclerosis and Cardiovascular Risk Factors

Overt hypothyroidism is associated with increased cardiovascular morbidity. The relationship between subclinical hypothyroidism and atherosclerotic risk factors has been widely investigated, with major interest on serum lipid abnormalities. Several cross-sectional studies found serum lipid concentrations, mainly total cholesterol levels, within the normal range, whereas others have detected significant elevations of total cholesterol and/or LDL-cholesterol concentrations, especially in smokers (Muller *et al.*, 1995). In addition, reduced HDL-cholesterol levels were reported in some studies. Data are conflicting whether thyroxine replacement shows a beneficial effect on serum cholesterol levels. Our "Basel Thyroid Study" was the first randomized trial demonstrating significant effect of thyroxine on total cholesterol and atherogenic LDL-cholesterol levels (Meier *et al.*, 2001). These results were confirmed by other randomized trials evaluating patients mainly with serum TSH concentrations >10 mIU L^{-1}. However a meta-analysis including seven trials analyzing lipid levels after T4 replacement revealed no lowering effect of treatment on total cholesterol, HDL, LDL, triglycerides, apolipoprotein A and B and lipoprotein (a). Besides lipid abnormalities several mechanisms are discussed to be involved in the possible association between subclinical hypothyroidism and atherosclerosis. These include elevated markers of inflammation, vascular reactivity, endothelial effects and hypercoagulable state.

Several observational and prospective cohort studies observed an increased risk for coronary heart disease in patients with subclinical hypothyroidism. A meta-analysis considering data from a total of 55,287 participants (3450 with subclinical hypothyroidism) showed that the risk for coronary events and mortality—but not for total mortality—increases with higher concentrations of TSH, especially if >10 mIU L^{-1} (Rodondi *et al.*, 2010). The risk persisted after adjustment for age, sex or preexisting cardiovascular disease. Conversely, minimal TSH elevations up to 6.9 mIU L^{-1} were not associated with an increased cardiovascular risk. In another study subclinical hypothyroidism had no influence on mortality in elderly individuals (median age 83 years) over a follow-up period of 5 years (Waring *et al.*, 2012).

Subclinical hypothyroidism may also have an impact on heart failure. Myocardial function has been shown to be slightly impaired in patients with subclinical hypothyroidism. The identified functional abnormalities include impaired myocardial contractility and diastolic function, at rest or with exercise. A pooled analysis of data from several prospective cohort studies showed a significant increase of heart failure events in patients with TSH >10 mIU L^{-1} compared to euthyroid controls

Table 2 Causes of transient TSH elevation and of altered thyroid function tests

Transient TSH elevation
Subacute, silent or postpartum thyroiditis
Recovery from nonthyroidal illness
Altered thyroid function tests without thyroidal illness
Assay variability
Autoantibodies to TSH
Heterophilic antibodies or rheumatoid factors interfering with immunometric assays
Drugs (e.g., amiodarone)
Others
Morbid obesity
Untreated adrenal insufficiency
TSH producing pituitary adenomas
Resistance to thyroid hormone
Mutation of the TSH receptor

(Gencer *et al.*, 2012). Minimal elevations were not associated with an increased risk of heart failure (levels <6.9 mIU L^{-1}) and in patients with moderate augmented TSH levels (7.0–9.9 mIU L^{-1}) the increased risk was not statistically significant.

In summary, data of cardiovascular mortality and all-cause mortality are conflicting. The former seems to be significantly elevated in patients with TSH levels above 10 mIU L^{-1}, but especially in elderly individuals and in those with lower TSH elevations the association is not clear.

So far it remains unclear, whether cardiac risk may be influenced by thyroxine replacement therapy. Although several cardiovascular risk factors and surrogate cardiovascular endpoints (e.g., dyslipidemia, vascular smooth muscle proliferation, ventricular function) may improve under treatment, current data cannot clearly conclude whether cardiovascular outcome can be optimized. In an analysis of the United Kingdom General Practitioner Research Database thyroxine replacement was associated with reduced ischemic heart events in patients aged 40–70 years, but was not beneficial in older individuals (Razvi *et al.*, 2012). In a recent retrospective register-based cohort study analyzing 1192 patients with established heart disease and subclinical hypothyroidism (mean age 74 years) thyroxine treatment was not associated with a significant benefit nor risk of all-cause mortality, major adverse cardial events or hospital admission (Andersen *et al.*, 2016). Thus, appropriately powered randomized clinical trials are needed to answer this fundamental question. Similarly, the risk of cardiovascular effects of a potential overtreatment with thyroxine has yet to be established.

Others

In patients with subclinical hypothyroidism, abnormalities in peripheral-nerve function and neuromuscular activity, skeletal muscle abnormalities, intraocular pressure and ovulatory dysfunction have been described in subclinical hypothyroidism. However, the role of subclinical hypothyroidism in these circumstances, especially in reproductive abnormalities, is not well defined. The prevalence of subclinical hypothyroidism seems to be elevated in women with infertility compared to women with confirmed fertility (Abalovich *et al.*, 2007); moreover, thyroid autoimmunity was linked to an increased risk of unexplained subfertility according to a meta-analysis of four studies (van den Boogaard *et al.*, 2011). Conversely, a recent prospective cohort study found no association between mild preconception subclinical hypothyroidism or the presence of antithyroid antibodies and fecundity (Plowden *et al.*, 2016). During pregnancy, subclinical hypothyroidism is associated with complications such as placental abruption, pregnancy loss and neonatal death, hence replacement therapy is mandatory (Maraka *et al.*, 2016).

Diagnostic and Therapeutic Recommendations

Screening and Diagnosis

Screening for thyroid disease is still a controversial issue (Surks *et al.*, 2004; Gharib *et al.*, 2005). TSH screening in women older than 35 years of age has been shown to be cost-effective. Some authors favor TSH screening for thyroid dysfunction in asymptomatic adults, others deny this policy because the effects of subsequent thyroxine therapy are not beneficial in all patients and put them at risk for potential overtreatment with adverse cardiovascular or skeletal effects. Subclinical hypothyroidism is a frequent finding in women older than 40 years (affecting about 10% of the female population of this age) and its clinical presentation may be subtle. Therefore, TSH screening should be advocated if risk factors are present (**Table 1**) and by a case-finding approach, focusing on patients visiting their physicians for an unrelated reason. Since smoking impairs both thyroid hormone secretion and thyroid hormone action, smoking status should be considered in the evaluation of patients in whom hypothyroidism is suspected.

If the initial screening test ist positive with an elevated TSH level, a second measurement (TSH and fT4) after 1–3 months ist needed to confirm the diagnosis and exclude a transient elevation. **Table 2** summarizes causes of transient TSH elevations and altered thyroid hormone tests, which have to be considered in the differential diagnosis. Further evaluation of patients includes a

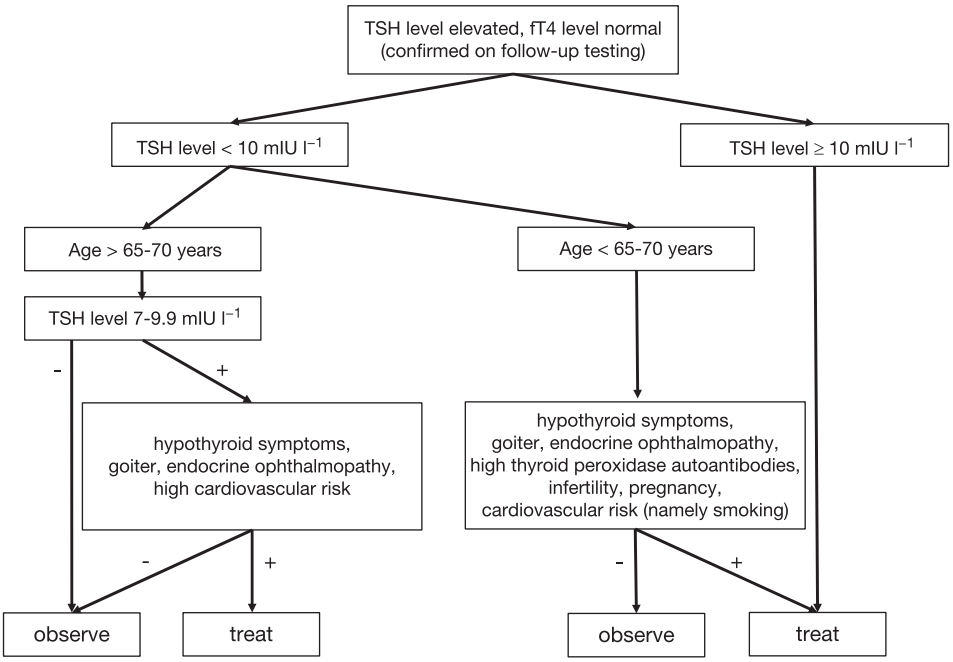

Fig. 2 Algorithm for the management of patients with subclinical hypothyroidism.

thorough history and a examination for a thyroid gland enlargement and a endocrine ophthalmopathy. Although most patients will have chronic autoimmune thyroiditis, we do not routinely measure antithyroid peroxidase antibodies. Similarly, an ultrasound of the thyroid is not required in the management of subclinical hypothyroidism unless there are additional clinical indications (Pearce *et al.*, 2013).

Replacement Therapy With Thyroxine

The goal of treating patients with mild thyroid failure is to reverse clinical and metabolic alterations by hormone supplementation and, in addition, to prevent progression of the subclinical form to the overt stage of hypothyroidism with its considerable morbidity and possible mortality. Thyroxine treatment is indicated in virtually all younger patients who have elevated TSH levels above 10 mU L^{-1}. Routine replacement of asymptomatic patients with TSH levels between 4.5 and 10 mU L^{-1} remains controversial (Cooper and Biondi, 2012). Patients at risk with special conditions like goiter, thyroidectomy, depression, infertility, pregnancy, high thyroid peroxidase autoantibodies, endocrine ophthalmopathy and hypercholesterolemia, in particular in the presence of other cardiovascular risk factors, such as smoking and hypertension may benefit from early treatment. In patients with minimal or moderate TSH elevations (<10 mU L^{-1}) with no clinical or metabolic changes treatment can be withhold, but annual follow-up is required (**Fig. 2**).

Overtreatment can produce overt or subclinical hyperthyroidism with its consequences on morbidity (e.g., atrial fibrillation and osteopenia) and mortality. Therefore, fine-tuning of thyroxine replacement therapy with the goal to restore serum TSH to physiological, euthyroid levels is mandatory.

TPO Thyroid peroxidase
Tregs Regulatory T cells
TSH Thyroid stimulating hormone

Glossary

Autoimmune thyroiditis A predominantly lymphocytic inflammatory response in the thyroid gland caused by autoreactivity to thyroid autoantigens, especially thyroglobulin, thyroid peroxidase, or the TSH receptor.
Cytokines Soluble factors released by leukocytes and, in some cases, other cell types that have immunomodulatory properties; T cells can be categorized by their profile of cytokine expression.
Epitope The part of an antigen recognized during an immune response. T-cell epitopes are short linear peptide sequences of the antigen, whereas B-cell epitopes are not limited to amino acid sequences and may be composed of discontinuous sequences that constitute the three-dimensional part of the antigen to which an antibody binds.
HLA The human leukocyte antigen, a gene complex encoding the major histocompatibility complex (MHC) proteins in humans, which encodes specialized cell surface molecules able to present antigenic peptides to T-cell receptors and is thus an integral part of the adaptive immune system. Some HLA alleles have been associated with an increased risk of specific autoimmune diseases (i.e., HLA-DR3 and Graves' disease or Hashimoto's thyroiditis).
Thyroid autoantibodies Antibodies, usually of the IgG class, directed against thyroid autoantigens, such as thyroglobulin, thyroid peroxidase, or the TSH receptor.
Tolerance A state of nonresponsiveness to an antigen recognized by the immune system that depends on how the antigen is presented to the T cell or B cell; usually categorized as central (thymic) or peripheral, depending on the site at which tolerance is induced.

Introduction

Autoimmune disease affects the thyroid gland more often than any other organ (McLeod and Cooper, 2012). Autoimmune thyroid diseases comprise a spectrum of disorders, representing two clusters of pathogenic mechanisms. Hashimoto's thyroiditis (a term used synonymously with chronic autoimmune thyroiditis and autoimmune hypothyroidism) and postpartum thyroiditis/painless thyroiditis share a predominately T cell-mediated autoimmunity, while Graves' disease is characterized by a primarily humoral response and the presence of antithyroid stimulating hormone (TSH) receptor antibodies (McLachlan and Rapoport, 2013; Rapoport *et al.*, 1998).

The most common type of thyroid autoimmunity is focal thyroiditis, which is found in 40% of all Caucasian women and 20% of Caucasian men (**Table 1**) (Vanderpump, 2011). The condition is half as common in Japanese and black Americans, and in all races it increases in incidence with age. Focal thyroiditis is closely associated with the presence of antibodies against thyroid peroxidase (TPO) and, often, thyroglobulin, but thyroid function is either normal (also designated asymptomatic autoimmune thyroiditis or only mildly affected (subclinical hypothyroidism), as indicated by an elevated thyroid-stimulating hormone (TSH) concentration and normal free thyroid hormone levels. The incidence of focal thyroiditis is increased in thyroid cancer, and its presence is associated with a slightly better prognosis.

Postpartum thyroiditis is defined as the appearance of transient thyroid dysfunction during the year after delivery, occurring particularly in women who have preexisting subclinical thyroid autoimmunity (Pearce, 2015). Silent or painless thyroiditis is a

☆*Change History*: March 2018. Ulla Feldt-Rasmussen, Sofie Bliddal, and Claus H Nielsen updated Abstract, revised all sections including the "Reference" section, added section "Breach of self-tolerance," deleted section "Animal Models," revised Tables 1, 2, 3, and added Table 4 and Figures 2 and 3.

This article is an update of Anthony P. Weetman, Thyroid Autoimmunity, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, pp. 372–384.

 doi:10.1016/B978-0-12-801238-3.96017-3

Table 1 Types of thyroid autoimmunity

Type	*Thyroid antibodies*	*Thyroid function*	*Other features*
Focal thyroiditis	TgAbs or TPOAbs, in most cases at low titer	Normal or subclinical hypothyroidism	May progress to overt hypothyroidism
Silent thyroiditis	TPOAbs, in most cases, TgAbs variable	Transient thyrotoxicosis and/or hypothyroidism	Most commonly occurs one year after delivery as postpartum thyroiditis; may progress to overt hypothyroidism
Hashimoto's (goitrous) thyroiditis	TgAbs and/or TPOAbs, usually high titer; occasionally TBAbs	Euthyroid or hypothyroidism	Associated rarely with thyroid lymphoma
Atrophic thyroiditis (primary myxedema)	TgAbs and/or TPOAbs at variable titer; TBAbs in up to 20% of cases	Hypothyroidism	May evolve from Hashimoto's thyroiditis
Graves' disease	TSAbs in all cases; TPOAbs in 80% and lower frequency of TgAbs	Hyperthyroidism and rarely hypothyroidism	Strongly associated with GO

Abbreviations: *GO*, Graves' orbitopathy; *TBAb*, TSH receptor-blocking antibodies; *TgAbs*, thyroglobulin antibodies; *TPOAbs*, thyroid peroxidase antibodies; *TSAb*, TSH receptor-stimulating antibodies.

similar transient disturbance in thyroid function in nonpregnant patients. In both types of thyroiditis, there is classically a phase of thyrotoxicosis caused by release of stored thyroid hormone and then a phase of hypothyroidism as destruction continues, before resolution. However, in many individuals only one phase may be observed. In approximately half of cases, either type may progress over 5–10 years to overt hypothyroidism.

Autoimmune hypothyroidism is caused by destruction of the thyroid follicles leading to low circulating thyroid hormone concentrations and an elevated TSH. Two main types are identified histologically, marked by the presence or absence of a goiter, but some patients progress from goitrous to atrophic thyroiditis and no clear autoimmune features distinguish one type from the other (Caturegli *et al.*, 2014).

Graves' disease is characterized by the presence of antibodies that stimulate the TSH receptor, resulting in elevated circulating thyroid hormone levels and suppressed TSH levels (Smith and Hegedus, 2016). In some patients, there is progression to autoimmune hypothyroidism, and in others there is fluctuation between hyperthyroid and hypothyroid phases over weeks or months. The reason for this might sometimes be TSH receptor antibodies penduling between stimulating and blocking varieties (McLachlan and Rapoport, 2013), and it could indicate the close relationship between the various types of thyroid autoimmunity. Graves' orbitopathy is an orbital disorder in which there is swelling of the extraocular muscles due to glycosaminoglycan accumulation and water trapping; orbital fat content may also increase (Bahn, 2010). These events cause a variety of soft tissue changes, including periorbital edema, proptosis, diplopia, and, in severe cases, optic nerve compression. Approximately 90% of patients with Graves' orbitopathy have Graves' disease, 5% have autoimmune hypothyroidism, and almost all of the remaining have subtle evidence of thyroid autoimmunity.

Epidemiology

With the reservation that the prevalence and incidence of autoimmune thyroid diseases depend highly on the iodine intake in a given population, approximately 10%–16% of women of fertile age have TPO antibodies and/or thyroglobulin antibodies (Bliddal *et al.*, 2015; Pedersen *et al.*, 2011), and approximately 30%–50% of these develop postpartum thyroiditis following pregnancy (Feldt-Rasmussen *et al.*, 1990). Thus, approximately 5% of pregnancies are followed by postpartum thyroiditis, although clinically significant features occur in only a small percentage of these cases. However, a substantial number of these women has persistent hypothyroidism at 1 year postpartum (Stagnaro-Green *et al.*, 2011), with a high risk for permanent hypothyroidism in the longer term (Sarvghadi *et al.*, 2005). The general prevalence of autoimmune hypothyroidism in women is 1% or 2%, and in men it is 5–10 times less frequent (McLeod and Cooper, 2012). Approximately 2% of individuals with thyroid antibodies and presumed focal thyroiditis progress to overt autoimmune hypothyroidism annually; the rate is more than double if there are thyroid antibodies and subclinical hypothyroidism (Vanderpump *et al.*, 1995). The peak incidence of autoimmune hypothyroidism occurs in individuals between 50 and 60 years of age. It is important to be aware of the burden of autoimmune thyroid disease, its geographic differences, and trends over time (McLeod and Cooper, 2012). For example, an increased incidence of overt hypothyroidism as well as thyroid autoimmunity was seen after iodine fortification of salt in Denmark during prospective monitoring of the effect of iodine fortification on thyroid function and autoimmunity (Pedersen *et al.*, 2007; Pedersen *et al.*, 2011). During the same period there was a doubling of prescriptions for thyroid replacement therapy (Cerqueira *et al.*, 2011).

Graves' disease accounts for 60%–80% of all cases of thyrotoxicosis in iodine-replete areas, while it is lower in mildly iodine deficient populations; for example, 38% in a Danish population study (Carle *et al.*, 2006; Laurberg *et al.*, 1991). It has a prevalence of approximately 1% in women, peaking in those aged 30–60 years. In men, the frequency is 5- to 10-fold lower than in women. Approximately 50% of patients with Graves' disease have clinically obvious thyroid-associated orbitopathy (or Graves' orbitopathy), but subclinical evidence of this complication can be found in more than 90% of cases by using imaging techniques (Bahn, 2010).

Pathological Features

In Hashimoto's thyroiditis, the thyroid is enlarged, usually symmetrically, due to a diffuse infiltration by lymphocytes, plasma cells, and macrophages, together with the formation of lymphoid germinal centers. Thyroid cells undergo hyperplasia and oxyphil metaplasia, with the latter leading to the formation of Hürthle or Askanazy cells. Progressively, however, thyroid cell destruction occurs, together with variable amounts of fibrosis. In primary myxedema (atrophic thyroiditis), there is more extensive fibrosis and follicular destruction and minimal or moderate lymphoid infiltration (Caturegli *et al.*, 2014).

In Graves' disease, there is hypertrophy and hyperplasia of the thyroid follicles, which have columnar, folded epithelium and less colloid than usual. There is a variable degree of lymphoid infiltration, sometimes with germinal center formation. All these changes are largely reversed by antithyroid drug treatment (Smith and Hegedus, 2016). The changes seen in Graves' orbitopathy consist of variable lymphocytic infiltration of the extraocular muscles and orbital connective tissue, edema, and, in the later stages, fibrosis and possibly muscle atrophy. Fat content may increase, especially late in the disease process, and mast cells may be prominent (Shan and Douglas, 2014). The levator palpebrae muscle fibers are enlarged. Lymphocytic infiltration of the eyelids is uncommon, but can often be seen in the lacrimal glands. This might be due to a concomitant occurrence of Sjögren syndrome (Bliddal *et al.*, 2017) and not Graves' orbitopathy per se.

Determinants of Thyroid Autoimmunity

Like almost all autoimmune disorders, those associated with thyroid autoimmunity are the result of a complex interaction between a large number of genetic, environmental, and endogenous factors, with the same disease resulting from different combinations of factors in different patients. The contribution of genetic factors to disease susceptibility is unknown, but concordance rates in monozygotic twins are approximately 20%–30%, considerably higher than in dizygotic twins (Brix and Hegedus, 2012). Different autoimmune thyroid diseases may occur in the relatives of a proband in a single family, and there is a well-known set of associations with other autoimmune diseases (**Table 2**), suggesting that these share common susceptibility factors, most likely genetic (Bliddal *et al.*, 2017).

Genetic Factors

In common with the majority of autoimmune diseases, the highly polymorphic alleles of the major histocompatibility complex (MHC) molecules, called human leukocyte antigen (HLA) in man, have been the most intensively studied and are

Table 2 Diseases associated with thyroid autoimmunity

Endocrine disorders
Type 1 diabetes mellitus
Addison's disease
Premature ovarian failure
Lymphocytic hypophysitis
Autoimmune polyglandular syndrome types 1 and 2
Organ-specific autoimmunity
Vitiligo
Alopecia areata
Pernicious anemia
Celiac disease and dermatitis herpetiformis
Myasthenia gravis
Autoimmune serositis
Chronic active hepatitis
Primary biliary disorders
Crohn's disease
Ulcerative colitis
Autoimmune thrombocytopenia
Autoimmune hemolytic anemia
Nonorgan-specific autoimmunity
Rheumatoid arthritis
Systemic lupus erythematosus
Sjögren syndrome
Sarcoidosis
Relapsing polychondritis
Systemic sclerosis
Other conditions
Breast cancer
Depression or bipolar affective disorder
Recurrent miscarriage

the most frequently associated genetic factors in thyroid autoimmunity (**Table 3**). There are several reasons why HLA alleles might confer susceptibility to autoimmune thyroiditis (Weetman, 2003). The MHC class II genes are crucial for antigen presentation (**Fig. 1**), and it is possible that only certain class II molecules can bind particular autoantigenic epitopes and thus initiate an autoimmune response (determinant selection). Particular class II alleles may also be critical for the thymic selection of T cells, either permitting the evolution of autoreactive T cells (positive selection) or preventing their development (negative selection); in the latter case, the allele would have a protective effect. Alternatively, some MHC class II alleles may determine selection of an increasingly better defined subpopulation of regulatory T cells (Tregs), previously called suppressor cells (McLachlan and Rapoport, 2014). Finally, associations between MHC class II alleles and autoimmune disease may also be related to the effects of polymorphisms in other genes in linkage disequilibrium with MHC class II molecules, such as complement components or the cytokine tumor necrosis factor.

Table 3 Major HLA associations in thyroid autoimmunity

Condition	*Ethnic group*	*Association*
Hashimoto's thyroiditis/autoimmune hypothyroidism	Caucasian	HLA-DR3, DR4
	Chinese	HLA-B46, DR9
	Japanese	HLA-DR53, DR9
Postpartum thyroiditis	Caucasian	HLA-DR5, possibly DR3
Graves' disease	Caucasian	HLA-DR3 (DR17 and DR18 subtypes)
	Japanese, Korean	HLA-DR5, DR8, DPB1*0501 (DQB1*0501 protective)
	United States Black	None
	South African Black	HLA-DR1, DR3
Graves' orbitopathy	Caucasian and Japanese	As for Graves' disease; HLA-DPB1*0201 may be protective

Associations between specific major HLA alleles and thyroid autoimmune disease entities according to ethnic groups.
Abbreviations: *HLA*, human leukocyte antigen.

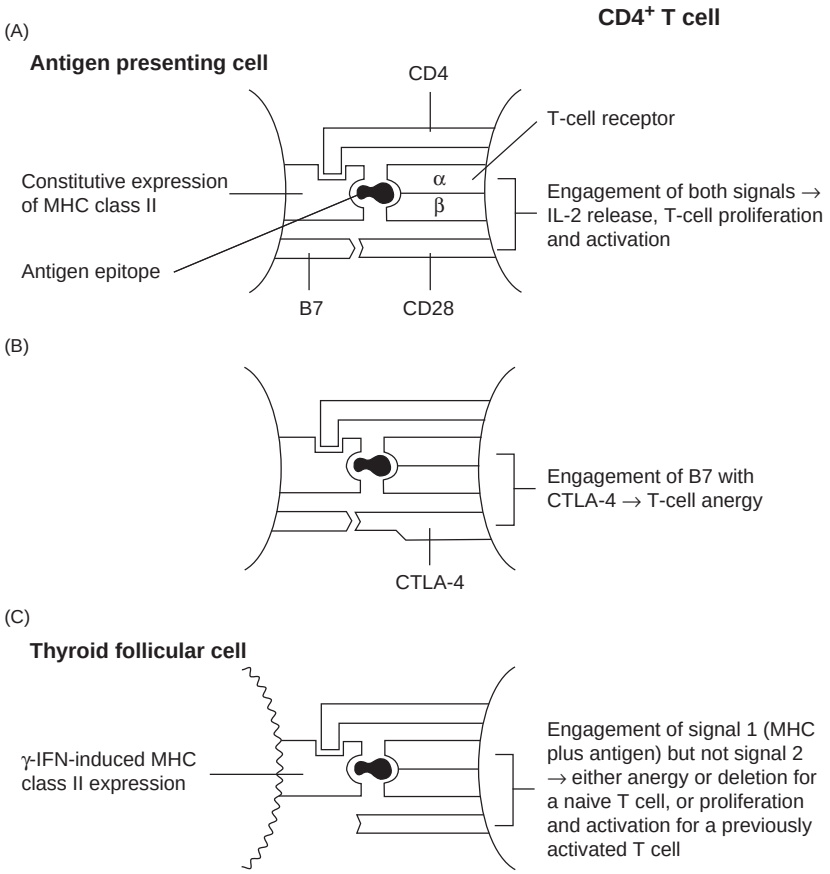

Fig. 1 Pathways of antigen presentation leading to $CD4^+$ T-cell stimulation. (A) Acute antigen presentation or anergy; (B) Chronic antigen presentation; (C) Antigen presentation by endocrine cell. However, it is clear that many individuals have HLA-DR alleles that confer susceptibility but never develop autoimmune thyroid disease. Conversely, approximately half of individuals with autoimmune thyroid disease do not have any known HLA allele associated with susceptibility. The inevitable conclusion is that other genes must be involved, and these may act independently or interact with MHC-encoded susceptibility, making the determination of their effect more difficult. This genetic diversity is also demonstrated by the three to four times higher concordance rate for Graves' disease in monozygotic twins compared to dizygotic twins (Brix and Hegedus, 2012).

According to current evidence (Lee *et al.*, 2015; McLachlan and Rapoport, 2014), susceptibility genes to thyroid autoimmune disease can be categorized as either thyroid specific (thyroglobulin, TSH receptor) or immune-modulating (*FOXP3*, *CD25*, *CD40*, *CTLA-4*, *HLA*), with HLA-DR3 carrying the highest risk. Of these susceptibility genes, *FOXP3* and *CD25* play critical roles in the establishment of peripheral tolerance while the HLA genes are pivotal for antigen presentation and CD40 and CTLA-4 determine T-cell activation. Polymorphisms in these immune-modulating genes, in particular, significantly contribute to the predisposition for Graves' disease and Hashimoto's thyroiditis and, not surprisingly, many other autoimmune diseases. Emerging evidence suggests that single nucleotide polymorphisms in the immunoregulatory genes may induce functional hindrance to proper development of central and peripheral tolerance and alter the interaction of T cells with antigen presenting cells. *CTLA-4* is an attractive candidate autoimmunity gene because the CTLA-4 molecule is critical to the termination of immune responses (**Fig. 1**) and CTLA-4 knockout mice develop a lymphoproliferative syndrome associated with widespread lymphocytic infiltration of tissues. The susceptibility conferred by CTLA-4 polymorphisms is modest and similar in both Graves' disease and autoimmune hypothyroidism; despite initial observations, these polymorphisms do not confer any heightened risk of complications such as Graves' orbitopathy. Moreover, the same polymorphisms are shared with other disorders, such as type 1 diabetes mellitus, vitiligo, and Addison's disease, and therefore seem to confer a general propensity to develop organ-specific autoimmunity, which in turn may partially explain the frequent co-occurrence of these disorders.

Mutations in the autoimmune regulator (*AIRE*) gene give rise to more or less severe phenotypic forms of polyautoimmunity (Bliddal *et al.*, 2017; McLachlan and Rapoport, 2014; Weetman and DeGroot, 2016), while other genes may be involved in the thymic T-cell selection process such as those coding for apoptosis for example, Fas (CD95). As indicated above, polyautoimmunity is most often due to increased genetic susceptibility to autoimmune diseases in general and thyroid autoimmunity in particular, as recently reviewed in Bliddal *et al.* (2017) and further substantiated in **Table 4**.

Environmental Factors

The importance of environmental factors in causing autoimmune thyroiditis is illustrated by the incomplete concordance in monozygotic twins (Brix and Hegedus, 2012) and the lack of any family history of autoimmunity in many patients. Genetic factors are more likely to exert their effects in early onset cases, in cases with more than one autoimmune disease in an individual (Ottesen *et al.*, 1995), or in case of polyautoimmunity (Bliddal *et al.*, 2017; Kahaly and Frommer, 2018), while environmental factors, which require exposure of the individual, likely operate at later stages in life, but matters are even more complex because there are certainly interactions between genetic and environmental factors. Our inadequate knowledge stems largely from the difficulty of analyzing such heterogeneous interactions.

Infections are frequently suggested to play a role in producing autoimmunity by causing release of autoantigens from damaged tissue, by molecular mimicry in which epitope sequences of the organisms provoke an immune response against matching host protein sequences, or by altering target cell surface molecules that render the cell susceptible to autoimmune attack. However, there is no good evidence that thyroid autoimmunity is precipitated by infection and, indeed, subacute thyroiditis caused by viral infection of the thyroid is characterized by recovery of normal thyroid function. *Yersinia* infection has been examined as a potential trigger because there is evidence that the organism contains TSH-receptor-like sequences, but any role is likely to be small, at best, because few patients with Graves' disease have evidence of infection. There is even less reliable support for the involvement of retroviruses, but the subject of infectious relationship with thyroid autoimmunity is still being explored (Kohling *et al.*, 2017). Thus, the emerging research field of gut microbiota is also of interest in autoimmune thyroid disease research. Studies on this topic are, however, still sparse (Kohling *et al.*, 2017).

Iodide intake may determine the frequency of thyroid autoimmunity, because there is epidemiological evidence that increases in dietary iodide are associated with an increase in the incidence of thyroid antibodies, autoimmune hypothyroidism, and Graves' disease. Animal models of autoimmune thyroiditis and epidemiological studies (see earlier) have provided support for such an enhancing role; conversely, iodide depletion appears to be protective. Excess iodide may be toxic to thyroid cells or may have immunological effects, including enhanced immunogenicity of thyroid autoantigens (Zimmermann and Boelaert, 2015).

Major stress may precipitate Graves' disease, at least based on evidence from retrospective surveys, and such an effect could be produced by the neuroendocrine consequences of stress, especially on glucocorticoids (Morshed *et al.*, 2012; Mizokami *et al.*, 2004). Smoking is weakly associated with Graves' disease and is the strongest known determinant of Graves' orbitopathy. The reasons for these associations are not known, but it is possible that smoking may either modulate the immune response in some way (e.g., by affecting cytokine production) or enhance orbital fibroblast responses secondary to partial hypoxia.

At low doses, radiation may initiate thyroid autoimmunity because both Graves' disease and autoimmune hypothyroidism have been reported after mantle irradiation for lymphoma, and there is an increase in thyroid antibodies in the survivors of irradiation from nuclear weapon or reactor fallout (Agate *et al.*, 2008), though only transitory. Some drugs may also precipitate thyroid autoimmunity,

Table 4 Polyautoimmune endocrine syndromes including thyroid disease

Clusters	*Proposed pathogenic mechanism*
Autoimmune polyendocrine syndromes	
Type I (APECED or Whitaker syndrome): Mucosal and cutaneous candida infections, Addison's disease, hyposplenism, hypoparathyroidism, and multiple autoimmune presentations that is, hypothyroidism, hypogonadism, vitiligo, alopecia, pernicious anemia, chronic autoimmune hepatitis	*Mutation of autoimmune regulator (AIRE)* gene involved in central tolerance development. Phenotype possibly affected by HLA subtypes
Type II (Schmidt's syndrome): Addison's disease and hypothyroidism or type 1A diabetes as well as pernicious anemia, primary hypogonadism, vitiligo, coeliac disease, myasthenia gravis (by some further classified in types III and IV according to specific entities of the above)	Polygenetic with increased risk of disease linked to specific HLA-DR and HLA-DQ genotypes
Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome	
Immune-dysfunction, enteropathy, dermatitis, autoimmune endocrinopathies (often type 1 diabetes, autoimmune thyroid disease), autoimmune skin diseases (i.e., bullous pemphigoid), multiple organ involvement	Mutation of *FOXP3* gene on the X-chromosome
Multiple autoimmune syndromes (MAS)	
Type I: Myasthenia gravis, thymoma, polymyositis, and giant cell myocarditis	
Type II: Sjögren syndrome, rheumatoid arthritis, primary biliary cirrhosis, scleroderma, and autoimmune thyroid disorders	
Type III: Autoimmune thyroid disease, myasthenia and/or thymoma, Sjögren syndrome, pernicious anemia, idiopathic thrombocytopenic purpura, Addison disease, insulin-dependent diabetes, vitiligo, autoimmune hemolytic anemia, systemic lupus erythematosus	Genetic predisposition with phenotype HLA B8 and/or DR3 or DR5 seems to be an important factor
Thyrogastric cluster	
Autoimmune thyroiditis, chronic gastritis/pernicious anemia, autoimmune adrenalitis (Addison's)	Polygenetic
Lupus-associated cluster	
Autoimmune hemolytic anemia, immune thrombocytopenia, systemic lupus erythematosus, rheumatoid arthritis, autoimmune hepatitis, Sjögren syndrome	Polygenetic
Trisomy 21 and Turner syndrome	
Chronic thyroiditis, type 1A diabetes and others	Chromosomal abnormalities
Kearns–Sayre syndrome	
External ophthalmoplegia, retinal degeneration, diabetes, thyroiditis, and hypoparathyroidism	Mitochondrial myopathy

Abbreviations: *APECED*, Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; *FOXP3*, forkhead box P3; *HLA*, human leucocyte antigen.
Reproduced with kind permission from Bliddal, S., Nielsen, C. H. and Feldt-Rasmussen, U. (2017). Recent advances in understanding autoimmune thyroid disease: The tallest tree in the forest of polyautoimmunity. *F1000Research 6*, 1776.

particularly in those who are genetically predisposed; examples include lithium, α-interferon, and other cytokines. For example, Graves' disease occurs in one-third of multiple sclerosis patients treated with monoclonal antibodies to deplete T cells (Rotondi *et al.*, 2017).

Endogenous Factors

Pregnancy is associated with amelioration of autoimmune thyroiditis, and patients with Graves' disease can usually stop drug treatment during the last trimester. However, a rebound in the autoimmune process occurs during the year after delivery. This is when postpartum thyroiditis emerges and Graves' disease appears with an increased incidence. These changes are largely unexplained but presumably relate in part to massive fluctuations in various hormones during and after pregnancy, and may constitute a similarity to reconstitution of immunity after the general immunosuppression during pregnancy (Singh and Perfect, 2007). Sex hormones are likely the major determinants of the increased risk of thyroid autoimmunity in women, but thyroid epigenetics in the form of X chromosome inactivation seems a player in patients with autoimmune thyroid disease (Yin *et al.*, 2007). However, the causes of the increased risk in Turner and Down syndromes are unknown. Weetman (2013) has envisaged the multifactorial causes of the typical autoimmune thyroiditis as conforming to the Swiss-cheese model of catastrophe in which multiple small genetic (and nongenetic) events, none in themselves sufficient to precipitate autoimmune destruction, line up like the holes in slices of such cheese to allow the untoward event to occur (**Fig. 2**).

Thyroid Autoantigens

Understanding any autoimmune disease is contingent on a thorough knowledge of the nature of the autoantigens involved and their B- and T-cell epitopes. In addition to aiding in the determination of the etiology and pathogenesis of an autoimmune disease,

autoantigen identification is central to assays for antibodies that may be markers or predictors of disease or for the delineation of particular subsets of patients, and it may lead to novel treatments, such as that based on modified T-cell peptide epitopes. Indeed, our poor understanding of the pathogenesis of Graves' orbitopathy is due directly to an inadequate understanding of the autoantigens involved. A summary of the main thyroid autoantigens is shown in **Table 5**.

Thyroglobulin

This was the first tissue autoantigen to be identified, based on the pioneering work by Witebsky *et al.* (1955), who immunized rabbits with thyroid extract in adjuvant, eliciting Tg antibodies and thyroiditis, and work by Roitt *et al.* (1956), who first showed the presence of Tg antibodies in patients with Hashimoto's thyroiditis. Thyroglobulin is the thyroid hormone storage system; tyrosine molecules at hormonogenic sites are iodized to form T3 and T4. The protein is secreted into the follicular lumen, in which it is endocytosed and hydrolyzed to release T3 and T4. Iodination of the molecule is important for its immunogenicity in animal models of autoimmune thyroiditis: there is no clear evidence that this is important in humans.

Two major epitopes and one minor conformational epitope exist on each thyroglobulin subunit for human autoantibodies, but the B-cell immune response becomes even more diverse with chronicity and increasing antibody titer, and some autoantibodies in Hashimoto's thyroiditis bind to linear determinants of thyroglobulin. The majority of Tg antibodies belong to the IgG-1 and IgG-4 subclasses (McLachlan *et al.*, 1987), but do not fix complement because the spacing of the autoantigenic epitopes prevents cross-linking of C1q subunits (Forouhi *et al.*, 1987; McLachlan and Rapoport, 2014; Weetman and DeGroot, 2016). In

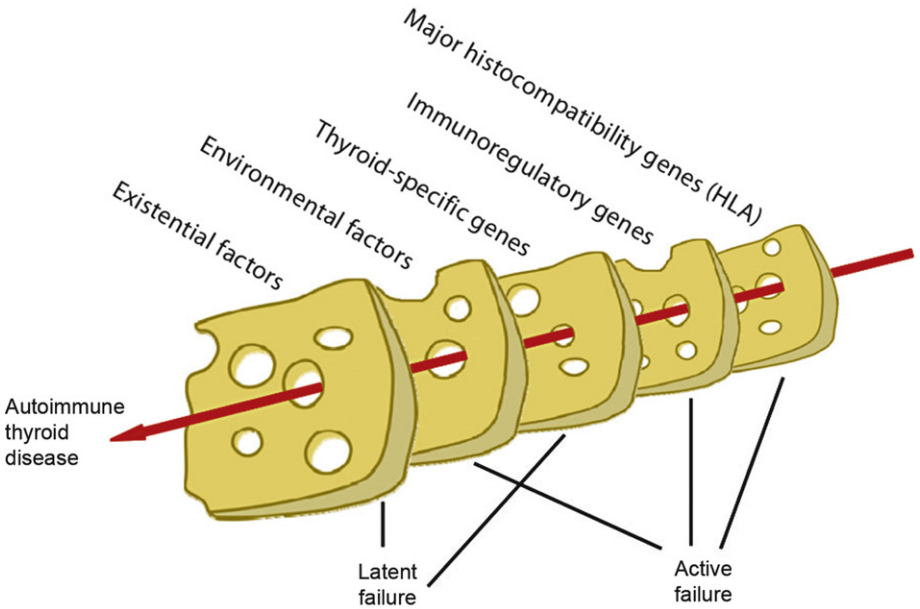

Fig. 2 Swiss cheese model for the causation of autoimmune thyroid disease. A Swiss cheese model for the causation of autoimmune thyroid disease, showing the effect of cumulative weaknesses lining up to allow a catastrophic event to occur, like the holes in slices of cheese. Each of the broad slices represented is composed of many individual components, which also have to line up. The Swiss cheese model for human accident causation incorporates active failures (e.g., pilot error) and latent failures (which lie dormant until the accident for example, aircraft maintenance deficiencies). Some factors contributing to the initiation of Hashimoto thyroiditis may be regarded as latent (e.g., aging, growing up in a hygienic environment) and others as active (e.g., possession of an HLA allele which permits presentation of a thyroid autoantigen). Reproduced with kind permission from Weetman, A. P. (2013). The immunopathogenesis of chronic autoimmune thyroiditis one century after hashimoto. *European Thyroid Journal* ***1***, 243–250.

Table 5 Key properties of thyroid autoantigens

	Chromosomal location	*Size (kDa)*	*Protein type*	*Functions*	*Homology*
Thyroglobulin	8	660	Iodinated glycoprotein	T3 and T4 prohormone and storage	Acetylcholinesterase
Thyroid peroxidase	2	105–110	Hemoprotein enzyme	Iodination and coupling of tyrosine	Myeloperoxidase
TSH receptor	14	85	G protein-coupled receptor	Thyroid stimulation by TSH	Related receptors (e.g., luteinizing hormone)
Na^+/I^- symporter	19	65–77	Transmembrane transporter	Iodide uptake	Na^+/glucose transporter

the past, Tg antibodies were detected by immunofluorescence or hemagglutination assays, but these have generally been superseded by enzyme-linked immunosorbent assays and radioimmunoassays, which express levels in units related to a standard antibody preparation (Verburg *et al.*, 2013). The most sensitive assays indicate that low levels of Tg antibodies can be detected in up to 20% of the healthy female population.

Thyroid Peroxidase

There are two forms of thyroid peroxidase, TPO-1 and -2, but only the first has enzymatic activity and is expressed on the cell surface, where it catalyzes the iodination and coupling of tyrosine molecules to form T3 and T4. Originally, antibodies against TPO were called microsomal antibodies because they bound to an antigen in this subcellular fraction, although they were also recognized from immunofluorescence to bind to the apical microvillar surface of the thyroid cells. It was subsequently shown that binding of these complement-fixing microsomal antibodies could be inhibited by TPO-specific monoclonal antibodies, and studies of recombinant TPO confirmed that essentially all the binding to thyroid microsomes is directed against TPO.

Further work localized two linear B-cell epitopes, C-2 (amino acids 590–622), and C-21 (amino acids 710–722), but these are only recognized by antibodies arising late in the disease process. In the early phase of any autoimmune response involving TPO, antibodies are directed against conformational epitopes in two overlapping domains, A and B, and relative antibody binding to each of these domains is fairly constant over time. This narrow response seems to be related to the marked restriction of the immunoglobulin variable (V) region gene usage in TPO antibody formation, with each domain being recognized by antibodies encoded by different V gene sequences, indicating a genetic component to the control of antibody production. In contrast, T-cell epitopes are heterogeneous, with several different epitopes typically recognized by T cells from patients and only partially shared between patients. Such diversity is typical of a chronic immune response in which only one dominant T-cell epitope may initiate the process, but this is followed by "spreading" of the response to involve other epitopes over time, including so-called cryptic epitopes that only become exposed during the phase of tissue destruction.

TPO antibodies are measured using the same techniques as those used to measure Tg antibodies and are also found in healthy subjects in the absence of overt thyroid disease (Mariotti *et al.*, 1987). They are predominantly of the IgG-1 and IgG-4 subclasses (McLachlan *et al.*, 1987). Approximately one-fourth of patients with thyroid autoimmunity have TPO antibodies that can also bind thyroglobulin, so-called TGPO antibodies (Estienne *et al.*, 1999; Ruf *et al.*, 1992). Their pathological significance is unknown, and more recent evidence has indicated that antibodies against both thyroglobulin and TPO in the same individual arise due to breaking self-tolerance to each individual autoantigen separately (McLachlan and Rapoport, 2014).

TSH-Receptor

This receptor is similar to other G-coupled receptors and comprises two subunits, corresponding to the extracellular and transmembrane domains, joined by disulfide bonds. The fundamental importance of the TSH-receptor to Graves' disease was first established by the identification of a long-acting thyroid stimulator (LATS) in the serum of Graves' patients that matched the thyroid stimulatory action of TSH but had a much longer time course and, hence, could not be TSH. LATS was soon identified as an IgG antibody and assays were developed for these thyroid-stimulating antibodies that relied on the ability of IgG to stimulate cyclic AMP production—that is, the second messenger produced from TSH-receptor interaction with its ligand. Other intracellular signaling pathways may be activated by certain TSH-receptor antibodies, which may lead to goiter formation.

Considerable effort has been directed at identifying the B-cell epitopes on TSH-receptor recognized by antibodies, but the results are not conclusive. However, multiple species of TSH-receptor antibodies exist and some actually prevent TSH from stimulating the receptor without causing any stimulation themselves (Davies and Latif, 2015; McLachlan and Rapoport, 2014). The effect of these blocking antibodies is hypothyroidism. Other "neutral" TSH-receptor antibodies bind but have no functional effects. Although the detection of TSH-receptor-stimulating and-blocking antibodies depends on bioassays, most commonly measuring the cyclic AMP responses of the FRTL-5 rat thyroid cell line or Chinese hamster ovary cells transfected with TSH-receptor; these are cumbersome and not suited to rapid diagnostic testing. Antibodies that bind to TSH-receptor can be measured simply in solid-phase assays that estimate competition between antibody and radiolabeled TSH for binding to the receptor. Results from assays of these so-called TSH-binding inhibiting immunoglobulins (TBIIs) correlate well with the results of thyroid-stimulating antibodies in thyrotoxic patients, but TBII is also positive when TSH receptor blocking antibodies are present. Therefore, a positive TBII cannot be equated with the presence of the TSH-receptor-stimulating antibodies that cause Graves' disease.

There are multiple B-cell epitopes in the TSH-receptor that are generally conformational, comprising discontinuous segments that overlap the TSH binding site. Antibodies that bind to the carboxyl terminus of the extracellular domain have blocking activity, and those against the amino terminus have stimulating activity. Further dissection of these epitopes may allow the development of solid-phase assays for TSH-receptor-stimulating and -blocking antibodies that would render bioassays obsolete. In some Graves' patients, the TSH-receptor-stimulating antibody response is restricted in terms of light and heavy-chain use, implying genetic control of these strongly pathogenic antibodies. Another noteworthy feature is the very low concentration of these antibodies in sera, which makes their study difficult.

T-cell epitopes are heterogeneous and no clear dominant epitope has been identified. Nonetheless, the production of TSH-receptor antibodies is T-cell dependent, and presumably there are such dominant epitopes in the earliest phase of disease.

Other Autoantigens

The Na^+/I^- symporter is recognized by antibodies in 5%–30% of patients with Graves' disease or autoimmune hypothyroidism. Some of these antibodies have weak blocking effects on symporter activity in vitro, but in vivo iodide uptake is not a rate-limiting step in thyroid hormone synthesis and it is unknown whether there is any pathogenic role for these antibodies. A poorly characterized second colloid antigen (i.e., in addition to thyroglobulin) has been recognized for decades based on immunofluorescence studies with patient sera, but its nature is obscure. It has been suggested that a set of thyroid growth-stimulating and growth-inhibiting antibodies, separate from TSH-receptor antibodies, cause goitrous and atrophic thyroiditis, but this hypothesis is controversial and these antibodies are poorly characterized.

The biggest enigma is the nature of the orbital autoantigen(s) in Graves' orbitopathy. To explain the close association between this condition and thyroid autoimmunity, especially Graves' disease, the existence of an orbital autoantigen that cross-reacts with one in the thyroid has been proposed. The most attractive candidate is the TSH-receptor, which is expressed by the preadipocyte subset of fibroblasts; however, whether this is sufficient to explain pathogenesis is debated (Davies and Latif, 2015; Wall, 2014). A wide variety of extraocular muscle and fibroblast antigens have been suggested during the past 20 years based on enzyme-linked immunosorbent assays and immunoblotting studies, and it seems likely that several autoantigens are targets of the autoimmune response, at least in the later stages of disease, akin to the situation in autoimmune thyroiditis and type 1 diabetes mellitus.

Breach of Self-Tolerance

Central self-tolerance develops in the thymus and is essential for self-/nonself discrimination. Expression of the *AIRE* gene allows medullary thymic epithelial cells to express thousands of self-proteins specific for other organs, for example, the thyroid gland, and present peptides derived from these proteins in the context of MHC molecules to T cells under maturation. As a consequence, T cells with strong reactivity against self-peptides are eliminated. The system is, however, not a perfect one; some self-reactive T cells are not deleted and must be regulated peripherally in order to avoid development of autoimmune disease (McLachlan and Rapoport, 2014; Weetman and DeGroot, 2016).

Peripheral self-tolerance is normally ensured by Tregs that suppress autoimmune responses partly via mechanisms that involve cell-to-cell contact, and partly via production of immunoregulatory cytokines such as interleukin (IL)-10 and tumor growth factor (TGF)-β. Some T cells leave the thymus as Tregs (natural Tregs), while other Tregs (inducible Tregs) are induced from naïve T cells in the periphery under the influence of TGF-β. A shift in this balance between Tregs and pro-inflammatory T-cell subsets may lead to autoimmune diseases (**Fig. 3**) (Bliddal *et al.*, 2017; McLachlan and Rapoport, 2014). While many investigators have failed to show reduced Treg proportions or functional capacity in human thyroid autoimmunity, there is some evidence of a skewed balance between thyroglobulin-specific Tregs and pro-inflammatory T-helper-17 (Th17) cells in Hashimoto's thyroiditis (Kristensen *et al.*, 2015). Interestingly, overexpression of a truncated form of FOXP3, the transcription factor governing Treg induction, has been observed in Hashimoto's thyroiditis (Kristensen *et al.*, 2015).

Recently, a subset of B cells known as regulatory B cells (Bregs) have been shown to contribute to maintenance of peripheral tolerance by virtue of IL-10, transforming growth factor (TGF)-β, Fas ligand (FasL), and TRAIL expression (Fillatreau *et al.*, 2002; Klinker and Lundy, 2012; Mauri *et al.*, 2003). Particularly transitional B cells are enriched with Bregs. Significantly lowered frequencies of IL-10 producing B cells have been observed in new-onset Graves' disease patients (Zha *et al.*, 2012) as well as in Hashimoto's thyroiditis where transitional B cells showed impaired capacity to suppress T-cell proliferation and production of pro-inflammatory cytokines (Yu *et al.*, 2017).

Pathogenesis of Autoimmune Hypothyroidism

Cell-Mediated Effects

T cells play a critical role in the pathogenesis of autoimmune thyroiditis in animals, and considerable evidence supports a similar role in humans. $CD4^+$ T-helper (Th) cell and $CD8^+$ cytotoxic T (Tc) cells accumulate in the thyroid and the majority of these cells express markers of activation. Although some studies have suggested that these T cells are clonally restricted, others have found diverse uses of T-cell receptor Vα and Vβ genes, and this type of polyclonal response is in agreement with the known multiplicity of autoantigens and their epitopes and the likely spreading of antigenic determinants over time. Circulating T cells have an increased percentage of $HLA\text{-}DR^+$ T cells, marking a state of activation, and the proportion of $CD8^+$ T cells is probably decreased, but these are features of many autoimmune disorders and may have no autoantigen-specific cause or effect. More importantly, circulating and intrathyroidal T cells from patients with autoimmune hypothyroidism can be activated by and proliferate in response to thyroglobulin or thyroid peroxidase.

Conventional antigen presentation in the initiation of an immune response is primarily a function of dendritic cells, which can process antigen and present it with appropriate costimulatory molecules (**Fig. 1**). B cells and macrophages can also present antigen under appropriate conditions, and for B cells there is the additional feature that specific antigens can be processed because these are taken up by binding to antigen-specific antibody, the B-cell receptor, on the B-cell surface. This allows cells to up-concentrate

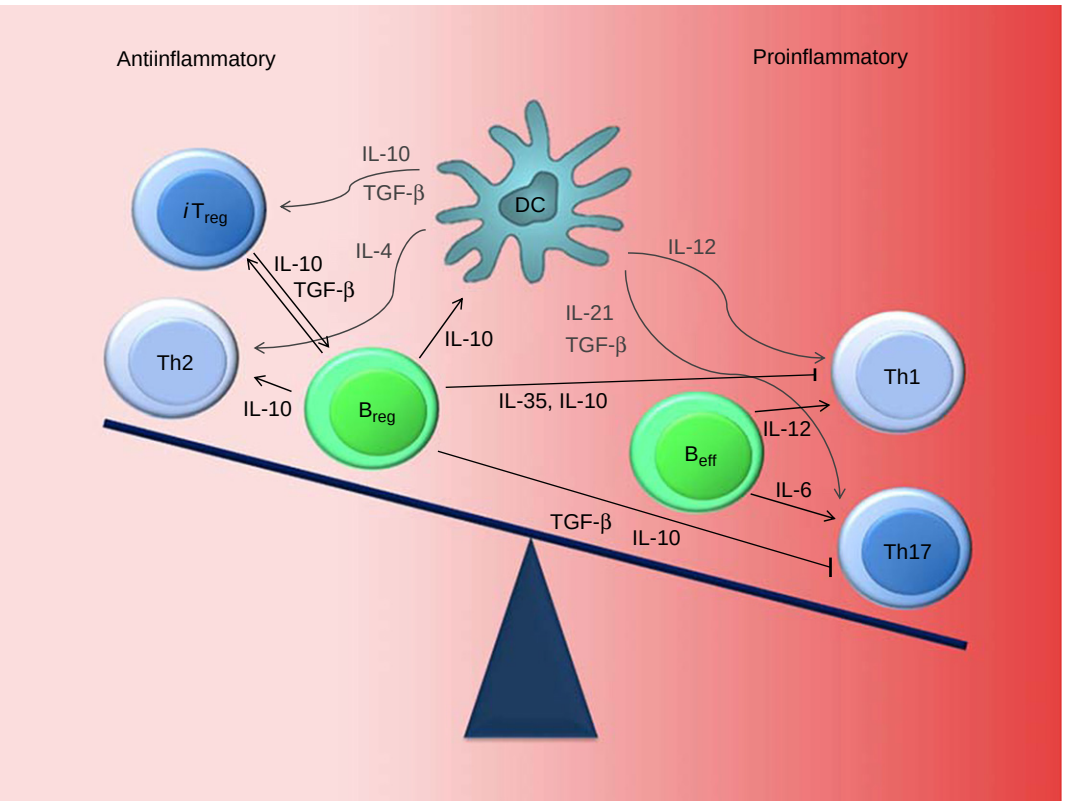

Fig. 3 B-cell and T-cell subsets involved in autoimmunity. Peripheral self-tolerance is ensured by regulatory T cells and regulatory B cells. Autoimmunity (loss of self-tolerance) is considered to be due to a shift in favor of pro-inflammatory cells. *Abbreviations*: iT_{reg}, induced regulatory T cells; $Th_{1,2,17}$, Effector CD4+ T-cell subsets with different cytokine profiles; B_{reg}, regulatory B cells; B_{eff}, effector B cells. antigens that are present in small quantities in the circulation which favors antigen-presentation by B cells over that of dendritic cells that simply sample a variety of antigens from the surroundings for presentation. Both types of antigen-presenting cells accumulate in the thyroid gland at the early stages of autoimmune thyroid disease. Like T cells and B cells, dendritic cells may be immunogenic or tolerogenic—and may thereby drive T cells into the appropriate directions—but their role in the pathogenesis of autoimmune thyroid disease is poorly understood.

When it was discovered that thyroid follicular cells express MHC class II molecules in autoimmune hypothyroidism and Graves' disease, there was considerable interest in the idea that this could be the precipitant of the autoimmune process because the thyroid cell would be capable of presenting thyroid autoantigens to any specific T cells in the vicinity. It is now clear that such MHC class II expression is a secondary rather than primary event, depending on the production of interferon-γ by locally infiltrating T cells, which clearly must have been activated by other antigen presenting cells. Moreover, the initiation of an immune response depends on the delivery of a second costimulatory signal to T cells at the same time as the first signal, namely the MHC class II molecule complexed with the antigenic epitope (**Fig. 1**). Failure to provide this second signal leads to anergy or even deletion—that is, the opposite outcome to activation. In general, thyroid cells do not appear to express B7 (CD80 or CD86), the most important costimulatory molecule, although there is a single report suggesting its expression in Hashimoto's thyroiditis. However, it seems that MHC class II expression by thyroid cells, from a teleological standpoint, is a protective mechanism to provide peripheral tolerance, for instance, in the event of viral thyroiditis.

Once activated, T cells can be restimulated by cells presenting antigen in the absence of B7 and thus, in the setting of autoimmune thyroiditis, MHC class II expression of thyroid cells may have an important role in expanding the intrathyroidal pool of T cells and thus exacerbating the autoimmune process (**Fig. 1**). It is also possible that differences in the regulation of T cells at this critical stage of disease (e.g., through genetically determined variability in class II expression or cytokine availability) may determine whether a focal thyroiditis progresses to full-blown disease.

Following these observations, it has become clear that thyroid follicular cells express a vast array of immunologically active molecules, including adhesion molecules and cytokines (**Table 6**). Many of these are induced by the cytokines known to be present in the intrathyroidal milieu in autoimmune thyroid disease, especially IL-1, tumor necrosis factor-α, and γ-interferon. Their expression tends to exacerbate the autoimmune response, although in some cases, such as the upregulation of complement regulatory proteins, the cell is protected from immune attack.

Since the original observation that Th cells may be divided into Th1 and Th2 cells on the basis of their cytokine production (interferon-γ and IL-4, respectively), investigators have suggested that Th cells producing IL-17, IL-9, and IL-22 be designated Th17, Th9, and Th22 cells, respectively. Of these subsets, Th1, Th2, and Th17 cells have been well-described in relation to autoimmune thyroid disease. The nature of the cell presenting antigen, and particularly the cytokines it secretes, plays a key role in determining the direction of the Th-cell response. Traditionally, an increased Th1 cell response has been viewed as a main cause of Hashimoto's thyroiditis by means of triggering a strong lymphocyte inflammatory infiltrate of the thyroid (thyroiditis) and, consequently, thyroid gland destruction. However, cytokines related to Th17 responses have also been shown to be excessively present in Hashimoto's thyroiditis and Graves' disease (Ramos-Levi and Marazuela, 2016; Shao *et al.*, 2018). Notably, a high degree of plasticity exist between Th17 cells and inducible Tregs, allowing these subsets to be converted to each other, and a skewed balance between them is likely to contribute to the pathogenesis of Hashimoto's thyroiditis (**Fig. 3**) (Kristensen *et al.*, 2015; Yang *et al.*, 2008). Of notice, cytokine profiles have been characterized by varying methods, that is, from isolated peripheral blood mononuclear cells, cells from thyroid gland tissue, or by ex vivo stimulation of such cells.

How thyroid cells are destroyed is unresolved. Data from animal models indicate that $CD8^+$ T cells kill thyroid follicular cells, and perforin-containing cells exist in the thyroid infiltrate in human autoimmune thyroid disease. Recently, attention has focused on apoptosis as a major mechanism for thyroid cell loss. Thyroid follicular cells in Hashimoto's thyroiditis overexpress Fas (CD95), likely the result of locally released cytokines, especially IL-1β. This could lead to an increased risk of thyroid cell destruction through interaction with $CD8^+$ T cells that bind to Fas and thereby trigger apoptosis. Several groups have described expression of FasL on thyroid follicular cells in autoimmune thyroid disease, although normally this molecule is restricted to $CD8^+$ T cells and sites of immunological privilege (e.g., trophoblast and testis), where it prevents T-cell recognition of antigen by deleting these T cells through Fas engagement. In some studies, IL-1β upregulated FasL expression by Hashimoto's thyroid cells in vitro, leading to the suggestion that exposure to this cytokine in vivo may cause suicide or fratricide within the Fas-positive thyroid cell population. However, questions have been raised over technical aspects of these experiments and, even if correct, the proportion of $FasL^+$ thyroid cells is often low. Upregulation of Bcl-2 and other antiapoptotic intracellular proteins, especially in Graves' disease, may limit thyroid cell death. Finally, the opposite view of FasL expression could be taken; namely, that such expression may protect thyroid cells from immune attack by creating the conditions of immunological privilege. Much work remains to be done before the roles of Fas/FasL and other cytotoxic pathways in the thyroid can be determined.

Humoral Effects

Overwhelming evidence indicates that thyroid antibodies alone cannot cause thyroid cell destruction. Tg antibodies do not fix complement. These antibodies and those against TPO and the Na^+/I^- symporter can cross the placenta and yet neonates born to mothers with high levels of such antibodies have normal thyroid function, as do many adults who have detectable thyroid antibodies. Experimental data indicate that these antibodies cannot access their antigens within an intact thyroid follicle. Nonetheless, there may be a secondary role for TPO antibodies: they cause tissue injury once the follicular architecture is disrupted by cytokines or T-cell-mediated cytotoxicity. Also, there is in vitro evidence that Tg antibodies and TPO antibodies can affect antibody-dependent, cell-mediated cytotoxicity by engaging Fc receptors on natural killer cells. There is certainly widespread complement activation within the thyroid in both Hashimoto's thyroiditis and Graves' disease. Although heightened expression of complement regulatory proteins (**Table 6**) may protect the thyroid cells from overt lysis, sublethal complement attack impairs the metabolic response of thyroid cells to TSH and induces cytokine production, which may exacerbate the autoimmune process.

Table 6 Immunological active molecules expressed by thyroid cells in autoimmune thyroiditis

Molecule	*Functions*	*Upregulatory factors*
MHC class I	Recognition by $CD8^+$ cytotoxic T cells	γ-IFN, TNF increase basal expression
MHC class II	Recognition by $CD4^+$ helper T cells	γ-IFN induces expression; enhanced by TNF
Adhesion and homing molecules (ICAM-1, LFA-3, Hermes-1, CD44, NCAM)	Binding of T and NK cells	γ-IFN, IL-1, TNF
Cytokines (IL-1, IL-6, IL-8, IL-13, IL-15)	Multiple effects on bystander lymphocytes	γ-IFN, IL-1, TNF
Complement regulatory proteins (CD46, CD55, CD59)	Prevention of lethal complement attack	γ-IFN, IL-1, TNF
CD40	Binds CD40 ligand on T cells, acting as a costimulatory	γ-IFN, IL-1
Nitric oxide	Tissue injury	γ-IFN, IL-1, TNF (decreased by IL-4, α-IFN, TGF-β)
Fas/Fas ligand	Apoptosis	IL-1

Abbreviations: *CD*, cluster of differentiation; *ICAM-1*, intercellular adhesion molecule-1; *IFN*, interferon; *IL*, interleukin; *LFA-3*, lymphocyte function-associated antigen 3; *NCAM*, neural cell adhesion molecule; *NK cells*, natural killer cells; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor.

Thyroid autoantibodies may further promote presentation of thyroglobulin and TPO and induce proinflammatory cytokine responses by enhancing their uptake by antigen-presenting and cytokine-producing cells (Nielsen *et al.*, 2009; Nielsen *et al.*, 2004).

TSH-receptor-blocking antibodies, in contrast, have pathogenic effects, causing hypothyroidism. This is most clearly demonstrated in the transient neonatal hypothyroidism that follows placental transfer. This effect lasts only as long as the antibodies persist and is therefore a functional rather than cytotoxic effect. As many as 20% of patients with hypothyroidism may have TSH-receptor-blocking antibodies, and these appear particularly common in patients with atrophic rather than goitrous thyroiditis in Asia, whereas in other regions TSH-receptor-blocking antibodies show no such dichotomy. Unexplained fluctuations in these antibodies (and sometimes in coincident TSH-receptor-stimulating antibodies) account for most, if not all, cases of hypothyroidism that show spontaneous recovery. The role of other potentially cytotoxic molecules, such as lymphotoxin-α, nitrous oxide, and reactive oxygen metabolites, in causing thyroid injury is unclear (**Fig. 4**).

Pathogenesis of Graves' Disease

Cell-Mediated Effects

Similar findings as those for autoimmune thyroiditis are found for Graves' disease, the latter also being caused by a T-cell abnormality, but the clinical presentation of hyperthyroidism being caused by production of the pathognomonic TSH-receptor-stimulating antibodies as described in the above. Thus, *Graves' hyperthyroidism is antibody-mediated but is predominantly a Th1-type cytokine disease* (Rapoport and McLachlan, 2014). Circulating T cells show an increase in HLA-DR$^+$ and a decrease in CD8$^+$ subsets, and the thyroid infiltrate comprises CD4$^+$ and CD8$^+$ cells with little evidence of clonal restriction. Thyroglobulin-, TPO-, and TSH-receptor-specific T cells can be demonstrated in the circulation and thyroid infiltrate, but there is no evidence of a specific defect in their regulation. The same issues have been raised regarding antigen presentation as those for autoimmune hypothyroidism, and there is a mixed intrathyroidal cytokine profile with evidence of various Th-cell responses. These observations help explain the transition of Graves' disease to autoimmune hypothyroidism seen in some patients spontaneously and in others years after treatment with antithyroid drugs. There is also indirect evidence that hypothyroidism is more likely to occur after radioiodine or surgery in Graves' patients with the most marked autoimmune responses against thyroglobulin and TPO.

Humoral Effects

Graves' disease is the prime exemplar of a disease caused by antibodies with a stimulatory action (previously termed type V hypersensitivity). The role of TSH-receptor-stimulating antibodies was discussed previously. Virtually all patients have detectable TSH-receptor-stimulating antibodies, provided the most sensitive assays are used. The few who do not, most likely have antibodies, but in an amount that is below the current limit of detection. The level of TSH-receptor-stimulating antibodies correlates loosely with the severity of hyperthyroidism due to the ongoing intrathyroidal T-cell-mediated events, the secondary effects of TPO antibody causing thyroid injury, and the simultaneous presence of TSH-receptor-blocking antibodies in some patients. There is a much clearer relation between

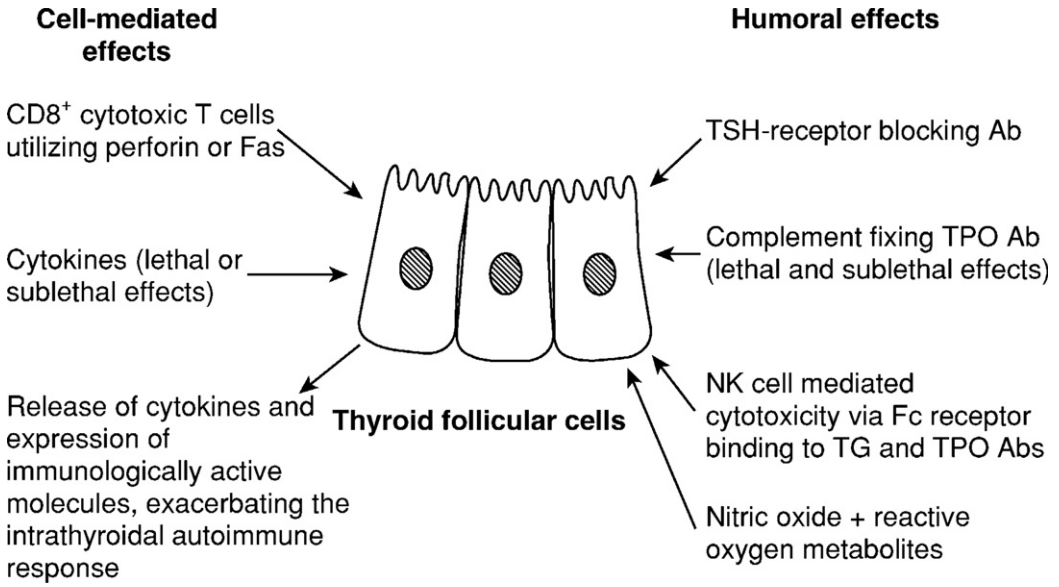

Fig. 4 Pathogenetic mechanisms in autoimmune hypothyroidism. *Abbreviations*: *Ab*, antibody; *NK cell*, natural killer cell; *TPO*, thyroid peroxidase; *TG*, thyroglobulin.

the maternal level of TSH-receptor antibodies in women with Graves' disease in the last trimester of pregnancy and the occurrence of neonatal thyrotoxicosis, suggesting that the first two processes, which do not affect fetal or neonatal thyroid, are most important.

Effects of Treatment

Spontaneous remission of Graves' disease appears to be unusual, unless autoimmune hypothyroidism intervenes. Accurate data are not available, but clinical remission was seen in only 10%–20% of patients treated decades ago with beta-blockers, and these patients had the mildest degree of thyrotoxicosis (Codaccioni *et al.*, 1988). Remission of other receptor antibody-mediated diseases, such as myasthenia gravis, is also rare. Therefore, the 40%–50% remission rate of Graves' disease after treatment with the antithyroid drugs carbimazole, methimazole, or propylthiouracil indicates an immunomodulatory effect of these agents. TSH-receptor antibody levels decline during treatment and remain low in those who do not relapse, although there is not a clear correlation between levels of TSH-receptor antibodies and relapse/remission rate after medical treatment (Feldt-Rasmussen *et al.*, 1994). It may, however, depend on the method used for measurement since a recent study found higher predictive value by a method assessing thyroid stimulating antibodies by a bioactivity stimulation assay, than when using TBII (Kwon *et al.*, 2016). Furthermore, levels of nonthyroid autoantibodies do not decline during medical antithyroid therapy. This apparent paradox is most likely explained by the actions of antithyroid drugs on the thyroid cells, including suppression of cytokine, reactive oxygen metabolite, and prostaglandin production. As a result, the thyroid lymphocytic infiltrate declines and the production of thyroid antibodies are curtailed. Remission is not expected in patients in whom the autoimmune process has spread beyond the thyroid gland because antithyroid drugs do not easily influence any extrathyroidal autoreactivity; this is in accord with the observation that patients with the most severe disease do poorly on antithyroid drugs.

Subtotal thyroidectomy usually leads to cessation of thyroid antibody production, although this may continue in some patients due to the persistence of specific B cells in the bone marrow and lymph nodes. Thyroid antibodies show a characteristic rise and then fall usually during the year after ^{131}I therapy: this may be due to release of autoantigen from the damaged thyroid, followed by death of the intrathyroidal lymphocyte population. TSH-receptor antibodies have, however, been demonstrated to remain in the circulation years after radioiodine therapy, unlike after thyroidectomy or only medical treatment (Laurberg *et al.*, 2008).

Activated T cells increase in the circulation in the first few months after ^{131}I and these cells, by homing to the orbit, may be responsible for the exacerbation of Graves' orbitopathy seen in up to 15% of patients after such treatment. This worsening can be prevented by glucocorticoids (Shiber *et al.*, 2014).

Graves' Orbitopathy

The pathogenesis of Graves' orbitopathy is complex and unclear. The extraocular muscles are the main focus of the autoimmune process, but occasional patients appear to have a primary expansion of the retro-ocular connective tissue, including fat. A separate process is likely involved in the clinical sign of lid retraction (which is more extreme than in any type of thyrotoxicosis), at least based on the histological findings. There is no evidence that tissue destruction plays a role in initiating these changes, although extraocular muscle cell damage may occur late in severe disease; thus, attempts to find cytotoxic autoantibodies or lymphocytes seem ill founded. Apart from lid retraction, which could be mediated by the sympathetic overactivity secondary to thyrotoxicosis, no convincing signs of Graves' orbitopathy have been reported in neonates born to women with Graves' orbitopathy, arguing against a primary role for orbital autoantibodies (Weetman and DeGroot, 2016). However, antibodies that activate insulin-like growth factor I (IGF-I) receptor have been detected in patients with Graves' orbitopathy and have been shown to synergistically enhance TSH action and stimulate fibroblast action in the orbit (Smith *et al.*, 2017). Thus, the most likely explanation for Graves' orbitopathy is that fibroblasts in the extraocular muscles and orbital connective tissue are activated by cytokines from the infiltrating T cells and macrophages. IL-1β, tumor necrosis factor, and γ-interferon all affect fibroblast function and may cause the increase in expression of HLA-DR and other immunologically active molecules found in Graves' orbitopathy. More important, they enhance glycosaminoglycan production, leading to water trapping and edema. An identical or related pathway of cytokine-induced activation may lead to fibrosis later in disease, the so-called burnt-out stage of Graves' orbitopathy. Smoking may exacerbate this pathogenetic process by affecting cytokine secretion or action or by inducing partial hypoxia, which increases glycosaminoglycan production. Indeed, as the orbital contents increase, the pressure effects within the confines of the bony orbit may lead to partially hypoxic and congested conditions with impaired venous drainage, which in turn may cause further edema in addition to being a proinflammatory environment. In such a scenario, relatively modest initial increases in orbital tissue volume may quickly increase as in congestive orbitopathy. Anatomical differences between the capacity of the two orbits in an individual may accommodate different degrees of swelling, leading to the asymmetric form of Graves' orbitopathy seen in 5%–10% of cases. Another factor accounting for Graves' orbitopathy is the likely heightened sensitivity of the orbital fibroblast population to cytokine activation compared to that of fibroblasts from other sites. Together with the presumed intraorbital location of a thyroid cross-reactive autoantigen, this susceptibility may explain the localization of disease.

Approximately 1% of patients with Graves' disease develop thyroid dermopathy, often situated over the shins, where it is called pretibial myxedema. These patients almost always have marked Graves' orbitopathy, and dermopathy seems to be a more flagrant

form of the same process, in which immunologically mediated fibroblast activation occurs within the dermis, presumably via the action of cytokines. Dermopathy is usually localized to sites where fluid retention and injury occur, suggesting that a cascade of events similar to those of Graves' orbitopathy may cause worsening of the disease.

The expanding knowledge of the immunologic processes involved in autoimmune thyroid disease has great potential in the understanding and of treatment of otherwise treatment-resistant Graves' orbitopathy. The B-cell-depleting agent rituximab improves Graves' orbitopathy (as well as numerous other autoimmune diseases) (El *et al.*, 2006; Salvi *et al.*, 2015). Also, targeting and thus inhibiting the IGF-1-receptor by use of teprotumumab significantly improved outcome in 88 patients with Graves orbitopathy (Smith *et al.*, 2017). More recently, a randomized trial of the effect of adding the B-cell and T-cell-suppressant mycophenolate to prednisolone treatment in patients with active moderate-to-severe Graves' orbitopathy failed to show improvement of response rates, although results in subgroup analyses were improved (Kahaly *et al.*, 2018). Thus, immunomodulatory drugs may become key players in understanding and treating severe Graves' orbitopathy in years to come.

Conclusion

Thyroid autoimmunity is the most common autoimmune phenomenon in humans and is caused by T-cell and B-cell self-reactivity against the thyroid gland. Several clinically overt, common, and distinct thyroid diseases result from thyroid autoimmunity, although there are also many individuals who have subclinical evidence of thyroid autoimmunity. The pathogenesis is most often multifactorial including genetic susceptibility (i.e., HLA-DR3 alleles), environmental factors (iodine consumption, smoking) and endogenous factors (female sex, previous pregnancies, increasing age). Future studies (i.e., studies of next-generation sequencing, immune regulation, and microbiota) will further evolve our understanding of this heterogenous group of autoimmune diseases and help identify potential beneficial targets of treatment in those with treatment-resistant disease.

Thyrotoxicosis; Overview of Causes☆

Claudio Marcocci and Roberto Rocchi, University of Pisa, Pisa, Italy

Glossary

Graves' disease Autoimmune thyroid disease characterized by goiter, hyperthyroidism, and ophthalmopathy (in its classic form, also known as "Merseburg triad," from the name of the small village in Germany where Karl von Basedow first observed a patient).

Hyperthyroidism Active overproduction of thyroid hormone by the thyroid follicular epithelial cells that can cause thyrotoxicosis.

Thyrotoxicosis The clinical syndrome that results from the exposition of tissues to an excess of circulating thyroid hormone.

Thyrotoxicosis factitia Thyrotoxicosis due to a voluntary surreptitious ingestion of excess thyroid hormone preparations with various purposes.

Toxic adenoma Benign thyroid tumor characterized by autonomous overproduction of thyroid hormone (in most cases due to a somatic activating mutation of the thyrotropin receptor gene) functioning autonomously.

Classification

The various causes of thyrotoxicosis can be classified according to their pathogenic mechanism. In **Table 1**, the most common forms of thyrotoxicosis are categorized into two broad groups: thyrotoxic syndromes of thyroidal origin and thyrotoxic syndromes of nonthyroidal origin. The first group, the most frequent one, can be further divided into forms associated with thyroid hormone hypersecretion (hyperthyroidism) and into forms characterized by the release of preformed hormones, secondary to destructive processes (destructive thyrotoxicosis). The second group includes a heterogeneous group of rare disorders in which the thyroid gland is not primarily involved as a source of thyroid hormone. Thyroid radioiodine uptake (RAIU) and thyroid 99m-pertechnetate scintigraphy although not always performed nowadays, have for many decades represented the primary tests in broadly defining the cause of thyrotoxicosis (De Leo *et al.*, 2016; Ross *et al.*, 2016).

Causes of Hyperthyroidism

Graves' Disease

The most frequent cause (40%–70% according to the iodine intake in the population) of thyrotoxicosis is Graves' disease (Carle *et al.*, 2011). The prevalence of Graves' disease may be as high as 1%, with a predominance of the female sex. Graves' disease is an autoimmune disorder characterized, in its classic form, by goiter, hyperthyroidism, ophthalmopathy (Merseburg triad), and (less frequently) dermopathylocalized in the pretibial region (pretibial myxedema). Hyperthyroidism is caused by an autoimmune reaction to the thyroid, leading to the production of autoantibodies to the thyrotropin (TSH) receptor (TSH receptor-stimulating antibodies (TSABs)) (Chiovato *et al.*, 1994). These antibodies stimulate the TSH receptor on thyroid follicular cells. Because there is no feedback of thyroid hormone on the production of TSABs, uncontrolled stimulation of the receptor causes a diffuse enlargement of the thyroid gland and overproduction and release of thyroid hormone that lead to hyperthyroidism. In some cases, thyroid nodularities can be felt as a consequence of either long-standing disease or preexisting nodular goiter. Physical examination reveals signs of Graves' ophthalmopathy in 30%–45% of patients, and when studied with imaging techniques, suggestive findings can be observed in up to 70% of cases. Local myxedema is a peculiar and rare skin manifestation of Graves' disease characterized by edema, inflammation, and lymphocytic infiltration localized mostly to the pretibial dermis. It occurs almost exclusively in patients who also have Graves' ophthalmopathy (Bartalena *et al.*, 2016; Ross *et al.*, 2016; Smith and Hegedüs, 2016).

Toxic Adenoma

Toxic adenoma is a quite frequent cause of hyperthyroidism, especially in iodine-deficient countries, where its prevalence has been reported to be as high as 4.5% (10% of all cases of thyrotoxicosis) (Carle *et al.*, 2011). A lower prevalence (2.7%) has been reported in iodine-sufficient areas. Toxic adenomas are benign isolated thyroid tumors that function autonomously. The nodular tissue acquires the capability of producing thyroid hormones independently of TSH stimulation. The increased thyroid hormone secretion first suppresses pituitary TSH secretion and eventually leads to overt hyperthyroidism. Because of TSH suppression, the

This article is an update of Claudio Marcocci and Roberto Rocchi, Thyrotoxicosis, Overview of Causes, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 554-559.

Table 1 Classification of known causes of thyrotoxicosis, epidemiology, and distinctive diagnostic features

Group	*Disease*	*Relative frequency (%)*	*Dstinctive features*	*Neck RAIU*	*Serum TSH*	*Serum thyroglobulin*
Thyrotoxicosis of thyroidal origin associated with hyperthyroidism	Graves' disease	40–70*	Diffuse goiter, ophtalmopathy, positive TRABs	High	Undetectable	High
	Toxic adenoma	5	Single "hot" nodule at thyroid scan	High	Undetectable	High
	Toxic multinodular goiter	20–40*	Multiple "hot" nodules at thyroid scan	High	Undetectable	High
	Iodine induced thyrotoxicosis	<1	High urinary iodine	Low to high	Undetectable	High
	TSH-secreting adenomas	<1	Inappropriately high TSH level	High	Normal to high	High
	Familial gestational hyperthyroidism	Extremely rare	Pregnancy-associated DNA analysis	Presumably high	Undetectable	High
	Trophoblastic tumors	<1	High chorionic gonadotropin	High	Undetectable	High
	Neonatal thyrotoxicosis	<1	Positive TRABs	High	Undetectable	High
	Familial hypersensitivity to hCG	<1	TSH receptor mutation with inc. sensitivity to hCG	High	Undetectable	High
	Non-autoimmune congenitaland familial hyperthyroidism	Extremely rare	TSH receptor gene mutations by DNA analysis	High	Undetectable	High
Associated with thyroid destruction	Subacute thyroiditis	3	Neck pain, high erythrocte sedimentation rate	Low	Undetectable	High
	Silent thyroiditis	3	Positive thyroid autoantibodies	Low	Undetectable	High
	Type II amiodarone-induced thyrotoxicosis	<1	High urinary idine, highserum interleukin-6	Low	Undetectable	High
Thyrotoxicosis of non-thyroidal origin	Factitious thyrotoxicosis	<1	Low serum thyroglobulin	Low	Undetectable	Low
	Thyroid hormone intoxication	<1	Low serum thyroglobulin	Low	Undetectable	Low
	Dermoid tumors (struma ovarii)	Very rare	Abdominal RAIU	Low	Undetectable	High
	Metastatic differentiated thyroid cancer	Very rare	Bone RAIU (whole body scan)	Low	Undetectable	High

*According to iodine intake in the population and endemic goiter areas (Carle et al., 2011).
TRAbs: Antibodies against TSH receptor; *RAIU*: Radioiodine uptake; *hCG*: human chorionic gonadotropin.

extranodular thyroid tissue becomes functionally quiescent and may undergo some degree of atrophy. Toxic adenomas are more frequent in the aged population and in females. The natural history of toxic adenoma is characterized by slow growth over many years with a progression of its functional properties through various stages. During the early stages, the excess of secretion of thyroid hormones is not sufficient to completely suppress TSH secretion (partial autonomy) and the extranodular tissue. With further growth of the nodule, TSH suppression becomes complete, whereas circulating thyroid hormones are in the upper range of normality (complete autonomy). Eventually, overt thyrotoxicosis ensues with frankly elevated thyroid hormone levels. Recent studies have shown that somatic mutations of the TSH receptor gene are the cause of 20%–80% of toxic adenomas. In other cases, the Gs-α-subunit of the TSH receptor coupled adenyl cyclase is mutated. Both kinds of mutations cause permanent activation of the TSH receptor intracellular signaling pathway in the absence of the natural ligand (TSH); therefore, they fully explain the autonomous functioning of the nodules (Tonacchera *et al.*, 1998; Ross *et al.*, 2016; Siegel and Lee, 1998).

Toxic Multinodular Goiter

Toxic multinodular goiter is also more frequent in iodine-deficient countries and primarily affects women (Carle *et al.*, 2011). Epidemiological studies have clearly shown that toxic multinodular goiter represents the long-term outcome of many long-standing nontoxic goiters; therefore, it is most often found in aged persons. Somatic activating mutations of the TSH receptor have

been observed occasionally in toxic multinodular goiter as well. The natural history of toxic multinodular goiter is similar to that of toxic adenoma, with a slow formation of multiple autonomously functioning nodular areas in the setting of an overall nodular goiter. Progression of autonomous function may lead to subclinical hyperthyroidism and overt thyrotoxicosis. The clinical manifestations are scanty due to the advanced age of patients and the slow progression of thyrotoxicosis (Hegedus 2004; Siegel and Lee, 1998).

TSH-Secreting Adenoma

Hyperthyroidism caused by excessive TSH secretion by a pituitary adenoma (central hyperthyroidism) is very rare. TSH-secreting adenomas completely or partially lose feedback regulation by thyroid hormone and, therefore, cause sustained stimulation of the thyroid gland, leading to the development of goiter and hyperthyroidism. The severity of thyrotoxicosis is highly variable, ranging from modest elevations to very high levels of thyroid hormones; therefore, the patient may report few or no symptoms or may present with overt thyrotoxic symptoms. TSH-secreting adenomas may cosecrete growth hormone (GH) and prolactin, with clinical presentation of acromegaly and galactorrhea. Most TSH-secreting adenomas are macroadenomas and may lead to hypopituitarism and visual field defects (Beck-Peccoz *et al.*, 1996; Tjörnstrand and Nyström, 2017).

Human Chorionic Gonadotropin-Dependent Hyperthyroidism

Human chorionic gonadotropin (hCG) is secreted in large amounts by placental tissue in normal pregnancy and also by trophoblastic tumors such as hydatidiform mola. hCG has a partial homology with TSH and can act as a weak TSH agonist. Therefore, large amounts of hCG in the bloodstream can over stimulate the thyroid gland and cause hyperthyroidism (Ross *et al.*, 2016; Reinwein *et al.*, 1988; Ross, 1998).

Trophoblastic Tumors

In hydatidiform mola, hyperthyroidism is caused by tumor secretion of large quantities of hCG. However, overt thyrotoxicosis is observed in only a minority (10%) of patients with extraordinarily high levels of hCG (>3 million IU/L) (Ross *et al.*, 2016).

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by prominent nausea and vomiting, weight loss ketosis, and electrolyte abnormalities. It is a poorly understood early complication of pregnancy associated with inappropriately high levels of circulating hCG that causes clinical or subclinical hyperthyroidism in about one-third of cases (Pearce, 2015; Ross *et al.*, 2016).

Familial Gestational Hyperthyroidism

This inherited pregnancy-associated form of hyperthyroidism has been described in one family. Hyperthyroidism was due to a mutation in the TSH receptor gene, causing increased sensitivity of the receptor to the effect of hCG. For this reason, hyperthyroidism manifests only during pregnancy and recurs every time an affected woman becomes pregnant (Pearce, 2015; Ross *et al.*, 2016).

Fetal and Neonatal Thyrotoxicosis

TSABs in the serum of mothers with Graves' disease can cross the placenta and cause fetal and neonatal hyperthyroidism through direct stimulation of the fetal thyroid. The disease can be very severe and is characterized by tachycardia, jaundice, heart failure, and failure to thrive. A goiter is usually present. The thyrotoxicosis is transient and resolves within 3 months after birth because there is no source of TSABs in the neonate (Zimmerman, 1999).

Nonautoimmune Congenital and Familial Hyperthyroidism

Recently, a new form of congenital hyperthyroidism has been reported. The disease is caused by a germ line de novo mutation of the TSH receptor gene, causing constitutive permanent activation of the receptor and, therefore, diffuse goiter and overproduction of the thyroid hormone, in turn causing severe hyperthyroidism in the neonate. The clinical presentation is similar to the presentation of neonatal thyrotoxicosis, and the diagnosis should be suspected when no history of Graves' disease is present in the mother. Familial nonautoimmune hyperthyroidism has been described in two kindreds. In this case, hyperthyroidism is due to dominant inherited activating mutations of the TSH receptor, but because the effect of the mutation is mild, hyperthyroidism and goiter develop only during adult age. The clinical manifestations are mild and variable in patients bearing the same mutation (Ferraz and Paschke, 2017; Ross *et al.*, 2016).

Causes of Destructive (Low-RAIU) Thyrotoxicosis

Subacute Thyroiditis

Transient thyrotoxicosis occurs in approximately 50% of patients with subacute thyroiditis. Subacute thyroiditis is an inflammatory disorder of the thyroid, probably due to a viral agent. The viral origin is suggested by the frequent association with a history of recent upper respiratory tract infection.

Clinically, patients with subacute thyroiditis present with pain in anterior neck, variable degrees of thyroid swelling, and systemic symptoms such as malaise and fever. From a histopathological point of view, the thyroid gland indicates a leukocytic and granulomatous infiltrate with follicles disruption. Thyrotoxicosis results from the destruction of thyroid follicles by the inflammatory process with release of preformed thyroid hormones. When present, thyrotoxicosis lasts for 3–8 weeks and is sometimes followed by a phase, also transient, of mild hypothyroidism. Complete recovery of thyroid function eventually occurs, but permanent hypothyroidism has also been reported (Akamizu *et al.*, 2013; Weetman and McGregor, 1994).

Painless Thyroiditis

Painless thyroiditis is probably due to an autoimmune thyroid disorder that can generate an inflammation of the gland with chronic lymphocytic infiltration closely resembling that of Hashimoto's thyroiditis. Similar to subacute thyroiditis, the disease is characterized by a transient phase of thyrotoxicosis, but neck pain and general symptoms are usually absent. Circulating thyroid autoantibodies are found in the majority of cases, and the progression to spontaneous permanent hypothyroidism is observed in as many as 20% of cases in long-term follow-up. In some cases, painless thyroiditis is precipitated by radiotherapy in the region of the neck for a variety of neoplasms that induce thyroid damage with discharge of preformed thyroid hormone. Cytokine treatments, particularly with interferon-1 alpha and interleukin-2, have also been shown to cause a clinical syndrome resembling classical painless thyroiditis. These cytokines may also cause classical Graves' disease by acting as generic triggers of thyroid autoimmunity in predisposed individuals. The most likely mechanism in these cases is activation of preexisting thyroid autoreactive T-cell clones. Findings suggestive of painless thyroiditis are the presence of a goiter, low radioiodine uptake with transient thyrotoxicosis, and occasional progression toward hypothyroidism. These cases may be classified as a variant of Graves' disease with predominant cytotoxic aspects, quickly leading to a clinical picture of Hashimoto's thyroiditis. Painless thyroiditis may be seldom associated with Graves' ophthalmopathy (Akamizu *et al.*, 2013).

Postpartum Thyroiditis

Postpartum thyroiditis is a subacute thyroid inflammation that occurs during the early postpartum period in susceptible woman. It represents a variant of painless thyroiditis. Postpartum thyroiditis is a rather common disorder, occurring in 5%–10% of pregnancies. Most women with postpartum thyroiditis have circulating antithyroglobulin and antithyroperoxidase antibodies before or during the onset of the disease. Some human leukocyte-associated antigen(HLA) haplotypes, such as B35, confer a clear-cut predisposition to the disorder, making it distinct from classical Hashimoto's thyroiditis. From a clinical point of view, the disease is similar to painless thyroiditis with absence of nonspecific or local symptoms and with transient thyrotoxicosis that occurs in approximately 50% of cases. Approximately one-third of cases present with a second phase of transient hypothyroidism that may develop up to 10 years later. The risk of recurrent postpartum thyroiditis in subsequent pregnancies is as high as 70% in women who have already had an episode (Masiukiewicz and Burrow, 1999).

Other Forms of Destructive Thyrotoxicosis

Rarely, destructive thyrotoxicosis can be precipitated by anterior neck injuries. Thyrotoxic crises following thyroid surgery were frequent at the beginning of thyroid surgery era. It has become extremely rare considering the optimal preparation of patients with antithyroid drugs and the refinement of surgical procedures. Finally, thyrotoxicosis may transiently worsen or recur in patients who are treated with radioiodine for Graves' disease, toxic adenomas, and multinodular toxic goiter. This phenomenon can be explained with two mechanisms: ongoing thyroid hyperfunction before radioiodine fully takes effect and radiation-induced thyroid destruction (De Leo *et al.*, 2016; Ross *et al.*, 2016).

Iodine- and Amiodarone-Induced Thyrotoxicosis

Iodine-induced thyrotoxicosis, secondary to the consumption of large amounts of iodine through the diet or other routes (some medications and diagnostics (e.g., contrast media, disinfectants, drugs) and some foods), has been recently reported with increased frequency. Thyrotoxicosis can precipitate through several mechanisms. When high doses of iodine are administered, the normal thyroid responds with inhibition of organification. This is an autoregulatory defense mechanism known as the Wolff–Chaikoff effect. Eventually, an escape phenomenon ensues and thyroid hormone synthesis resumes. The protection mechanism appears to be defective in autonomous thyroid tissue, and excess iodine or even simple dietary supplementation may precipitate hyperthyroidism in patients with a preexisting thyroid disorder through the "jodbasedow" phenomenon. Most of these disorders

Table 2 Thyroid disorders predisposing to iodine-induced thyrotoxicosis

- Autonomous or pretoxic thyroid adenoma
- Nontoxic, autonomous, or pretoxic multinodular goiter
- Euthyroid or "latent" Graves' disease
- Graves' disease in remission after or during antithyroid drug treatment

(Table 2) are characterized by thyroid autonomy; therefore, iodine-induced thyrotoxicosis is by far more prevalent in areas of iodine deficiency and in aged patients (Stanbury *et al.*, 1998).

Among drugs, the antiarrhythmic amiodarone deserves a special mention due to the dual mechanism by which it can cause thyrotoxicosis. One tablet of 200 mg of amiodarone contains approximately 75 mg of organic iodide and will release approximately 8 mg of free iodine, a tremendous amount when compared with the daily recommended dose of 200 μg. This amount of iodine can precipitate hyperthyroidism in predisposed patients simply through the jodbasedow phenomenon in a manner similar to that of iodine of other sources (type I amiodarone-induced thyrotoxicosis). However, amiodarone has been shown to be directly cytotoxic to thyroid follicular cell in vitro and can precipitate a form of thyrotoxicosis similar to that observed in subacute thyroiditis and due to the release of preformed hormones (type II amiodarone-induced thyrotoxicosis). The distinction between the two forms is crucial because the treatments are quite different. A mixed form of amiodarone-induced thyrotoxicosis may occur (Martino *et al.*, 1984; Ross, 1998).

Thyrotoxicosis of Extrathyroidal Origin

Thyrotoxicosis Factitia

Thyrotoxicosis factitia is due to the voluntary surreptitious ingestion of excess thyroid hormone preparations with the purpose of mimicking thyrotoxicosis. It should be distinguished from iatrogenic thyrotoxicosis, which is caused by excessive doses of thyroid hormones administered by the physician or inadvertently taken by the patient. However, the term has been widely applied to all forms of thyrotoxicosis due to the ingestion of thyroid hormone (Mariotti *et al.*, 1982). True thyrotoxicosis factitia is most often observed in women with psychiatric disturbances. Very often, thyroid hormone is taken to reduce weight or to receive medical attention. Denial of thyroid hormone consumption may be extreme in these patients, and the diagnosis is rarely obtained at history taking. Sometimes, thyroid hormone is inadvertently taken as a component of "herbal" or "alternative" medications, usually for weight-reducing purposes. Finally, accidental grinding of cattle thyroids in hamburger meat has been reported to be the cause of an outbreak of thyrotoxicosis among hamburger consumers in the United States.

Struma Ovarii

Struma ovarii is a rare teratoma of the ovary that may contain functional thyroid follicular tissue, among others. Struma ovarii causes overt thyrotoxicosis only rarely, depending on the amount of follicular tissue present in the neoplasia. Because complete TSH suppression occurs in struma ovarii, the neoplastic thyroid tissue is assumed to be functionally autonomous to cause thyrotoxicosis. A suspicion of the struma ovarii can be confirmed at the time of RAIU by scanning the pelvic area with the probe. The presence of functional thyroid tissue can be demonstrated by the finding of significantly increased uptake of iodine in the ovarian region. Computed tomography or ultrasound scan will confirm the presence of an ovarian mass (De Leo *et al.*, 2016; Ross *et al.*, 2016).

Functional Metastatic Thyroid Cancer

Differentiated thyroid cancer, even when metastatic and with large tumor burdens, rarely produces physiologically relevant amounts of thyroid hormone. On the other hand, thyroid follicular cancers with extensive bone metastases may cause thyrotoxicosis (Ross *et al.*, 2016).

Thyrotoxicosis; Diagnosis☆

Claudio Marcocci and Roberto Rocchi, University Hospital of Pisa, Pisa, Italy

Glossary

Thyroglobulin A large thyroid glycoprotein molecule that functions in the storage of iodine and from which the thyroid hormones thyroxine and triiodothyronine are formed.

Thyroid radioiodine uptake (RAIU) A functional thyroid test, based on the use of radioactive isotopes of iodide, that is useful in the determination of the etiological diagnosis of thyrotoxicosis.

Thyroid 99m-pertechnetate scintigraphy A functional thyroid test, based on the use of radioactive isotopes of iodide, that is useful in the determination of the etiological diagnosis of thyrotoxicosis.

Thyroid ultrasound A harmless and useful technique for examining the thyroid gland. It uses high-frequency sound waves that are emitted and received by a transducer (a handheld instrument) and penetrate the body. By electronic conversion, the sound waves are arranged into the picture image seen on a screen. It allows the presence of thyroid nodules to be determined and is helpful in the diagnosis of autoimmune diseases of the thyroid gland.

Thyroxine (T4) and triiodothyronine (T3) Hormones secreted by the thyroid gland. They are essential for the function and metabolism of every cell in the body.

Diagnosis of Thyrotoxicosis

Thyrotropin Measurements

Measurement of serum thyrotropin (TSH) by immunometric assay is probably the single most useful test for confirming the presence of thyrotoxicosis. The assays of the past generation are very sensitive (detection limit 0.001 mU/L) and can measure TSH concentrations well below the normal range. Because pituitary TSH secretion is tightly downregulated by thyroid hormone level, TSH is undetectable in most cases of thyrotoxicosis. The only remarkable exception is TSH-secreting adenomas, in which high or inappropriately normal TSH levels are found in spite of overt thyrotoxicosis. A subclinical thyrotoxic status can be found when TSH levels are detectable but low (<0.4 mU/L). Low or undetectable TSH levels can also be observed in a number of conditions not associated with thyrotoxicosis (**Table 1**).Very rarely, the presence in the serum of anti-mouse immunoglobulin antibodies may interfere with the TSH assay, causing falsely elevated TSH levels (Braverman, 2000; Ross *et al.*, 2016).

Thyroid Hormone Measurements

Low serum TSH concentrations alone are not sufficient to obtain a quantitative measure of the severity of thyrotoxicosis. The estimate measurement of circulating thyroid hormone levels is mandatory in all patients being evaluated for the disorder. Only the very small amount of nonprotein-bound or free thyroxine (FT4) and free triiodothyronine (FT3) in the blood can enter the cell and interact with its specific receptor. Estimation of total T4 (tT4) and total T3 (tT3) can be easily measured in blood, but because of the large variations of the binding protein concentrations in healthy individuals, this might not parallel the free thyroid hormone concentrations. This makes the estimate value of tT4 and tT3 measurements somewhat less useful in the evaluation of thyrotoxicosis. Free thyroid hormone estimate level measurements, although not completely exempt from flaws, are more satisfactory. In most iodine-sufficient countries, a single FT4 estimate measurement is sufficient to confirm or reject the suspicion of thyrotoxicosis. In contrast, in iodine-deficient countries, a significant proportion of hyperthyroid patients (up to 12%) may have normal estimate FT4 levels with elevated FT3 levels (T3toxicosis). Conversely, FT4 estimate can be falsely elevated in conditions causing reduced peripheral conversion of T4 to T3 such as amiodarone or high-dose propranolol treatment. We prefer to assess both FT4 andFT3 levels together with TSH to obtain a complete baseline panel of the thyroid function status in every patient where the diagnosis of thyrotoxicosis is suspected. A condition characterized by low or undetectable TSH level and normal free thyroid hormone levels, detected occasionally at routine thyroid function testing or in patients complaining of mild thyrotoxic symptoms, is termed "subclinical thyrotoxicosis" (Bartalena *et al.* 1996, Ross *et al.* 2016).

Differential Diagnosis of Thyrotoxicosis: Laboratory and Instrumental Investigations

History and physical examination are usually sufficient to identify the cause of thyrotoxicosis. However, in some cases, a careful differential diagnosis is needed to establish an etiological diagnosis. This is necessary to plan the correct treatment. For many years, radioiodine uptake (RAIU) has representing a mainstay of the differential diagnoses of thyrotoxicosis. RAIU performed by administering a minimal (tracer) dose of radioactive iodine and then measuring the percentage of administered radioactivity accumulated in the thyroid. Thyroid 99m-pertechnetate scintigraphy is another in vivo imaging technique that gives informations on the etiology of the thyrotoxicosis and in most cases it can replace RAIU reducing the radiation hazard. Actually 99mTc scintigraphy is more environmentally appropriate. Thyroid 99m-pertechnetate scintigraphy represents an indirect method of estimating the thyroidal intracellular mechanisms for iodine trapping. Whenever excessive active formation of thyroid hormone takes place in the thyroid gland, a brighter scan of the thyroid gland is obtained. Therefore, a bright 99mTc scintigraphy identifies true hyperthyroidism (e.g., with thyroid hyperfunction). In contrast, thyrotoxicosis with a feeble or absent scan of the thyroid gland indicates either thyroidal destruction, with release of preformed hormone, or an extrathyroidal source of thyroid hormone. In thyroid destruction, the damaged follicular cell loses its capability of iodine trapping (Mariotti *et al.*, 1982). Conversely, when exogenous hormones are administered in excess, the suppression of the pituitary secretion of TSH causes a block of the trapping capacity of follicular cells. (De Leo *et al.*, 2016; Bartalena *et al.*, 2016).

Graves' Disease

Anti-TSH Receptor Antibodies

A mainstay in the diagnosis of Graves' disease resides in serum detection of TSH receptor antibodies(TRABs). TRABs can be measured by different methods. TRABs were originally detected with in vivo bioassays, but this method has been replaced by in vitro systems. In the clinical practice, the detection of TRABs has, nowadays, become a routine test in presence of a thyrotoxicosis of unknown origin. The most commonly used assay is based on the displacement of radiolabeled TSH from its receptor by the patients' sera. Antibodies detected with this method have been termed "TSH binding-inhibiting immunoglobulins" (TBIIs). This test does not provide any information on the biological activity of the detected antibodies and, therefore, cannot distinguish between antibodies with stimulating activity and those with blocking activity that can also be detected in thyroid autoimmune disorders. The stimulating activity of TRAB scan be tested by employing cellular systems carrying a functional TSH receptor (e.g., Chinese hamster ovary cells transfected with cloned human TSH receptor) and detecting the release of cyclic AMP (cAMP)in the culture medium on challenge with serum or purified immunoglobulins (Chiovato *et al.*, 1994). In a modification of the assay, antibodies with blocking activity can be detected as well. Antibodies stimulating the thyroid activity are the cause of hyperthyroidism in Graves' disease (Burch, 1993). The assay is quite expensive and requires cell culture capabilities, making it available only to research centers. For clinical purposes, the TBII assay is most frequently used. By past-generation assays, positive TBII tests are found in 75%–95% of patients, with a high specificity (99%). Therefore, the TBII test represents an excellent tool in the diagnosis of Graves' disease. In spite of its efficiency, a TBII test is needed only in the minority of cases where the clinical picture is unclear, for example, in the differential diagnosis of hyperemesis gravidarum, in the nodular variants of Graves' disease that must be differentiated from toxic nodular goiter, and in patients with exophthalmos without thyrotoxicosis (euthyroid Graves' disease) (Ross *et al.* 2016). Therefore, the TBII test should be considered a second-line test in the diagnosis of Graves' disease. The finding of TBIIs after long-term treatment with antithyroid drugs may be useful to identify patients prone to recurrence of hyperthyroidism. Recently, an in vitro antibodies stimulating the thyroid activity bioassay based on a Chinese hamster ovary cell-line that express chimeric TSHr has been developed by Kahaly and coworkers (Li *et al.*, 2013). The bioassay

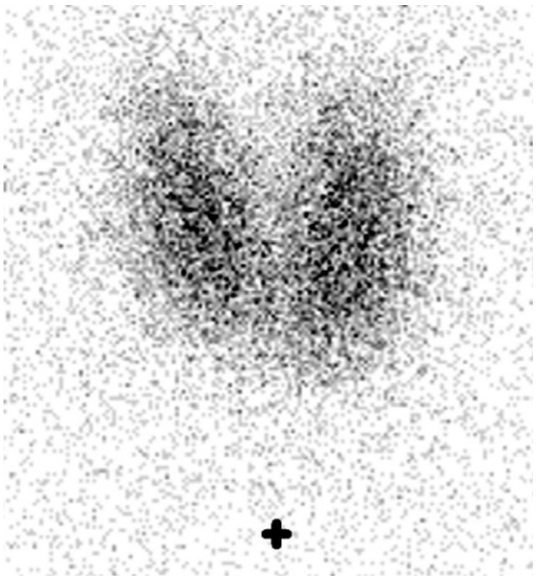

Fig. 1 Thyroid scanning (performed with radioiodine) in Graves' disease. It should be underlined that both radioiodine and 99m-pertechnetate can be taken up by the thyroid cell, but the only radioiodine can be organificated, scan images of thyroid nodules can be different.

detects both antibodies with stimulating activity and those with blocking activity and measures the net activity of a mixture of both types of antibodies. The antibodies stimulating the thyroid activity bioassay is approximately 20-fold more sensitive than commercially available TBII assay.

Antithyroid Peroxidase and Antithyroglobulin Antibodies

Antithyroid peroxidase (AbTPO) antibodies can be found by commercial radioimmunoassays in up to 90% of patients with untreated Graves' disease, whereas antithyroglobulin (AbTG) antibodies are less frequently positive (in about 50%–80% of cases). However, both antibodies are also present in other forms of thyroid autoimmune disorders, some of which may cause thyrotoxicosis, such as postpartum thyroiditis and silent thyroiditis. A relatively high percentage (up to 25%) of positive tests is also found in normal individuals, especially women. Thus, anti-TPO and anti-TG tests do not establish the diagnosis of Graves' disease as the cause of thyrotoxicosis but may be useful as complementary tests in confirming the presence of thyroid autoimmunity (Mariotti *et al.* 1990).

Thyroid Scan and RAIU

99m-pertechnetate is a radioactive tracer with 4–6 h of half-life, that can be administered i.v. and electively trapped by the thyroid gland and therefore used to obtain a true thyroid scan. Thyroid scintigraphy based on 99m-pertechnetate administration is an easy and safe exam, that is helpful in identifying the etiology of the hyperthyroidism In particular cases a RAIU can be still performed. A high value of 24th hour RAIU is always found as a distinctive feature in untreated hyperthyroid Graves' disease patients. In some cases, the 3rd- or 6th-hour value can be even higher than the 24th-hour value, as an expression of an extremely high iodine turnover. The test is useful for ruling out transient thyrotoxicosis due to hashitoxicosis or painless or subacute thyroiditis, factitious thyrotoxicosis, and type II amiodarone-induced thyrotoxicosis. Thyroid scanning in Graves' disease is useful when coexisting nodules are detected by palpation and their functional status needs to be evaluated. Thyroid imaging can be performed with radioiodine (131-I or 123-I) at the time of RAIU or by using 99m-pertechnetate (**Fig. 1**). 131-I has a higher half-life (8 days) if compared with 123-I (12 hours), but it is cheaper than 123-I. Due to its shorter half-life, the use of 123-I is indicated in young people (Martino *et al.*, 1988; Hegedus, 2004; Smith and Hegedüs, 2016; Siegel, 1998).

Thyroid Ultrasound

The thyroid gland in Graves' disease hyperthyroidism has a typical ultrasound pattern. Because of both the reduction in the colloid content and the lymphocytic infiltrate, the gland becomes diffusely hypoechoic. A similar pattern is also observed in goitrous autoimmune thyroiditis. Therefore, thyroid ultrasound can be useful for confirming the suspicion of thyroid autoimmunity during the evaluation of thyrotoxicosis. Moreover, thyroid ultrasound scanning allows an accurate measurement of the goiter size. This information is important in choosing the most appropriate treatment. Finally, thyroid ultrasound accurately distinguishes true thyroid nodules from the lobulations that can be felt occasionally at palpation in Graves' disease glands. Therefore, the

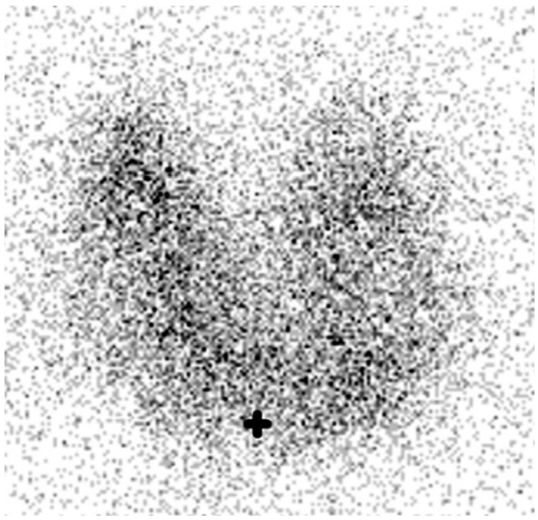

Fig. 2 Thyroid scanning (performed with 99m-pertechnetate) in toxic multinodular goiter. Thyroid ultrasound scan is also useful in measuring the size of the goiter. Moreover, relative to radionuclide scanning images, it is helpful in identifying cold nodules. Fine needle biopsy should be performed in any palpable dominant nodule that is cold at scan.

information provided by thyroid ultrasound is quite useful in the initial evaluation of Graves' disease patients, although it is not strictly needed from a diagnostic standpoint (Marcocci *et al.* 1991, Smith and Hegedüs 2016).

The measurement of blood flow to the thyroid gland by color flow Doppler ultrasound has also been used experimentally in Graves' disease patients. In untreated Graves' disease, the color Doppler pattern is characterized by markedly increased signals with a patchy distribution. In the setting of a hypoechoic pattern at ultrasound, the detection of an increased blood flow allows the distinction from Hashimoto's thyroiditis. Therefore, color Doppler studies of the thyroid gland can be useful, as is 99mTc scan, indistinguishing Graves' disease from other forms of thyrotoxicosis such as amiodarone-induced destructive thyrotoxicosis, subacute thyroiditis, and painless thyroiditis (in which the blood flow is reduced or absent) (Ross *et al.*, 2016).

Toxic Adenoma

The presence of a toxic adenoma must always be suspected in a thyrotoxic patient with a single thyroid nodule revealed at neck palpation. In confirming the diagnosis of thyrotoxicosis, it is important to measure both FT4 and FT3 levels because T3 toxicosis is distinctly frequent in toxic adenomas. At 99 m'technetium or radioiodine thyroid scanning, the nodule will appear "warm" when only partial autonomy is present, with the extranodular thyroid tissue clearly visible. In this case, parallel thyroid function tests will show a low but detectable TSH and thyroid hormone levels that are normal or at the upper limit of the normal range. When TSH is completely suppressed (e.g., complete autonomy, overt thyrotoxicosis), the scan will show only the autonomous nodule with complete suppression of the extranodular tissue. Ultrasound scanning of the neck provides no direct diagnostic information on the functional property of the nodule, but it is useful in detecting coexisting nodules (which can eventually be cold at scan) and accurately defines the size of the nodule. Preliminary reports have shown a distinctive color Doppler pattern in autonomously functioning thyroid nodules, characterized by an increased blood flow in the nodular tissue, in good correlation with radionuclide scans. This technique is not able to distinguish benign nodules from malignant ones; therefore, it is of limited value. Fine needle aspiration biopsy is not useful in the evaluation of a thyroid hot nodule and provides inconclusive findings that often show undetermined follicular neoplasm. The risk of malignancy in hot nodules is extremely low, although they are occasionally reported. Therefore, in the presence of a low TSH, fine needle aspiration is needed only when coexisting nodules detected by palpation or ultrasound are cold at radionuclide scanning. Further imaging, such as neck X rays, barium swallow, and computed tomography scans, may be needed in selected patients with large nodules to evaluate the presence of significant tracheal and/or esophageal compression. It is important to remember that computer tomography scan, when done with this purpose, should always be performed without the administration of iodinated contrast media because these may worsen thyrotoxicosis or precipitate it in partially autonomous nodules (Siegel, 1998; Ross *et al.*, 2016).

Toxic Multinodular Goiter

The same alterations of thyroid function tests described in toxic adenomas can be observed in toxic multinodular goiter. Physical findings and history are often sufficient to suspect the presence of a toxic multinodular goiter. Thyroid radionuclide scanning is

Table 2 Laboratory investigations in the differential diagnosis of the syndrome of inappropriate Secretion of TSH

Test	*TSH-secreting adenomas*	*Resistance to thyroid hormone*	*Comment*
Peripheral markers of thyroid hormone action	High	Normal to high	Non specific
Alpha-subunit/TSH molar ration	>1	1	High during menopause
TSH after T3 suppression test	Unchanged or slightly reduced	Frankly reduced or suppressed	Hazardous in elderly and cardiac patients
TSH after TRH	Unchanged	Increased	
Thyroid hormones after 3 months of somatostatin analogs treatment	Reduced	Unchanged	
Pituitary imaging	Positive	Negative	Confirmatory

quite useful for identifying and mapping autonomous nodules and cold nodules that are often coexistent (**Fig. 2**). Scanning is also useful as an adjunct to TRAB measurement in distinguishing true toxic multinodular goiter from Graves' disease hyperthyroidism over imposed on a preexisting nontoxic multinodular goiter. RAIU is always elevated, unless iodine overload is present, but is not always necessary to establish the diagnosis. Thyroid 99m-pertechnetate scan can show an irregular distribution of the tracer with one or more "warm" nodules with suppression of the extranodular thyroid tissue (Siegel 1998, Tonacchera *et al.* 1998).

TSH-Secreting Adenomas

Patients with TSH-secreting adenomas present a detectable TSH in the presence of clearly elevated circulating thyroid hormone levels (inappropriate secretion of TSH). · The first step in the evaluation of inappropriate secretion of TSH is making sure that interferences in the measurement of TSH (by heterophilic antibodies) or thyroid hormone levels (by thyroid hormone antibodies) are not the cause of the laboratory findings. Once these interferences are ruled out, further investigations are required to differentiate patients with TSH-secreting pituitary adenomas from those with resistance to thyroid hormone. TSH-secreting adenomas abnormally secrete the α-subunit of TSH in molar excess with respect to TSH. A serum α-subunit/TSH ratio greater than one is observed in approximately 90% of patients with TSH secreting adenomas. High ratios can also be observed in postmenopausal women and even in normal individuals, making this test alone unable to establish the diagnosis (Faglia *et al.* 1987, Ferraz 2017). Growth hormone (GH), insulin-like growth factor-1 (IGF-1), and prolactin serum measurements are useful because approximately 30% of TSH-secreting adenomas cosecrete these hormones. Dynamic tests may be useful for demonstrating the unresponsiveness of TSH in patients with TSH secreting adenomas. In most TSH-secreting tumors (92%), the TSH level fails to increase in response to a standard TRH stimulation test, whereas a normal or increased response is observed in resistance to thyroid hormone. It can be useful to investigate the response of pituitary TSH to exogenous T3. T3 is administered orally, and the dose is increased every 3 days (up to 200 μg daily). Before every increase, basal and TRH-stimulated TSH levels are measured together with peripheral markers of thyroid hormone action. Only partial or no suppression of TSH secretion is observed in TSH-secreting adenomas, whereas complete suppression is observed in resistance to thyroid hormone. The test is contraindicated in elderly patients and in patients with arrhythmias and/or coronary artery disease. Available tests in the differential diagnosis of the syndrome of inappropriate secretion of TSH are described in **Table 2** (McDermott and Ridgway 1998).

Pituitary imaging is very important in confirming the diagnosis. Fully 90% of TSH-secreting adenomas are larger than 1 cm at diagnosis and, therefore, are easily detected at pituitary magnetic resonance imaging (MRI) scanning. As a complement, radiolabeled octreotide pituitary scintigraphy can be used and may be particularly useful for detecting small tumors (Tjörnstrand and Nyström, 2017).

Human Chorionic Gonadotropin-Dependent Thyrotoxicosis

The diagnosis of thyrotoxicosis during hyperemesis gravidarum can be particularly difficult. Because of weight loss and malnutrition, FT3 levels may be disproportionately low or even normal in comparison with FT4 levels due to a reduced peripheral conversion of T4 to T3. The TSH level is often low during early normal pregnancy, but it is seldom undetectable as it is in true thyrotoxicosis. The only distinctive laboratory feature is an inappropriately high human chorionic gonadotropin (hCG) level, but a large overlap with normal pregnancies exists. Therefore, the diagnosis of thyrotoxicosis in hyperemesis gravidarum relies mainly on the clinical picture and on appropriate exclusion of other more common forms of hyperthyroidism by specific testing. It is important to remember that RAIU, as well as any other in vivo radioisotopic procedure, is absolutely contraindicated during pregnancy. The presence of a trophoblastic tumor should be suspected when thyrotoxicosis is diagnosed in an amenorrheic woman, especially when a palpable abdominal mass is present. The diagnosis is readily confirmed by the finding of extremely high circulating hCG levels and a pelvic mass at ultrasonography. Given the extreme rarity of the disorder, no diagnostic guidelines are

available for familial gestational hyperthyroidism. The diagnosis can be suspected only on a history of recurrent pregnancy-associated hyperthyroidism and can be confirmed only by the demonstration of a mutation of the TSH receptor gene, available in very few research laboratories worldwide (Ross *et al.* 2016, Masiukiewicz and Burrow 1999).

Fetal and Neonatal Hyperthyroidism

Mothers with a past or current history of Graves' disease should be carefully monitored throughout pregnancy. The persistence of high TRAB levels in the maternal serum by the end of pregnancy, when the transplacental passage is maximal, is a predictor of hyperthyroidism in the neonate. Fetuses of mothers with Graves' disease who have been previously treated with radioiodine or surgery may be at higher risk because they lack the protective effect of antithyroid drugs administered to the mothers. The presence of a fetal heart rate >160 beats per minute, in the absence of other fetal abnormalities, is suggestive of fetal hyperthyroidism. It is very useful to test neonatal cord blood at the time of delivery for thyroid function tests and TRABs. When the mother has been treated with high-dose antithyroid drugs, the neonate should be retested 10 days after birth given that transplacental passage of methimazole or propylthiouracil may initially mask hyperthyroidism. A TRAB-negative neonatal hyperthyroidism, in the absence of a maternal history of Graves' disease, should direct diagnosis to the suspicion of nonautoimmune congenital hyperthyroidism. Nowadays, the diagnosis can be confirmed only by sequencing of the TSH receptor gene (Pearce, 2015; Zimmerman, 1999).

Iodine-Induced Thyrotoxicosis

Iodine urinary excretion in patients with thyrotoxicosis due to excessive iodine consumption is always high, and excessive iodine consumption should always be suspected when hyperthyroidism appears abruptly in patients with a history of nodular thyroid disease. A careful history often identifies the source of iodine, and all patients should be asked about recent exposure to any of the compounds listed in **Table 3**. With the exception of type II amiodarone-induced thyrotoxicosis, RAIU is usually low in thyrotoxic patients with heavy iodine contamination, but it is almost never $<1\%$, a feature that allows distinction from subacute and painless thyroiditis. Thyroid 99m-pertechnetate scintigraphy usually does not give image of the gland (Ross, 1998; Martino *et al.*, 1984).

Amiodarone-Induced Thyrotoxicosis

In the presence of amiodarone-induced thyrotoxicosis, further testing is required to distinguish between type I (nondestructive) and type II (destructive) forms given that treatments may be radically different. Because of the concomitant underlying presence of thyroid disease, such as Graves' disease or nodular thyroid disease, type I amiodarone-induced thyrotoxicosis differs somewhat from other forms of iodine-induced thyrotoxicosis. It usually can be diagnosed with appropriate tools. Accordingly, RAIU is usually low but by definition never $<1\%$. In contrast, in type II amiodarone-induced thyrotoxicosis, RAIU is always $<1\%$ and often no clear underlying thyroid disorder can be identified. In both cases, thyroid 99m-pertechnetate scintigraphy, generally, does not give image of the gland. High circulating interleukin-6 levels have been proposed as a useful marker of thyroid tissue destruction, and color flow Doppler ultrasound imaging shows a distinctive absence of vascularization in the gland (Martino *et al.*, 1984, 1988).

Subacute, Painless, and Postpartum Thyroiditis

Subacute, painless, and postpartum thyroiditis are classically characterized by a feeble 99mTc scan during the thyrotoxic phase. This test alone, in the presence of a suggestive clinical presentation, allows the diagnosis in nearly all cases. High-titer anti-TG and anti-TPO antibodies are usually found in postpartum and painless thyroiditis as a marker of prominent thyroid autoimmunity, whereas only weakly and transiently positive tests are occasionally found in subacute thyroiditis. A very high ($>$ 50 mm/h) erythrocyte sedimentation rate is an additional distinctive diagnostic feature in subacute thyroiditis. Other inflammation indexes may be high in subacute thyroiditis, and a mild leukocytosis is often observed. As in other thyroidal destructive processes, interleukin-6 levels are elevated in all three disorders and, therefore, have no differential values. Ultrasound findings are generally characterized by patchy areas of hypoechogenicity in subacute thyroiditis, whereas a more diffuse hypoechoic pattern, closely resembling Hashimoto's thyroiditis, is found in postpartum and painless thyroiditis. The color flow Doppler pattern shows reduced vascularity in all three disorders. Occasionally, and especially when patients are first seen during the recovery or hypothyroid phase, a more subtle picture can emerge from testing, with a low but not nil RAIU (as well as with thyroid 99m-pertechnetate tracer) and with only mild elevations of the erythrocyte sedimentation rate, making the differential diagnosis more difficult (Woolf 1980, Masiukiewicz and Burrow 1999).

Thyrotoxicosis of Extrathyroidal Origin

An extrathyroidal source of thyroid hormone should always be suspected when more frequent causes of low RAIU thyrotoxicosis have been ruled out. When thyrotoxicosis factitia is suspected, a serum thyroglobulin measurement can be extremely useful in confirming the diagnosis because this disorder represents the only condition (TgAb in which thyrotoxicosis is associated with an undetectable thyroglobulin level. Indeed, the presence of TgAb may cause falsely low thyroglobulin levels. Given the high prevalence of thyroid nodules in the general population, especially in iodine deficient areas, it is also useful to perform ultrasound scanning of the neck because, in the presence of thyroid nodules, thyroglobulin may be elevated in spite of the assumption of exogenous thyroid hormone (Ross *et al.* 2016).

The suspicion of struma ovarii can be confirmed at the time of RAIU by simply scanning the pelvic area with the probe. The presence of functional thyroid tissue is demonstrated by the presence of significantly increased uptake of iodine in the ovarian region. Further imaging (computed tomography or ultrasound scan)will confirm the presence of an ovarian mass. When the source of thyroid hormone is metastatic thyroid follicular cancer, the presence of the latter is usually evident from the history. Because all patients with differentiated thyroid cancer after thyroidectomy take L-T4 in TSH-suppressive doses, thyroid function tests should be repeated after tapering the medication to rule out iatrogenic thyrotoxicosis. Confirmation is obtained with whole body radioiodine scanning that will show multiple foci of uptake in several skeletal regions (Ross *et al.*, 2016).

Thyrotoxicosis; Systemic Manifestations☆

Claudio Marcocci, University of Pisa, Pisa, Italy
Filomena Cetani, University Hospital of Pisa, Pisa, Italy

Glossary

Arrhythmia Irregularity of the heartbeat.
Dyspnea A subjective difficulty in breathing, usually caused by heart or lung disease.
Goiter An enlargement of the thyroid gland.
Hormone A chemical compound synthesized in one organ and carried in the blood to another organ.
Hyperphagia Condition of overeating.
Polydipsia Excessive and prolonged thirst.
Polyuria Excessive excretion of urine.
Tachycardia Rapid beating of the heart, with a rate of >100 beats per minute.
Vitiligo The appearance of nonpigmented white patches bordered by hyperpigmented areas on otherwise normal skin; the skin lesions are of variable size and often symmetrical.

Introduction

The clinical features of thyrotoxicosis depend on the severity and duration of the disease, the age of the patient, the presence or absence of extrathyroidal manifestations, and the specific disorder producing the thyrotoxicosis. Older patients tend to show fewer findings, and the rare patient with "apathetic" hyperthyroidism will lack nearly all of the usual clinical manifestations of thyrotoxicosis.

Peripheral Manifestations

Nearly all organ systems in the body are affected by thyroid hormone excess (Trzepacz *et al.*, 1989). The high levels of circulating thyroid hormones are responsible for most of the systemic effects observed in these patients (**Tables 1** and **2**).

Skin and Appendages

Cutaneous manifestations are nearly always present when hypermetabolism is significant (Jabbour, 2003). The patient feels hot and prefers a cold environment. Active sweating occurs under circumstances that would provoke no response in normal persons. The hand of the thyrotoxic person is erythematous, hot, and moist in a state of hot hyperhidrosis. Occasionally, diffuse pruritus or urticaria occurs. Pigmentation may be increased and is often diffuse, or localized in areas such as the knuckles, and skin creases. Vitiligo of variable extent may also occur (Jabbour, 2003).

The hair is fine and friable, and hair loss can be excessive. Alopecia areata and loss of axillary, pubic, body, and eyebrow hair have been noted since the initial description by von Basedow but are uncommon.

Localizing nonpitting edema occurs along the shins (so-called pretibial myxedema); it can also occur elsewhere, generally on extensor surfaces (**Fig. 1**). The lesion reflects the deposition of increased amounts of glycosaminoglycans in the subcutaneous connective tissue (Herskovitz *et al.*, 2017).

Thyroid acropachy is the rarest manifestation of Graves' disease (**Fig. 2**). Nearly all reported patients have had localized myxedema as well as hyperthyroidism and ophthalmopathy.

The nails become shiny and may be soft and friable. In many patients, the nails are separated prematurely from the nail beds (onycholysis). Onycholysis is not specific to thyrotoxicosis, but when it occurs in this setting, it usually begins under the distal central portion of the fourth fingernail.

Eyes

Retraction of the upper eyelid, evident as the presence of a rim of sclera between the lid and the limbus, is frequent in all forms of thyrotoxicosis and is responsible for the bright-eyed "stare" or "fish eyes" of the patient with thyrotoxicosis (**Fig. 3**). Lid lag is caused by the

☆*Change History*: March 2018. C Marcocci and F Cetani updated section "Reproductive System."

Table 1 Systemic effects of thyrotoxicosis

System	*Effects*
General	Weight loss, fatigue, heat intolerance, insomnia, nervousness, tremulousness
Skin	Fine, warm, and moist; hyperpigmentation; hyperhidrosis; onycholysis; fine and friable hair; urticaria
Eye	Exophthalmos, lid edema, lid lag, globe lag, chemosis, ophthalmoplegia, optic nerve involvement
Cardiovascular	Tachycardia, overactive heart, widened pulse pressure, bounding pulse; occasionally cardiomegaly, signs of congestive heart failure, paroxysmal tachycardia, atrial fibrillation
Gastrointestinal	Hyperphagia, increased thirst, increased frequency of stools or diarrhea, elevated liver function tests, hepatomegaly
Muscular	Tremulousness, weakness of proximal muscles, quickened and hypermetric reflexes, myopathy, muscle atrophy, periodic paralysis
Nervous	Anxiety, inability to concentrate, irritability, restlessness, lability, depression, psychiatric reactions
Respiratory	Dyspnea
Renal	Mild polyuria, polydipsia
Skeletal	Osteopenia or osteoporosis
Hematopoietic	Anemia (usually normochromic or normocytic), lymphocytosis, splenomegaly, lymphadenopathy, enlarged thymus
Endocrine	Irregular menses or amenorrhea, gynecomastia, decreased fertility
Metabolic	Elevated serum calcium, decreased serum magnesium, increased bone alkaline phosphatase, hypercalciuria

Table 2 Clinical findings in patients with Graves' hyperthyroidism and controls (percentages)

	Hyperthyroid	*Controls*
Cases	880	880
Symptoms		
Palpitations	65	13
Increased perspiration	45	7
Heat intolerance	55	8
Weight loss	61	13
Weight gain	12	21
Increased appetite	42	5
Decreased appetite	11	6
Increased number of bowel movements	22	2
Increased appetite with weight loss	24	0
Tiredness	69	41
Irritability	45	18
Nervousness	69	15
Signs		
Fine finger tremor	69	6
Pulse rate $\geq$ 90 beats/min	19	78
Atrial fibrillation[a]	3	–
Thyroid size ($\times$ normal)	1.9 $\pm$ 0.6	1.3 $\pm$ 0.4

[a]The presence of atrial fibrillation was not assessed in controls.

fact that the upper lid lags behind the globe when the patient is asked to gaze downward; globe lag occurs when the globe lags behind the upper lid when the patient gazes slowly upward. These ocular manifestations appear to be the result of increased adrenergic activity. It is important to differentiate these ocular manifestations from those of infiltrative ophthalmopathy characteristic of Graves' disease.

Cardiovascular System

The vascular manifestations of thyrotoxicosis constitute some of the most profound and characteristic symptoms and signs of the disorder (Klein and Danzi, 2007). Tissue blood flow is increased in response to accelerated metabolism and increased oxygen consumption. Hemodynamic changes in thyrotoxic patients are characterized by an elevated cardiac output and a decreased peripheral vascular resistance. The mechanism responsible for the reduced vascular resistance is unclear. Thyroid hormone itself may be involved directly through its action on smooth muscles of blood vessels. Moreover, the finding in thyrotoxic patients of elevated levels of plasma adrenomedullin and proadrenomedullin-N-terminal 20-peptide, which have a potent vasodilatory activity, raises the possibility that these substances might also be involved in the decrease of vascular resistance in these patients.

Tachycardia is nearly always present, even at rest. The heart rate is also elevated during sleep; this helps to distinguish tachycardia of thyrotoxic origin from that of psychogenic origin. The pulse pressure is widened as a result of both an increase in cardiac output and a decrease in peripheral vascular resistance. Other common cardiovascular symptoms include exercise

Fig. 1 Dermopathy of Graves' disease. Marked thickening of the skin is noted, usually over the pretibial area. Thickening will occasionally extend downward over the ankle and the dorsal aspect of the foot but almost never above the knee.

Fig. 2 Thyroid acropachy. Photograph of the hands in a patient with acropachy shows clubbing and swelling of fingertips.

intolerance and dyspnea on exertion. The latter is usually present with sustained activity but may also arise with an activity as limited as climbing a flight of stairs. Because of the diffuse and forceful nature of the apex beat, the heart may appear to be enlarged on physical examination, but echocardiography is usually normal.

In aged thyrotoxic patients, the cardiovascular manifestations may be limited to resting tachycardia. Other classic thyrotoxic symptoms may be absent, possibly due to the relative paucity of adrenergic activity.

Thyrotoxic patients may have chest pain similar to angina pectoris in nearly all respects, probably caused by either relative myocardial ischemia or coronary artery spasm. However, in older patients, the increased myocardial oxygen demand due to thyrotoxicosis may unmask coronary artery disease. The plasma level of homocysteine, an independent risk factor for cardiovascular disease, in thyrotoxic patients did not differ significantly from that in controls.

Heart sounds are loud and ringing, and a systolic murmur—or even a late diastolic or presystolic murmur—may be present at apex. Auscultation may reveal a systolic ejection murmur and a gallop rhythm caused by rapid flow of blood through the aortic outflow tract. Systolic murmurs may arise from valve prolapse, left ventricular dilatation, or dysfunction of the mitral valve apparatus (Anakwue *et al.*, 2015). Mild edema sometimes occurs in the absence of heart failure. Heart rarely occurs in thyrotoxic patients unless an underlying cardiac disease is also present.

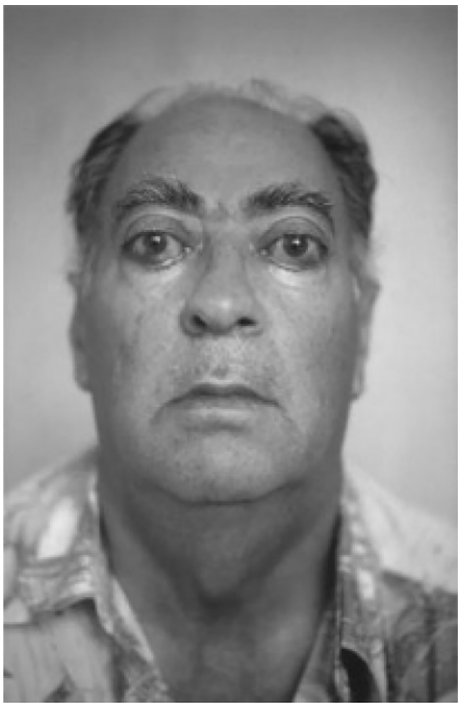

Fig. 3 Clinical presentation of Graves' ophthalmopathy. Photograph shows proptosis, marked conjunctival injection and chemosis, and retraction of lower eyelids.

Cardiac arrhythmias are common with thyrotoxicosis and are almost invariably supraventricular. Approximately 10% of patients with thyrotoxicosis have atrial fibrillation, and a similar percentage of patients with otherwise unexplained atrial fibrillation are thyrotoxic. This manifestation may be the presenting symptom of thyrotoxicosis, particularly in the elderly, and the risk of developing persistent atrial fibrillation is approximately three times that in normal individuals. Paroxysmal supraventricular tachycardia may be demonstrable or may be suggested by the history. Ventricular premature contractions are rare. Angina pectoris and myocardial infarction may occur rarely in the absence of coronary artery disease.

Nonspecific electrocardiographic changes may occur in thyrotoxicosis. A shortening of the PR interval is common, secondary to the increased rate of conduction through the atrioventricular node.

Thyrotoxicosis alone may determine heart failure in both old patients and (much less often) young patients (Burch and Wartofsky, 1993). In large clinical studies, thyrotoxic patients with heart failure were generally old and, therefore, at risk for underlying heart disease and had chronic thyrotoxicosis. Elderly patients with rhythm disturbances, including atrial fibrillation, are at the greatest risk for heart failure (Chiovato *et al.*, 1997; Boelaert *et al.*, 2010). In the absence of atrial fibrillation, heart failure is rare. In the absence of underlying heart disease or in young patients, the heart failure is thought to be "high output." High-output heart failure might not be a true heart failure; instead, it might be a circulatory congestion caused by fluid retention. In thyrotoxicosis, cardiac output is potentially near to maximal at rest and cannot increase in response to exercise, stress, surgery, or pregnancy. As a consequence, atrial filling pressures rise, leading to pulmonary and peripheral edema. This situation may be worse if atrial fibrillation is present. Left ventricular function is impaired because the persistent tachyarrhythmia alters this function. Sustained tachycardia causes abnormal ventricular systolic and diastolic function that resolves when arrhythmia is treated. β-Adrenergic receptor blockade-mediated slowing of the heart rate can rapidly reverse even severe degrees of left ventricular dysfunction in thyrotoxic patients.

Gastrointestinal System

The classical gastrointestinal manifestations of thyrotoxicosis are rapid intestinal transit, increased frequency of semiformed stools, and weight loss from increased caloric requirement or malabsorption (Kyriacou *et al.*, 2015). These changes are not necessarily frequent. An increase in appetite, both during and between meals, is a common symptom but is usually not seen in patients with mild disease. In severe disease, the increased intake of food is usually inadequate to meet the increased caloric requirements, and weight loss occurs. Anorexia, rather than hyperphagia, sometimes accompanies severe thyrotoxicosis. It occurs in approximately one-third of elderly patients and contributes to the picture of "apathetic" thyrotoxicosis.

Frequent bowel movements are significantly more common in thyrotoxic patients than in normal controls. Diarrhea is rare. When constipation is present before the development of thyrotoxicosis, bowel function may become normal. More often, stools are less well formed and the frequency of bowel movements is increased. Gastric emptying and intestinal motility are increased,

and these changes appear to be responsible for slight malabsorption of fat. Gluten enteropathy and Graves' disease may coexist more frequently than can be accounted for by chance due to their common autoimmune origin.

Hepatic dysfunction occurs in thyrotoxicosis, particularly when the disease is severe; hypoproteinemia and increased serum alkaline phosphatase and transaminase levels may be present. In severe cases, hepatomegalia and jaundice may be found.

Nervous System

Hyperactivity, emotional lability, distractibility, and anxiety observed in thyrotoxicosis may reflect changes in the nervous system, but the pathogenetic mechanisms remain obscure (Trzepacz *et al.*, 1988). The reaction to all sorts of stimuli is distinctly excessive. Examination reveals a fine rhythmic tremor of the hands, tongue, or slightly closed eyelids. Emotional lability causes patients to lose their tempers easily and to have episodes of crying without any apparent reason. Crying may be evoked by merely questioning patients about the symptom. In rare cases, mental disturbance may be severe. Rarely, patients develop visual or auditory hallucinations or a frank psychosis. It is probable that thyrotoxicosis makes manifest an abnormality already present rather than inducing a psychosis de novo. Anxiety is characterized by restlessness, shortness of attention span, and a compulsion to be moving around despite a feeling of fatigue (Swee du *et al.*, 2015).

Fine hand tremor is a frequent finding and may sometimes mimic that of Parkinsonism, and a preexisting Parkinsonian tremor can be accentuated. Chorea seldom appears as a manifestation of thyrotoxicosis. The neurological manifestation of thyrotoxic crisis rarely includes coma and status epilepticus. Patients with a convulsive disorder may become more difficult to control with the usual medications, and seizures may appear in patients who never manifested such symptoms previously.

The electroencephalogram of most thyrotoxic patients reveals an increased fast wave activity. The basal metabolic rate tends to correlate with the frequency of brain waves, but the correlation is usually poor at the extremes of thyroid abnormality.

Muscle

Muscle weakness and fatigue are frequent (Kung, 2007). In most instances, they are not accompanied by objective evidence of local disease of muscle except for the generalized wasting associated with weight loss. Weakness is often most prominent in the proximal muscles of the limbs, causing difficulties in climbing stairs or in maintaining the leg in an extended position. In severe untreated cases, muscle wasting occasionally occurs as a predominant symptom (thyrotoxic myopathy). In extreme forms, the patient may be unable to rise from a sitting or lying position and may be virtually unable to walk.

Muscle manifestations affect men with thyrotoxicosis more commonly than they do women and may overshadow other manifestations of the syndrome. In severe forms, the myopathy involves mainly distal muscles of extremities and the muscles of the trunk and face. The involvement of ocular muscles may mimic myasthenia gravis. Graves' disease occurs in approximately 3%–5% of patients with myasthenia gravis, and approximately 1% of patients with Graves' disease develop myasthenia gravis (Kung, 2007). Myasthenia gravis associated with Graves' disease has a mild expression characterized by preferential involvement of the eye muscles. Another myopathy sometimes observed in association with thyrotoxicosis is hypokalemic periodic paralysis. It is characterized by sporadic attacks (which may last from minutes to many hours), most commonly involving flaccidity and paralysis of legs, arms, and/or trunk, although any muscle can be involved. Episodes can occur spontaneously, after carbohydrate ingestion, or after exercise. Hypokalemic periodic paralysis is most frequent in Asians.

Respiratory System

Dyspnea is present in the large majority of severe thyrotoxic patients, and several factors may contribute to this condition, including reduction of vital capacity, decreased pulmonary compliance, weakness of the respiratory muscles, and increase in respiratory dead space ventilation. In some cases, it is difficult to separate patients with pure respiratory muscle weakness from patients who have only decreased lung compliance. Manifestations of respiratory muscle dysfunction include rapid shallow respirations, respiratory dyskinesis, hypoventilation, respiratory acidosis, and easy fatigability. Most patients with overt thyrotoxicosis have diminished proximal muscle strength. Pulmonary function returns to normal when the eumetabolic state is restored (Siafakas *et al.*, 1992).

Renal System

Most of the renal effects in thyrotoxic patients produce no symptoms except mild polyuria. Renal plasma flow and glomerular filtration rate are increased in thyrotoxicosis, probably because of the increase in cardiac output and decrease in peripheral resistance (Iglesias *et al.*, 2017). Intrarenal vasodilation also occurs. The mean 24-h urine creatinine excretion is significantly lower in thyrotoxic patients than in normal individuals. The latter finding has been attributed to loss of muscle mass and occurs despite an increase in urea clearance. These changes are normalized when a normal metabolic state is restored.

Thyrotoxicosis is generally not associated with abnormalities in water metabolism. Serum electrolytes are usually normal. Some thyrotoxic patients have polydipsia, with 24-h urine volumes up to 3–4 L. Polyuria in these patients is due to increased thirst, as in primary polydipsia, and could be secondary to an increase of plasma angiotensin II concentration.

Skeletal System: Calcium and Phosphorus Metabolism

Thyrotoxicosis is associated with an increase of bone turnover and eventually bone loss, especially in postmenopausal women (Williams and Basset, 2018). Patients with a long-standing history of thyrotoxicosis may have overt osteoporosis and an increased risk of fractures (Cummings *et al.*, 1995). Bone turnover is increased, but the increase in bone resorption is relatively greater than that of bone formation, so the urinary excretion of calcium, phosphorus, and hydroxyproline is increased. As a consequence of this acceleration in bone resorption, hypercalcemia may occur in a significant proportion of patients with thyrotoxicosis. Total serum calcium may be slightly increased in up to 27% of these patients, and the ionized serum calcium level may be increased in up to 47%. The concentration of alkaline phosphatase and osteocalcin is also frequently increased. Parathyroid hormone and 1,25-dihydroxy-vitamin D3 levels tend to be low as a result of the increased calcium released from bone. Excretion of calcium in the feces is also increased in thyrotoxic patients. The secretions of the gastrointestinal tract are altered in thyrotoxicosis, and the transit time of calcium in the intestine is shortened.

Hematopoietic System

The red blood cells are usually normal, but the red blood cell mass is increased. The increase in erythropoiesis appears to be due both to a direct effect of thyroid hormones on the erythroid marrow and to an increased production of erythropoietin. A parallel increase in plasma volume also occurs; therefore, hematocrit value is normal.

The most common red blood cell morphological abnormality is microcytosis, which is found in at least 37% of patients. The cause of this change is unclear. Iron deficiency is occasionally reported in thyrotoxic states. Microcytosis usually resolves with the restoration of euthyroidism. Some patients with severe thyrotoxicosis may develop a normocytic anemia. Defective iron use has been shown to occur in thyrotoxic patients and may be responsible for the development of anemia. Approximately 3% of patients with Graves' disease have pernicious anemia, and a further 3% have antibodies to intrinsic factor but normal absorption of vitamin B12. Autoantibodies against gastric parietal cells are present in about one-third of patients with Graves' disease, and the requirements for vitamin B12 and folic acid appear to be increased.

The total white blood cell count is often low because of a decrease in the number of neutrophils. The absolute lymphocyte count is normal or increased, leading to a relative lymphocytosis. The numbers of monocytes and eosinophils may also be increased.

Blood platelets and the intrinsic clotting mechanism are normal. However, the concentration of factor VIII is often increased and returns to normal when thyrotoxicosis is treated. Furthermore, there is an enhanced sensitivity to coumarin anticoagulants because of an accelerated clearance of vitamin K-dependent clotting factors.

Endocrine System

Thyrotoxicosis affects the secretion of most pituitary hormones, in particular the secretion of growth hormone (GH), prolactin (PRL), adrenocorticotropin (ACTH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH).

Children with thyrotoxicosis grow more rapidly than do normal children. Growth acceleration in thyrotoxicosis suggests that GH secretion might be greater than normal. However, serum GH concentrations are lower in thyrotoxic patients than in normal individuals. This decrease is probably due to the increased metabolic clearance rate. Serum insulin-like growth factor-1 (IGF-1) concentration is higher in thyrotoxic patients and returns to normal values after restoration of the euthyroid state.

Thyrotoxicosis has several effects on adrenocortical function and adrenocortical hormone metabolism, with an increased clearance of the latter. The half-life of cortisol is shortened, but both the number of bursts of ACTH and the resulting burst of cortisol secretion are increased and maintain serum cortisol levels. The plasma concentration of corticosteroid-binding globulin is normal. The urinary excretion of the free cortisol and 17-hydroxycorticosteroids is normal or slightly increased, whereas the urinary excretion of 17-ketosteroids may be reduced. The rate of turnover of aldosterone is increased, but its plasma concentration is normal. Plasma renin activity is increased, and the sensitivity to angiotensin II is reduced.

β-Adrenergic receptor blockade ameliorates most of the cardiovascular manifestations of thyrotoxicosis. This suggests that catecholamines play a role in their genesis, but the secretion rate and plasma levels of epinephrine and norepinephrine are normal in thyrotoxic patients. Indeed, the apparent sympathetic hyperactivity appears to be the consequence of a direct effect of thyroid hormones on peripheral tissues.

Thyrotoxicosis during early life may cause delayed sexual maturation, although physical development is normal and skeletal growth may be accelerated.

Reproductive System

Thyrotoxicosis, after puberty, influences the reproductive function, especially in women. An increase in libido occurs in both genders. The intermenstrual interval may be prolonged or shortened, and menstrual flow initially diminishes and ultimately ceases. Fertility may be reduced. The incidence of miscarriage, premature delivery and pre-eclampsia may be increased by maternal thyrotoxicosis. High maternal thyroid hormone levels may lead to the suppression of fetal TSH, lower fetal weight and fetal death. In some women, menstrual cycles are predominantly anovulatory with oligomenorrhea; however, in most women, ovulation occurs. With treatment, menstrual cycles return to their regular pattern. Thyrotoxicosis in prepubertal girls may result in slightly delayed menarche. In premenopausal women with thyrotoxicosis, basal plasma concentrations of LH and FSH are normal but may display an enhanced responsiveness to LH-releasing hormone.

An increase in sex hormone-binding globulin is a prominent feature of thyrotoxicosis and is responsible for many of the alterations in steroid metabolism. Because of the increase in sex hormone-binding globulin, the metabolic clearance rates of testosterone and (to some extent) estradiol are decreased (Rosner, 1990; La Vignera *et al.*, 2017). Testosterone levels are elevated because of the increased concentration of sex hormone-binding globulin. Free testosterone levels tend to be normal. The metabolic clearance rate of estradiol is normal, suggesting that tissue metabolism of the hormone is increased. Conversion rates of androstenedione to testosterone, estrone, and estradiol, as well as conversion rates of testosterone to dihydrotestosterone, are increased. Extragonadal conversion of androgens to estrogens is increased, and this could be the mechanism responsible for gynecomastia observed in a consistent minority of thyrotoxic men. A reduction of sperm motility (astheno-zoospermia) has been reported in about 60% of adult thyrotoxic patients; it normalize after treatment with antithyroid drugs. Other seminal fluid alterations namely low sperm count and an increased number of spermatozoa with altered morphology has been found in about 42% and 40%, respectively. Premature ejaculation, erectile dysfunction, hypoactive sexual desire has also been reported. However, the major limitations of the studies performed so far is that semen parameters have been performed in patients from infertile couples in whom fertility of the partner has not always been studied.

Energy Metabolism: Protein, Carbohydrate, and Lipid Metabolism

One of the most prominent symptoms in the hyperthyroid patient is heat intolerance. The symptom reflects an increase in the basal metabolism of many substrates. The increase in metabolic activity results in increased consumption of adenosine triphosphate and oxygen. Despite the increased food intake, a state of chronic caloric inadequacy often ensues, depending on the degree of increased metabolism, and becomes more pronounced with age. In addition to losing fat stores, there is often a loss of muscle mass, making weakness a common complaint. Both synthesis and degradation of proteins are increased, with the latter increased to a greater extent than the former, so that there is a net decrease in tissue protein content.

The oral glucose tolerance test is often abnormal. The most common abnormality is a faster rise in plasma glucose after glucose ingestion, but some patients have a delayed peak plasma glucose or a peak value that is higher than that in normal individuals. These abnormalities may reflect changes in glucose absorption rather than metabolism given that many patients who have abnormal oral glucose tolerance have normal responses to intravenous glucose administration. Preexisting diabetes mellitus is aggravated by thyrotoxicosis, with one cause being increased degradation of insulin.

Both synthesis and clearance of cholesterol and triglycerides are increased, but the latter effect predominates, so that serum levels are generally low. Plasma phospholipid and low-density lipoprotein cholesterol concentrations fall, whereas high-density lipoprotein cholesterol levels increase. Finally, thyroid hormones may influence cholesterol metabolism by increasing its conversion to bile acid and its clearance through the membrane surface low-density lipoprotein receptors. Although fatty acid synthesis is increased in both adipose tissue and liver, degradation of most lipids appears to be stimulated out of proportion to synthesis; consequently, body lipid deposits become depleted and plasma concentrations of various lipid components fall.

Several studies have investigated the relationship between leptin level and thyroid status. With the exception of a couple of reports suggesting a relative hypoleptinemia, most clinical studies have found no effect of thyrotoxicosis on leptin levels.

Thyrotoxicosis; Treatment☆

Claudio Marcocci, University of Pisa, Pisa, Italy
Filomena Cetani, University Hospital of Pisa, Pisa, Italy

Introduction

The treatment of thyrotoxicosis is directed to reduce overproduction of thyroid hormones by inhibiting their synthesis or release or by ablating thyroid tissue with surgery or radioiodine. Amelioration of the impact of thyroid hormones on peripheral tissues is an additional objective of treatment. There are several means of accomplishing these goals, and their efficacy depends, to some extent, on the cause of thyroid hormone hypersecretion. Because of this, the pathogenesis of hyperthyroidism should be determined by means of history, physical examination, and selected laboratory tests before making a decision on the plan of therapy. The patient should participate in the choice of treatment and must be informed of the therapeutic alternatives. This article discusses the various therapeutic options and the treatment of the three most frequent causes of hyperthyroidism: toxic diffuse goiter (Graves' disease), toxic adenoma, and toxic multinodular goiter. In addition, it briefly discusses other rare etiologies of hyperthyroidism and exogenous thyrotoxicosis.

Medical Treatment

Antithyroid Drugs (Thionamides)

The main action of thionamides (e.g., methimazole, MMI; carbimazole, propylthiouracil, PTU) is to inhibit the organification of iodide and the coupling of iodotyrosines, thereby blocking the synthesis of thyroid hormones. Because carbimazole is almost completely converted to MMI in the body, the effects of these two drugs are comparable. PTU has the additional effect of inhibiting the conversion of thyroxine (T_4) to triiodothyronine (T_3) in peripheral tissues (He *et al.*, 2004). Despite this property of PTU, in most patients, MMI therapy results in a more rapid normalization of serum T_4 and T_3. This may be due to the greater intrinsic potency of MMI and to its longer duration of action. The main pharmacological features of antithyroid drugs are summarized in **Table 1**. The half-life in plasma of MMI is approximately 6 h, whereas that of PTU is approximately 1–2 h.

Both MMI and PTU are extremely effective in controlling hyperthyroidism; therefore, in most instances, the choice between the two drugs is largely a matter of personal preference and local availability. Because these compounds do not inhibit iodide transport or block the release of stored thyroid hormones, control of hyperthyroidism is not immediate and in most cases will not occur for 2–6 weeks.

MMI should be used in virtually every patient who chooses antithyroid drugs, except during the first trimester of pregnancy when PTU is preferred, in the treatment of thyroid storm, and in patients with minor reactions to MMI who refuse RAI therapy or surgery (De Groot *et al.*, 2012; Hegedüs *et al.*, 2011; Laurberg and Andersen, 2015).

The starting dose should be targeted to the degree of thyroid dysfunction, because a too low dose will not restore an euthyroid state in patients with severe disease and an high dose can cause iatrogenic hypothyroidism if used in patients with mild disease. Most physician would start treatment with a dose of 10 mg three times daily for MMI and 200 mg three times daily for PTU (Elbers *et al.*, 2011).

The latest guidelines of the American Thyroid Association recommend a more personalized approach, suggesting that the staring dose of MMI should chosen according to the severity of hyperthyroidism: 5–10 mg if free T_4 is 1–1.5 times the upper limit of normal; 10–20 mg if free T_4 is 1.5–2 times the upper limit of normal; and 30–40 mg if free is T_4 2–3 times the upper limit of normal (Ross *et al.*, 2016). These rough guidelines should be tailored to the individual patient, incorporating additional information on symptoms, gland size, and total T_3 levels where relevant. Further treatment can be continued according to two different strategies: (1) titration mode: the daily dose of MMI and PTU should progressively be reduced according to the levels of thyroid hormones and TSH and treatment maintained for 12–18 months; (2) block and replace mode: the starting daily dose of MMI and PTU is maintained for the entire treatment period, combined with L-thyroxine to maintain euthyroid levels. However, the latest guidelines of the American Thyroid Association indicate that this therapeutic approach is not generally recommended because of the higher rate of side effect compared with the titration mode (Ross *et al.*, 2016).

Serious side effects (**Table 2**) are not common with antithyroid drugs, being observed in approximately 3 of every 1000 patients. Patients should be informed of their side effects and the necessity of informing the physician promptly if they should

☆*Change History:* March 2018. C Marcocci and F Cetani updated sections Antithyroid drugs, B-adrenergic antagonist drugs, Choice of therapy Graves disease, Toxic adenoma and multinodulare goiter.

Table 1 Pharmacological features of thionamides

	Methimazole	*Propylthiouracil*
Serum half-life (hours)	4–6	1–2
Serum protein binding (percentage)	–	80–90
Metabolism of drug during illness		
Severe liver disease	Decreased	Normal
Severe kidney disease	Normal	Normal
Levels in breast milk	Higher	Low

Table 2 Side effects of thionamides

Major (<1%)
Rare
Agranulocytosis
Very rare
Severe vasculitis and Lupus-like syndrome
Cholestatic jaundice
Toxic hepatitis
Aplastic anemia
Thrombocytopenia
Minor (1–5%)
Common
Cutaneous manifestations (e.g., rash, pruritus, urticaria)
Transient granulocytopenia
Arthralgia
Less common
Fever
Gastrointestinal manifestations
Loss of taste sensation

develop pruritic rash, jaundice, acholic stools or dark urine, arthralgias, abdominal pain, nausea, fatigue, fever, or pharyngitis. Before starting the therapy and at each subsequent visit, the patient should be alerted to stop the medication immediately and call their physician if there are symptoms suggestive of agranulocytosis or hepatic injury (Kim *et al.*, 2001).

Agranulocytosis (granulocyte count <500 per cubic milliliter), the most feared problem, may be observed with both MMI and PTU, but a low dose of MMI is safer than a high dose of either drug. Agranulocytosis may develop suddenly and usually occurs during the first months of therapy. It typically presents with fever and evidence of infection. In addition to prompt discontinuation of the antithyroid drug, treatment of agranulocytosis involves the administration of broad-spectrum antibiotics and growth factors to stimulate recovery of bone marrow. Patients usually recover within 2–3 weeks, but a few deaths from this complication have been reported. Hepatitis, vasculitis, and lupus-like syndromes are rare complications but make the discontinuation of antithyroid drugs mandatory. Minor side effects are much more frequent, occurring in 1%–5% of patients. Among them, pruritus, rash, and (less commonly) urticaria are the most prominent manifestations. These side effects may resolve spontaneously despite continued therapy, or using concurrent antihistamine therapy but they generally call for substitution of one thionamide for the other, although cross-sensitivity to these drugs may occur **Table 2**.

According to the latest guidelines of the American Thyroid Association, prior to start antithyroid drugs, patients should have a baseline complete blood count, including white blood cell (WBC) count with differential, and a liver profile including bilirubin and transaminases (Ross *et al.*, 2016). There is insufficient information to recommend for or against routine monitoring of liver function tests or white blood cell counts in patients taking antithyroid drugs. Clinical judgment is required. Liver function and hepatocellular integrity should be assessed in patients taking MMI or PTU who experience pruritic rash, jaundice, light-colored stool or dark urine, joint pain, abdominal pain or bloating, anorexia, nausea, or fatigue.

β-Adrenergic Antagonist Drugs

These drugs are an integral part of the management of hyperthyroidism. Blockade of β-adrenergic receptors rapidly ameliorates some manifestations of thyrotoxicosis such as tremor, palpitation, and anxiety (Ventrella and Klein, 1994). β-Adrenergic antagonists do not affect thyroid hormone synthesis and release; therefore, they should not be used alone except for short periods before and/or after radioiodine therapy in selected patients preparing for thyroid surgery or in patients with self-limited forms of thyrotoxicosis (Tagami *et al.*, 2012). Propranolol, a nonselective beta1 and beta2-blocker, is frequently used to treat this condition.

It is highly lipid soluble, allowing it to become sufficiently concentrated in tissues to inhibit monodeiodinase activity and has a short half-life.

Since the introduction of propranolol, a number of new agents with a longer duration (e.g., atenolol, metoprolol, nadolol), or with greater cardioselectivity (e.g., atenolol, metoprolol, bisoprolol), have become available. Calcium channel blockers, such as verapamil or diltiazem can be used to reduce heart rate in patients who cannot tolerate beta blockers.

The usual contraindications of β-adrenergic antagonists, such as asthma, should be considered. Despite the initial concern, propranolol or other β-adrenergic antagonists are widely used in thyrotoxic heart disease in view of the notion that tachycardia and tachyarrhythmia are the most prominent factors involved in this condition.

Iodide and Iodine-Containing Agents

Inorganic iodide given in pharmacological doses (as Lugol's solution or as saturated solution of potassium iodide, SSKI) decreases its own transport into the thyroid, inhibits iodide organification (the Wolff–Chaikoff effect), and rapidly blocks the release of T_4 and T_3 from the gland. However, after a few days or weeks, its antithyroid action is lost and thyrotoxicosis recurs or may worsen. The usual dose of Lugol's solution is three to five drops three times daily and that of SSKI is one drop three times daily. Short-term iodide therapy is used to prepare patients for surgery, usually in combination with a thionamide drug. Iodide is also used in the management of severe thyrotoxicosis (thyroid storm) because of its ability to inhibit thyroid hormone release acutely.

Iopanoic acid and sodium ipodate, widely used in the past as oral cholecystographic agents, may be useful in the management of thyrotoxicosis (Tyer *et al.*, 2014). These compounds have a dual action: they produce a fall in the serum concentration of thyroid hormones (resulting from the block of thyroid hormone secretion due to the inorganic iodide released from the drug) and inhibit the peripheral conversion of T_4 to T_3. Some reports have confirmed the efficacy of these compounds as a primary therapy of hyperthyroidism. These agents may be particularly useful when a rapid decrease in T_3 levels is desired. Although an early escape from the therapeutic effect has been suggested, other studies have not found this to be the case for up to nearly 2 years of therapy.

Perchlorate

Perchlorate interferes with accumulation of iodide by the thyroid. In conjunction with thionamides, it has been used successfully in the treatment of amiodarone-induced hyperthyroidism. Gastric irritation and toxic reactions (aplastic anemia) limit the long-term use of perchlorate in the management of hyperthyroidism.

Glucocorticoids

Glucocorticoids in high doses inhibit the peripheral conversion of T_4 to T_3. In Graves' hyperthyroidism, glucocorticoids appear to decrease T_4 secretion by the thyroid, but the efficiency and duration of this effect are unknown. In severe hyperthyroidism, short-term glucocorticoid administration may be used as a general supportive treatment. The immunosuppressive effect of glucocorticoids in high doses is commonly exploited in the treatment of ophthalmopathy and dermopathy of Graves' disease but not in the management of uncomplicated Graves' hyperthyroidism (Marcocci and Marinò, 2012; Bartalena *et al.*, 2015, 2016).

Rituximab

Rituximab (RTX) is a human/murine chimeric monoclonal antibody which targets CD20, a transmembrane protein present on immature and mature B cells, but absent on most pro-B cell or plasma cells. It was originally used in the treatment of B cell lymphomas and subsequently RTX proved useful in the treatment of a variety of autoimmune diseases. So far, three studies have been conducted examining the effect of RTX on thyroid function in Graves' hyperthyroidism and ophthalmopathy Stan and Salvi (2017). The results of these studies suggest that RTX may prolong remission for hyperthyroidism over that seen with antithyroid drugs, at least in mild Graves' disease.

Radioiodine

Among different radioactive isotopes of iodine, ^{131}I is the agent of choice in the treatment of thyroid hyperfunction. After oral administration, radioiodine is completely absorbed, rapidly concentrated, oxidized, and organified by thyroid follicular cells. The destruction of thyroid cells produced by radioiodine results from the ionizing effects of β-particles that have a path length of 1–2 mm. Specifically, 1 μCi of ^{131}I retained per gram of thyroid tissue delivers approximately 70–90 rads. Biological effects of radioiodine include necrosis of follicular cells, shorter survival and impaired replication of nondestroyed cells, and vascular

occlusion. In the long run, there is atrophy and fibrosis, as well as a chronic inflammatory response that ultimately may result in thyroid failure.

The goal of radioiodine therapy of hyperthyroidism is to destroy sufficient thyroid tissue to cure hyperthyroidism with one dose of ^{131}I. The administered dose is calculated on the basis of thyroid size and uptake of ^{131}I using the following formula:

$$\text{Dose (mCi)} = \text{Estimated thyroid weight (g)} \times \text{Planned dose } (\mu\text{Ci/g})/\text{fractional 24 h radioiodine uptake.}$$

In other centers, standard fixed doses are given. Because of radiation safety restrictions, in some centers, especially in Germany, repeated 2- to 3-mCi doses of radioiodine are administered. It is a common experience that small glands appear to be destroyed more readily by radioiodine than do larger ones and that toxic adenomas or toxic multinodular goiters are usually more radioresistant than Graves' glands (Ma *et al.*, 2016).

The therapeutic effect of radioiodine is delayed, and in some patients up to several months may be required for the complete control of hyperthyroidism (Villagelin *et al.*, 2015). Thus, a course of antithyroid drugs before the administration of radioiodine is frequently used, particularly in cases of severe thyrotoxicosis, to avoid the inconveniences of persistent hyperthyroidism. In selected patients with significant comorbidity, antithyroid drugs may also be administered following radioiodine, but doing so may decrease the efficacy of treatment.

Radioiodine therapy may lead to worsening of Graves' ophthalmopathy when present. This worsening can be prevented by concomitant glucocorticoid therapy, beginning after radioiodine administration (Bartalena *et al.*, 2015, 2016).

In the past, the major concerns with radioiodine therapy derived from the possible carcinogenic effects of ionizing radiation and from the risks of congenital malformations in offspring of women treated during their childbearing years. No association was found between radioiodine administration and thyroid cancer in large epidemiological studies. Similarly, there is no evidence that radioiodine therapy for hyperthyroidism increases the risk of leukemia or solid tumors. No association between radioiodine treatment for hyperthyroidism and congenital abnormalities in subsequent offspring has been observed.

Thyroidectomy

Subtotal or near-total thyroidectomy is performed in Graves' disease and toxic multinodular goiter, whereas lobectomy is the procedure of choice in toxic adenoma. Restoration of euthyroidism before surgery is mandatory (Fortuny *et al.*, 2015). The classical approach combines a course of thionamide treatment to restore and maintain euthyroidism and the preoperative administration of iodide for approximately 10 days to decrease blood flow of the gland. Care must be taken not to discontinue or decrease the dose of antithyroid drugs when iodide is added. We do not favor a preoperative program based only on the use of a β-adrenergic antagonist associated with iodide. Euthyroidism is not restored in these patients because iodide alone normalizes the concentration of thyroid hormones in serum only a few days before the operation but does not produce "tissue" euthyroidism. Furthermore, the risk of thyroid storm is not completely prevented even when high-dose propranolol is administered for several days after surgery.

Possible complications of thyroid surgery include thyroid storm (which is extremely rare nowadays), bleeding, injury to the recurrent laryngeal nerve, and hypoparathyroidism. In particular, the risk of laryngeal nerve injury and hypoparathyroidism cannot be disregarded. Although an incidence of these complications of $<2\%$ is reported from clinics with wide experience in thyroid surgery, much higher figures of up to 10%–15% are encountered in some series. These complications are, of course, less frequent when lobectomy for toxic adenoma is performed.

Choice of Therapy

The choice of treatment for Graves' hyperthyroidism involves both physician's prejudice, advantage and disadvantage of available options and, last but not least the patient's preference.

Graves' Disease

All patients should receive treatment with MMI for restoring euthyroid function. Afterwards two strategies can be considered: (1) maintaining MMI therapy for up to 12–18 months, hoping that meanwhile the mechanism responsible of thyroid hyperfunction goes into permanent remission (in up to 30% of cases); (2) definitive treatment with radioiodine of surgery (near total thyroidectomy). Long-term MMI therapy is usually employed in children and adolescent ad also appropriate to use for patients who are not willing to consider as neither radioiodine or surgery as first option.

Radioiodine could be the first option for middle-aged and elderly people, but can also be considered for young adults. The reasons for choosing radioiodine could be the relative high recurrence rate of hyperthyroidism after antithyroid drugs an the notion that radioiodine is effective, inexpensive, and safe. When radioiodine is considered in patients with mild and active Graves' ophthalmopathy, particularly if smokers and with recent onset of hyperthyroidism, a course of prednisone (0.2–0.3 mg/kg body weight for 8 weeks) should be advise to avoid the possible worsening of eye disease which has been reported to occur in about

15% of cases (Marcocci and Marinò, 2012; Bartalena *et al.*, 2015). Acute complications of radioiodine are extremely rare if patients are rendered euthyroid with antithyroid drugs for a period of time sufficient to deplete intrathyroidal stores of hormones.

Surgery should be advised to patients with large goiters, in whom the likelihood that MMI therapy may induce long-term remission of hyperthyroidism is low and in young patients with releasing hyperthyroidism after MMI therapy who are unwilling to receive neither a second course of MMI therapy or radioiodine. Patients should be informed of adverse events of surgery even though in experienced hand thyroidectomy is a rather safe procedure (Fortuny *et al.*, 2015).

Hypothyroidism should be the aim, and not an adverse event, of either radioiodine of surgery in patients with Graves' disease since hypothyroidism make very unlikely the relapse of hyperthyroidism and is easily and stably corrected by levothyroxine.

It is still debate which treatment modality for Graves' hyperthyroidism and ophthalmopathy, especially in those with moderate-to-severe eye disease (Bartalena *et al.*, 2016). In these patients it is important to promptly restore euthyroidism with antithyroid drugs. Two strategies have been proposed over the last 20–30 years, namely consider definitive treatment with radioiodine or surgery, as appropriate and at the same time star the specific treatment for the ophthalmopathy (Bartalena *et al.*, 2015, 2016). This approach is aimed to a permanent control of thyroid dysfunction and likely to short the active phase of the disease. The other option is to maintain the patients under antithyroid drug therapy until the treatment of ophthalmopathy is completed and the disease is inactive and to consider permanent treatment of hyperthyroidism thereafter. To date there is no evidence supporting either of the two options. A recent study has evaluated the outcome of long-term antithyroid drugs (as the block-and-replace [B-R] regimen) [median of 41 months (range: 24–132)] for Graves' hyperthyroidism in patients with ophthalmopathy by assessment, after discontinuation of B-R therapy of the recurrence rate of hyperthyroidism and the course of Graves' ophthalmopathy and its association with recurrent hyperthyroidism and/or 131-I therapy. The study suggests that a long term antithyroid drug treatment is associated with a lower recurrence rate of hyperthyroidism ($\sim$37%). With the regimen employed, recurrence of hyperthyroidism and recurrence of hyperthyroidism followed by treatment with 131-I appears not to be a likely cause of relapse of ophthalmopathy.

Thionamides are the first-choice treatment in pregnant women with hyperthyroidism. Radioiodine therapy is contraindicated during pregnancy, and surgery is restricted to exceptional cases. Both PTU and MMI cross the placenta and, in excessive doses, may cause hypothyroidism and goiter in the fetus and the neonate. PTU was until recently the preferred choice particularly in the United States because, compared to MMI, is less lipid soluble and more highly protein bound, and therefore its placental transfer appears to be lower. However, there is no difference between PTU and MMI in suppressing fetal thyroid function (Laurberg and Andersen, 2015). The drug chosen should be given at the lowest possible dose (but not higher than 10 mg MMI or 100 mg PTU daily as maintenance dose), aiming to maintain maternal-free T_4 and free T_3 in the high–normal range. A recent large international looking to antithyroid drug treatment-related birth defects confirmed an association between maternal use of MMI and omphalocele and choanal atresia in offspring. The study identified three malformations (situs inversus, unilateral renal agenesis/dysgenesis, and cardiac outflow tract lesions) associated with prenatal PTU exposure. The results were, however, of marginal statistical significance and the authors point out that a firm conclusion that PTU is teratogenic will require further studies. For the time being, PTU, if available, is recommended by the Endocrine Society of Endocrinology as the first-line drug for treatment of hyperthyroidism during the first trimester of pregnancy because of the possible association between MMI use and specific congenital abnormalities that may occur during early organogenesis. In this regard, it would be appropriate to shift from MMI to PTU when the pregnancy is planned. Recent analyses reported by the US Food and Drug Administration indicate that PTU may rarely be associated with severe liver toxicity. For this reason a change treatment from PTU to MMI is recommended after the completion of the first trimester. It reasonable to monitor liver function in pregnant women on PTU every 3–4 weeks. MMI may also be prescribed if PTU is not available or if a patient cannot tolerate or has an adverse response to PTU.

Graves' disease is the main cause of hyperthyroidism in children and adolescents. AT this age, the peak incidence of the disease is between 11 and 15 years of age, but it may occur in children under 5 years of age. Antithyroid drugs, radioiodine, and surgery have been successfully used in children, but thionamides is usually considered the first-choice treatment.

Toxic Adenoma and Multinodular Goiter

Hyperthyroidism due to toxic adenoma responds well to radioiodine, and the nodule is partially reduced by this form of therapy. In severe hyperthyroidism, pretreatment with thionamides is indicated, but radioiodine should be given before restoration of extranodular thyroid function to limit the rate of postradioiodine hypothyroidism.

Surgery is a more appropriate choice in large ($>$5 cm) nodules, particularly if associated with compressive symptoms (**Table 3**). Young age also favors surgery with respect to radioiodine. Lobectomy is indicated in classic toxic adenoma in otherwise normal thyroid glands. When single hyperfunctioning thyroid nodules occur in a multinodular goiter, subtotal or near-total thyroidectomy is indicated.

Toxic multinodular goiter is more frequent in patients older than 50 years, who might have an increased risk of surgery because of concomitant comorbidities (**Table 3**). Therefore, many patients with toxic multinodular goiters receive radioiodine. Hyperthyroidism is cured in virtually all cases, although more than one dose of ^{131}I may be required. However, the reduction in thyroid size is only partial because of the presence of intrathyroidal calcifications, fibrosis, and large areas of nonfunctioning tissue. Nevertheless, in patients with large mediastinal goiters and contraindications to surgery, radioiodine may be used with beneficial effects on thyroid hyperfunction and partial relief of compressive symptoms.

Table 3 Factors favoring specific forms of treatment of toxic adenoma and uninodular and toxic multinodular goiter

Surgery
Young-adult age
Large goiter or adenomas >5 cm
Low radioiodine uptake and large areas of poorly functioning tissue within the goiter
Airway obstruction or compression of other structures
Refusal to take radioiodine
Radioiodine
Small adenomas (<5 cm)
Old age
Contraindications to surgery

Surgery is generally regarded as a better option in patients with large goiters, especially if there is evidence of substernal extension and compression of airways and blood vessels (Fortuny *et al.*, 2015). Surgery is also indicated in those instances when radioiodine uptake by the gland is relatively low, as frequently occurs in large multinodular goiters. In the latter cases, when there is a true contraindication to surgery, the application of recombinant human TSH before radioiodine therapy should be considered. The use of recombinant human TSH in this setting is off-label and not generally recommended.

Treatment of Other Etiologies of Hyperthyroidism and Thyrotoxicosis

It is of importance to recognize other etiologies in order to choose the most appropriate therapeutic option and long-term surveillance.

Administration of moderate or high doses of iodine may induce thyrotoxicosis in patients with or without apparent preexisting thyroid disease. There are numerous sources of iodine, for example drugs, contrast agents, disinfectants, and food components. A notorious iodine-containing agent is the antiarrhythmic drug amiodarone, which may induce thyrotoxicosis (AIT) because of its high iodine content and/or a drug-induced thyroiditis (Bogazzi *et al.*, 2012). If possible, amiodarone should be discontinued. Patients with type 1 AIT, that is., caused by increased hormone synthesis because of exposure to high amounts of iodine, are preferably treated with methimazole (initially 40–60 mg/day, followed by gradual adjustment of the dose), but the response to thionamides is modest. In selected patients, treatment with potassium perchlorate (1 g/day for 4–6 weeks) can be considered. Potassium perchlorate is a drug that can cause aplastic anemia and its use should be limited to patients who cannot be controlled by methimazole, or who are allergic to thionamides. For patients with AIT Type II, that is., cytotoxic destruction of thyrocytes, prednisone (0.5–0.7 mg/kg body weight per day) is recommended, with tapering of the starting dose of prednisone once euthyroidism has been restored. Because the distinction between AIT Type I and II is difficult and not always clear, and because some patients have mixed forms of AIT, these therapies are occasionally combined.

Any form of thyroiditis, including subacute thyroiditis, silent thyroiditis and, occasionally, Hashimoto's thyroiditis may be accompanied by mild symptoms of thyrotoxicosis, particularly in the early phases of the disease, because the disruption of thyroid follicles can result in an increased release of stored iodothyronines. In these diseases treatment with beta-blocking agents is often sufficient. The thyrotoxic phase may be followed by transient or permanent hypothyroidism. Symptomatic treatment with nonsteroidal antiinflammatory drugs or aspirin is often sufficient. A subset of patients needs therapy with prednisone for variable amounts of time. Therapy with levothyroxine may be necessary during the hypothyroid phase of the illness.

Subclinical Hyperthyroidism☆

Bernadette Biondi, University of Naples Federico II, Naples, Italy

Introduction

Subclinical hyperthyroidism (SHyper) is a disorder characterized by subnormal or undetectable serum thyrotropin concentration (TSH) with serum free triiodothyronine and serum free thyroxine levels in the normal range for the general population, more often in the upper half (Biondi and Cooper, 2008; Cooper and Biondi, 2012).

The advent of the immunometric measurement of serum TSH concentration resulted in a progressive increase in the diagnostic rate of SHyper. Subsequently, a number of clinical investigations have established that this condition is not a simple biochemical abnormality but rather a mild tissue thyrotoxicosis "sensu strictu."

Etiology

SHyper can be transient or persistent and related to exogenous or endogenous causes (Biondi and Cooper, 2008, 2010; Cooper and Biondi, 2012). The exogenous variant of SHyper is related to TSH-suppressive treatment with levothyroxine (L-T4) in patients with differentiated thyroid carcinoma or to an unintentional excessive replacement L-T4 therapy in hypothyroid patients (Biondi and Cooper, 2010). About 200 million people worldwide take L-T4 and might be at risk for exogenous SHyper.

The endogenous variant is related to Graves' disease (GD), autonomously functioning thyroid adenoma (TA), and multinodular goiter (MNG) (Biondi and Cooper, 2008; Cooper and Biondi, 2012).

While GD is the most common cause of SHyper in younger patients (<65 years) in iodine-replete areas, TA and toxic MNG are relatively more frequent in iodine-deficient areas and in older persons (≥ 65 years).

Epidemiology and Natural History

Considering geographical aspects (iodine intake) and methodological differences (sensitivity of TSH assays), the prevalence of endogenous SHyper ranges between 0.6% and 16% and is, in general, more frequent in female and elderly patients (Biondi and Cooper, 2008; Cooper and Biondi, 2012). As for the spontaneous evolution of endogenous SHyper, prospective studies have demonstrated that overt hyperthyroidism develops frequently in patients with undetectable serum TSH compared to patients with low but detectable serum TSH (Vadiveloo *et al.*, 2011). Overt hyperthyroidism is often precipitated by iodine supplementation or by iodide contrast agents.

Clinical Implications

SHyper can be associated with signs and symptoms of mild thyroid hormone excess resembling adrenergic over activity (Biondi *et al.*, 1993, 1994). In general, SHyper negatively affects the quality of life of adult patients and induces supraventricular arrhythmias (atrial premature beats in middle-aged people and atrial fibrillation in the elderly) (Biondi *et al.*, 1993, 1994, 1996, 2000; Sawin *et al.*, 1994). Various authors have reported SHyper patients scoring higher on a symptom rating scale (specifically designed for clinically overt hyperthyroid patients) than euthyroid controls (Biondi *et al.*, 1993, 1994; Mercuro *et al.*, 2000). These findings clearly indicate that the term "subclinical hyperthyroidism" is a misnomer. Patients with persistent SHyper can have important alterations involving the morphology and function of the cardiovascular system and/or bone and mineral metabolism (**Table 1**) (Biondi *et al.*, 1993, 1994, 1996, 2000; Mercuro *et al.*, 2000; Fazio *et al.*, 1995). Therefore, SHyper is not merely a laboratory condition, but rather a mild tissue hyperthyroidism that may be particularly dangerous in the elderly.

Effects on the Cardiovascular System

Cardiovascular morbidity and mortality are significantly increased in patients with endogenous SHyper (Collet *et al.*, 2012; Gencer *et al.*, 2012; Parle *et al.*, 2001).

☆*Change History*: February 2018. Bernadette Biondi updated the text and references to this article.

This article is an update of Bernadette Biondi, Emiliano A. Palmieri, Gaetano Lombardi, Serafino Fazio, Hyperthyroidism, Subclinical, In Encyclopedia of Endocrine Diseases, edited by L Martini, Elsevier, New York, 2004, Pages 621–623.

 doi:10.1016/B978-0-12-801238-3.99453-4

Table 1 Clinical implications of subclinical hyperthyroidism

- Impaired quality of life
- Higher heart rate
- Increased prevalence of supraventricular arrhythmias and increased risk of AF
- Increased left ventricular mass
- Impaired diastolic function
- Impaired systolic function on effort
- Increased cardiovascular morbidity and mortality
- Reduced bone mineral density
- Increased risk of fractures

An increased risk of atrial fibrillation (HR 1.68, 95% CI 1.16–2.43) has been reported in a recent meta-analysis on individual participant data from five prospective cohort studies in patients with SHyper. The risk was higher for TSH levels <0.1 mU/L compared to 0.1–0.44 mU/L (HRs 2.54 vs. 1.63) (Collet *et al.*, 2012).

SHyper has also been associated with relevant changes in left ventricular properties. Increased left ventricular mass, in some cases above the hypertrophic threshold, is a consistent finding in adult SHyper patients, variably associated with impaired diastolic function and reduced exercise tolerance (Biondi *et al.*, 1993, 1994, 2000; Mercuro *et al.*, 2000).

A meta-analysis on 718 patients with endogenous SHyper has recently reported that the risk of coronary heart disease events is higher in patients with serum TSH <0.1 mU/L (HR 1.21, 95% CI 0.99–1.46) (Collet *et al.*, 2012). Moreover, a pooled analysis of individual participant data from six prospective cohort studies has demonstrated that patients with TSH levels <0.10 mU/L may have a higher risk of heart failure than euthyroid controls (HR 1.94, 95% CI 1.01–3.72) (Gencer *et al.*, 2012). Cardiovascular mortality is increased in patients with endogenous SHyper (HR 1.29, 95% CI 1.02–1.62) and this risk is higher for TSH levels <0.1 mU/L compared to levels between 0.1 and 0.44 mU/L (HRs 1.84 vs. 1.24) (Collet *et al.*, 2012).

Effects on Bone and Mineral Metabolism

Although clinically overt hyperthyroidism is a well-recognized risk factor for osteoporosis and fractures, it is still debatable whether this is also the case for persistent SHyper. Serum concentration of osteocalcin and urinary excretion of markers of collagen bone degradation and reabsorption (pyridinoline cross-links, hydroxyproline, and telopeptide type I) have been found to be increased in patients with SHyper. Congruent with these findings, various studies have showed a significant reduction in bone mineral density and an increased risk of fractures in women with SHyper; both features become more apparent during the postmenopausal period and in elderly patients (Greenspan and Greenspan, 1999; Bauer *et al.*, 2001).

Management Strategies

In general, the treatment of SHyper should be modulated according to the underlying etiology, the patient's age, and the presence of comorbidities (Biondi *et al.*, 2015; Ross *et al.*, 2016). In patients with exogenous SHyper, in whom the L-T4 dose cannot be reduced (e.g., in patients with high-risk thyroid cancer), beta-blocking drugs can attenuate the effect of adrenergic overactivity on the cardiovascular system, thereby mitigating cardiac abnormalities and improving the quality of life. Conversely, in all cases where L-T4 may be tailored (i.e., in benign thyroid diseases and in some cases of low-risk thyroid cancers), this is the mandatory treatment, eventually corroborated by beta blockade in case of persistent symptoms of increased adrenergic overactivity (Biondi and Cooper, 2010). The treatment of endogenous SHyper, similarly to that of overt hyperthyroidism, is aimed at redressing euthyroidism by means of antithyroid drugs, radioiodine, or surgery. Bisphosphonates and/or estrogens may be used in postmenopausal women and in individuals who have a high risk of fractures (Biondi *et al.*, 2015; Ross *et al.*, 2016).

Antithyroid Drugs☆

Jacques Orgiazzi, Claude Bernard University Lyon 1, Lyon, France

Glossary

Graves' disease Graves' disease is the most common cause of hyperthyroidism, accounting for approximately 75% of cases. An autoimmune disease, it results from the production of autoantibodies directed to the thyrotropin (TSH) receptor which stimulate the thyroid gland to secrete excessive quantities of thyroxine (T4) and triiodothyronine (T3).

Hyperthyroidism This is the clinical condition arising from sustained raised concentrations of T4 and/or T3 in the circulation resulting from the excessive and deregulated synthesis and secretion of thyroid hormones, T4 and T3 by the thyroid gland. In this situation, TSH secretion is suppressed and serum TSH concentrations are undetectable or low. Thyrotoxicosis is defined as an excess of T4 and T3 concentration in serum resulting from the release of intrathyroid thyroid hormones through inflammatory cytolysis of thyroid tissue as in subacute thyroiditis or certain forms of autoimmune thyroiditis.

Thionamides A group of antithyroid drugs comprising carbimazole and its active metabolite, methimazole, and propylthiouracil. Their main action is to inhibit the iodination of tyrosyl residues in thyroglobulin, one of the early stages of thyroid hormone synthesis.

Antithyroid drugs are used in the treatment of hyperthyroidism of Graves' disease. The antithyroid drugs carbimazole (CBZ) and methimazole (MMI), as well as propylthiouracil (PTU), are heterocyclic compounds known as thionamides that contain a thiourylene group. Antithyroid drugs inhibit thyroid hormone synthesis hence opposing the overproduction of the hormones due to Graves' disease.

Introduction

Antithyroid drugs are rapidly and almost completely absorbed from the gastrointestinal tract, with peak serum concentrations at 1 or 2 hours. CBZ and MMI are interchangeable since CBZ is immediately metabolized in serum to MMI, 10 mg of CBZ yielding 6 mg of MMI. In the blood, MMI is virtually non-protein-bound while PTU is about 80% protein-bound. The half-life of MMI is 3 to 5 hours, that of PTU 1 to 2 hours. MMI and PTU cross the placenta and are transferred into breast milk, with a somewhat greater rate for the former. Both MMI and PTU are actively transported and concentrated into the thyroid, where they inhibit the synthesis of triiodothyronine (T3) and thyroxine (T4), principally by interfering with the iodination of tyrosine. They serve as preferential substrate for the iodinating intermediate of thyroid peroxidase so that oxidized iodine is diverted from the tyrosyl iodination sites in thyroglobulin. This intrathyroidal inhibitory effect of MMI and PTU on thyroid hormone synthesis outlasts by several hours, and longer for MMI than PTU, the presence of the drugs in blood. Consequently, MMI may be given as one daily dose, PTU two or three. The iodinated antithyroid drugs are desulfurated and further oxidized to inactive metabolites (Kampmann and Hansen, 1981; Cooper, 2005).

Two other effects of antithyroid drugs have to be discussed:

- PTU, but not CBZ/MMI, at high dose, inhibits T4 to T3 conversion by blocking type 1 iodothyronine deiodinase, not only in peripheral tissues, but also within the hyperactive thyroid gland (Laurberg *et al.*, 2007). This effect would be of clinical significance in the management of thyrotoxic crisis, when it is important to lower the raised serum T3 concentration as quickly as possible.
- Antithyroid drug therapy of hyperthyroid Graves' disease may be associated with a remission of the disease far more often than would be the case spontaneously. Moreover, it is common observation that, during antithyroid drug treatment, the serum level of circulating autoantibodies against the TSH receptor (TSH receptor antibodies, TRAb) declines and may even become undetectable. Hence, the concept of the immunosuppressive effect of the antithyroid drugs. However, the crucial question is whether this effect results from a direct action of the antithyroid drugs or would be associated with the restoration of the euthyroid state (Laurberg, 2006). While there are experimental in vitro data in favor of the former, the fact that remissions are independent from the dose of antithyroid drugs and that remissions as well as decrease of serum TRAb level are also observed

with non-thionamide drug treatment (perchlorate, for instance) or after partial thyroidectomy is in favor of the latter, that is, the restoration of the euthyroid state. Obviously, more is to be learned in this domain.

Depending on availability in given countries, CBZ or MMI is the drug of choice in all areas of the world. PTU is no longer the first-line antithyroid drug in the Americas because of the risk of liver side-effects, uncommon but severe (see below). Currently, PTU is restricted to use during the first trimester of pregnancy. Methimazole is available as 5- and 10-mg tablets and CBZ as 5- and 20-mg tablets. PTU is available as 50-mg tablets.

The Treatment of Graves' Disease: Overview

The perfect single treatment of Graves' disease—an autoimmune condition with a relapsing and remitting long-lasting course—which would cure every patient, is not available, yet. In Graves' disease, the hyperfunction of the thyroid gland, responsible for the overproduction of thyroid hormone, results from the presence of TRAb that activate the TSH receptor. Currently available treatments are not targeted to the causal immune system derangement but to the resultant hyperthyroidism. There are two types of treatment strategies:

(a) *Antithyroid drug administration*: Antithyroid treatment restores euthyroidism in all patients in a few weeks but, in addition, after a 12–18 month-long continuous treatment course it may lead to a long-lasting (2 years or more) remission of the disease in approximately 40% of the patients
(b) *Eradication of thyroid tissue*: the radical/ablative strategy using thyroid irradiation with radioactive iodine or surgical thyroid ablation. Obviously, these two types of intervention are followed by a definitive hypothyroid state requiring substitutive levothyroxine treatment.

Antithyroid drug treatment is used not only in the first option strategy, but also in the second, to restore the euthyroid state before the radical treatment.

Initial identification of the patients more likely to go into remission after the long-term cure with antithyroid drug treatment remains uncertain at the individual level. However, prognostic criteria have been identified. Clinical characteristics such as younger age, male gender, and large thyroid gland volume are associated with a higher risk of relapse. Biologically, the severity of hyperthyroidism as assessed by a marked elevation of the serum concentration of T4 and/or of T3 (current assays measure the free forms of T4 called free T4-FT4, rather than the total T4-TT4; assays for FT3 or TT3 are both in use) and a high initial level of TRAb is also associated with a high relapse risk. Recently, it has also been observed that *PTPN22* C/T polymorphism and HLA subtypes *DQB1*02, DQA1*05, and DRB1*03* are independent predictors for recurrence (Vos *et al.*, 2016). Although these markers are highly significantly predictive only at group level, they are helpful to orient the discussion of the treatment selection with a given patient. This is why the treatment strategy remains somewhat empirical, individually tailored, also influenced by cultural/educational regional biases, by the prejudices of the physician and the patient, and by the local expertise availability, for example, trained team in thyroid surgery, or nuclear medicine center. In the past, there were major differences in the management of Graves' disease from center to center and between countries. For instance, radioiodine treatment was the first-line therapeutic option in the United States, antithyroid drugs in Europe and in Japan. Thanks to the work of several thyroid associations, guidelines and recommendations have been published so that therapeutic option differences between specialists tend to level off.

Antithyroid drugs are not normally indicated in the treatment of toxic nodular goiter, a condition which requires a radical/ablative therapy since no remission is to be expected, unless, in fragile or elderly patients, prior restoration of euthyroidism is necessary. There is no role for antithyroid drugs in subacute or postpartum thyroiditis, in which the thyrotoxicosis does not result from the overproduction of thyroid hormone but is due to the release of preformed thyroid hormones from the damaged gland (Ross *et al.*, 2016).

The Treatment of Graves' Disease: Management of the Therapy With the Antithyroid Drugs

In practical terms, the treatment of Graves' disease must be considered as a two consecutive step process. The initial one, following the diagnosis and the evaluation of the severity of the case, aims at restoring the euthyroid state using antithyroid drugs, the second, at implementing the more appropriate treatment strategy to cure the disease.

Initiation of Antithyroid Drug Treatment: Treatment Strategy Selection

The objective is to reach normal or near-normal serum T4 and T3 concentrations by 6–8 weeks. The initial dose of CBZ or MMI is 30–40 or 15–30 mg daily, respectively, depending on the severity of the hyperthyroidism assessed clinically and on the degree of serum T4 and T3 elevation. For instance, 30 mg/day of MMI is considered as advisable for severe cases (FT4 $\geq$ 90 pmol/L), 15 mg/day of MMI for mild and moderate cases. Clinical evaluation and the control of serum T4 and T3 levels are mandatory after 3–4 weeks of treatment. As the serum concentrations of T4 and T3 decrease, the daily dose of MMI can then be reduced to 10–20 mg and that of CBZ to 20–30 mg. Further adjustment of the dose is mandatory on the basis of measurements of serum

concentrations of T4 and T3 in order to prevent iatrogenic hypothyroidism due to inappropriately high doses of antithyroid drug. Adjunct treatments are not discussed here.

In newly diagnosed patients, the end of this first phase is the point in time when to select or confirm, and/or implement, the subsequent treatment strategy, either the "medical" one with the prolongation of the antithyroid drugs for a total of 12–18 months, or the "radical/ablative" with radioactive iodine administration or thyroidectomy.

Antithyroid Drug for the "Medical" Option

This is the more frequent option selected in the newly diagnosed patients. It requires patient's adhesion to treatment and regular follow-up. The antithyroid drug may be prescribed alone—the so-called "titration method", or in combination with the thyroid hormone levothyroxine (T4)—the "block and replace" method.

Duration of treatment

Approximately 40% of the patients in whom this modality has been elected remain in remission for the 2 years after the end of the antithyroid drug treatment. However, this percentage is significantly decreased if treatment duration is shortened to less than 12–18 months. On the contrary, the prevalence of remission is not increased by prolonging therapy for up to 3 years. There are a few reports of very long, or ultra-long (a few years up to 10 years) antithyroid drug administration (Azizi *et al.*, 2005). This approach may be considered in some patients provided the dose of antithyroid drug required of is very low ($<$5–10 mg/day), the drug is well tolerated, the patient is compliant to treatment and follow-up and, accordingly, there is no indication of radical/ablative treatment.

Management of the dose of antithyroid drug

With the titration method, the dose of the antithyroid drug must be closely adapted to the evolution of the thyroid hormone levels and, after 10–12 weeks of treatment, of the levels of serum TSH levels no longer suppressed as the result of hyperthyroidism. Usually, a maintenance dose of 5 or 5–15 mg of MMI or CBZ, respectively, may be achieved. The decrease in antithyroid drug dose requirement parallels that of the degree of thyroid overstimulation. Adaptation of antithyroid dose prevents iatrogenic hypothyroidism. After a further 6–12 month treatment, possibly at even lower dosage, antithyroid drugs may be stopped, with the patients being closely followed up.

The combination of both antithyroid drug and levothyroxine in the block and replace allows maintaining the high initial dose of antithyroid drug after the patient is euthyroid without the risk of iatrogenic hypothyroidism thanks to the substitutive daily dose of 100–150 μg of levothyroxine. In this method, it is the dose of levothyroxine which is adjusted to maintain the serum TSH level at the lower reference range.

While the two methods have been shown to be equivalent in term of remission rate, the block-replace regimen might be simpler to monitor since iatrogenic hypothyroidism is prevented and controls may be less frequent. As explained below, the block-replace regimen should not be used during pregnancy.

There is no single good marker to determine when to stop the antithyroid drug treatment after the 12–18 month course. However, the absence of reduction of the goiter volume and/or the persistence of thyroid hypervascularity, and, in the case of the titration method, persistently suppressed level of TSH and the requirement for a full dose of antithyroid drugs are indicative of persistent disease activity and, consequently, of recurrence at drug withdrawal. Similar information is provided by persistently elevated serum levels of TRAb.

Antithyroid Drug Treatment and the Radical/Ablative Strategy

Treatment with radioactive iodine

Although not mandatory, except in severe forms of hyperthyroidism and in fragile patients, many centers elect to moderate the degree of hyperthyroidism with antithyroid drugs before radioiodine administration. Also, since radioactive iodine requires approximately 6–8 weeks to be effective, antithyroid drug may be continued for 6 weeks after irradiation. Antithyroid drugs confer some degree of radioresistance to the thyroid tissue so that the drug must be discontinued and resumed 5–7 days before and after radioactive iodine administration. Alternatively, the dose of radioactivity may be increased by 15%–25%, a recommendation currently of less importance taken into account the general rule of using larger ablative doses of radioactive iodine.

Surgical thyroid ablation

As a rule, as much as possible, euthyroid state must be restored before thyroidectomy is considered in order to prevent post-operative thyroid crisis. Usually, an 8–16 week antithyroid drug treatment is appropriate. Care must be taken to prevent iatrogenic hypothyroidism due to an excessive dose of antithyroid drug that could favor goitrogenesis and thyroid gland hypervascularisation.

Side Effects of Antithyroid Drugs

Patients should be informed of the potential adverse effects of antithyroid drugs. They usually occur within the first 3–6 weeks of treatment. They appear to be dose-related for CBZ/MMI, more than for PTU. The adverse effects may be minor, the more frequent, or severe, much more uncommon (Cooper, 2005).

The more frequent are minor, occurring in approximately 5% of the patients, as cutaneous rashes of the urticaria or macular type, arthralgia or myalgia. Minor forms of rashes do not require stopping CBZ/MMI treatment and may resolve with antihistamine. There is a 50% cross-sensitivity between CBZ or MMI and PTU so that it was usual to switch to the alternative antithyroid drug in the event of a minor adverse reaction, a possibility to adapt to the current restriction of the use of PTU. A potentially severe adverse effect, migratory polyarthritis, may occur alone or in association with the rash and resolves within 4 weeks of stopping treatment.

Severe, potentially life-threatening or even lethal, adverse reactions may occur. These are uncommon. Agranulocytosis is the more dreadful. It may occur in 0.2%–0.7% of the patients, with a greater risk in older patients, with high doses of antithyroid drugs and during the first three months of treatment, but it may occur later, at reinitiating of the drug. Agranulocytosis is defined as a granulocyte count $<500/mm^3$. It should not be mistaken for the mild granulocytopenia (granulocyte count $<1500/mm^3$) sometimes observed in patients with Graves' disease before the treatment is started, so that it is useful to have a baseline white cell count available. If baseline neutrophil count is less than $1000/mm^3$, it is recommended that treatment with antithyroid drug be reconsidered. Agranulocytosis is of sudden onset, therefore routine monitoring of the white blood cell count is not recommended. Agranulocytosis is characterized by fever, throat infection and malaise and patients should be instructed to contact their medical practitioner as soon as they present with these signs and symptoms. Antithyroid drug must be stopped immediately. Along with proper management (isolation, broad-spectrum antibiotics therapy), the white blood cell count returns to normal within 1–3 weeks, usually. The benefit of the treatment with granulocyte-colony-stimulating factor is unsettled. Occurrence of agranulocytosis is an absolute contraindication to further antithyroid drug therapy. Hepatotoxicity of the antithyroid drugs is a severe side-effect, occurring in 0.1%–0.2% of the patients, either as cholestatic hepatitis or toxic hepatitis (Lin *et al.*, 2017). The prevalence is about the same with CBZ/MMI and PTU. Onset of hepatotoxicity of PTU may be acute and, if not recognized lead to hepatic failure in adults and in children and adolescents, requiring liver transplantation, or even to death (Glinoer and Cooper, 2012). Accordingly, the use of PTU is no longer recommended as the first-line treatment for Graves' hyperthyroidism, except in special conditions (vide infra). Since untreated hyperthyroidism is associated with a 30%–40% incidence of a biochemical liver test abnormality, it might be useful to obtain a baseline liver profile and to reconsider the treatment with antithyroid drug if transaminases levels are more than five times the upper limit of normal. Antinuclear-cytoplasmic-antibodies (ANCA)-associated small-vessel vasculitis related to antithyroid drugs has been recently reviewed (Balavoine *et al.*, 2015). Association with PTU is more frequent than with CBZ/MMI (75% vs 25%). Occurrence of ANCA is more frequent in young patients and on antithyroid drug therapy of long duration. Only 15% of ANCA-positive patients treated with antithyroid drugs exhibited clinical evidence of vasculitis, corresponding to 3% of all patients so treated. Clinical presentations (systemic symptoms, renal, lung, skin manifestations) of ANCA-associated vasculitis related to antithyroid drugs are extremely heterogeneous. Drug withdrawal is usually followed by rapid clinical improvement of vasculitis and a favorable prognosis. Because the decreasing use of PTU, ANCA screening is not systematically recommended on antithyroid drug therapy.

Antithyroid Drugs in Pregnancy

The incidence of thyrotoxicosis during pregnancy, in majority due to Graves' disease, approximates 0.1% (Mestman, 1998). During pregnancy, untreated hyperthyroid Graves' disease may cause maternal congestive heart failure and increases the risk of spontaneous abortion, premature labor, low birth weight, fetal death, and also of malformation in the infants. As other organ-specific autoimmune diseases, Graves' disease, after a transient exacerbation of clinical symptoms likely related to the first-trimester peak of human chorionic gonadotropin, usually tends to spontaneously improve or even remit in the second half of pregnancy. Maternal circulating antibodies cross the placenta, therefore high level of TRAb in the mother may cause fetal hyperthyroidism. Antithyroid drugs also cross the placenta. Consequently, restoration of euthyroidism in the mother requires that the dose of the antithyroid drug be maintained at the minimum to avoid fetal hypothyroidism. Since the transfer of thyroxine from mother to fetus is limited, the "block-replace" method is inappropriate during pregnancy, except in the more severe cases of maternal hyperthyroidism requiring full dose antithyroid drug treatment. In usual cases, the classical rule of thumb is to adjust the antithyroid drug dose so that the maternal serum FT4 level is maintained at the upper normal limit (Alexander *et al.*, 2017). In a good proportion of the cases, however, antithyroid treatment can be withdrawn after midpregnancy. Close clinical and biological surveillance of the mother, as well as multidisciplinary endocrinological, obstetrical and when appropriate, neonatal management, including expert fetal thyroid ultrasonography, are mandatory especially if the maternal level of TRAb is high, in order not to overlook fetal dysthyroidism. Measurement of the TRAb concentration in maternal serum before delivery is helpful since a high level is predictive of neonatal thyrotoxicosis. Hyperthyroidism occurs in 2%–10% of babies born to women with active Graves' disease.

Antithyroid drugs may be teratogenic and birth defects of all types are observed in 2%–3% of exposed children. The high risk period encompasses gestational weeks 6–10, the major period of organogenesis. Birth defects are more severe in newborns of CBZ/

MMI (the "CBZ/MMI embryopathy" representing approximately less than half of all defects: choanal atresia, esophageal atresia, omphalocele, omphalomesenteric duct abnormalities, aplasia cutis) than PTU (urinary system, face and neck region malformations) treated mothers. Consequently, PTU should be preferred as early as possible in the first trimester of pregnancy, or even prior to conception and patients on CBZ/MMI should be switched to PTU (Andersen *et al.*, 2013). Subsequently, patients may be switched back to CBZ/MMI.

Antithyroid Drugs and Breast-Feeding

In hyperthyroid patients in whom lactation is not impaired antithyroid drug treatment is not a contraindication to breast-feeding. Only minute amounts of the antithyroid drugs are detected in breast milk ranging from 0.01% to 0.1% for PTU and CBZ/MMI, respectively, providing the baby with a dose well below a therapeutically active dose. Nevertheless, it is recommended that the dose of antithyroid drug to the mother should not exceed 20 mg/day dot CBZ/MMI or 450 mg/d for PTU. A classical well-controlled dose–effect study of 88 lactating mothers treated with doses of MMI up to 20 mg daily showed no deleterious effects in thyroid function and physical and intellectual development of breast-fed infants (Azizi *et al.*, 2000).

Radioactive Iodine☆

Barbara Jarzab and Jolanta Krajewska, Maria Sklodowska-Curie Memorial Institute - Cancer Center, Gliwice, Poland

Glossary

Differentiated thyroid cancer The most common endocrine malignant neoplasm arising from the follicular thyroid cell, which exhibits thyroid differentiation features.

Hyperthyroidism An excessive production of thyroid hormone by the thyroid gland in the course of Graves' disease, multinodular goiter with autonomous nodule, and/or autonomously functioning thyroid nodule.

Radioactive iodine (RAI) Radioisotopes of iodine used in the diagnostics and treatment of benign thyroid diseases and thyroid cancer, mainly I-131 (therapy) and/or I-123 (diagnostics).

Introduction

Iodine plays an essential role for normal functioning of the thyroid gland, its homeostasis, and thyroxine (T4) and triiodothyronine (T3) production. Iodine is actively transported into thyroid cells via the sodium–iodide symporter (NIS) and accumulates in the thyroid follicles being a substrate for thyroid hormone production. Normal thyroid takes up to 20%–30% of orally administered iodine, whereas in patients with hyperthyroidism this rate may increase even up to 80%.

The ability to uptake radioiodine (RAI) by thyroid cells in the same way as normal nonradioactive iodine was reported in the late 1930s. The first therapeutic RAI activity was administered to a patient with Graves' disease by Dr. Saul Herz in Massachusetts General Hospital in early 1941. In 1942 Keston and coworkers demonstrated RAI avidity in metastatic lesions of differentiated thyroid carcinoma (DTC). A year later, in 1943 in New York, United States, Dr. Samuel Seidlin applied RAI for the first time in a clinical practice to treat metastatic DTC. During the subsequent years RAI has been widely implemented in clinical thyroidology. Currently RAI is used in diagnostics and treatment of both benign thyroid diseases and DTC.

Radiation Physics

Only two among more than 20 known iodine radioactive isotopes are used in a daily clinical practice: I-123 for diagnostics and I-131 for both diagnostics and treatment. Iodine-131 is a beta- and gamma-emitter (principle $\beta^{-} = 0.807$ MeV; gamma rays ranging from 80 to 637, mainly 364 keV), showing a physical half-life of 8.02 days. Gamma radiation is related to the necessity of patients' isolation and the use of a strict radiation protection in treated subjects, whereas beta radiation serves for therapeutic purposes. The average range of the 0.807 MeV beta particles in soft tissues is about 1–2 mm, what results in high intrathyroidal/intratumor doses. Beta decay is responsible for causing DNA mutation and death in affected cells and other cells up to several millimeters away. For this reason, lower doses of I-131 may be more dangerous than higher doses, since they do not kill thyroid cells and may lead to cancerogenesis as a result of the irradiation. Therefore I-131 administration, particularly its lower activity in children is disputable.

Iodine-123 is characterized by a shorter half-life of 13.13 h and lower gamma radiation emission energy of 159 keV. It does not emit beta radiation. Such properties make I-123 an excellent isotope for thyroid imaging. It delivers far less radiation (1%) to the thyroid that of I-131. In addition the use of I-123 in the DTC diagnostics is not related to so called "stunning" of the tissue and loss of RAI avidity due to its low radiation burden. However, a high cost limits a clinical use of I-123.

Technetium-99m (Tc-99m) is another radioisotope used in the diagnostics of thyroid diseases, also transported into thyroid cells via NIS. It emits gamma rays with photon energy of 140 keV and half-life of nearly 6 h.

Biological Effects of RAI

Radioiodine administration leads to direct and indirect radiobiological effects on affected tissues. The direct effect is related to ionization of the thyroid cell and results in DNA damage, whereas indirect effect leads to the production of free radicals that react with the critical macromolecules.

☆*Change History:* February 2018. Barbara Jarzab and Jolanta Krajewska prepared the update. The following sections have been updated: Introduction; Radiation Physics; Biological Effects of RAI; Radioactive Iodine Uptake in Thyroid Function Testing and Imaging (currently: Radioactive Iodine in the Diagnostics of Thyroid Disorders and Radioactive Iodine in the Treatment of Thyroid Disease); Safety and Side Effects (currently: RAI Treatment-Related Complications). A new section "Contraindications for RAI Administration" has been added.

This article is an update of Amit Allahabadia and Jayne A. Franklyn, Iodine, Radioactive, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 100–102.

 doi:10.1016/B978-0-12-801238-3.96009-4

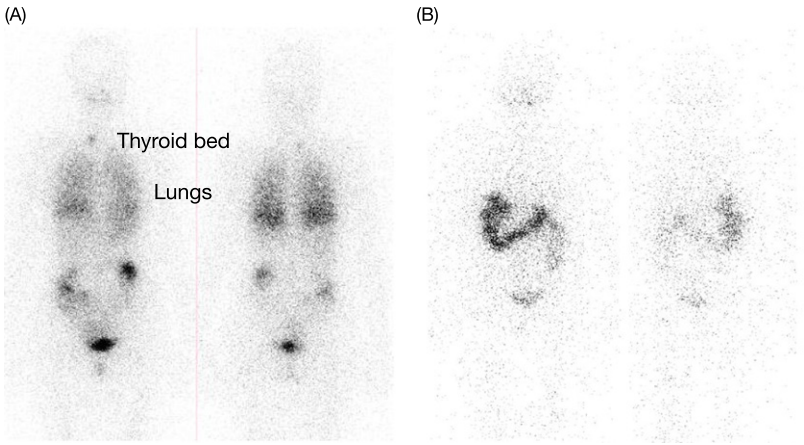

Fig. 1 Whole body scintigraphy in a DTC patient: (A) performed after the first RAI therapy—RAI uptake in thyroid bed and in both lungs; (B) performed after three courses of RAI treatment (complete remission). Physiological RAI uptake in digestive system and urinary tract is also present.

Among basic factors that determine the effectiveness of RAI therapy are the effective half-life of I-131, discrete energy of its β decay, the effective range of β radiation, used therapeutic activity, the ability to take up radioiodine, and the absorbed total radiation dose. The biological factors influencing the efficacy of RAI treatment in DTC are defined as "five R" and include radiosensitivity, repair, redistribution, reoxygenation, and repopulation (Suwiński and Gawkowska-Suwińska, 2001).

Radioactive Iodine in the Diagnostics of Thyroid Diseases

The use of RAI in the diagnostics of benign thyroid disease plays a minor role due to widely accessible thyroid sonography. Thyroid scanning allows visualization of the thyroid gland and functioning thyroid tissue elsewhere in the body, identifying the reason of hyperthyroidism, and evaluating thyroid enlargement and functionality of thyroid nodules. Currently, the indications for RAI thyroid scintigraphy in benign thyroid conditions are limited to patients, in whom RAI therapy is considered and in case of retrosternal goiter (technetium should not be used for the diagnostic of retrosternal goiter due to bone attenuation).

RAI uptake measurement is recommended in patients before RAI therapy to provide the information regarding the feasibility of RAI treatment and to calculate RAI activity.

Whole body RAI scintigraphy is still widely used in DTC patients. It allows visualization of the thyroid remnants and functioning, RAI-avid metastases (**Fig. 1**).

Radioactive Iodine in the Treatment of Thyroid Disease

Benign Thyroid Disease (Allahabadia and Franklyn, 2004; Stokkel *et al.*, 2010; Dietlein and Schmidt, 2014; Wong and Goh, 2014; Ross *et al.*, 2016)

The purpose of RAI therapy in benign thyroid disease is to resolve hyperthyroidism and/or to reduce the goiter volume. Indications for RAI administration involve the presence of a single toxic nodule, toxic nodular goiter, and Graves' disease. RAI treatment may be considered in selected cases of nontoxic nodular goiter, particularly in patients in whom surgery is contraindicated.

Pretreatment diagnostics should involve laboratory examinations (fT3, fT4, TSH, TRAb), thyroid scintigraphy (the assessment of the presence autonomous thyroid tissue or hypofunctioning lesions) with 24 h RAI uptake (at least 20% of administered RAI activity should be taken up by the thyroid gland to achieve a sufficient treatment effect), thyroid sonography (to assess thyroid volume and the presence of thyroid nodules), fine needle aspiration biopsy (to exclude malignancy), and pregnancy test (in women of childbearing potential).

Hyperthyroid patients are usually pretreated with antithyroid drugs to achieve clinical euthyreosis before RAI administration. One should remember that antithyroid drug has to be withdrawn at least 3–10 before RAI therapy because these drugs attenuate radiation effect in thyroid. Because RAI treatment of Graves' disease may lead to a transient exacerbation of hyperthyroidism, according to the American Guidelines β-adrenergic blockade should be considered even in asymptomatic patients. If it is clinically indicated antithyroid drug may be reintroduced 3–10 days following RAI administration. Patients with Graves' orbitopathy if not already on steroids therapy should be given prednisolone to avoid eye disease worsening after RAI administration.

Regarding autonomously functioning thyroid nodule TSH level before RAI treatment in patients with an autonomous thyroid nodule should be <0.1 uIU/mL to protect healthy thyroid tissue against radiation.

Recombinant human TSH (rhTSH) administration before RAI therapy may be considered to increase the absorbed radiation dose in selected cases of nontoxic nodular goiter. However, so far it is not a routine clinical practice.

The aim of RAI therapy in hyperthyroid patients is to restore euthyreosis, what is possible mainly in nonimmunological autonomous thyroid nodules. The only exception is Graves' disease in which RAI therapy has to result in hypothyroidism to effectively prevent recurrent hyperthyroidism. To calculate an optimal RAI activity to cure hyperthyroidism on one hand and to avoid hypothyroidism on the other hand is still challenging. The choice between estimation with administration of "fixed" RAI activities versus calculation, based on RAI uptake measurements, depends on physicians or site preference. Radioiodine doses used in the treatment of toxic or nontoxic nodular goiter have been already empirically established. The recommended absorbed radiation dose used in the treatment of toxic and nontoxic nodular goiter ranges between 100 and 150 Gy, requiring about 3.7–5.5 MBq per gram of thyroid tissue, corrected for the 24 h I-131 uptake. In patients with autonomous nodules the recommended absorbed radiation dose is 300–400 Gy. Considering patients with Graves' disease the lower absorbed RAI dose of ~150 Gy seems to be sufficient to restore euthyreosis because the radiosensitivity is higher than in other thyroid diseases. While higher absorbed doses, ranged between 200 and 300 Gy, are required for complete ablation of thyroid tissue.

Indications for RAI therapy in children, mainly due to Graves' disease are disputable due to a potential risk of development of thyroid carcinoma after irradiation. Children, who received RAI below the age of 5 years has twofold higher risk of thyroid neoplasm than children treated between 5 and 9 years of age and fivefold higher than children treated between 20 and 14 years of age. Therefore RAI therapy should be avoided in children below 5 years of age, whereas it may be considered in older children.

Differentiated Thyroid Cancer (Haugen *et al.*, 2016)

The ability to take up radioiodine is preserved in DTC cells therefore RAI has become a basic treatment modality in DTC. However, its routine use following thyroid surgery has been a matter of debate during the recent years, particularly in low-risk DTC due to the lack of unequivocal proofs, fulfilling evidence-based medicine criteria, confirming its efficacy. The primary goal of postoperative RAI administration after total thyroidectomy includes

(a) remnant ablation to facilitate further DTC monitoring and recurrence detection by thyroglobulin measurement or whole body scanning,
(b) adjuvant therapy to improve disease-free and overall survival by destroying potential undetected micrometastases, and
(c) RAI therapy to improve disease-specific and disease-free survival in high-risk patients.

Current 2016 ATA Guidelines (Haugen *et al.*, 2016) do not routinely recommend remnant ablation in ATA low-risk DTC. RAI adjuvant therapy should be considered in ATA intermediate-risk patients and it is definitely recommended for ATA high-risk patients. These guidelines met with EANM criticism (Verburg *et al.*, 2017). In case of RAI-avid inoperable, locally advanced or disseminated DTC RAI still constitutes the most effective first-line treatment.

ATA 2016 Guidelines (Haugen *et al.*, 2016) recommend a low RAI activity of 30 mCi for remnant ablation in patients after total thyroidectomy, whereas higher activities may be considered for patients after less than total or near-total thyroidectomy with a larger volume of thyroid remnants or for adjuvant treatment. When postoperative RAI therapy is given to treat suspected microscopic residual disease, in absence of macroscopic distant metastases, high RAI activities up to 150 mCi are recommended. Considering RAI therapy for loco-regional or metastatic DTC ATA 2016 Guidelines do not precise which method has to be used: empiric high RAI activity versus blood/or body dosimetry versus lesional dosimetry because there is a lack of evidences supporting of any approach.

DTC cells show expression of the genes responsible for RAI avidity (NIS, pendrin, and thyroid peroxidase genes), however this expression is significantly lower comparing to the normal thyroid cells. Moreover, there are some differences between primary tumor cells and metastases. Therefore a healthy thyroid tissue has to be surgically removed before RAI treatment. In addition, to increase RAI uptake in DTC lesions, TSH stimulation either by L-thyroxine withdrawal or rhTSH administration is necessary.

Considering pediatric DTC, the current ATA Guidelines for Children (Francis *et al.*, 2015) do not routinely recommend postoperative RAI treatment in low-risk DTC children, whereas intermediate and high-risk patients should first be evaluated for evidence of persistent disease. RAI administration is recommended only if persistent DTC is confirmed. Thyroxine withdrawal is preferred to achieve TSH stimulation in children. The routine administration of rhTSH is not recommended in children due to a limited data concerning its use in this age group. This recommendation also raised controversies in Europe. However, in selected cases, when endogenous stimulation has to be avoided due to comorbidities or is impossible, ATA Guidelines accept the use of rhTSH.

RAI Treatment-Related Complications

Acute Side-Effects

Benign thyroid disease: Acute radiation thyroiditis and transient goiter swelling may be observed in patients in whom RAI was given due to hyperthyroidism in the course of Graves' disease, toxic nodular goiter, or due nontoxic nodular goiter. Transient elevation of free T3 and T4, related to the release of thyroid hormone from disrupted thyroid cells, occurs usually approximately 7 days

following RAI administration. In some cases analgesics, β-blockers, or even steroids might be required. Some patients, particularly those with uncontrolled hyperthyroidism and large goiter, may develop thyroid storm. Autoimmune thyroiditis may be rarely noticed in patients with autonomous nodule or toxic goiter (Stokkel *et al.*, 2010).

Differentiated thyroid cancer: Acute radiation sialadenitis or gastrointestinal disturbances are common complication observed in DTC patients treated with higher RAI activities. Acute radiation thyroiditis may be observed in DTC patients with large thyroid remnants. Among other acute complications, noticed in DTC patients, are low platelets and leucocyte number due to transient myelosuppression, tumor swelling, or tumor bleeding. In rare cases, particularly when DTC metastases are localized in the central nervous system and respiratory tract, tumor swelling may be life threatening. In such cases RAI has to be administered under steroids cover (Suwiński and Gawkowska-Suwińska, 2001).

Late Side-Effects

Benign thyroid disease: Shorter cell survival, impaired replication of surviving thyroid cells, atrophy and fibrosis, and a chronic inflammatory response resembling Hashimoto thyroiditis are among long-term effects responsible for the development of hypothyroidism following RAI treatment in hyperthyroidism and nontoxic nodular goiter. The risk of hypothyroidism increases over time therefore lifelong TSH monitoring is necessary. However, it has to be emphasized that in Graves' disease hypothyroidism is rather an unavoidable consequence than side effect (Stokkel *et al.*, 2010).

Differentiated thyroid cancer: Late RAI treatment-related side-effects, noticed in DTC patients, involve salivary glands fibrosis, lung fibrosis (in patients treated due to highly RAI-avid lung metastases), hypogonadism, and bone marrow aplasia. The estimated bone marrow absorbed dose after the administrated RAI activity of 100 mCi is 0.3–1.0 Gy. It should not exceed 2 Gy (Suwiński and Gawkowska-Suwińska, 2001).

Another important issue is the risk of radiation-induced neoplasms, among them leukemia, breast, urinary bladder, and colon cancer (Brown *et al.*, 2008; de Vathaire *et al.*, 1997; Rubino *et al.*, 2003). The risk of secondary malignancies in DTC patients treated with RAI may increase with higher RAI cumulated activity. A relative risk of the development of radiation-induced leukemia is approximately 2.3. Considering solid cancer a relative risk ranges between 1.2 and 2.5 and it may be even higher regarding breast cancer—3.4. However, one should remember that any paper analyzing the risk of secondary malignancies did not consider a possible genetic predisposition common for thyroid cancer and other neoplasms. However, the supporters of RAI therapy in DTC believe that benefits resulting from RAI administration significantly exceed the risk of potential secondary malignancies.

Contraindications for RAI Administration

Pregnancy constitutes of an absolute contraindication for RAI treatment. Also according to 2016 ATA Guidelines (Haugen *et al.*, 2016) women of childbearing potential should avoid pregnancy for 6–12 months following RAI therapy. Some specialists also recommend 3-month waiting period for men to avoid any potential transient chromosomal abnormalities.

Radioactive iodine should not be given to nursing women. 2016 ATA Guidelines (Haugen *et al.*, 2016) recommend to stop breastfeeding or pumping for at least 3 months before RAI administration. The use of dopaminergic agents may be useful to decrease breast exposure in recently nursing women, however the risk of serious side-effects related to their administration to suppress lactation should be considered.

Uncontrolled hyperthyroidism and tracheal stenosis constitute relative contraindications for RAI therapy in benign thyroid disease. RAI therapy may lead to transient elevation in free T3 and T4 levels approximately 7 days after RAI administration therefore patients should be pretreated with antithyroid drugs. It is worthy to be considered that antithyroid drugs protect thyroid against ionizing radiation. In rare cases, when antithyroid drugs or surgery are contraindicated I-131 may be given under the cover of steroids and β-blockers. A large goiter caused tracheal stenosis, with tracheal diameter <1 cm, may be treated with RAI under steroids cover. When tracheal diameter is <5–6 mm surgery rather than RAI is recommended due to a high risk of serious dyspnea after therapy (*Stokkel et al.*, 2010).

The association between RAI administration and the worsening of eye disease has been shown therefore EUGOGO and EANM Guidelines recommend the use of steroids cover in patients demonstrating eye symptoms, treated with RAI. According to EANM Guidelines severe Graves' orbitopathy is a contraindication for RAI therapy (Stokkel *et al.*, 2010), whereas EUGOGO statement is not so categorical (Bartalena *et al.*, 2016).

Hypersensitivity reaction is very unlikely due to very low stable iodine content of RAI preparations (0.05–0.18 μg).

Thyrotoxicosis Factitia☆

Fausto Bogazzi and Enio Martino, University of Pisa, Pisa, Italy

The term "thyrotoxicosis factitia" describes thyrotoxicosis due to the voluntary and surreptitious ingestion of excess thyroid hormone(s). The ingested thyroid hormone is most frequently represented by thyroxine (T4), but triiodothyronine (T3) or a mixture of these two hormones (T4 and T3) may be the product responsible for the occurrence of this syndrome.

Thyrotoxicosis factitia should be distinguished from iatrogenic thyrotoxicosis, which is related to excessive doses of thyroid hormones erroneously given by the physician or inadvertently taken by the patient (**Table 1**).

Thyrotoxicosis factitia is usually observed in psychiatrically disturbed patients. They are almost invariably women who have psychoneurotic disturbances such as obsessive preoccupation with body weight, conflict with gender identity, hysterical personality, and emotional instability. By voluntarily inducing thyrotoxicosis, they often seek attention of their partners to their "sickness." Alternatively, these women can be driven by the erroneous idea that thyroid hormones can help them to look younger or to lose weight. The main psychopathological disturbances range from anorexia to depression, anxiety panic disorder, or phobic disorders. Acute schizophrenia like psychosis has been reported as main clinical manifestation of thyrotoxicosis factitia in few cases.

Patients with thyrotoxicosis factitia usually deny the deliberate assumption of excess thyroid hormones. The age of these patients appears to have been increasing during recent decades (Bogazzi *et al.*, 1999).

Clinical Features

The clinical picture of thyrotoxicosis factitia does not differ from that of classical spontaneous hyperthyroidism (Bartalena *et al.*, 1996; Roti *et al.*, 1993). Patients may complain of tachycardia, tremors, loss of weight, increased perspiration, heat intolerance, extreme anxiety and nervousness, increased bowel activity and/or insomnia. Goiter and ophthalmopathy, as seen in Graves' disease, are absent. However, the presence of goiter does not exclude the diagnosis of thyrotoxicosis factitia. Thyroid pain and tenderness, commonly observed in subacute thyroiditis, are absent (**Table 1**). Cardiovascular complications (e.g., tachyarrhythmias, heart failure, myocardial infarction) as well bone loss (osteopenia) may occur as a consequence of prolonged excess thyroid hormone ingestion. These complications are more likely to take place in the older patients.

Poisoning with thyroid hormone may be particularly severe, in selected patients: the burst of enhanced, excessive sympathetic activity arising from thyrotoxicosis factitia has been proposed as a cause of Takotsubo cardiomyopathy (Tsao *et al.*, 2010); clinical presentation may consist in thyroid storm, febrile confusion and fatal malignant hyperthermia (Artl *et al.*, 2012).

Diagnosis

Diagnosis of thyrotoxicosis factitia requires a high grade of suspicion (Rose *et al.*, 1969; Cohen *et al.*, 1989).

Laboratory evaluation reveals the typical increase in free T4 (FT4) and free T3 (FT3) concentrations associated with undetectable serum thyrotropin (TSH) levels. An isolated increase in serum FT3 concentration associated with low/absent FT4 levels and suppressed TSH levels indicates that the ingested thyroid hormone preparation contained only T3. Circulating autoantibodies to thyroglobulin or thyroperoxidase, as well TSH receptor autoantibodies, responsible for Graves' disease, are usually absent. Thyroidal radioactive iodine uptake (RAIU) is characteristically very low or suppressed (**Table 2**). Scan should be extended to the abdomen, to exclude rare cases of struma ovarii. Serum thyroglobulin concentration is typically markedly reduced or undetectable in thyrotoxicosis factitia (Mariotti *et al.*, 1982; Hamolsky, 1982 and **Table 2**). Accordingly, its measurement is a useful tool for differentiating thyrotoxicosis factitia from other thyrotoxic conditions associated with low RAIU values (**Table 2**). However, the presence of thyroglobulin antibodies may generate either a false-positive or a

☆*Change History:* March 2018. Bogazzi and Martino updated Clinical Features, Diagnosis, References and Table 2.

This article is an update of Enio Martino, Fausto Bogazzi, Luigi Bartalena, Thyrotoxicosis Factitia, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 551-553.

Table 2 Differential diagnosis of main forms of thyrotoxicosis with low-suppressed thyroidal radioiodine uptake

	Subacute thyroiditis	*AIT2*	*Thyrotoxicosis factitia*	*Struma ovarii*
Serum free thyroid hormones	Increased	Increased	Increased	Increased
Serum TSH	Undetectable	Undetectable	Undetectable	Undetectable
Serum thyroglobulin	Increased	Increased/normal	Low/undetectable	Increased/normal
Urinary iodine excretion	Normal	Increased	Normal	Normal
Thyroid echogenicity	Markedly reduced and not homogeneous	Slightly reduced, homogeneous	Normal	Normal
Thyroidal increased vascularity	No	No	No	No
Thyroid pain/tenderness	Yes	No	No	No
Radioiodine abdomen uptake	No	No	No	Yes
Pathogenesis	Destructive thyroiditis	Destructive thyroiditis	Surreptitious ingestion of thyroid hormone	Ectopic functional thyroidal tissue
Duration	Weeks	Months	Unpredictable	Weeks to months

AIT, Amiodarone-induced thyrotoxicosis type 2 (i.e., destructive thyroiditis induced by amiodarone).

false-negative thyroglobulin result depending on the used immunoassays (Jahagirdar *et al.*, 2008). Measurement of thyroid hormones in stool may be useful for identifying the abnormally high fecal excretion of ingested thyroid hormones, particularly, in these patients (Bouillon *et al.*, 1993). Urinary iodine excretion is normal (**Table 2**). Color flow Doppler sonography of the thyroid shows an absent increased vascularity and normal-low peak systolic velocity in spite of the thyrotoxic state (Bogazzi *et al.*, 1999) (**Table 2**).

The patient usually denies the surreptitious thyroid hormone intake; in those situations, it may be necessary to hospitalize him or her to be sure that the deliberate ingestion does not continue. Under strict medical controls, a rapid improvement in the clinical and laboratory features of thyrotoxicosis is frequently observed after hospital release unless reasons for surreptitious thyroid hormone intake are identified.

Treatment

Treatment of thyrotoxicosis factitia obviously requires withdrawal of thyroid hormones. It may be useful to associate a short-term treatment with beta- adrenergic blocking drugs to control tachycardia and tremors promptly. However, for a full recovery of the patient, psychiatric aid or counseling is mandatory in all cases (Da Silva *et al.*, 2009).

Thyrotoxic Storm☆

Leonard Wartofsky, Georgetown University School of Medicine, Washington, DC, United States

Glossary

Euthyroid sick syndrome In patients with non-thyroidal systemic illness, laboratory tests that include a low total T4, a normal or high free T4, a normal TSH, and a low serum T3, that is a "low T3 syndrome".

Hemoperfusion Experimental technique of filtration of blood through extracorporeal special filters or adsorbents to remove excess thyroid hormone.

Hyperglycemia Elevated blood concentration of glucose.

Ophthalmopathy Pathologic condition of the orbital content; in Graves' disease marked by swollen eye muscles, increased fat content, conjunctival injection, proptosis, pressure sensation, and in most severe form, optic nerve compression and risk of blindness.

Proptosis Forward protrusion of the eye globes; exophthalmos.

Sick euthyroid syndrome A state of altered thyroid function tests in response to systemic illness without primary thyroid pathology. Laboratory tests typically include a low total T4, a normal or high free T4, a normal TSH, and a low serum T3, that is, a "low T3 syndrome".

Tachycardia A rapid heart rate, generally greater than 100 bpm.

Thyrotoxic storm Severe hyperthyroidism with systemic decompensation.

Clinical Features

Usually, the presentation of thyrotoxic storm follows some specific precipitating event such as surgery, burns, emotional stress, or even vigorous palpation of the thyroid gland. Most of these patients will have some or all of the classic signs and symptoms of thyrotoxicosis such as goiter and Graves' ophthalmopathy. However, in older patients, particularly those who may have an underlying toxic multinodular goiter rather than Graves' disease, the thyrotoxic storm may present as so-called masked or "apathetic" thyrotoxicosis. The clinical presentation includes tachyarrhythmias other than sinus tachycardia, and signs and symptoms of congestive heart failure may be present. Systolic hypertension with widened pulse pressure is a common finding at least initially. Cardiac compromise may be seen in relatively young and middle-aged patients without known antecedent cardiac disease. Postural hypotension in the common setting of volume depletion secondary to vomiting or diarrhea may be demonstrable. The extreme expression of the latter is with shock and vascular collapse, which has a very high risk of mortality. Gastrointestinal manifestations include presentations such as an acute abdomen, intestinal obstruction, diffuse abdominal pain, hepatomegaly, splenomegaly, and various abnormalities in liver function tests. Congestive failure or hepatic necrosis may cause the liver to be tender to palpation. The presence of jaundice is another serious prognostic sign.

Distinguishing between true storm and uncomplicated infection in a thyrotoxic patient may be quite difficult because of the likely presence of signs of tachycardia and fever in both. In such cases, fever that is seemingly out of proportion to an apparent infection along with profound diaphoresis strongly suggests thyrotoxic storm. It is imperative at this point to initiate an intensive treatment plan because no other clear-cut signal of the presence of thyrotoxic crisis may present itself prior to the inexorable decline of vital functions in the patient and an attendant high risk of mortality. As the thyroid crisis progresses, symptoms of central nervous system dysfunction may appear, including increasing agitation and emotional liability, confusion, paranoia, psychosis, and finally even frank coma.

Laboratory Findings

Diagnosing thyrotoxic storm using laboratory findings is extremely difficult because of relatively similar thyroid test results in storm as in uncomplicated thyrotoxicosis. Indeed, serum total triiodothyronine (T3) levels actually may be within normal limits, probably due to the fact that these patients have some underlying illness that precipitated the storm and that is responsible for altering the thyroid function tests in the direction of these patients, that is, congruent with the "low T3" or "euthyroid sick syndrome." This may initially obscure a diagnosis of coexistent thyrotoxicosis. Perhaps the most rapid confirmation of the diagnosis in a patient with previously undiagnosed thyrotoxicosis may be obtained by performance of a 2-h radioiodine uptake, although it should be feasible to obtain the result of serum T4 determination within a few hours on an emergency basis in most

☆*Change History*: February 2018. Leonard Wartofsky did miscellaneous edit of text, expanded glossary, and updated and added new reference citations.

This article is an update of Leonard Wartofsky, Thyrotoxic storm, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 573-576.

hospitals today. However, initiation of therapy should not be postponed when there is a high index of suspicion merely because one is awaiting laboratory confirmation of the diagnosis.

Other laboratory abnormalities often include modest hyperglycemia in the absence of diabetes mellitus. Moderate leukocytosis with a mild shift to the left is common even in the absence of infection. Increased serum calcium levels may be seen, perhaps due to both hemoconcentration and the known effects of thyroid hormone on bone resorption, but other serum electrolytes are usually normal. Hepatic dysfunction in thyrotoxic storm will result in elevated levels of serum lactate dehydrogenase, aspartate aminotransferase, and bilirubin.

Because serum cortisol levels are usually slightly elevated in thyrotoxic individuals, a normal value may be interpreted as being inappropriately low. In view of the known coincidence of adrenal insufficiency with Graves' disease, one should maintain a reasonably high index of suspicion for this disorder, particularly if there is hypotension and suggestive electrolyte abnormalities. It would be prudent to obtain a serum sample for cortisol determination prior to the administration of corticosteroid. Even in the absence of adrenal insufficiency, adrenal reserve may be exceeded in thyrotoxic crisis due to the inability of the adrenal gland to meet the demand placed on it as a result of the accelerated turnover and disposal of glucocorticoids that occur in thyrotoxicosis.

Pathogenesis

The precise pathogenesis underlying the progression of uncomplicated hyperthyroidism to the precipitation of thyrotoxic storm is likely not to be the same in all cases and remains incompletely understood, although the magnitude of serum hormone levels per se does not appear to be a critical factor. However, acute discharge of hormone from the thyroid gland resulting in rather sudden changes of its concentration, in the appropriate clinical setting, certainly can trigger crisis. This may be seen after 131-I therapy, withdrawal of propylthiouracil (PTU) therapy, vigorous palpation of the thyroid, or administration of lithium, stable iodine, or iodinated contrast dyes.

A possible interaction between the effects of excessive levels of circulating thyroid hormone and the catecholamines has been proposed. This is evidenced by the dramatic clinical improvement that follows the use of agents that either deplete their tissue levels, such as reserpine, or block β-adrenergic receptors, such as propranolol. Although these agents are useful adjuncts to therapy, they should not be used by themselves because they might not prevent the occurrence of storm.

Treatment

We believe that to avoid a fatal outcome, it is important to implement a four-pronged approach to the management of thyrotoxic storm. The relative importance for survival of each arm of therapy will vary in a given patient. First, specific antithyroid drugs must be used to decrease the increased thyroid production and release of thyroxine (T4) and T3. The second part of management consists of treatment intended to block the effects of the remaining, but excessive, circulating concentrations of free T4 and T3. The third component addresses any underlying precipitating illness such as infection or ketoacidosis. The final arm of therapy is composed of those several specific treatments that are directed against the underlying systemic decompensation that may be characterized by fever, congestive failure, shock, and the like. In view of the poor prognosis associated with incompletely treated thyrotoxic storm, no one component of this four-pronged therapeutic approach should be neglected.

Therapy Directed Against the Thyroid Gland

Inhibition of new synthesis of the thyroid hormones is achieved by administration of thionamide antithyroid drugs, such as PTU and methimazole (Tapazole), given orally. There are no available parenteral preparations of these compounds in the United States although intravenous PTU or methimazole may be available in parts of Europe. Either methimazole or PTU may also be administered via the rectum if necessary. In view of the gravity of thyrotoxic storm, thionamide doses are much higher than those for otherwise uncomplicated thyrotoxicosis. Some experienced clinicians believe that PTU will provide more rapid clinical improvement because it has the additional advantage of inhibiting conversion of T4 to T3, a property not shared by methimazole. Separate treatment must be administered to inhibit the continuing release of T4 and T3 into the blood because thionamides act to reduce new hormone synthesis but have no effect on thyroidal secretion of preformed stores of hormone. Either inorganic iodine or lithium carbonate may be used for this purpose. Iodides may be given either orally as Lugol's solution or as a saturated solution of potassium iodide (eight drops every 6 h). When iodine is administered together with full doses of antithyroid drugs, dramatic decreases in serum T4 can be seen. The sequence of administration of these agents is extremely important. Use of iodine without prior thionamide dose is contraindicated because the iodine will provide extra substrate to enrich hormone stores within the gland, thereby generating the potential for further exaggeration of thyrotoxicosis.

In patients who may be allergic to iodine, lithium carbonate may be used as an alternative agent to inhibit hormonal release, although some caution has been raised in regard to its use in the setting of storm. This drug also may be used in thyrotoxic patients who are known to have serious toxic reactions to the thionamides.

Therapy Directed Against Ongoing Effects of Thyroid Hormone in the Periphery

For the purpose of acutely reducing the circulating hormones, peritoneal dialysis and plasmapheresis have been employed, as has experimental hemoperfusion through a resin bed or charcoal columns. Such aggressive management should be considered in severe cases.

Beta blockers are also commonly used. Propranolol is the agent most commonly used in the United States today. Large doses, such as 60 to 120 mg every 6 h, are used in crisis or impending crisis. Indeed, because of the more rapid metabolism of the drug in severe thyrotoxicosis, even larger oral doses, or preferably intravenous doses, should be given. Initial intravenous doses should be given cautiously, whereas the patient's cardiac rhythm is monitored continuously. Added benefits of β-adrenergic blockade in these patients include improvement in agitation, convulsions, psychotic behavior, tremor, diarrhea, fever, and diaphoresis. Very short-acting β-adrenergic antagonists, such as esmolol or landiolol, can be given intravenously instead of propranolol. For esmolol, an initial intravenous dose is 0.25 to 0.5 mg/kg given in 5 to 10 min, followed by a continuous infusion of 0.05 to 0.1 mg/kg/min. For patients with asthma or who present other concerns if treated with beta blockers, short half-life calcium antagonists such as verapamil have been employed.

Therapy Directed Against the Precipitating Illness

In most cases of thyrotoxic storm, therapy is not complete unless a diagnosis of the possible precipitating event is made and early treatment as indicated for that underlying illness is implemented.

It is important to be alert to the fact that conditions such as ketoacidosis, pulmonary thromboembolism, and stroke may underlie thyrotoxic crisis, particularly in the obtunded or psychotic patient, and require the same vigorous management ordinarily indicated. In the patient with thyrotoxic crisis in whom none of the latter precipitating factors is apparent, a diligent search for some focus of infection must be carried out. Empirical, broad-spectrum antibiotic coverage may be warranted while awaiting results of cultures. In most patients who survive thyrotoxic crisis, clinical improvement is dramatic and demonstrable within 12–24 h.

Therapy Directed Against Systemic Decompensation

Fluid depletion caused by the hyperpyrexia, diaphoresis, vomiting, or diarrhea must be vigorously replaced to avoid vascular collapse. Fluid management must be individualized. Shock may be refractory to cautious fluid resuscitation in younger patients, whereas judicious replacement of fluids is necessary in elderly patients with congestive heart failure or other cardiac compromise. Intravenous fluids containing 10% dextrose in addition to electrolytes will allow repletion of the depleted hepatic glycogen. For fever, acetaminophen, rather than salicylates, is the preferred antipyretic because salicylates inhibit thyroid hormone binding and could increase free hormone, thereby transiently worsening the thyrotoxic crisis.

Vasopressor therapy may become necessary on a temporary basis to provide adequate hemodynamic support if hydration with intravenous fluid replacement is not effective. Stress dose glucocorticoids have been given on empirical grounds on the basis of postulated relative adrenal insufficiency. This approach has the added benefit of further blockade of peripheral conversion of T4 to T3, and this is an additional justification for their use.

Graves' Disease☆

Irene Campi, University of Milan, Milan, Italy
Mario Salvi, Fondazione IRCCS Cà Granda, Milan, Italy and University of Milan, Milan, Italy

Glossary

Antigen presenting cells (APCs) APCs are immune cells mediating immune responses by processing and presenting antigens to lymphocytes. APCs include dendritic cells, macrophages, Langerhans cells and B cells.

Autoantibody An antibody directed against one or more of the patient's own (self) proteins.

Autoimmunity Dysregulation of the immune system leading to recognition of "self" components (autoantigens), which are attacked by autoantibodies and/or autoreactive T lymphocytes.

Dyscrasia The term derived from the ancient Greek medicine meaning the imbalance of the four humors which were believed to be present in the body: blood, black bile, yellow bile, and phlegm. This imbalance was considered the direct cause of all disease.

Glycosaminoglycans (GAGs) GAGs are long unbranched polysaccharides consisting of a repeating disaccharide unit. Hyaluronic acid is the GAG most commonly found in thyroid dermopathy.

Goiter An enlarged thyroid gland.

Gut microbiota (formerly called gut flora) Gut microbiota is the microbe population living in the intestine, Its role in human health and disease is becoming clearer when high throughput sequencing technologies have become available.

Hyperthyroidism A condition caused by increased secretion of thyroid hormones by the thyroid gland, leading to a hypermetabolic state and overactivity of the sympathetic nerve system.

Next generation sequence Next generation sequence is a high-throughput sequencing allowing to sequence DNA and RNA much more quickly and cheaply than the previously used Sanger sequencing.

Radioiodine or radioactive iodine Radioactive isotopes of iodine: 123I is used for diagnostic (thyroid scan) purposes, while 131I is used to achieve thyroid ablation.

Single nucleotide polymorphisms (SNPs) SNPs are the most common type of genetic variation among people. Although most SNPs have no effect on health, some of these may help to predict an individual's response to certain drugs, susceptibility to environmental factors such as toxins, and risk of developing diseases.

Susceptibility locus An allele that increases the risk of disease occurrence, but is neither necessary nor sufficient for disease expression.

TSH receptor (TSHR) Receptor for thyroid-stimulating hormone (TSH) secreted by the pituitary; through binding to its receptor, TSH stimulates thyroid hormone synthesis and secretion.

Introduction

The first descriptions of autoimmune hyperthyroidism were reported from 1802 to 1840 by four physicians (Parry, Flajani, Graves, and Basedow). However the real etiology was discovered only in the 1950s and 1960s when thyroid stimulating class G immunoglobulins were identified. Interestingly, Basedow in his original publication hypothesized that the combination of tachycardia, goiter and exophthalmos was due by a dyscrasia of the blood, suggesting that a circulating factor was responsible for syndrome.

Graves' disease (GD) is the most common cause of hyperthyroidism in iodine sufficient areas: the annual incidence rate has been estimated of 14–50 cases per 100,000 persons.

Although, the disease may affect every age, the peak incidence is between 30 and 50 years. The lifetime risk of developing GD is higher in women compared to men, with a 6:1 ratio.

Etiology

GD is an autoimmune disorder but its etiology is not completely understood and is likely multifactorial, as a result of a combination of genetic and environmental factors.

☆*Change History:* March 2018. Irene Campi and Mario Salvi have added Keywords and Etiology and Pathogenesis paragraphs have been updated and expanded. Diagnosis and Therapy paragraphs have been added and Table 1 has been included. The list of references has been updated.

This article is an update of Mark F. Prummel, Graves' Disease, Hyperthyroidism in, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, pp. 354–356.

 doi:10.1016/B978-0-12-801238-3.98495-2

Genetic Factors

The familial clustering and the studies in twins suggest genetic factors in the pathogenesis of the disease. Wiersinga et al. found that 33% of the families included in a study had cooccurrence of Hashimoto's thyroiditis (HT) and GD indicating a common genetic basis for autoimmune thyroid disorders (AITD). HLA loci have been associated with an increased risk of GD development in different population, in particular HLA-B8 and HLA-DR3 in Caucasians, HLA-A2 in Japanese, and of HLA-B46 in Chinese.

With next generation sequence (NGS) techniques, several other susceptibility loci for GD have been identified. In particular, two SNP locates in intron 1 the TSHR gene have been found in two large independent Caucasian datasets of GD patients; another locus associated with GD predisposition is CD40, which is a well-known gene regulating B-cell responses. Thyroglobulin, CTLA-4 and *PTPN22* have been associated with both GD and HT. The R620W SNP of *PTPN22* (*gene coding for* lymphoid tyrosine phosphatase) is a gain of function variant that enhance the inhibitory properties of the protein on T cells. This may confer a sort of resistance of self-reactive T cells from thymic deletion, thus inducing autoimmune reactions. Genetic factors may also influence the severity of GD: CTLA-4 polymorphism are associated with GO development.

Environmental Factors

Iodine intake may have a role in the development of GD, since the prevalence of hyperthyroidism is higher in iodine-deficient than in iodine-sufficient areas. In 1991, Laurberg et al. conducted a survey in two European areas with a divergent iodine intake (East-Jutland and Iceland with low and high iodine intake, respectively) and found that hyperthyroidism from toxic nodular goiter was more common in East-Jutland, while the incidence of GD was significantly higher in Iceland, especially in younger individuals. In a relatively isolate rural population of Italy, an increased incidence of HT and hypothyroidism was found 15 years following a salt iodization program. The risk of development of Graves' orbitopathy does not seem not influenced by salt iodization.

Infectious diseases have been often evoked as a potential trigger for autoimmunity. It has been suggested that viral infections, by increasing serum IFN-α levels, may increase the risk of GD. Yersinia enterocolitica (YE) might cause GD by a mechanism of molecular mimicry of the outer membrane porin F protein of the bacterium and a leucine-rich domain of TSHR. Healthy female relatives of AITD patients have been found to have an increased prevalence of anti-YE antibodies. In contrast, a prospective study did not find any correlation between YE infection and the development of thyroid dysfunctions or de-novo occurrence of thyroid antibodies. Recently, the role of gut microbiota has been investigated; Zhou L et al. found a decrease of Bifidobacterium and Lactobacillus and an increase of Enterococcus in hyperthyroid patients compared with controls. Further studies are needed to better understand these issues; data coming from a EU funded project, which is currently exploring the role of gut microbiota and antibody responses of food derived antigens in GD, will probably increase our knowledge on the pathogenesis of GD (Covelli & Ludgate). Smoking, which is an established risk factor for GO, also increases the risk of developing GD.

Pathogenesis

Hyperthyroidism is caused by autoantibodies against the TSH receptor (TRAbs) which mimic the action of its natural ligand (TSH). The biochemical feature of GD is characterized by high circulating free thyroid hormones (TH) causing TSH suppression, due to negative feed-back of TH on the pituitary gland. The elevated serum FT3 concentrations found in GD are mainly due to the increased intrathyroidal conversion of T4 to T3 by deiodinase type 2 (DIO2). Whether TRAbs are also responsible for the extrathyroidal manifestations of GD (GO, pretibial myxedema and acropachy) is still controversial. Although the TSHR is expressed on fibroblasts derived from orbital retrobulbar tissues and the pretibial skin, the coexpression of other antigens such as the IGF-1 receptor has been evoked as a potential trigger for GO. Autoantibodies against thyroid peroxidase (TPO-Ab) are also detected in approximately 70% of GD patients and their titers are related to the degree of lymphocytic infiltration of the thyroid gland in Hashimoto's thyroiditis (HT). The importance of these antibodies in GD is unclear, but they may explain why some patients with long standing GD become hypothyroid. In addition, the occurrence of primary hypothyroidism in GD patients may also be due to the presence of TRAbs with a TSHR-antagonist action.

Diagnosis

GD diagnosis is usually straightforward especially when extrathyroid manifestations are present. The clinical manifestations of an overt hyperthyroidism are generally easily recognizable (**Table 1**).

TSH and FT4 assay are often used as a first line test to confirm the diagnosis of GD.

Thyroid ultrasonography (US) is the most cost-effective way to image the thyroid gland; in GD US scan is useful to estimate the thyroid volume and to study palpable nodules; the estimation of thyroid volume is particularly useful in order to plan future therapies such as radioiodine or total thyroidectomy.

Although not essential, nowadays TRAb are routinely measured to support the diagnosis of GD and to predict response to therapy, since this assay has become easily available. TRAb are also important to predict the risk of neonatal hyperthyroidism in newborn of woman affected with GD, even in those previously submitted to radioiodine (RAI) or total thyroidectomy.

Table 1 Signs and symptoms of hyperthyroidism

Hyperthyroidism
Heat *intolerance* and excessive sweating
Weight loss with increased appetite
Goiter, thyroid thrill and bruit
Irritability, emotional lability, insomnia, hyperkinetic behavior
Fatigue, muscle wasting, and weakness
Tachycardia, rarely paroxysmal tachycardia, arrhythmias (atrial fibrillation), dyspnea, and angina
Tremors
Rarely hypokalemic periodic paralysis (more common in Asians)
Menstrual irregularity or amenorrhea, infertility
Increased frequency of stools
Polyuria
Ankle edema (without cardiac disease)
Thinning of hair, alopecia, change in texture of skin and nails (onycholysis)
Hypermetric reflexes
Graves' Orbitopathy and other systemic manifestation
Exophthalmos
lids edema
Lid retraction
Pain or irritation of eyes
Blurred vision/diplopia
Lid lag
Chemosis
Decreased visual acuity and decreased color discrimination in case of optic neuropathy
Pretibial myxedema
Acropachy
Hyperpigmentation or vitiligo

Therapy

The therapy of Graves' disease (GD), aims at achieving restoration of euthyroidism as rapidly as possible, especially when associated to GO. In fact, rapid control of hyperthyroidism may induce spontaneous improvement of milder GO and may increase responsiveness to immunosuppressive treatments for moderate to severe GO. Available treatments for Graves' hyperthyroidism include antithyroid drugs as the initial approach, and subsequent definitive ablation of thyroid tissue by surgery or radioiodine therapy.

The choice among the different therapeutic approaches for GD is based on several considerations such as the patient's age, thyroid volume, the presence and the degree of GO. Thioamides are the most common anti thyroid drugs which act by inhibiting the enzyme thyroid peroxidase, thus reducing the synthesis of TH in the thyroid; propylthiouracil (PTU) also has an inhibitory effect on DIO2. Methimazole (MMI) and carbimazole (CMI) (converted in vivo to MMI) are the first choice, because of their higher efficiency and low toxicity, while PTU is preferred during the first trimester of pregnancy or in case of intolerance to MMI/CMI. Thioamides are usually well tolerated; the most common side effect of MMI, found in about 10% of the patients, is a skin reaction (urticaria and dermatitis) which is generally responsive to antihistamines and reversible with the titration of the drug. PTU has been associated with hepatic failure. Agranulocytosis is an uncommon but severe side effect of thioamides and requires discontinuation of the drug.

Restoration of permanent euthyroidism is generally obtained only after radioiodine (RAI) or surgery, as spontaneous remission of hyperthyroidism after MMI discontinuation is infrequent. In patients with or without preexisting GO, low dose steroid prophylaxis should be prescribed after RAI, in order to prevent worsening or de novo occurrence of GO. No conclusive data are available so far in the literature on the possible risk of GO reactivation after thyroidectomy.

Extrathyroid Manifestations of Graves' Disease

Orbitopathy, pretibial myxedema (PTM) and thyroid *acropachy* are extrathyroid manifestations that may occur in patients with GD. Hyperthyroidism is the most common manifestation, and some ophthalmopathy occurs in 25%–50% of these patients, although severe eye disease is rather rare and develops in only approximately 5% of patients. Pretibial myxedema or dermopathy is present in 1% of patients, usually in those with GO. Acropachy is even less frequent and it is associated with both GO and PTM. It is characterized by digital clubbing, swelling of digits and toes, and periosteal reaction of extremity bones. Skin biopsy demonstrates typical findings of pretibial myxedema (fibroblast activation and glycosaminoglycan deposition). Although isolated case of

GO (the so-called euthyroid GO or EGO), PTM and *acropachy* have been described, these signs are usually correlated with the degree of severity of the autoimmune process.

The natural course of GD suggests that the thyroid disorder and GO are pathogenically linked. In fact, it supports the theory of GD as a multiple-organ disease: autoantibodies against a thyroidal antigen may cross-react with a similar antigen in the skin and the retrobulbar tissues. Radioactive iodine treatment leads to a slow destruction of the thyroid, and thyroidal proteins (including the TSH receptor) leak into the circulation and are presented to the immune system. A minority of patients subsequently mount an autoimmune response to the TSH receptor, leading to hyperthyroidism, and a small number also develop GO. The nature of this antigen is unknown, but the TSH receptor is a good candidate because TSH receptor autoantibodies are the cause of the hyperthyroidism and the TSH receptor is expressed on retrobulbar fibroblasts and possibly also on skin fibroblasts in patients affected by PTM.

Hyperthyroidism in Graves' Disease☆

Danila Covelli and Mario Salvi, University of Milan, Milan, Italy

Glossary

Hyperthyroidism Overproduction of thyroxine and triiodothyronine by an overactive thyroid gland.

Orbitopathy Inflammatory condition of the orbital tissues causing protrusion of the eye globe and diplopia. Most frequent extrathyroidal manifestation of Graves' disease.

Pretibial myxedema and acropachy Other more rare extrathyroidal manifestations of Graves' disease characterized by remodeling of the dermis and of the bone-connective tissue of the extremities.

T_3 receptor Receptor for triiodothyronine (T_3) present in the cytoplasm and nucleus of most human cells; after T_3 binding, this T_3 receptor complex influences gene transcription.

Thyrotoxicosis Elevated thyroxine (T_4) and triiodothyronine (T_3) levels, regardless of their cause; may result from an overactive thyroid gland, but also may result from exogenous T_4 and/or T_3 use or from destruction of the thyroid gland.

Thyroxine (T_4) Inactive prohormone produced by the thyroid gland and containing four iodine atoms.

Triiodothyronine (T_3) The active thyroid hormone mainly produced locally in the tissues by deiodination of thyroxine; approximately 20% of circulating T_3 is produced by the thyroid gland itself.

TSH—receptor The target of TSH in a physiological state and of autoreactive immunoglobulins in Graves' hyperthyroidism.

Thionamides Antithyroid drugs such as methimazole, carbimazole and propylthiouracil.

Introduction

Hyperthyroidism is the main clinical feature of Graves' disease (GD) and is due to the excess of thyroid hormones produced by follicular cells, as a result of stimulation by autoantibodies against the thyroid-stimulating hormone (TSH) receptor.

Manifestations of hyperthyroidism in Graves' patients were first described by Caleb Perry in the first half of 19th century but the link with thyroid hyperfunction was recognized only after the description of Robert Graves and Karl A. von Basedow.

As in all autoimmune diseases, when self-tolerance is broken, T cells recognize self-antigens and B cells produce antibodies targeting host cells. In this case, autoantibodies are directed against the TSH receptor. The binding of these antibodies causes an overfunction of the follicular cell, and thus thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), thyroglobulin and small amounts of an iodinated albumin-like protein and iodotyrosines are released into the blood stream at increased rates.

The overproduction of hormones by the thyroid itself is defined as hyperthyroidism and is the main cause of thyrotoxicosis, the clinical pattern due to the exposure of peripheral tissues to excess thyroid hormones.

Clinical Manifestations

The presenting symptoms are mainly attributable to the effect of the excessive serum concentrations of thyroid hormones; ocular changes and abnormalities of the skin and connective tissue are instead more related to the multi-organ autoimmune involvement.

The classical clinical picture includes weight loss, despite increased appetite, weakness, dyspnea, palpitations, increased bowel movement, irritability, profuse sweating, sensitivity to heat or increased tolerance to cold and tremor. The most common clinical manifestations are outlined in **Table 1**.

The involvement of the entire body in the hyperthyroid syndrome is due to the widespread distribution of T_3 receptors in tissues, although the cardiovascular system and the muscles are the main targets for thyroid hormones. Tachycardia is the most common clinical sign of hyperthyroidism and it may eventually lead to atrial fibrillation, especially in elderly patients. A recent study has shown that older age, elevated serum free T4 concentrations at diagnosis and male gender were independently associated with the risk of atrial fibrillation (Boelaert *et al.*, 2010).

In hyperthyroid patients a fine, rapid tremor of the outstretched fingers and generalized tremor, involving also the tongue, may be evident. Muscular weakness occurs in nearly all patients and this may lead to myalgia and fatigue of the larger proximal limb muscles. The weakness of respiratory muscles can induce dyspnea on exercise. 20%–40% of patients, mainly women, can experience friable nails and diffuse loss of scalp hair.

 doi:10.1016/B978-0-12-801238-3.98496-4

Table 1 Common clinical manifestations of thyrotoxicosis

Symptoms	Nervousness, hyperactivity
	Fatigue, weakness, diminished sleep
	Increased perspiration, heat intolerance
	Palpitations
	Tremor
	Weight loss despite increased appetite
	Menstrual disturbances
Signs	Hyperactivity
	Tachycardia, atrial fibrillation
	Systolic hypertension
	Warm moist skin
	Fine skin and hair
	Tremor
	Hyperreflexia
	Stare and eyelid retraction
Only in Graves' disease	Diffusely enlarged thyroid (goiter)
	Orbitopathy
	Pretibial myxedema and acropachy

The increased production of thyroid hormones initially may induce a condition of hyperactivity, which is perceived favorably by some patients, who may then delay the time of reporting to a doctor and therefore the time of diagnosis. Later on, nervousness, anxiety, irritability, attention deficits, and some memory loss may also be misinterpreted as a syndrome of anxiety or depression. The change in the body weight is variable: some patients are wasting, but on the average the weight loss in 2–10 kg. The weight loss is the most frequent complaint of hyperthyroid patients seeking medical advice.

Hyperdefecation is not uncommon and is associated with increased motility of the gastrointestinal tract. Interestingly, some studies have evidenced an imbalance of gut microbiota in hyperthyroid patients (Zhou *et al.*, 2014). Since the gut microbiota has an essential role in the function of the immune system, it would not be surprising that its alteration may be involved in the pathogenesis of Graves' disease. What is not clear at the moment is if the microbiota imbalance is the cause or the consequence of the bowel discomfort.

In women, oligomenorrhea is common, but fertility is not severely impaired. In men, there is no evidence of an effect of hyperthyroidism on spermatogenesis, but the biological activity of estrogens is increased and mild gynecomastia may be found.

The action of high thyroid hormones on the palpebral Muller's muscles generally induce lid retraction causing a sort of a frightened expression in the patient. This sign will disappear when the euthyroid state is restored. On the other hand, proptosis of the eyes, lid swelling, redness or edema of the conjunctiva and ocular pain or diplopia suggest associated orbitopathy (GO) and this needs to be accurately diagnosed and classified. Approximately one third of patients with GD have some evident clinical signs and/or symptoms of GO.

Most of the systemic effects of hyperthyroidism disappear when the euthyroid state is achieved. Interestingly, increasing age was associated with reduced adjusted odds ratio for the presence of most classical symptoms, except for weight loss and shortness of breath, and smokers had increased odds ratios for most symptoms (Boelaert *et al.*, 2010).

Mortality is increased in both treated and untreated hyperthyroidism and mainly in males (Schwensen *et al.*, 2017) and is related to the cumulative periods in which serum TSH concentrations are low. This implies that it may not be caused by the fact that the disease has not been treated, but rather to the inability to keep patients euthyroid during the course of therapy (Lillevang-Johansen *et al.*, 2017).

There is no clear evidence for direct toxic effects of elevated thyroid hormones on the liver, although a mild elevation of transaminases is common during the initial phase of the disease. Thus, liver function should be assessed at least once before starting thyrostatic drugs in order to be able to properly monitor the safety of the treatment. Serum alkaline phosphatase concentrations may correlate with serum T3, with a pattern showing an equal distribution of the bone and the liver isoenzyme. After therapy, serum alkaline phosphatase tends to increase, and the bone isoenzyme prevails, probably due to the skeletal repair (Cooper *et al.*, 1979). Patients with even mild increases in thyroid hormone lose bone mass, especially if postmenopausal and not receiving estrogen therapy. Severe and premature osteoporosis might be seen in disease with a longer duration or not properly treated. Even if the skeletal mass is recovered with therapy, bone density in not usually restored in the elderly (Cooper *et al.*, 1979). Hypercalcemia and hypercalciuria are common in hyperthyroid patients, but usually only moderate. While serum magnesium concentrations may decrease, serum phosphate concentrations are generally higher. Red blood cells may be microcytic, but anemia is usually not seen. Mild thrombocytopenia, due to shortened platelet survival may occur: if persistent after restoration of euthyroidism, autoimmune thrombocytopenia should be excluded.

Diagnosis

When only some of the signs and symptoms described above are present it may take long to consider a thyroid disease as the cause of the clinical manifestations. It is the combination of several signs and symptoms and their persistence that will lead the physician

to suspect hyperthyroidism. All patients with suspected hyperthyroidism should undergo a comprehensive history (including iodine intake or exposure, drugs, family history for thyroid and autoimmune diseases) and physical examination, including measurement of pulse rate, blood pressure, respiratory rate, and body weight. In addition, thyroid size, presence or absence of thyroid tenderness, symmetry and nodularity; pulmonary, cardiac, and neuromuscular function and presence of eye signs or pretibial myxedema should be assessed (Bahn *et al.*, 2011).

When thyrotoxicosis is suspected, the biochemical diagnosis is straightforward and characterized by elevated serum concentrations of T4 and T3 in the presence of low or undetectable serum TSH concentrations. Usually, both serum free T4 and T3 concentrations are elevated and in GD serum T3 is relatively higher than serum T4.

In milder hyperthyroidism, as in the earliest stages of GD, only serum T3 concentrations may be elevated (T3 toxicosis).

The presence of prominent eyes and lid retraction, the anxious behavior, the increased volume of the neck, due to the presence of a goiter, signs of ocular involvement and a family history of autoimmune disease help distinguish GD from other forms of hyperthyroidism (e.g., toxic multinodular goiter, toxic adenoma) or thyrotoxicosis (e.g., silent or subacute thyroiditis, exogenous thyroid hormone use). The measurement of serum TSH-receptor autoantibodies (TRAb) will help confirm this diagnosis.

A recent study has shown that the measurement of TRAb for the diagnosis of GD, when compared to radioactive iodine uptake (RAIU) determination, reduced costs by 47% and resulted in a 46% quicker diagnosis (McKee and Peyerl, 2012). TRAb bioassays have a sensitivity of 96%–97% and a specificity of 99% for GD (Diana *et al.*, 2017).There are two standardized methods for measuring serum TRAb. Third generation TSH Binding Inhibiting Immunoglobulin (TBII) competition assays are very precise but unable to distinguish the TSH-R antibody subtypes (stimulating or inhibitor). Newer bioassays for the Thyroid Stimulating Immunoglobulin (TSI) specifically detect simulating antibodies by measuring the ability of TSI to increase the intracellular level of cAMP.

RAIU should only be performed when the diagnosis is not clear, despite clinical examination, thyroid function assessment and TRAb detection. The iodine uptake pattern in GD is diffuse, unless there are coexistent nodules or fibrosis. Technetium 99 may also be used. The total body radiation exposure with technetium is lower than that with 123 iodine scintiscans.

When RAIU is contraindicated, such as during pregnancy or breastfeeding, thyroid ultrasound is performed. Increased color Doppler flow may be helpful in confirming the diagnosis of thyroid hyperactivity. About 70% of patients with GD have been reported to exhibit a low thyroid echogenicity pattern at ultrasonography (Vitti *et al.*, 1992). A thyroid scan should be performed also in the presence of thyroid nodularity at the neck examination or at a thyroid scintigram.

Management

The first goal of the treatment is to promptly alleviate the signs and symptoms of thyrotoxicosis. Physicians should recommend to temporarily avoid pregnancy to all thyrotoxic fertile women and to quit smoking, especially in patients who have some degree of ocular involvement.

Beta-adrenergic blocking drugs are recommended in all patients with symptomatic thyrotoxicosis, especially in elderly patients and those with resting heart rates in excess of 90 beats per minute or coexistent cardiovascular disease. In the latter, reduction of intense activity is also suggested.

Anti-thyroid drugs such as methimazole (MMI), carbimazole (CBZ; rapidly converted in methimazole in the serum) and propylthiouracil (PTU) reduce the synthesis and the secretion of thyroid hormones.

Initial daily therapy with 10–30 mg of MMI or CBZ or with 300–400 mg of PTU will render most patients euthyroid in 4–6 weeks. PTU has a shorter duration of action and is usually administered two or three times daily. When euthyroidism has been achieved, the physicians can choose between progressively decreasing the dose ("titration method") or maintaining the same dose and adding L-thyroxine ("block and replace treatment").

MMI or CBZ should not be used during the first trimester of pregnancy, when PTU is preferred, in the treatment of thyroid storm, and in patients with minor reactions to MMI who refuse RAI therapy or surgery. The most common side effects during thyrostatic treatment are a skin rash and mild abnormalities of liver function tests. Interestingly, thyrotoxicosis itself can induce cutaneous irritation and mildly abnormal liver function tests in up to 30% of patients and this may be misdiagnosed as an adverse effect of antithyroid drugs. Drug-induced cutaneous reactions are more common with PTU or higher dose MMI (30 mg/day) compared with lower dose MMI (15 mg/day) and usually appear after a median of 18–22 days of treatment, significantly earlier than transaminase elevations (median 28 days). They usually spontaneously regress in a few days, thus can be managed by using anti-histaminic drugs and not discontinuing the thyrostatic treatment. PTU may cause transient elevations of serum aminotransferases in approximately one-third of patients. Significant elevations to threefold above the upper limit of normal are seen in up to 4% of patients taking PTU, more than observed with MMI. Hepatotoxicity is usually seen in the first 120 days of treatment.

Agranulocytosis is a very rare, but life-threatening, event induced by thyrostatic drugs.

It occurs usually in the first 90 days of therapy and it manifests with acute pharyngitis and fever. Prompt discontinuation of the medical treatment is mandatory: this will generally allow the leukocyte count to normalize within a week.

No consensus exists on the usefulness of periodic monitoring of WBC counts and liver function tests for predicting drug-induced adverse reaction. Thus, patients have to be warned of discontinuing medications and measuring WBC in case of fever and sore-throat during therapy and to assess liver function in case of pruritic rash, jaundice, light-colored stool or dark urine, joint pain, abdominal pain or bloating, anorexia, nausea, or fatigue. A recent study provided evidence that switching from one thyrostatic

drug to another is safe as far as the occurrence of minor side effects, but not in the case of agranulocytosis or other serious side effects, because of the risk of cross-reactivity between anti-thyroid medications.

Serum TSH, free T4 and T3 should be tested about 4–6 weeks after initiation of therapy, depending on the severity of the thyrotoxicosis, and the dose of medication should be adjusted accordingly. TSH may remain suppressed for several weeks after starting therapy, therefore serum T3 and T4 concentrations are better variables for monitoring therapy. Anti-thyroid treatment is usually continued for 12–24 months, after which time up to 50% of patients may achieve remission of hyperthyroidism.

Measurement of serum TRAb levels before withdrawing thyrostatic drugs is suggested in order to assess the chances of remission. GD is considered in a remission phase when serum TSH, free T4, and T3 concentrations remain normal for 1 year after the discontinuation of anti-thyroid therapy. The remission rate varies considerably between geographical areas. A lower remission rate has been described in men, smokers (especially men), and those with large goiters (>80 g). Higher initial doses of MMI (60–80 mg/day) do not improve remission rates, while they increase the risk of side effects: thus they are not recommended.

During disease remission, thyroid function should be tested at 2- to 3-month intervals for the first 6 months, then at 4- to 6-month intervals for the following 6 months, and then every 6–12 months in order to eventually detect relapse as early as possible. The patient should be counseled to contact the treating physician if symptoms of hyperthyroidism are recognized or in case of an upcoming pregnancy. In general, factors that may predict remission are: a decrease in goiter size, normalization of serum TSH levels during treatment, decline or negativity of serum TSH receptor antibodies titers, and the patient not smoking.

If hyperthyroidism persists after 18–24 months of medical treatment or relapses soon after a period of remission, a definitive treatment by surgical thyroidectomy or radioactive iodine ablation (RAI) is suggested. In elderly patients, or in people with contraindication to RAI and surgery, a long term medical treatment may be continued as the only treatment option. Definitive treatment is also suggested in women planning a pregnancy: near-total or total thyroidectomy may be indicated if the woman desires pregnancy within 6 months, RAI ablation can otherwise be programmed at least 12 months before in particular situations.

The long-term quality of life (QoL) following treatment for GD was found to be the same in patients randomly allocated to either of the available treatment options. The goal of RAI therapy in GD is to control hyperthyroidism by rendering the patient hypothyroid; this treatment is very effective, provided that a sufficient radiation dose is taken up by the thyroid. This can be accomplished equally well by either administering a fixed 131-iodine activity or by calculating the dose based on the size of the thyroid and its ability to trap RAI. Low activities are not recommended in order to avoid more than one cycle of treatment. Thyrostatics must be withdrawn 2–3 days before RAI in order not to reduce the success rate of the treatment. A special diet is not required before RAI therapy, but nutritional supplements that may contain excess iodine and seaweeds should be avoided for at least 7 days.

RAI can induce a transient exacerbation of hyperthyroidism due both to follicular damage and increase of TRAb levels. Moreover persistent hyperthyroidism has been found to be associated with a long-term increase in cardiovascular and cerebrovascular deaths (Boelaert *et al.*, 2013). Thus, using beta-blockers or resuming anti-thyroid drugs 3–7 days after RAI might be considered in the presence of severe hyperthyroidism, in elderly patients and when severe comorbidity is an issue.

A recent meta-analysis found no increase in overall cancer risk after RAI treatment for hyperthyroidism, thus this treatment is a safe option. However, a trend towards increased risk of thyroid, stomach, and kidney cancer was also recently reported (Hieu *et al.*, 2012). Conception after RAI ablation should be delayed for at least 6–12 months and, anyway, until stable euthyroidism is achieved. In men, a delay of 3–4 months is suggested, to allow for turnover of sperm production.

Thyroid function must be assessed within the first 30–45 days after RAI and then monitored at 4- to 6-week intervals for 6 months, or until the patient becomes hypothyroid and is stable on thyroid hormone replacement. Hypothyroidism may occur from 4 weeks on, with 40% of patients being hypothyroid by 8 weeks and $>80\%$ by 16 weeks (Stan *et al.*, 2013). Since TSH may take longer to normalize or increase, FT4 should be the variable to be assessed also during the patients' follow-up and when serum FT4 concentrations fall below normal range, L-thyroxine replacement treatment should be commenced. Overt hypothyroidism should be avoided, especially in patients with GO, since it may trigger disease reactivation. If hyperthyroidism persists after 6–12 months following one cycle of RAI therapy, retreatment may be advised.

Surgical ablation is generally preferred for patients with larger goiters, in the presence of multinodular goiter or when the patients require a quick restoration of euthyroidism.

Patients should be rendered euthyroid prior to the surgical procedure with thyrostatic treatment, with or without beta-adrenergic block. Total thyroidectomy has a nearly 0% risk of recurrence, whereas near total thyroidectomy may result in 8% risk of persistence or recurrence of hyperthyroidism at 5 years (Guo *et al.*, 2013). The most common complications of total thyroidectomy are hypocalcemia due to hypopara-thyroidism, recurrent or superior laryngeal nerve injury, postoperative bleeding, and complications related to general anesthesia.

After thyroidectomy, L-thyroxine is started at a daily dose appropriate for the patient's weight and age, and serum TSH concentrations are first measured 6–8 weeks postoperatively. PTH and calcium levels need to be monitored in all patients immediately after surgery. The detection of low intact PTH concentrations (<10–15 pg/mL) in the immediate postoperative setting appears to predict symptomatic hypocalcemia and need for calcium and calcitriol (1,25 vitamin D) supplementation. Thus, postoperative routine supplementation with oral calcium and calcitriol is continued until serum calcium concentrations remain normal over a 24-h period, upon withdrawal.

In the pediatric population anti-thyroid drugs are the first-line treatment and MMI is preferred, since PTU is associated with an increased risk of hepatotoxicity, particularly in children. In case of disease relapse or persistent hyperthyroidism, RAI or surgical ablation are suggested following the same indications adopted for deciding therapy in the adult patients.

Glossary

Autoimmunity Dysregulation of the immune system leading to recognition of "self" components (autoantigens), which are attacked by autoantibodies and/or autoreactive T lymphocytes.

Glycosaminoglycans (GAGs) Long unbranched polysaccharides consisting of a repeating disaccharide unit. Hyaluronic acid is the GAG most commonly found in thyroid dermopathy.

Graves' disease Condition caused by anti-TSH receptor antibodies leading to increased secretion of thyroid hormones by the thyroid gland.

Graves' orbitopathy The most common extrathyroidal manifestation of Graves' disease characterized by inflammation of the peri- and retro-orbital tissues with forward displacement of the eye globe and altered ocular motility.

TSH receptor (TSHR) Receptor for thyroid-stimulating hormone (TSH) secreted by the pituitary; through binding to its receptor, TSH stimulates thyroid hormone synthesis and secretion.

Ultrasonography (US) Is a noninvasive procedure that can measure skin thickness, identifying two skin layers, the epidermis, dermis and subcutaneous tissue.

Introduction

Pretibial myxedema is an infiltrative lesion of the derma and the subcutaneous tissue, associated with autoimmune thyroid diseases (Smith *et al.*, 1989; DeGroot, 2000–2015), typically localized within the skin of the pretibial region, but occasionally described also in other areas of the limbs, such as the toes or the radial skin (Forgie *et al.*, 1994; Rice *et al.*, 2010; Singh *et al.*, 1985; Hasani-Ranjbar and Mohajeri-Tehrani, 2008). It was firstly described by Von Basedow in 1840 as a nonedematous fattening of the lower parts of the legs in a patient with thyrotoxicosis. The prevalence of pretibial myxedema has been estimated to be 0.5%–4% in patients with Graves' disease, and as high as 15% in those who have severe Graves' orbitopathy (Fatourechi, 2005) and markedly elevated serum TSH receptor antibodies (TRAb).

Etiology

Although the pathogenesis of pretibial myxedema is not known, it is thought that both mechanical and immunological factors may contribute to the pathophysiology of this disorder (Bahn, 2010). Prolonged standing and trauma to soft tissues may act as a trigger for the induction of pretibial myxedema, and once the immune reaction has been activated, the infiltrating T lymphocytes may lead to the release of cytokines, which then stimulate cell proliferation, the synthesis of glycosaminoglycans and the expression of immunomodulatory molecules (Bahn, 2010). Pretibial myxedema arises from the deposition of glycosaminoglycans, namely hyaluronic acid and chondroitin sulfate, either in the affected skin derma or in the surrounding tissues. Accordingly, the accumulation of these highly hydrophilic compounds produces edema and consequently the disruption of the dermal collagen and elastic fibers. This results in malfunctioning of the subcutaneous lymphatic network (Bull *et al.*, 1993).

Clinical Description

Pretibial myxedema has been classified into three clinical forms:

1. Diffuse pretibial myxedema: presented as diffusely cutaneous, but not definitely elevated over the surface of skin, of one-third to three fourths of the lower leg or more. The swelling is hard and is characterized by hyperpigmentation and/or nonpitting edema of the skin associated with dilated follicular openings;
2. Nodular- or plaque-like myxedema: the nodule is a circumscribed, solid lesion with a diameter of <2 cm. It can be elevated over the skin but is definitely palpable. A plaque is a superficial and flat-topped protrusion over the surface of skin, may be the only lesion or a major lesion of plaque variant. Its diameter is generally >1 cm. and the color may be reddish or pigmented.
3. Elephantiasic myxedema: this is characterized by a dramatic diffuse enlargement of the lower extremities with plaques, nodules, or masses scattered on the smooth or polypoid or papillary surface (Lan *et al.*, 2014; Chung-Leddon, 2001). The lesions of pretibial

Fig. 1 Clinical appearance of pretibial myxedema (PTM). (A) Nodular-like PTM. The hyperemic nodule is localized on the right pretibial region. (B) Plaque-like PTM: bilateral myxedematous lesions located on the tarsal area. (C) Elephantiasic PTM.

myxedema are also characterized by morphological diversity, inflammation, infiltration, and hyperplasia. In most cases, pretibial myxedema is mild and subclinical (Fatourechi *et al.*, 1994) with only aesthetic implications (Ramos *et al.*, 2015). If lesions are extended, they may cause local discomfort and when the feet are also involved, difficulties with wearing shoes and walking may occur.

In **Fig. 1** the clinical appearance of pretibial myxedema.

Diagnosis

The diagnosis of pretibial myxedema is clinical and is based on the characteristic pretibial lesions, the presence of Graves' orbitopathy and history of thyrotoxicosis. Recently, ultrasonography (US) has become a noninvasive and simple procedure that can be used to accurately measure and study skin thickness. US is performed with a 13–16 MHz probe and two skin layers, one that includes the epidermis, dermis and of subcutaneous tissue and a second one that includes the subcutaneous tissue up to the muscular fasciae, are measured. The accuracy of this technique in patients has been validated by Salvi et al. (1994). A schematic representation of the skin layers measured and a US image of a patient's myxedema identified as D1 and D2 are shown in **Fig. 2**. If the clinical diagnosis of pretibial myxedema is uncertain and US imaging is not helpful, a confirmatory biopsy may be performed (Schwartz *et al.*, 2002). Histologically, the dermal tissue is characterized by wide spaces between collagen bundles, under hematoxilin and eosin staining, and accumulation of abundant mucopolysaccharides acid, through Alcian blue, coloidal iron or toluidine blue staining. Normal or slightly elevated amounts of fibroblasts may also be observed (Fatourechi, 2005).

Treatment

Treatment is often not required because the lesions are usually asymptomatic and up to 50% of patients have been reported to achieve a complete spontaneous remission, after several years (Fatourechi, 2005).

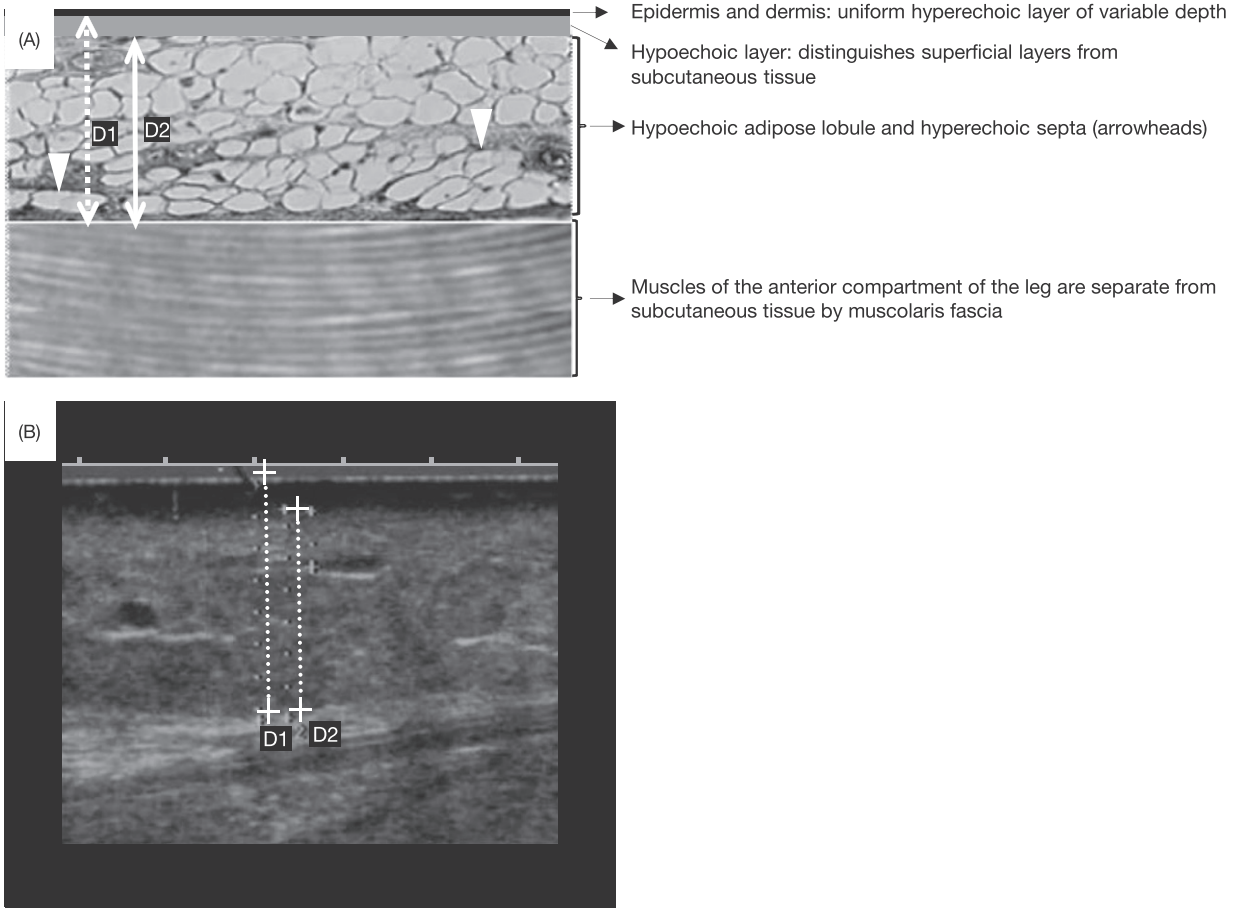

Fig. 2 (A) Schematic representation of skin layers. (B) US study by 13 MHz probe of the pretibial skin of a patient.

Only when there is local discomfort or the lesions become unsightly some treatment should be considered. In more severe cases, in which there is significant skin discomfort as well as a cosmetic issue, a number of therapeutic approaches have been proposed including compressive dressings with topical corticosteroids (Kriss *et al.*, 1967; Takasu *et al.*, 2010), intradermal injections of glucocorticoid (GC) (Fatourechi, 2005; Lang *et al.*, 1975) and hyaluronidase (Deng and Song, 2011; Rosman, 1950). Glucocorticoids have potent antiinflammatory properties, inhibiting hyaluronan synthesis and inducing skin atrophy (Stuhlmeier and Pollaschek, 2004; Gebhardt *et al.*, 2010). Hypodermal injections of triamcinolone have not been extensively used and evidence of a long-term efficacy of this therapy is lacking (Fatourechi, 2005). The occurrence of important adverse reactions, such as hypopigmentation, skin atrophy (Rosman, 1950; Friedman *et al.*, 1988) and lumpy skin (Takasu *et al.*, 2010) has been reported and may have hampered a more wide spread use of this treatment modality. An alternative route of steroid administration that may avoid the skin degeneration associated with hypodermal injection into the subcutaneous tissue is mesotherapy, also known as intradermotherapy. This treatment is carried out with needles 4–6 mm long and has been shown to induce significant and permanent reduction of pretibial dermal infiltration and improvement of the patient discomfort (Vannucchi *et al.*, 2013). By Cox's regression analysis models of the existing literature on pretibial myxedema treatment, Lan et al. have recently reported that pretibial myxedema variants influence the efficacy of intralesional steroid injection (Lan *et al.*, 2014). Nonsevere forms of pretibial myxedema generally respond well to therapy, while severe variants, such as giant plaque myxedema, are often resistant to treatment with intralesional steroids. In those cases, combined therapy with subcutaneous steroid injection could attain a therapeutic response satisfactory for patients (Chen *et al.*, 2016; Fatourechi *et al.*, 1994). More severe variants can even make patients disabled.

Conclusions

Pretibial myxedema is an uncommon dermopathy associated with autoimmune thyroid diseases. To date, it has been widely accepted that most cases of pretibial myxedema are asymptomatic and tend to resolve spontaneously. However, it is important to always examine the pretibial region of patients with Graves' disease to promptly diagnose the more severe forms of pretibial myxedema and eventually start the adequate treatment that can slow down the progression of this extrathyroidal manifestation.

Graves' Orbitopathy☆

Mario Salvi, Graves' Orbitopathy Center, Fondazione Cà Granda IRCCS Ospedale Policlinico, University of Milan, Milan, Italy

Glossary

Apical crowding Enlarged eye muscles in the posterior part of the orbit, the apex, where the optic nerve leaves the orbital cavity; local pressure of the swollen eye muscles may compress the optic nerve, resulting in sight loss.

Conjunctiva Transparent mucous membrane covering the inner surface of the eyelids and the outer surfaces of the cornea and sclera.

Extraocular eye muscles Seven muscles behind each eyeball; four rectus muscles and two oblique muscles move the eyeball, and one (levator palpebrales) lifts the upper eyelid.

Lagophthalmos Incomplete closure of the eyelids, leading to exposure of the cornea during sleep.

Ocular torticollis Abnormal head posture to correct for double vision; typically, the head is tilted backward to correct for impaired elevation of the eyeballs.

Orbit A recess in the skull containing the eyeball and behind the extraocular muscles, vessels, nerves, and connective tissues; apart from the eyeball, the orbital cavity is completely surrounded by bones.

Proptosis Forward displacement of the eyeball; it is also referred to as exophthalmos.

Sclera White membrane surrounding the entire eyeball except for the anterior transparent part that is covered by the cornea.

Epidemiology

The incidence of GO, also known as thyroid-associated ophthalmopathy or endocrine ophthalmopathy is 42.2 per million per year (20.1% of the incidence of Graves' hyperthyroidism). The incidence of moderate-to-severe and very severe GO has been reported as 16.1 per million per year in the general population, with a female to male ratio of 5:1 and peak incidence between 40 and 60 years, whereas the prevalence of moderate-to-severe and very severe GO in patients with Graves' hyperthyroidism varies between 4.9% in Denmark and 6.1% observed in Italy (Perros *et al.*, 2017). A recent study comparing characteristics of referrals to EUGOGO centers, showed a trend toward less active and less severe GO in patients referred in 2012 as compared to 2000.

Pathology

GO is characterized by swelling of the extraocular muscles and of the retrobulbar fat and connective tissues. The normally ribbon-like eye muscles, with a total volume of 3.5 mL, can become grossly (up to fourfold) enlarged (**Fig. 1**). This increase in volume occurs in the bone-confined space of the orbital cavity and therefore the increase of the inflamed orbital tissue causes forward displacement of the eyeball. The volume of the orbit is 26 mL, and it has been shown that an increase in muscle volume of only 4 mL will lead to a proptosis of 6 mm. Although all eye muscles can become enlarged, the inferior and superior rectus muscles are preferentially affected, followed by the medial and lateral eye muscles. The reason for this difference is unknown. In addition to the swelling of the eye muscles, an increase in the volume of retrobulbar fat and connective tissues is frequently seen. The disease is usually bilateral, but in 15% one eye seems preferentially involved. However, on computer-assisted tomography (CT) scanning, bilateral involvement of the eyes is frequently observed in these patients. True unilateral eye disease is rare and occurs in only 5% of patients. These patients often have no evidence of Graves' thyroid disease (Euthyroid GO) (Perros *et al.*, 2017), making it difficult to establish the diagnosis. In many instances, bilateral eye disease and hyperthyroidism will develop later during follow-up.

Etiology

Like Graves' hyperthyroidism, GO is an autoimmune disorder with a multifactorial background. The majority of patients have family members afflicted by Graves' hyperthyroidism, but a family history of orbitopathy itself is uncommon.

☆*Change History*: March 2018. The m/s has been prepared by Mario Salvi; new paragraphs: abstract end epidemiology; paragraphs expanded: pathology, relation with hyperthyroidism; the classification of GO according to the EUGOGO Consensus and GUIDELINES has been introduced in the clinical diagnosis and management paragraphs; the reference list has been updated.

This article is an update of Mark F. Prummel, Graves' Ophthalmopathy, In Encyclopedia of Endocrine Diseases, edited by L Martini, Elsevier, New York, 2004, Pages 357–363.

Fig. 1 CT scanning of the orbits of a patient with unilateral GO. The eye muscles in the right orbit are small and ribbon-like, whereas one eye muscle (the medial rectus) on the left is obviously swollen.

Certain exogenous and environmental factors are necessary to bring about the eye disease in patients with (a genetic predisposition for) Graves' hyperthyroidism. No genetic loci have been found to be associated with an increased risk for orbitopathy, with the possible exception of a CTLA-4 polymorphism (Smith and Hegedüs, 2016).

Pathogenesis

The main players involved in the pathogenesis of GO, in the so called "active phase," in which disease progresses to cause increasing orbital involvement with deterioration of visual function and of the patient's quality of life, are basically three: (1) the antigens expressed on the target organ of inflammation, namely the thyrotropin receptor (TSH-R) and the insulin-like growth factor I receptor (IGF-IR) on the fibroblasts; (2) the cytokines and other humoral factors involved in the various stages of disease progression; and (3) the immune effector cells, B, and T cells (Salvi, 2014).

Early inflammatory changes are characterized by sparse mononuclear cell infiltrates within the muscle endomysium and the connective tissue. The majority of cells are T lymphocytes, CD4+ or CD8+, and B lymphocytes are also observed. HLA-DR expression by interstitial cells—including fibroblasts, but not muscle fibers—are observed in both early and late stages. As lymphocytes, plasma cells and macrophages increase in number, fibroblasts proliferate producing collagen and mucopolysaccharides. Muscles become enlarged and edematous and fibrous with an increase in fat content, mucin, and water. Proliferation of fibroblasts subsequently leads to scarring and muscle fibrosis and sclerosis. Generally muscle fibers are spared in GO.

The TSH-R is uniquely targeted in Graves' disease by pathogenic autoantibodies known as thyroid-stimulating immunoglobulins (Smith and Hegedüs, 2016). These autoantibodies are detected in the serum of patients with Graves' disease with or without orbitopathy. The TSH-R has been found expressed in orbital tissues and this is suggestive of its potential contribution to the pathogenesis of GO. Antibodies to the TSH-R are not always detectable in patients with GO and therefore it is plausible that other autoantigens are also involved. IGF-IR has been shown to be overexpressed by orbital fibroblasts and by T cells and B cells in GD. Immunoglobulins that activate the IGF-IR signaling have been detected in patients with GD, and may synergistically enhance the effect of TSH-R antibodies on the orbital target antigens.

A subpopulation of fibroblasts (preadipocytes and/or mesenchymal stem/stromal cells) may differentiate into adipocytes. Orbit connective/adipose tissue and extraocular muscles are particularly rich in glycosaminoglycans (GAGs) mainly chondroitin sulphate and hyaluronan (HA), an especially hydrophilic molecule. HA synthases are strongly expressed by orbital fibroblasts and upregulated in the presence of various cytokines. Enlargement of intraorbital tissues is largely accounted for by the accumulation of GAG and edema within the connective tissue, both within and outside the muscles.

Relationship With Graves' Hyperthyroidism

GO is usually seen in patients with Graves' hyperthyroidism. In the majority of patients, the eye disease develops concomitantly with or some months after the onset of the thyroid disease. However, in 25% of patients, the eye disease precedes a diagnosis of hyperthyroidism by a number of months. At times, there may be considerable delay between the onset of the two manifestations, even of several years. In a small minority (5%), patients with orbitopathy present with primary hypothyroidism instead of hyperthyroidism. The pathogenesis of this thyroid failure is unclear but may be due to so-called TSH-blocking autoantibodies

against the TSH receptor. These antibodies render the thyroid gland devoid of the stimulating effect of TSH, resulting in atrophy and hypothyroidism.

Three situations/factors appear to precipitate the occurrence of GO: (1) Treatment of hyperthyroidism with radioiodine can potentially worsen GO especially in smokers and in the presence of markedly elevated T3 levels and in patients with shorter disease duration. It is likely that GO deterioration results from exacerbation of thyroid immune reactions, as evidenced by the rise in blood of circulating anti-TSH receptor antibodies (TRAb) which occurs 3–5 months after radioiodine. (2) Iatrogenic hypothyroidism has been recognized as a risk factor for GO. (3) Smoking has been identified as a strong risk factor for the development of this eye disease. Smoking increases the risk of orbitopathy 7.7-fold and is especially associated with more severe eye disease and resistance to therapeutic interventions. The reason behind the influence of smoking on the eye disease is unknown.

Clinical Manifestations

GO manifests with clinical heterogeneity and the signs and symptoms may be summarized in the so-called NO SPECS classification (**Table 1**). This classification system was first developed in 1969, was subsequently revised on a number of occasions, and now serves as a good memory aid. According to EUGOGO (Bartalena *et al.*, 2016), the following criteria of disease severity have recently been proposed:

Mild GO: Patients whose features of GO have only a minor impact on daily life insufficient to justify immunosuppressive or surgical treatment. They usually have one or more of the following: minor lid retraction (<2 mm), mild soft tissue involvement, exophthalmos <3 mm above normal for race and gender, no or intermittent diplopia, and corneal exposure responsive to lubricants.

Moderate-to severe GO: Patients without sight-threatening GO, whose eye disease has sufficient impact on daily life to justify the risks of immunosuppression (if active) or surgical intervention (if inactive). They usually have two or more of the following: lid retraction >2 mm, moderate or severe soft tissue involvement, exophthalmos >3 mm above normal for race and gender, inconstant or constant diplopia.

Sight-threatening GO (very severe GO): Patients with dysthyroid optic neuropathy (DON) and/or corneal breakdown.

Class 1: Only Signs, No Symptoms

This refers to the upper eyelid retraction frequently observed in patients with Graves' hyperthyroidism. The lid retraction causes stare and lid lag on downward gaze (Von Graefe's sign) and can be due to swelling of the superior levator muscle. However, thyrotoxicosis per se can also induce this sign by increasing the sympathetic tone, so Von Graefe's sign is sometimes also present in hyperthyroidism not caused by Graves' disease. Sympathetic overactivity is not the only cause of lid retraction given that upper eyelid retraction frequently remains present when orbitopathy patients are rendered euthyroid. If severe, lid retraction may lead to lagophthalmos, that is, incomplete closure of the eyelids at night.

Class 2: Soft Tissue Involvement

This entails chemosis (edema of the conjunctiva), conjunctival injection and redness, swelling of the caruncle, and swelling of the upper and lower eyelids (periorbital swelling). These findings are partly explained by impaired venous drainage as a result of the increase in volume of the retrobulbar tissues. Periorbital swelling is also due to herniation of retrobulbar fatty tissues through openings in the orbital septum covering the retrobulbar cavity.

Table 1 NO SPECS classification of eye changes in GO

Class	*Description*	*Signs and symptoms*	*Cause*
0	No signs or symptoms	—	—
1	Only signs, no symptoms	Lid retraction, stare, lid lag	Increased sympathetic tone
2	Soft tissue involvement	Swelling of eyelids, chemosis, photophobia, grittiness	Impaired venous drainage, herniated orbital fat
3	Proptosis	Exophthalmos	Increased retrobulbar pressure pushing globe forward
4	Extraocular muscle involvement	Restricted eyeball motility (often with diplopia)	Swollen eye muscles
5	Corneal involvement	Keratitis, corneal ulcer	Overexposure of cornea
6	Sight loss	Decreased visual acuity due to optic nerve involvement, impaired color vision, visual field defects	Pressure on optic nerve, apical crowding

Class 3: Proptosis

Because of the confining bony orbital walls, the swollen retrobulbar tissues have no other outlet than pushing the globe forward. Hence, exophthalmos may be seen as "nature's own decompression."

Class 4: Extraocular Muscle Involvement

One can easily imagine that swelling of the normally very thin extraocular eye muscles leads to impaired mobility. If the impairment is asymmetrical, the patient will have double vision. However, if the impairment is symmetrical, no diplopia will occur. Sometimes, the patient will keep the neck in a certain position (usually bent backward) to correct for impaired motility. This so-called ocular torticollis may lead to painful neck muscles.

Class 5: Corneal Involvement

Exophthalmos, lid retraction, lagophthalmos, and less frequent blinking all contribute to an excessive exposure of the cornea to air that can lead to inflammation of the cornea (keratitis). Early signs are photophobia, a gritty sensation, intolerance to contact lenses, and blurred vision. This phenomenon is different from diplopia in that the abnormal images disappear after blinking.

Class 6: Sight Loss

Sight loss can occur if the enlarged eye muscles compress the optic nerve. This can occur in the apex of the orbital cavity where the optic nerve leaves the orbit. On CT scanning, no room is seen between the optic nerve and the swollen muscles; this is called "apical crowding." Early signs of optic nerve involvement are impaired color vision and visual field defects. This severe complication is more often seen in males and in patients without significant proptosis. In those patients, a tight orbital septum precludes forward displacement of the globe, causing a rise in retrobulbar pressure that is damaging to the optic nerve.

Quality of Life

In view of these many and different clinical manifestations, it is not surprising that patients suffer from a diminished quality of life. The changes in appearance as a consequence of proptosis and periorbital swelling can be profound. Diplopia will hamper many activities in daily life such as reading and driving. In fact, studies have found that even patients with mild to moderately severe eye disease already have a markedly decreased sense of well-being. They rate their degree of social and role functioning lower than do patients with other chronic diseases such as diabetes mellitus. Use of a disease-specific quality of life questionnaire developed with the aid of patient self-support groups has shown unequivocally that GO is a seriously disabling disorder. The disease leads to feelings of social isolation in as many as 40% of these patients. Half of the patients notice unpleasant reactions from others, and many do not want to appear in photographs. As a consequence, as many as 70% of patients with mild to moderately severe orbitopathy report a marked decrease in self-confidence.

Diagnosis

The diagnosis of GO is almost always clinical, at least in the bilateral forms, but it may be less obvious in patients with unilateral disease or in patients without a thyroid disorder. There are no diagnostic procedures that may unequivocally confirm a diagnosis of GO, but several imaging procedures may be helpful. CT scanning of the orbits typically will reveal swelling of the extraocular eye muscles, of the retrobulbar tissues, or of both (**Fig. 2**). Magnetic resonance imaging (MRI) will also help suggest edematous swelling, by recording a prolonged T2 relaxation time. Other diagnostic imaging procedures, including ultrasound or octreotide scintigraphy, have not proven to be accurate or are very expensive. However, enlargement of the eye muscles or connective tissues is not definitive proof of the existence of orbitopathy. Other diagnoses that should be ruled out are lymphomas or metastases of carcinomas to the orbit and the rare orbital pseudotumor. The combination of various signs and symptoms of GO, together with evidence of an underlying autoimmune thyroid disease, will help the physician make the correct diagnosis.

General Management

The first step in the management of a patient with GO is to achieve adequate control of the underlying thyroid disorder (Bartalena *et al.*, 2016). Restoration of the euthyroid state frequently brings about some degree of amelioration of inflammation and even of

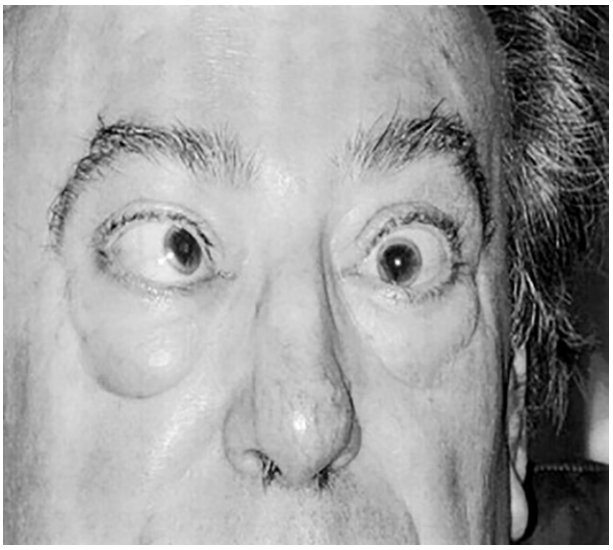

Fig. 2 A patient with severe GO. Note the abnormal eyeball position, resulting in double vision, swelling of the eyelids, increased lid aperture, and periorbital swelling.

diplopia in a few weeks. Generous application of lubricants (eye drops should be applied at least six times daily) prevents corneal damage and the use of a lacrimal gel at night protects the exposed cornea during sleep. Further therapeutic measures depend on the severity and stage of the eye disease.

Disease Activity

From observations by the Australian physician, F. F. Rundle, it has become clear that the disease has a tendency toward spontaneous improvement (**Fig. 3**). After reaching a peak in severity, the signs and symptoms gradually ameliorate over a highly variable period of time, from several months to a number of years. However, in most patients, a complete restoration to the premorbid state is hardly reached (Campi *et al.*, 2016). Immunosuppressive therapies are to be effective during the active disease stage only, whereas rehabilitative surgery is the treatment of choice for residual disease in the inactive stage. When symptoms and signs of inflammation are progressing and the eye condition is rapidly deteriorating, GO is in its active phase. When the eye signs have become stable for at least 6 months, GO can be considered inactive. However, in most patients with moderately severe disease, the assessment of disease progression relies on continuous monitoring of the eye changes on consecutive clinical examinations. A clinical activity score (CAS) has been developed by attributing a score to the clinical signs characteristic of the active phase of GO, upon clinical examination (**Table 2**).

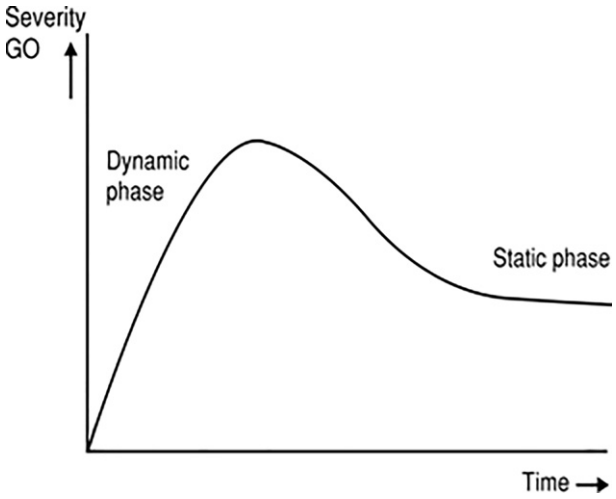

Fig. 3 Rundle's curve showing the natural history of GO and its tendency toward spontaneous improvement over a variable period of time. Note that the *x* axis (time) is not defined.

Table 2 The clinical activity score for assessing disease activity in GO

Parameter	*Points*
Pain or oppressed feeling on globe	1
Pain on attempted up, side, and/or down gaze	1
Redness of eyelids	1
Redness of conjunctiva	1
Swelling of eyelids	1
Swelling of caruncle	1
Chemosis	1
Active disease	$>2/7$

A CAS of three or more points will suggest active disease, if confirmed in two consecutive visits at 2–4 weeks-interval. Patients with active and progressive GO will be more likely to respond to immunosuppressive treatment, aimed at modifying the natural course of disease as shown by the Rundle's curve.

Management During the Active Stage

Mild GO

One option during the initial phase of the disease is to observe the patient over the course of several months. When GO is mild, the patient can simply be observed as the disease natural course is toward spontaneous improvement. Adequate antithyroid treatment and lubrication of the cornea will alleviate some of the symptoms until the disease has become inactive. In more severe cases, nonsurgical (immunosuppressive) treatment is indicated.

Moderate-Severe GO

To date, glucocorticoids (GC) represent the first line treatment for active moderate-severe GO, since they exert an antiinflammatory and, at high doses, also an immunosuppressive effect (Bartalena *et al.*, 2016). Response to treatment much relies on interindividual variability that leads to either treatment failure or drug induced toxicity. A significant response to therapy has been demonstrated for oral GC (prednisone). High doses of oral GC (daily administration of 50–100 mg of prednisone tapered down in 4–5 months) are effective on inflammatory signs of active GO in about 50%–60% of cases but the relapse of symptoms, after discontinuation or dose tapering, is not uncommon. Oral therapy is however more often associated to long term side effects, including hepatotoxicity, Cushing syndrome, osteoporosis, glaucoma, and diabetes mellitus. More recent studies have shown that pulsed intravenous methylprednisolone (ivMP) is more effective (70%–80% responders) and has a better safety profile compared with oral prednisone. A recent randomized study from EUGOGO has shown that a cumulative dose of 7.5 g of methylprednisolone is more effective in patients with moderate-severe GO than lower doses (5 g or 2.25 g, respectively), although it is associated with more frequent adverse events. Therefore high doses should be used in more severe cases of GO while intermediate doses (5 g) may be effective in most patients with moderate disease. A full cycle of treatment with ivMP should never exceed a total cumulative dose of 8 g. The limitation of ivMP treatment is that 20%–30% of patients are poorly responsive or unresponsive at all and that approximately 10%–20% of patients have disease relapse following drug withdrawal. The morbidity and mortality of GC therapy in GO patients have been estimated to 6.5% and 0.6%, respectively (Zhang *et al.*, 2011). Acute liver failure and cardiovascular events associated with GC administration are potentially fatal and careful monitoring during steroid therapy is mandatory. Marked increase of liver enzymes is the most common adverse event associated with ivMP, while acute liver failure seems caused by a direct toxic effect of GC on hepatocytes and appears to be dose-related. The onset of this damage is often not predictable, but preexistent viral hepatitis is probably associated with an increased risk. In patients with elevation of liver enzymes during ivGC therapy, the possibility of an autoimmune hepatitis should be ruled out.

Second line treatment is considered when patients do not respond to steroids or present with disease relapse after discontinuation of therapy. According to the recent EUGOGO Guidelines (Bartalena *et al.*, 2016), the decision on which therapeutic alternative is to be pursued in this situation is to be shared with the patient. This is because, among alternatives, the re-proposal of steroids, alone or in combination with other modalities of treatment, remains a possibility.

Retrobulbar irradiation has been used in active GO for many decades. Radiotherapy probably exerts its effect through the killing of infiltrating lymphocytes and activated (GAG-secreting) fibroblasts. The overall response rate is of approximately 65% and is effective mostly on periorbital swelling and inflamed extraocular muscle with a reduction of the degree of diplopia, but with only very little, and clinically insignificant, effect on proptosis. Radiotherapy is generally administered in 10 daily fractions of 200 cGy. Improvement of eye signs occurs earlier when corticosteroids are associated (usually some effect is seen within 2–4 weeks), whereas the beneficial effect of irradiation may take 3–6 months. The association with oral prednisone improves efficacy and the therapeutic response rate, although is almost always associated with side

effects. Combination therapy with ivMP has been reported more efficacious than radiotherapy alone, but it has not been challenged in randomized controlled trials. Radiotherapy causes no significant untoward effects and is safe in the long term, the only contraindication being diabetes mellitus, because irradiation can aggravate diabetic retinopathy.

Cyclosporine given as monotherapy is ineffective, but can be combined with oral prednisone, in which case a lower dose of prednisone can be used to achieve a similar response rate.

Many studies of B-cell function carried out in experimental animal models have provided evidence for their contribution to human autoimmune disease, recently reconsidered due to the therapeutic benefit of B-cell depleting therapies (Salvi *et al.*, 2015). Rituximab (RTX) is a humanized chimeric anti-CD20 monoclonal antibody whose variable (antigen-binding) region is derived from a mouse antibody that binds the CD20 antigen. It is approved for clinical use in non-Hodgkin's lymphoma and rheumatoid arthritis, but has recently been used off label in several other autoimmune diseases. The rationale of its use in GD is the blockade of the pathogenic TSH-R autoantibody by specifically targeting TSAb, the stimulating subpopulation of immunoglobulins targeting the TSH-R. The results of two randomized clinical trials employing RTX in GO have recently been published. One study showed GO inactivation after RTX in 100% of patients compared to 69% after IVMP and no disease relapse. The treatment was not effective on proptosis, but RTX proved to be more effective than steroids on motility and quality of life. Another study did not find RTX effective in treating active GO, when compared to placebo. Reasons for the conflicting results of these two studies are unknown, but differences in the duration of GO in the patients' population included may have had an important impact on the treatment outcomes (Stan and Salvi, 2017). The results of this work seem to suggest that RTX may act as a disease modifying therapy, compared to steroids. Further and larger randomized controlled trials are needed for definitive data on the potential disease modifying role of RTX and its superiority over standard treatment with steroids.

In vitro studies of orbital fibroblasts have shown that IGF-IR–targeting antibodies may inhibit the effect of IGF-I, thyrotropin, TSAb, and immunoglobulins isolated from patients with Graves' disease. Based on these data, a trial of teprotumumab, a fully human IGF-IR–inhibitory monoclonal antibody has recently been conducted and has shown promising results, especially in reducing the patients' proptosis. Patients on teprotumumab also showed reduction of the CAS, improvement of the quality of life (both the visual-functioning subscale and combined scales when compared to placebo). The marked reduction in proptosis was similar to that reported after orbital decompressive surgery. The findings suggest that therapy with teprotumumab in patients with active GO may modify the natural course of disease (Smith *et al.*, 2017).

Sight-Threatening GO

In patients with optic nerve involvement, characterized by apical crowding on CT scanning, visual field defects, and/or a decrease in visual acuity, a more aggressive approach is warranted. In those patients, methylprednisolone pulses can be administered (1000 mg intravenously on three consecutive days, repeated once 1 week later, followed by oral prednisone for 3–5 months), and this may even be combined with orbital irradiation. In case of an unsuccessful outcome, generally in about 60% of patients, acute surgical decompression of the orbits is the only option left.

Surgical Treatment

Once the disease has become inactive, most patients still experience disabling and often disfiguring symptoms, even after otherwise successful immunosuppressive therapy. These remaining manifestations can be treated successfully with various targeted surgical procedures by an experienced orbital surgeon (Bartalena *et al.*, 2016). The surgical procedures should be done in a strict order. First, an orbital decompression is performed if there is significant proptosis. During this procedure, several of the orbital walls are partly removed to increase the retrobulbar space. The degree of proptosis reduction varies with the number of walls removed. A three-wall decompression (coronal, transantral, and swinging eyelid approaches) typically results in a 6- to 8-mm reduction in proptosis. Complications include numbness of parts of the skin and worsening or even induction of diplopia. This latter complication occurs in 10%–20% of patients and is the reason why a decompression should always be done before squint (strabismus) surgery.

Squint surgery consists of a recession or resection of restricted extraocular eye muscles. The tendon of the muscle is severed from the eyeball and reinserted in a new position determined preoperatively during extensive orthoptic evaluations. Binocular single vision in all directions of gaze is seldom achieved, but single vision in the primary and reading positions is reached in 50%–80% of patients after one operation. Thus, frequently two or even more procedures are required to obtain an acceptable situation.

The final step in the rehabilitation of these patients consists of eyelid surgery. Upper eyelid retraction can be treated by recessing the levator muscle with or without a sclera interpositioning. Upper eyelid surgery is difficult, and in most patients various procedures (under local anesthesia) are needed. Lower eyelid surgery is often successful after just one attempt. Finally, redundant connective and fatty tissues can be removed by a blepharoplasty of the upper and/or lower eyelids.

Smoking and the Thyroid☆

Luigi Bartalena and Maria L Tanda, University of Insubria, Varese, Italy

Glossary

Chronic autoimmune thyroiditis (Hashimoto' thyroiditis) Autoimmune disease characterized in many instances by goiter in the presence of euthyroidism or hypothyroidism, and circulating thyroid autoantibodies to thyroglobulin and/or thyroid peroxidase.

Graves' disease Autoimmune disease typically characterized by diffuse goiter, eye involvement (Graves' orbitopathy), and, less frequently, dermopathy (pretibial myxedema). It is caused by thyroid-stimulating hormone receptor antibodies.

Thyroid hormones Hormones secreted by the thyroid gland, represented mostly by thyroxine (T4) and triiodothyronine (T3).

Effects of Smoking on Thyroid Function

Several studies have been carried out to ascertain whether smoking is associated with variations in thyroid homeostasis. Two large surveys (the NHANES III survey in the USA and the 5th Tromso study in Norway) showed that smokers have lower serum thyrotropin (TSH) concentrations than nonsmokers (Belin *et al.*, 2004; Jorde and Sundsfjord, 2006). In the Tromso study higher serum free thyroxine (FT4) and free triiodothyronine (FT3) in smokers were also reported (Jorde and Sundsfjord, 2006). In another study from Norway (HUNT study) active smokers had lower serum TSH levels than former smokers (Asvold *et al.*, 2007). In addition, there might be an inverse relationship between the number of daily cigarettes and TSH concentration, because heavy smokers tend to have lower serum TSH levels compared to mild-to-moderate smokers (Asvold *et al.*, 2007). Whether passive smoking may be associated with similar changes is unsettled. Conversely, smoking withdrawal is associated with a small and slow decrease in serum FT4 and a small and slow increase in serum TSH concentrations. This might suggest that cigarette smoking stimulates thyroid function, which would then be readjusted after smoking cessation (Wiersinga, 2013). One possible explanation for the above changes might reside with stimulation of the sympathetic nervous system, leading to stimulation of thyroid hormone secretion, in turn decreasing TSH release (Bartalena *et al.*, 1995). It should be mentioned that results in the literature are not, however, unequivocal, and several factors may influence the results, such as the inclusion of heavy versus moderate smokers, the evaluation of short-term versus long-term effects, or differences in age and body mass. In addition, the presence of substances in cigarette smoke that stimulate drug metabolism might also account for a decrease in thyroid hormone levels, since induction of liver microsomal enzymes involved in the metabolism of thyroid hormones might result in an enhanced hormonal catabolism (Bartalena *et al.*, 1995; Wiersinga, 2013). In summary, cigarette smoking seems to be associated with overall minor and controversial changes in thyroid function tests, whose pathophysiological relevance seems to be marginal. The most frequently observed change is a decrease in serum TSH concentration, reversible after smoking cessation (**Table 1**).

Smoking and Goiter

Several reports have documented that smoking is associated with an increased prevalence of goiter (Hegedus *et al.*, 1985; Berthelsen and Hegedus, 1994; Knudsen *et al.*, 2002; Vestergaard, 2002) (**Table 1**). In addition, it was shown that heavy smokers have an increased frequency of nodular goiter. These findings may be related to iodine intake, because many of these studies were performed in iodine-deficient areas, whereas no significant differences in the prevalence of goiter among smokers and nonsmokers were found in iodine-sufficient areas. It is likely that cigarette smoking represents only a cofactor and its goitrogenic effect becomes more apparent when other goitrogenic factors, particularly iodine deficiency, are also present.

It is not completely clear how cigarette smoking can contribute to the development of goiter, but a candidate goitrogen in smoke is thiocyanate, produced by detoxification of hydrogen cyanide. The role of thiocyanate in the pathogenesis of endemic goiter has been clearly shown in the presence of iodine deficiency (Wiersinga, 2013). Body fluids of smokers contain increased thiocyanate concentrations. The increase in the thyroid volume/birth weight ratio in newborns parallels the increase in cord serum thiocyanate levels, taken as an index of maternal smoking habits, suggesting that smoking during pregnancy may be a relevant cause of thyroid gland enlargement in the newborn. The effects of thiocyanate and other cigarette smoking products (nicotine,

☆*Change History:* January 2018. Luigi Bartalena and Maria Laura Tanda were involved in updating the chapter. Text and references have been updated.

This article is an update of Luigi Bartalena, Maria Laura Tanda, and Enio Martino, Smoking and the Thyroid, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 278–282.

Table 1 Smoking and the thyroid

	Effect	*Relevance*
Thyroid function	• Increase in serum free thyroid hormone and decrease in serum thyrotropin concentrations	Marginal
Goiter	• Goitrogenic effect, increase in multinodularity	Relevant cofactor in iodine-deficient areas
Thyroid cancer	• Reduced risk of thyroid cancer in current smokers	Possible protective effect (related to decreased TSH?)
Graves' hyperthyroidism	• Increased risk of occurrence of Graves' hyperthyroidism in smokers • Increased risk of recurrence of hyperthyroidism after antithyroid drug withdrawal	Relevant
Graves' orbitopathy	• Increased prevalence of smokers among patients with orbitopathy • Increased risk of developing severe forms • Decreased and slower response to immunosuppressive treatment	Relevant
Chronic autoimmune thyroiditis	• Lower prevalence of thyroid autoantibodies in smokers • Protective role against progression to hypothyroidism	Doubtful

cotinine) have also been studied in vitro using porcine thyroid follicles in culture; while nicotine and cotinine did not inhibit iodide transport or thyroid hormone synthesis, thiocyanate, at concentrations equivalent to those reached in the serum of smokers, inhibited iodide transport and iodine organification while increasing iodide efflux (Bartalena *et al.*, 1995). The possible role of thiocyanate is supported also by studies showing that serum thyroglobulin is increased concomitantly with a slight decrease in serum TSH concentration among smokers in a population living in a mild iodine deficiency area (Hegedus *et al.*, 1985). In addition to underscoring the role of thiocyanate, these findings may explain the interaction of cigarette smoking and iodine deficiency in the development of goiter.

In summary, it appears that smoking plays a role in the development of goiter and most reports agree on a higher prevalence of goiter, particularly multinodular goiter, in smokers (**Table 1**). Although it is conceivable that many others (and yet unidentified) smoke products may contribute, thiocyanate appears, for the time being, to be the most likely culprit, in view of the high circulating levels found in smokers and in view of its complex effects on thyroid function. Smoking-related goitrogenesis appears to be frequent, particularly in iodine-deficient areas, where smoke may also represent a relevant cause of neonatal thyroid enlargement.

Smoking and Thyroid Cancer

Cigarette smoking seems to be associated with a decreased risk of thyroid cancer, particularly the papillary histotype. In a study of 90,713 Radiologic Technologists followed for 24 years, smokers had a low hazard ratio of 0.54 (95% CI, 0.35, 082) of developing compared to nonsmokers, while the risk in former smokers (0.91, 95% CI, 0.67, 1.22) did not differ from that of nonsmokers (Meinhold *et al.*, 2009). Likewise, in a pooled analysis of 14 case-control studies, thyroid cancer risk was reduced in current smokers (odd ratio, 0.6; 95% CI, 0.6, 0.7), but not in former smokers (Mack *et al.*, 2003). Finally, in a large a pooled analysis of five prospective USA studies involving 413,979 women and 434,953 men, the risk of thyroid cancer increased with body mass index (BMI), and this effect was even stronger in never smokers (Kitahara *et al.*, 2011) Because an increase in BMI is associated with an increase in serum TSH, and the latter is associated with an increased risk of thyroid cancer, it might be conceived that the protective effect of smoking be related to the TSH-lowering effect of smoking (see previous paragraph).

Smoking and Thyroid Autoimmune Disorders

Cigarette smoking has a number of immunological effects involving both humoral and cellular components of the immune system. These include a depression of natural killer cell activity, an increase in the total number of T lymphocytes, with a relative decrease in $CD4^+$ (helper) and increase in $CD8^+$ (suppressor) subpopulations in heavy smokers (Bartalena *et al.*, 1995). Serum immunoglobulin (Ig) G, IgM, and IgA levels are decreased by 10%–20% in the serum of smokers, whereas IgE levels are increased in light-to-moderate smokers and decreased in heavy smokers (Bartalena *et al.*, 1995). A lower level of immunosuppression has been observed in mice as an effect of smoking. The numerous immunological effects of smoking may have some relevance in human pathophysiology. For example, it has been shown that, although smoking is associated with Crohn's disease, ulcerative colitis is strongly associated with not smoking. The underlying mechanism might not necessarily be related to immunological effects of smoking, but to substances contained in smoke that might be somehow beneficial to ulcerative colitis patients. An association between rheumatoid arthritis and cigarette smoking, as well as an increased prevalence of antinuclear antibodies in smokers, has been reported.

Graves' Hyperthyroidism and Orbitopathy

Graves' disease is an autoimmune disease contributed by both genetic and environmental factors (Bartalena, 2013). The latter may include stressful life events and infections. Smoking represents an additional and important environmental factor (Prummel and Wiersinga, 1993). An increased prevalence of smokers has been observed in patients with Graves' disease and smoking increases the risk with an odd ratio of 3.30 (2.09–5.22) (Prummel and Wiersinga, 1993; Bartalena *et al.*, 2000). Smoking cessation seems to reduce the risk of occurrence of Graves' hyperthyroidism. In addition, smoking increases the risk of recurrence of hyperthyroidism following antithyroid drug treatment withdrawal (Glinoer *et al.*, 2001). No association between smoking habits and toxic nodular goiter has been found.

Why should cigarette smoking be associated with an increased risk of developing Graves' disease? Smoking might simply be a coincidental, unrelated factor and Graves' patients might smoke more because they are nervous and stressed. Stress is indeed associated with an increased desire to smoke. It should be mentioned that, in most cases, Graves' patients smoked prior to the development of hyperthyroidism. Alternatively, smoking might enhance other activities or factors that bear the true responsibility for the occurrence of the disease. However, the possibility cannot be excluded that smoking may be effectively involved in the pathogenesis of the disease. This might occur through different smoke-related immunological mechanisms, such as an alteration of the TSH receptor structure, an enhancement of responsiveness to other factors responsible for the initiation of the disease, or an impairment of restoration of tolerance to thyroid autoantigens. Evidence that these hypothetical mechanisms participate in the development of Graves' disease is lacking.

Graves' orbitopathy is the most frequent extrathyroidal manifestation of Graves' disease and represents a complex therapeutic problem (Bartalena and Fatourechi, 2014). A possible relationship between cigarette smoking and Graves' orbitopathy was initially suggested in a small series of patients and subsequently confirmed in a large number of patients in different series (Bartalena *et al.*, 2000). Furthermore, there seems to be a relationship between smoking and disease severity (Prummel and Wiersinga, 1993). Interestingly, the current number of daily cigarettes smoked, but not lifetime tobacco consumption, appears to be an independent risk factor, and ex-smokers have a lower risk of developing severe Graves' orbitopathy than current smokers with a comparable lifetime tobacco consumption (Bartalena *et al.*, 2000). Interestingly, the prevalence of Graves' orbitopathy in newly diagnosed Graves' patients seems to be declining in recent years: a decrease in the proportion of smokers in the population might be a relevant factor for this trend (Tanda *et al.*, 2013). This association between cigarette smoking and Graves' orbitopathy is unexplained. In addition to direct irritative effects and smoke-related increase in oxidative stress, cigarette smoking might influence ongoing immune reactions in the orbit. It is well accepted that cytokines play an important role in the pathogenesis of Graves' orbitopathy. Cigarette smoking may affect the process, because smoking-induced hypoxia in the retrobulbar tissue increases the release of cytokines from orbital fibroblasts in vitro. Furthermore, it has been reported, but not unequivocally confirmed, that smokers, compared to nonsmokers, have lower circulating levels of soluble interleukin-1 (IL-1) receptor antagonist levels, an anti-cytokine antagonizing the effects of IL-1.

Cigarette smoking may also affect treatment outcomes of Graves' orbitopathy (**Table 1**). A more favorable response to immunosuppressive treatment for moderate-to-severe Graves' orbitopathy is more frequent in nonsmokers than in smokers. In addition, smokers may have a delayed response to treatment. In patients with nonsevere Graves' orbitopathy, radioiodine treatment may cause a progression of eye disease in approximately 15% of cases; postradioiodine progression is more likely to occur in smokers, whereas improvement of preradioiodine orbitopathy with the concomitant glucocorticoid treatment is more frequent in nonsmokers (Bartalena *et al.*, 1998).

In summary, although the mechanisms whereby cigarette smoking operates remain to be elucidated, the relationship between smoking, Graves' hyperthyroidism, and Graves' orbitopathy is well established, in terms of the epidemiology of the disease and its influence on the severity of the disease and the efficacy of its management. Accordingly, Graves' orbitopathy patients should be vigorously encouraged to refrain from smoking, even though it remains to be proven that smoking withdrawal beneficially affects the course of the disease.

Chronic Autoimmune Thyroiditis

Chronic autoimmune thyroiditis is the most common cause of spontaneous hypothyroidism in the adults. Several studies have shown that, at variance with Graves' disease and orbitopathy, smoking exerts a protective effect against hypothyroidism of autoimmune origin (**Table 1**). In the large HUNT study from Norway, the odds ratio for the occurrence overt and subclinical hypothyroidism in women were 0.60 (0.38–0.95) and 0.54 (0.46–0.66), respectively; figures were even lower in men (Asvold *et al.*, 2007). Three studies from the Netherlands, Denmark, and Iran showed that smokers have a lower prevalence of thyroid autoantibodies (anti-thyroid peroxidase and/or anti-thyroglobulin) than nonsmokers (Wiersinga, 2013). Smoking cessation has been associated with an increased risk of occurrence of positive tests for thyroid autoantibodies and development of autoimmune hypothyroidism. However, the risk of hypothyroidism after smoking withdrawal seems to be transient and disappears after 3 years or more after smoking cessation. Although results are not unequivocal, in most studies smoking apparently does not play a relevant role in the occurrence of postpartum thyroid disorders.

Mechanisms whereby smoking may have a protective effect on chronic autoimmune thyroiditis and related hypothyroidism remain obscure. They might, however, be related to receptor-mediated effects of nicotine or other tobacco alkaloids, causing a shift from Th1 and Th17 responses to Th2 responses.

Concluding Remarks

The relationship between cigarette smoking and the thyroid is complex and not yet completely understood. Marginal changes in thyroid function have been described in smokers, but they are unlikely to have a relevant pathophysiological significance. More clearly established is the goitrogenic effect of smoking, probably related to the action of thiocyanate (and possibly of other compounds liberated in smoke). This effect might be particularly important in iodine-deficient areas. An interesting observation is the high prevalence of smokers among patients with Graves' disease, but it is unclear whether this has a pathogenic importance or merely represents an epiphenomenon of behavioral changes related to thyroid hyperfunction. Even more striking is the association between smoking and Graves' ophthalmopathy. Although the underlying mechanisms need to be elucidated, smoking might play a role in the pathogenesis of Graves' ophthalmopathy and unfavorably affect its course. Conversely, cigarette smoking seems to play a protective effect on chronic autoimmune thyroiditis (and related hypothyroidism) and thyroid cancer.

Glossary

Autonomy The ability of thyrocytes to function and produce thyroid hormones (thyroxine and triiodothyronine) without stimulation from thyrotropin.

Constitutive thyrotropin (TSH) receptor activation State of activation of the TSH receptor in the absence of TSH caused by a mutation in the TSH receptor gene.

^{131}Iodine (^{131}I) A radioisotope of iodine.

Scintiscan Radionuclide scanning of the thyroid after administration of technetium (as isotope ^{99}Tc in the form of pertechnetate), or iodine (as isotope ^{123}I or ^{131}I), used for a functional assessment of the thyroid's ability to take up iodine.

Sodium-iodine symporter (NIS) A transporter of the basolateral membrane of thyroid follicular cells that facilitates uptake of iodine by active transport of two sodium cations and one iodide anion.

Thyrocyte Epithelial cells within the thyroid gland that are responsible for thyroid hormone synthesis. Also known as follicular cells.

Thyrotoxicosis Also known as hyperthyroidism. Systemic alteration of metabolism in which increased levels of thyroid hormone in the serum lead to biochemical and/or clinical signs of excess thyroid hormone at the tissue level.

Definition

The term solitary toxic adenoma refers to a benign monoclonal thyroid tumor with autonomous thyroid hormone production. This term is interchangeable with "toxic thyroid nodule" and "hot nodule." Increased thyroid hormone synthesis from these nodules leads to suppression of thyroid-stimulating hormone (TSH) and thyrotoxicosis.

Introduction

Epidemiology

Individuals with solitary toxic adenoma may present with a wide spectrum of disease, ranging from subclinical hyperthyroidism (suppressed TSH with normal levels of triiodothyronine and/or thyroxine) to overt thyrotoxicosis. Solitary toxic adenoma may occur as a solitary nodule within an otherwise normal thyroid gland (solitary toxic adenoma) or as multiple nodules in the setting of a multinodular goiter (also known as toxic multinodular goiter or abbreviated as TMG). For the purposes of this discussion, the term "solitary toxic adenoma" can be assumed to refer to a solitary toxic nodule.

The overall prevalence of both solitary toxic adenoma and TMG is inversely correlated with the iodine consumption of the population. Recent data suggests that solitary TA accounts for 5%–10% of cases of hyperthyroidism while toxic MNG represents 6%–47%; both conditions are relatively more common in regions with mild or moderate iodine deficiency (Carlé *et al.*, 2011; Laurberg *et al.* 2010). In populations that are iodine sufficient, solitary toxic adenoma has a similar prevalence to TMG, and represents the second most common cause of hyperthyroidism after Graves' disease (Laurberg *et al.*, 2010). Solitary toxic adenoma predominantly affects older individuals; increased incidence is observed after the sixth decade (Carlé *et al.*, 2011). While it is a common cause of hyperthyroidism in adults, this condition is exceedingly rare in children with only a few cases described in the literature (Grob *et al.*, 2014). Similar to other thyroid diseases, there is a female preponderance with a female to male ratio of 1.4:1 (Carlé *et al.*, 2011).

Etiology

Solitary toxic adenoma is understood to arise from acquired genetic mutations in the TSH receptor gene or the α-subunit of the G_s protein ($G_{s\alpha}$). TSH stimulates thyroid function by binding to the TSH receptor, which, through coupling to $G_{s\alpha}$, causes intracellular

☆*Change History*: February 2018. Kirstie Lithgow, Amita Mahajan, and Sana Ghaznavi introduced Abstract, updated Epidemiology, Etiology, Diagnosis, Natural History, and Treatment sections, updated Table 1. A Stephenson updated Fig. 3.

This article is an update of Knut Krohn, Dagmar Fuhrer and Ralf Paschke, Toxic Adenoma, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 594–599.

generation of the second-messenger cyclic AMP (cAMP) (**Fig. 1**). As demonstrated by in vitro cell culture experiments, TSH receptor mutations in solitary toxic adenoma cause constitutive activation (in the absence of the ligand TSH) of the cAMP signaling cascade. Stimulation of the cAMP cascade leads to increased iodide uptake by upregulation of the sodium iodine symporter (NIS), increased thyroid hormone synthesis, and growth of thyrocytes. Therefore, mutations in the TSH receptor gene or G_s protein ($G_{s\alpha}$) confer a growth and functional advantage to the affected thyroid cell leading to the development of an autonomously functioning thyroid nodule (**Fig. 2**) (Krohn and Paschke, 2001). Gradually, the increasing cell mass in the autonomously functioning thyroid nodule reaches a level of thyroid hormone production that exceeds the normal demand. Initially, this manifests as subclinical hyperthyroidism, but continued growth eventually results in biochemical hyperthyroidism and clinically apparent thyrotoxicosis (**Fig. 2**). Accordingly, the risk of hyperthyroidism is increased with larger nodule size (Sandrock *et al.*, 1993).

Activating mutations of the TSH receptor have also been implicated in familial non-immune hyperthyroidism and sporadic congenital non-autoimmune hyperthyroidism. In solitary toxic adenoma, the somatic mutation of the TSH receptor initially affects only a single cell, which undergoes clonal proliferation to ultimately form a hot nodule, whereas in the aforementioned disorders, a germline mutation in the TSH receptor affects all thyroid cells. **Fig. 3** shows a compilation of known somatic activating TSH receptor mutations in solitary toxic adenoma, which can be identified in up to 70% of cases (Trülzsch *et al.*, 2001; Gozu *et al.*, 2006). Mutations in $G_{s\alpha}$ have been detected in 1%–3% of cases. The cause of the remaining 20%–30% is currently unknown. Given the clonal origin of solitary toxic adenomas, there are presumably additional genetic mechanisms that have yet to be elucidated. Solitary toxic adenomas with known somatic TSH receptor or $G_{s\alpha}$ mutations lack a clear genotype/phenotype correlation, suggesting that their effects may be modulated by other mechanisms such as downstream signaling events, cross-talk with other signaling cascades, and negative feedback (Krohn *et al.*, 2005; Frenzel *et al.*, 2005; Kursawe and Paschke, 2007). Recently, mutations in the *EZH1* gene were found in 27% of solitary toxic adenomas and were strongly associated with those harboring TSH receptor mutations, suggesting a possible "two hit" model whereby *EZH1* mutations promote additional growth in the setting of underlying constitutive activation of the cAMP pathway (Calebiro *et al.*, 2016).

Diagnosis

Patients with toxic adenoma may present with signs and symptoms of hyperthyroidism or mass effect from a large nodule or goiter. Typically, the patient will present with features suggestive of hyperthyroidism, including anxiety, hyperactivity, weight loss despite increased appetite, palpitations, tremor, and heat intolerance (**Table 1**) (Ross *et al.*, 2016). Of note, these classical symptoms of hyperthyroidism are frequently absent in elderly patients with solitary toxic adenoma or TMG (Thomas *et al.*, 1970). Conversely, individuals may notice a palpable or visible lump in the neck, or experience mechanical symptoms such as difficulty swallowing or shortness of breath, due to local compression of the esophagus or trachea, respectively (Haugen *et al.*, 2016).

All patients presenting with a thyroid nodule should undergo a complete history and physical examination of the thyroid gland and cervical lymph nodes. The focus of the history and physical should be to assess the patient for signs and symptoms of hyperthyroidism, look for clues as to the etiology of hyperthyroidism, assess for obstructive symptoms, and evaluate the patient for their risk of thyroid malignancy.

As per clinical practice guidelines, upon confirmation of the presence of a thyroid nodule by neck ultrasonography, all patients with a nodule should have an evaluation of serum TSH (Haugen *et al.*, 2016). If the TSH value is subnormal or low normal, the

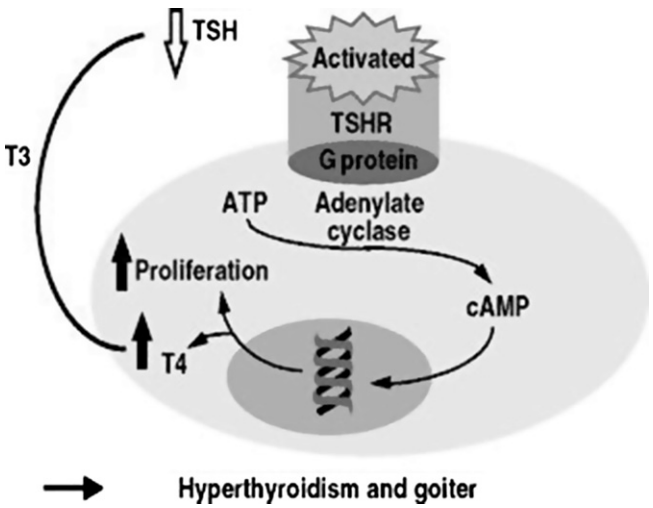

Fig. 1 Signal transduction in an autonomously functioning thyroid cell. The cAMP cascade is stimulated by the constitutively activated TSH receptor (or less frequently by the $G_{s\alpha}$ protein). cAMP stimulates thyroid function and growth, ultimately resulting in a phenotype of hyperthyroidism and goiter.

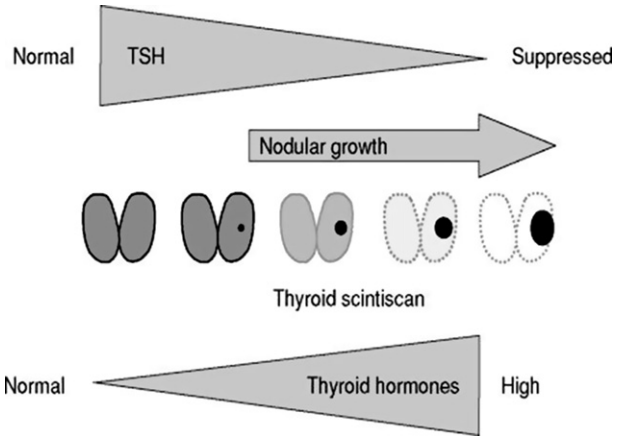

Fig. 2 Development of thyroid autonomy. A thyroid cell with a somatic gain-of-function TSH receptor mutation has a growth and functional advantage over unaffected thyrocytes. The autonomous nodule causes increased thyroid hormone synthesis independent of the TSH level. If the nodule reaches a critical mass, TSH Is suppressed and thyrotoxicosis becomes clinically apparent. On scintiscan, the toxic adenoma appears as a "hot" nodule due to increased NIS expression within the nodule with suppression of surrounding thyroid tissue.

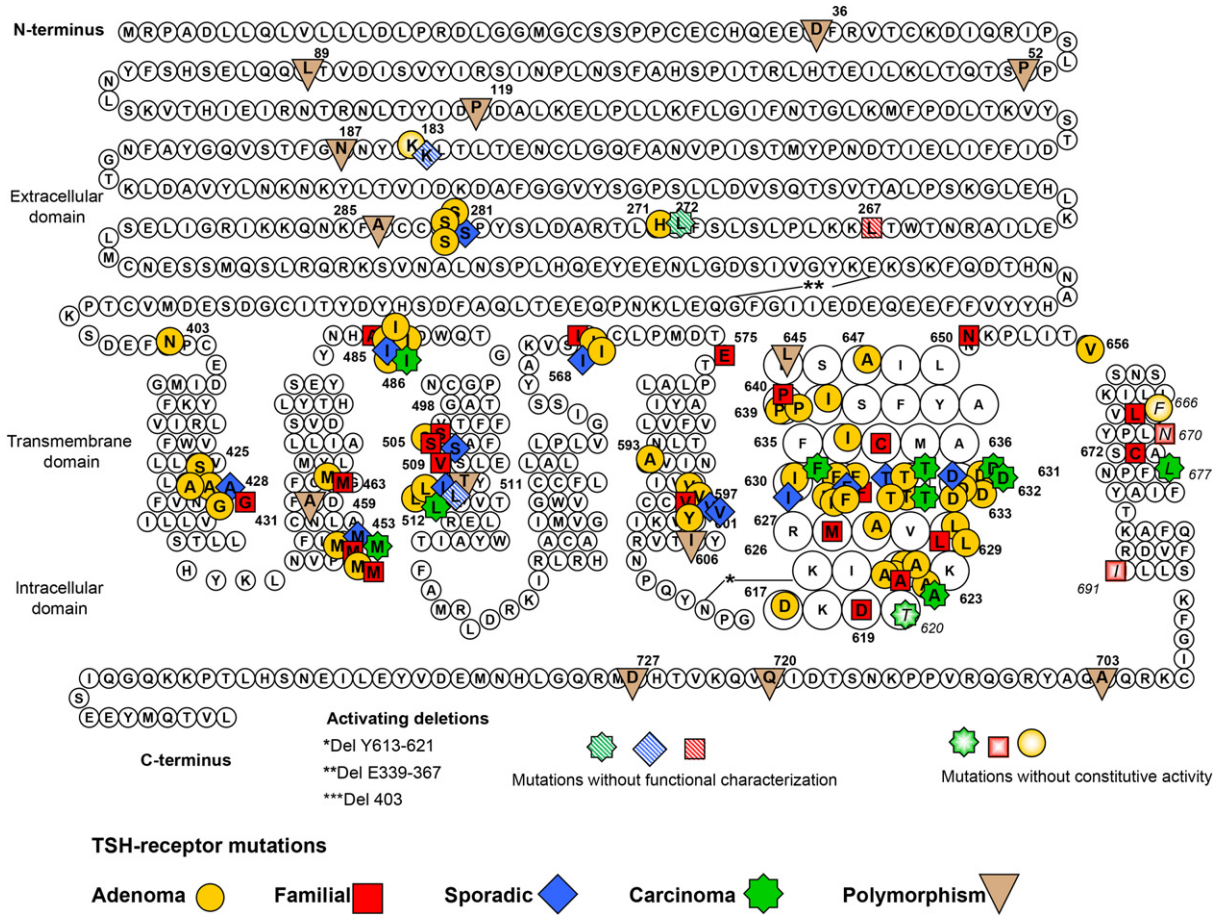

Fig. 3 All constitutively activating TSHR mutations and polymorphisms (nonfunctional variants) according to TSHR database (http://tshreceptor-mutation-database.org/) and all constitutively activating TSHR mutation publications since the 2012 update of the TSHR mutation database published as of 12/2017according Google Scholar and PubMed using the search terms "TSHR mutation" and "thyrotropin receptor mutation." Mutations are characterized with at minimum basal and TSH stimulated cAMP but ideally with linear regression analysis (LRA) of constitutive activity as a function of TSHR expression determined by 125I-bTSH binding or FACS analysis compared to the wild-type. Those without functional characterization are included based on their association with a clinical phenotype only.

Table 1 Clinical manifestations of thyrotoxicosis

History	*Physical exam*
Anxiety	Hyperactivity
Fatigue	Tachycardia/arrhythmia
Increased perspiration	Systolic hypertension
Heat intolerance	Warm, moist skin
Tremor	Tremor
Hyperactivity	Hyperreflexia
Palpitations	Proximal muscle weakness
Appetite change (usually increased)	
Weight loss	
Menstrual disturbances	

Note: Classic features of hyperthyroidism are often absent in the elderly.

next step is radionuclide scanning to determine whether the nodule is "hot" (i.e., displaying increased tracer uptake relative to surrounding tissue). Hot nodules very seldom harbor malignancy (<1% of patients), therefore, cytologic evaluation is not required in these cases, however, this risk can be as high as 29% in children (Haugen *et al.*, 2016; Pazaitou-Panayiotou *et al.*, 2012; Eszlinger *et al.*, 2014).

Diagnosis of a toxic adenoma is based on the presence of three characteristics: (1) thyroid function tests in keeping with overt hyperthyroidism (suppressed TSH, elevated thyroid hormones [triiodothyronine (T3) and (T4)]), or subclinical hyperthyroidism (suppressed TSH, T3, and T4 normal), (2) presence of a palpable and/or sonographically localized thyroid nodule (3) increased radioiodine or ^{99m}Tc-pertechnetate uptake in the nodule concomitant with decreased uptake in the surrounding extranodular thyroid tissue. (**Fig. 4**). If these three features are met, then one can conclude that an autonomous functioning nodule is the cause of hyperthyroidism, and the diagnosis of solitary toxic adenoma is confirmed. However, it should be noted that in some situations, patients with solitary toxic adenoma may have normal thyroid function tests; thyroid scintigraphy has been shown to be more sensitive than serum TSH for detection of solitary toxic adenoma (Ianni *et al.*, 2013).

Natural History

Longitudinal studies on patients with solitary toxic adenoma have demonstrated stability or insidious progression of nodule growth and development of hyperthyroidism. A previous study that followed 287 patients for up to 15 years demonstrated that only 9% of patients had interval nodule growth of >1 cm in size and 86% of patients had no detectable change in size (Sandrock *et al.*, 1993). Patients presenting with euthyroid solitary toxic adenoma show progression to thyrotoxicosis at a rate of approximately 4% per year. Risk of progression to hyperthyroidism is increased with older age, adenomas larger than 3 cm, and in individuals living in iodine deficient regions (Corvilain, 2003). However, as the driver of solitary toxic adenoma is an acquired mutation causing autonomy, spontaneous remission will not occur except perhaps in the rare scenario of infarction of the nodule. Therefore, once a solitary toxic adenoma causes hyperthyroidism, it is unlikely that the hyperthyroidism will spontaneously resolve and definitive treatment will be required.

Particularly in regions with iodine deficiency, exposure to excess iodine is a known precipitant of thyrotoxicosis in patients with solitary toxic adenoma or other conditions with thyroid autonomy. This clinical scenario can be seen following administration of iodinated contrast media used for computed tomography scanning or angiography. Thyrotoxicosis can occur weeks to months after the exposure to an iodine load and typically has a self-limited course; thyroid storm is rare (Lee *et al.*, 2015). If possible, administration of iodinated radiocontrast should be avoided in patients with overt hyperthyroidism or those at risk of serious decompensation should acute worsening of thyrotoxicosis occur. In these cases, prophylaxis using sodium perchlorate and a thionamide prior to radiocontrast administration should be considered (Ross *et al.*, 2016; Nolte *et al.* 1996; Lawrence *et al.*,1999; Vagenakis *et al.*, 1972). However, current guidelines recommend against routine prophylaxis for all patients after radiocontrast administration (Ross *et al.*, 2016).

Treatment

It is imperative that patients with solitary toxic adenoma be counseled about the advantages, disadvantages and potential risks of the available treatment modalities, discussed below. When deciding on a treatment, the clinician should take an individualized management approach with consideration of disease factors, comorbidities, and patient preference.

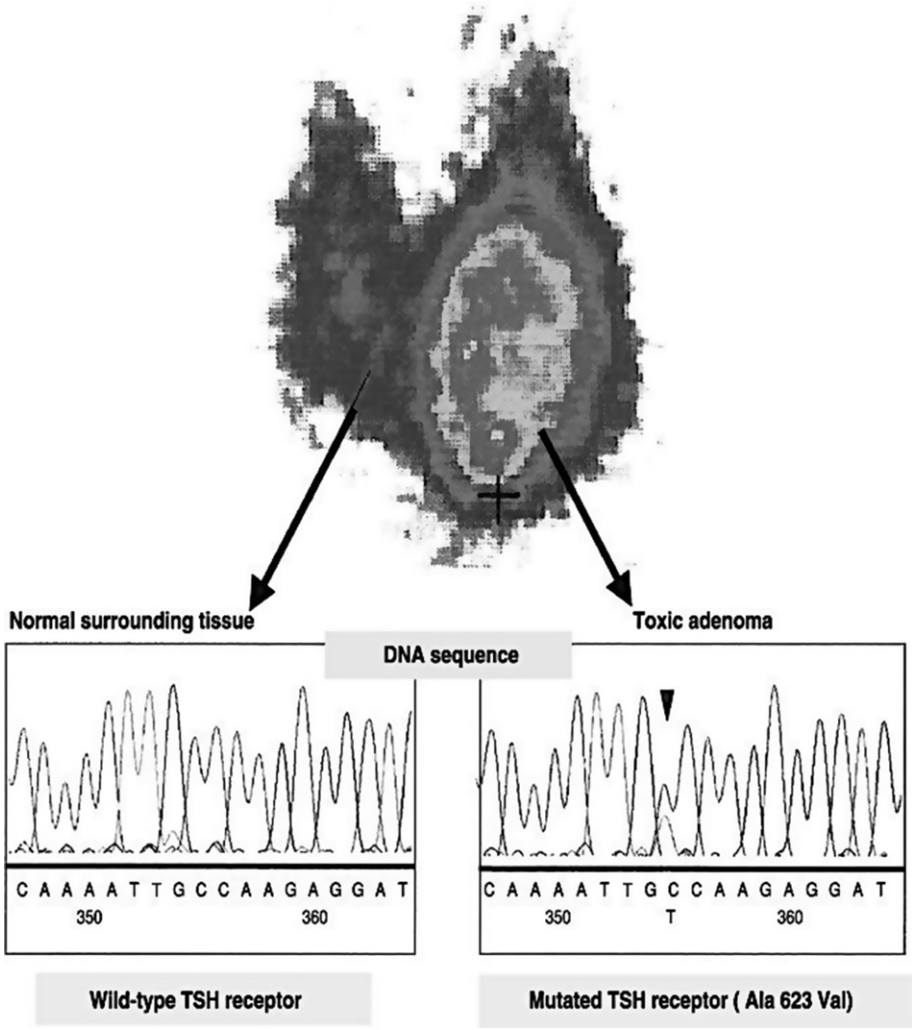

Fig. 4 Typical scintiscan finding of a TA that led to the notion of a "hot" nodule. A somatic gain-of-function TSH receptor mutation is the cause of a toxic adenoma. The mutation is present only in the hot nodule, whereas the wild-type TSH receptor sequence can be found in the normal thyroid tissue (hence the term somatic mutation).

Medical Therapy

In certain cases such as severe thyrotoxicosis or in patients at significant risk of complications due to worsening of hyperthyroidism, pre-treatment with thionamides and/or beta blockers should be considered. Thionamides such as carbimazole or methimazole should be used as first line. Beta blockers can be used as adjunctive therapy to control adrenergic symptoms such as anxiety, tremor, and palpitations. Achieving biochemical control of hyperthyroidism with a thionamide may take several weeks due to the 7 day long half-life of T4 and intra-thyroidal stores of thyroid hormone. Prior to initiation of therapy, patients should be counseled about common side effects including skin rashes (1%–5%) arthritis and rare but serious side effects including hepatotoxicity and agranulocytosis ($<0.5\%$) (Ross *et al.*, 2016).

Definitive Management

^{131}I therapy and surgery are the mainstays of definitive therapy. Alternative minimally invasive procedures are also now available, and these are discussed below. Therapy with ^{131}I therapy exploits the increased iodine uptake that is characteristic of solitary toxic adenoma, resulting in preferential accumulation of ^{131}I in the nodule and progressive destruction of the solitary toxic adenoma by ^{131}I beta radiation, with sparing of the surrounding normal thyroid tissue. ^{131}I can either be administered as an empiric fixed dose (10–20 mCi) or a calculated activity based on the size of nodule (150–200 μCi per gram) corrected for 24-h radioactive iodine uptake. The goal of treatment should be to administer a single dose of ^{131}I that will alleviate hyperthyroidism. ^{131}I therapy may lead to transient worsening of hyperthyroidism and swelling of the thyroid gland. Therefore, it should be used with caution in patients who are at risk of decompensation from cardiac disease, and in those with large goiters with compressive symptoms.

Following treatment with ^{131}I and depending on the treatment modalities, the cumulative incidence of hypothyroidism is 7.6% at 1 year, 46% at 10 years, and 60% at 20 years (Ceccarelli *et al.*, 2005). Patients who have received ^{131}I ablation should have follow-up thyroid function tests to monitor for the development of hypothyroidism. Radioiodine therapy results in the gradual resolution of hyperthyroidism, which occurs over weeks to months. Therefore, ^{131}I ablation is not the preferred treatment choice when immediate alleviation of hyperthyroidism is desired. Furthermore, ^{131}I is contraindicated in several clinical situations including pregnancy, lactation, women planning to conceive within the next 6 months, or in patients with known or suspected thyroid cancer (Ross *et al.*, 2016).

Surgery can provide rapid cure of thyrotoxicosis for patients with solitary toxic adenoma. The recommended surgical approach in solitary toxic adenoma is ipsilateral lobectomy, allowing the majority of patients to maintain euthyroidism post-operatively without thyroid hormone replacement. However, thyroid surgery is an invasive procedure that carries risks including permanent hypoparathyroidism (in case of total thyroidectomy) and vocal cord paralysis due to injury of the recurrent laryngeal nerve. Although these complications are rare in the setting of experienced, high volume surgeons, they should be discussed with patients prior to embarking on this treatment option. Relative contraindications to hemithyroidectomy include significant medical comorbidities precluding surgical candidacy or limited life expectancy. In patients that are poor surgical candidates, long-term treatment with low dose thionamides can be considered as an alternative to surgery or ^{131}I ablation (Ross *et al.*, 2016).

Alternative Treatment Approaches

Percutaneous ethanol injection involves several ethanol injections into the solitary toxic adenoma under ultrasound guidance by experienced clinicians. This procedure has good efficacy with an overall cure rate of $>90\%$ and a low complication rate (Tarantino *et al.*, 2008). A recent study evaluated radiofrequency ablation in a small multicenter cohort of 44 patients (Sung *et al.*, 2015). In this procedure, an electrode is inserted into the thyroid nodule under sonographic guidance, and delivery of thermal energy induces tissue necrosis. Normalization of thyroid function occurred in around 70% of patients and there were no major complications. Similarly, laser ablation can be used to treat solitary toxic adenoma by delivery of laser photons leading to rapid heating and necrosis, however, the efficacy of this approach has been inconsistent (Papini *et al.*, 2016). Cumulative experience with these novel alternative approaches is limited and as such, they should only be employed at specialized centers in circumstances where surgery and I^{131} are contraindicated.

Glossary

Autonomy The ability of thyrocytes to function and produce thyroid hormones without stimulation from thyrotropin.
Constitutive thyrotropin (TSH) receptor activation State of activation of the TSH receptor in the absence of TSH caused by a mutation in the TSH receptor gene.
Euthyroid goiters The most common form of thyroid enlargement without clinical or laboratory evidence of abnormal thyroid hormone production.
Goitrogens Substances such as food or drugs that disrupt normal thyroid hormone production, leading to increased stimulation and growth of the thyroid gland, that is, formation of a goiter.
Scintiscan Radionuclide scanning of the thyroid after administration of technetium (as isotope ^{99}Tc in the form of pertechnetate), or iodine (as isotope ^{123}I or ^{131}I), used for a functional assessment of the thyroid's ability to take up iodine.
Sodium-iodine symporter (NIS) A transporter found in the basolateral membrane of thyroid follicular cells that facilitates uptake of iodine by active transport via exchange of two sodium cations and one iodide anion.
T4 Thyroxine
T3 Triiodothyronine
Thyrocyte Epithelial cells within the thyroid gland that are responsible for thyroid hormone synthesis. Also known as thyroid follicular cells.
Thyrotoxicosis Also known as hyperthyroidism. A systemic alteration of metabolism in which increased levels of thyroid hormone production result in biochemical and/or clinical signs of excess thyroid hormone.
Toxic thyroid adenoma Benign monoclonal thyroid tumor with autonomous thyroid hormone production. This term is interchangeable with "toxic thyroid nodule" and "hot nodule."
TSH Thyroid-stimulating hormone; a pituitary hormone that regulates the functioning and growth of thyroid follicular cells.

Definition

Toxic multinodular goiter is a heterogeneous disorder, which is characterized by a mixture of thyroid nodules that are hyper-, iso-, and hypo-functioning by scintigraphic evaluation. The overall degree of thyroid autonomy in the gland determines the clinical status of the patient, which can range from euthyroidism to subclinical or overt hyperthyroidism.

Introduction

Goiter is a heterogeneous term that refers to diffuse or nodular enlargement of the thyroid gland, and can be associated with normal, increased, or decreased thyroid hormone production. Goiters are commonly seen in populations with mild to moderate iodine deficiency. The term toxic multinodular goiter more specifically refers to multiple autonomously functioning thyroid nodules on a background of iso- or hypo-functioning nodules. Toxic multinodular goiter arise from longstanding non-toxic multinodular goiters. In toxic multinodular goiter, the cumulative functional status from all nodules results in a net increase in thyroid hormone production, manifesting as either subclinical or overt hyperthyroidism (Krohn *et al.*, 2005).

Epidemiology

Recent data suggests that toxic multinodular goiter accounts for approximately 6% of all cases of hyperthyroidism in iodine sufficient populations (Laurberg *et al.*, 2010). However, the overall prevalence of toxic multinodular goiter is inversely correlated with the iodine status of the population, and in regions of iodine deficiency toxic multinodular goiter is the most common cause of hyperthyroidism, accounting for almost 50% of cases (Laurberg *et al.*, 2010; Carlé *et al.*, 2011). The introduction of iodized salt in previously iodine

☆*Change History*: February 2018. Amita Mahajan, Kirstie Lithgow, and Sana Ghaznavi introduced Abstract, updated Epidemiology, Etiology, Diagnosis, Natural History, Treatment, and the References sections, deleted the previous Figure 1, added Table 2, and Figures 1 and 2.

 doi:10.1016/B978-0-12-801238-3.96038-0

deficient regions has successfully led to a decline in the incidence of toxic multinodular goiter (Laurberg *et al.*, 2010). Toxic multinodular goiter is predominantly seen in older individuals; the median age of affected individuals is 75 years. A steep rise in incidence of toxic multinodular goiter is observed after the fifth decade, and continues to increase steadily with age thereafter. Similar to other thyroid diseases, toxic multinodular goiter has a female preponderance with a F:M ratio of 6:1 (Carlé *et al.*, 2011). Pazaitou-Panayiotou *et al.* (2012) reviewed the risk of malignancy in toxic multinodular goiter, and found a range in the literature from 1.8% to 8.8%. However, the common finding of incidental papillary microcarcinomas of the thyroid gland, along with the fact that several studies failed to accurately discriminate between malignancies occurring inside and outside of the hyperfunctioning nodule, has likely led to an overestimation of malignancy risk in toxic multinodular goiter. Given the overall low risk of malignancy in autonomous nodules, several guideline societies recommend against routine cytologic evaluation of these lesions (Haugen *et al.*, 2016; Gharib *et al.*, 2016).

Etiology

The development of toxic multinodular goiter is thought to occur in the following key steps: (1) iodine deficiency or exposure to other goitrogens leads to increased functional activity of the thyroid and thyrocyte hyperplasia; (2) nodular transformation occurs when increased proliferation and oxidative damage of thyrocytes induces somatic mutations of the TSH receptor or other genes that stimulate thyrocyte growth and/or function; (3) increased cell division, clonal formation and proliferation leads to subsequent formation of thyroid nodules (Krohn *et al.*, 2005). These steps are illustrated in **Fig. 1**, and will be discussed in detail below.

Previously multinodular goiter was regarded solely a consequence of iodine deficiency and persistent TSH elevation. Though iodine deficiency is recognized as the primary driver of goitrogenesis in most cases, TSH is not elevated in patients with multinodular goiter and several other contributing factors have been identified. Female gender has been associated with the development of multinodular goiter; this is thought to be due to the growth promoting effects of female sex steroid hormones on thyrocytes. Smoking has been implicated in multinodular goiter formation, presumably due to the competitive inhibition of the sodium iodine symporter (NIS) by the thiocyanate present in tobacco. Statins, lithium, and dietary goitrogens also appear to predispose individuals to developing multinodular goiter (Knobel, 2016). Numerous environmental chemicals are now recognized to disrupt thyroid function and subsequently contribute to multinodular goiter development; these are discussed in detail elsewhere.

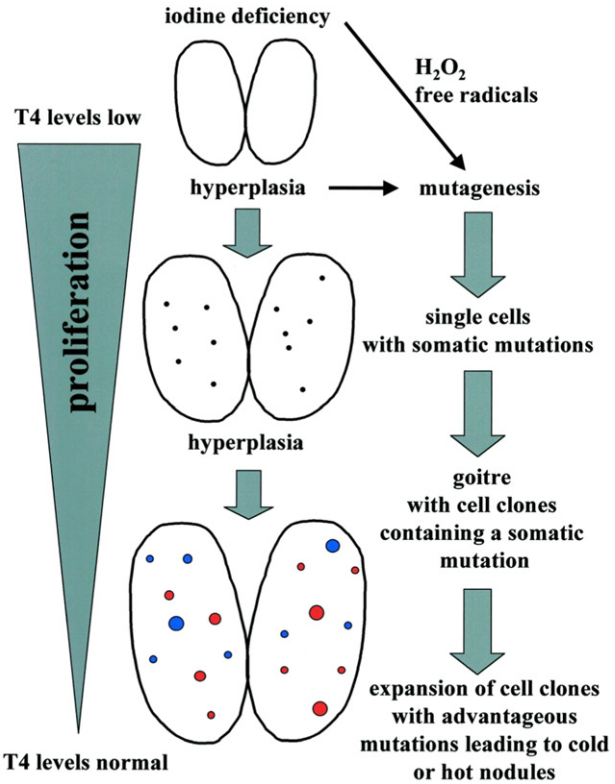

Fig. 1 Hypothesis for the evolution of clonal thyroid nodules in multinodular goiters. Hyperplasia due to iodine shortage increases the likelihood for somatic mutations that may confer a growth and functional advantage. Further expansion of cell clones ultimately results in "hot" and "cold" nodules that characteristically prevail together in multinodular goiters. Reproduced with permission from Krohn, K. and Paschke, R. (2001). Clinical review 133: Progress in understanding the etiology of thyroid autonomy. *Journal of Clinical Endocrinology & Metabolism* **87**(7), 3336–3345.

Individual genetic susceptibility is thought to play a crucial role in the development of multinodular goiter, as evidenced by familial clustering of goiters and higher concordance rates observed in monozygotic twins. Genes involved in thyroid hormone synthesis including thyroglobulin (TG), thyroid peroxidase (TPO), pendrin (PDS), NIS, and the TSH receptor have all been implicated as candidate genes. Genome wide linkage studies have identified several loci in families with multinodular goiter showing a dominant inheritance pattern (Neumann *et al.*, 1999; Bayer *et al.*, 2004; Krohn *et al.*, 2005). In summary, the development of multinodular goiter is likely a complex interplay of genetic and environmental factors, although the specific molecular mechanisms are not yet completely understood.

Exposure to iodine deficiency and the other aforementioned goitrogens leads to an increase in thyrocyte number and functional activity. Increased thyroid function induces activation of H_20_2, which is an important substrate in thyroid hormone synthesis. This causes increased generation of free radicals that may damage genomic DNA and subsequently cause spontaneous mutations and inhibit mutational repair (Krohn *et al.*, 2005). Some of these acquired mutations occur in areas such as the TSH receptor gene or in the α-subunit of the G_s protein ($G_{s\alpha}$) and confer a functional and/or proliferative advantage to the thyrocyte by causing a constitutive activation of the cAMP signaling cascade. Stimulation of the cAMP cascade leads to increased iodide uptake by upregulation of NIS, increased thyroid hormone synthesis, and growth of thyrocytes. Autonomous nodules are therefore likely to develop from small clones that contain these advantageous mutations within a multinodular goiter (Hébrant *et al.*, 2011). Over time, the autonomous function of these nodules may reach a level where net thyroid hormone production is increased causing subclinical or overt hyperthyroidism, leading to transformation of multinodular goiter to toxic multinodular goiter.

Natural History

Many patients with toxic multinodular goiter have a long-standing history of multinodular goiter, with evolution of thyroid autonomy over a number of years (Krohn *et al.*, 2005). The development of hyperthyroidism is insidious in onset, manifesting initially with subclinical hyperthyroidism and eventually progressing to overt hyperthyroidism. Longitudinal studies have demonstrated that around 10% of individuals with euthyroid goiter will progress to toxic multinodular goiter over a mean 12 year follow up period (Elte *et al.*, 1990; Wiener, 1987). The degree of thyroid autonomy is correlated with thyroid volume, which increases over time. Thus, advanced age is a risk factor for progression to toxic multinodular goiter (Carlé *et al.*, 2011; Krohn *et al.*, 2005). In rare cases, transient thyrotoxicosis due to hemorrhagic infarction can occur, followed by regression in size and autonomy (Hamburger and Taylor, 1979).

Autonomous function in patients with toxic multinodular goiter can be exacerbated by exposure to excess iodine, such as with iodinated contrast media in the setting of computed tomography scanning or angiography (Lee *et al.*, 2015). Thyrotoxicosis can occur weeks to months after the exposure to an iodine load and typically has a self-limited course; thyroid storm is exceedingly rare (Lee *et al.*, 2015). If possible, administration of iodinated radiocontrast should be avoided in patients with overt hyperthyroidism or those at risk of serious decompensation due to thyrotoxicosis. Alternatively, prophylaxis using sodium perchlorate and/or a thionamides prior to radiocontrast administration should be considered (Ross *et al.*, 2016).

Diagnosis

Patients with toxic multinodular goiter may come to the attention of physicians in several different ways. Firstly, they may present due to signs and symptoms of hyperthyroidism such as anxiety, tremor, palpitations, weight loss, heat intolerance, or increased frequency of bowel movements (summarized in **Table 1**). It is important to note that these classic symptoms of hyperthyroidism may be absent in the elderly (Thomas *et al.*, 1970). Secondly, subclinical or biochemical hyperthyroidism may be detected due to

Table 1 Clinical manifestations of thyrotoxicosis

History	*Physical exam*
Anxiety	Hyperactivity
Fatigue	Tachycardia/arrhythmia
Increased perspiration	Systolic hypertension
Heat intolerance	Warm, moist skin
Tremor	Tremor
Hyperactivity	Hyperreflexia
Palpitations	Proximal muscle weakness
Appetite change (usually increased)	
Weight loss	
Menstrual disturbances	

Note: Classic features of hyperthyroidism are often absent in the elderly.

routine screening of serum TSH. Alternatively, patients may present due to detection of a thyroid nodule or goiter by neck palpation, ultrasonography, or due to symptoms suggestive of obstruction, such as dysphagia, dyspnea, or cough. Therefore, the clinical pathway for the diagnostic workup of patients with toxic multinodular goiter will depend upon the presenting complaint.

In all cases, clinicians should begin their assessment with a detailed history and physical examination focused on delineating signs and symptoms of hyperthyroidism, obstruction, and risk factors for thyroid cancer. Physical examination of the thyroid may reveal diffuse, painless enlargement of the gland with multiple palpable nodules. Examination should also include palpation of the lower edge of the thyroid gland and percussion over the manubrium listening for dullness, to assess for retrosternal extension of the goiter.

Following this, patients should undergo measurement of serum TSH $+/-$ free T4 and free T3. Laboratory testing may reveal euthyroidism (normal TSH/T4/T3), subclinical hyperthyroidism (low TSH, normal T3/T4), or overt hyperthyroidism (low TSH, high T3/T4). Neck ultrasonography should be obtained to confirm the location, size, and number of thyroid nodules, the size of the gland, and presence of lymphadenopathy. Ultrasound of the thyroid is also a crucial step in risk stratification of thyroid nodules and determination of the need for fine needle aspiration biopsy. This is discussed in detail elsewhere.

If subclinical or overt hyperthyroidism exists in the context of solitary or multiple thyroid nodules, the next step is thyroid scintigraphy to determine the functional status of the gland and associated nodules. Scintigraphy also provides information about possible substernal extension of the goiter (Bahn and Castro, 2011; Becker *et al.*, 1996). Hyper-functioning nodules have a very low risk of malignancy, and fine needle aspiration biopsy of these lesions is not recommended (Pazaitou-Panayiotou *et al.*, 2012; Haugen *et al.*, 2016; Gharib *et al.*, 2016). As previously mentioned, toxic multinodular goiter is a heterogeneous condition and nodules can exhibit variable scintigraphic patterns including normal or decreased uptake, circumscribed areas of increased uptake with suppression of surrounding thyroid tissue, or areas of increased uptake without suppression of the surrounding parenchyma. In patients without complete scintigraphic suppression of the surrounding parenchyma, thyroid hormones may be administered prior to suppression scintigraphy in order to differentiate autonomous from normal thyroid tissue.

The clinical diagnosis of toxic multinodular goiter is based on the presence of three characteristics: (1) palpable and or sonographically localized thyroid nodules; (2) increased radioiodine or ^{99m}Tc-pertechnetate uptake in nodular structures typically concomitant with a decreased uptake in surrounding extranodular thyroid tissue; (3) excess thyroid hormone production causing thyrotoxicosis, concurrently with the suppression of TSH secretion from the pituitary gland (see **Fig. 2**).

It is important to differentiate toxic multinodular goiter from other causes of hyperthyroidism including Graves' Disease, solitary toxic adenoma, and painless or subacute thyroiditis. In iodine-deficient areas, the distinction between autoimmune and non-autoimmune forms of hyperthyroidism (i.e., Graves' Disease and toxic multinodular goiter) may be challenging due to a mixed clinical presentation. For example, patients may have Graves' Disease superimposed on pre-existing nodular thyroid disease. In this case, the scintiscan may be suggestive of toxic multinodular goiter but the presence of thyroid autoantibodies is suggestive of Graves' Disease. Another diagnostic challenge may occur in sporadic or familial autosomal dominant non-autoimmune hyperthyroidism when a germline TSH receptor mutation is found in the setting of undetectable TSH receptor antibodies (Ferraz and Paschke, 2017).

Treatment

Management of patients with toxic multinodular goiter should take into account several clinical and demographic factors, in addition to patient values and preferences. The goal of therapy is rapid and lasting elimination of the hyperthyroid state and alleviation of obstructive symptoms. Therefore, the main indications for treatment include a large goiter causing compressive symptoms or thyrotoxicosis. Subclinical hyperthyroidism has been associated with higher risk of atrial fibrillation, osteoporosis, and an increase in 10-year cardiovascular mortality (Krohn *et al.*, 2005). Current guidelines suggest that treatment for subclinical hyperthyroidism should be initiated for the following groups of patients: those >65 years old with cardiac risk factors, heart disease, or osteoporosis; post-menopausal women who are not taking medications for bone protection; and symptomatic patients (Ross *et al.*, 2016).

Medical Therapy

In patients with severe thyrotoxicosis or those at significant risk of complications due to worsening of hyperthyroidism, pre-treatment with thionamides and/or beta blockers should be considered. Low dose thionamides such as carbimazole or methimazole should be used as first line. Beta blockers can be used as adjunctive therapy to control adrenergic symptoms such as anxiety, tremor, and palpitations. Achieving biochemical control of hyperthyroidism typically takes several weeks as thionamides block new thyroid hormone synthesis, but intra-thyroidal stores continue to be released until they are depleted. Prior to initiation of therapy, patients should be counseled about common side effects of thionamides including skin rashes (1%–5%), arthritis and rare but serious complications such as hepatotoxicity and agranulocytosis ($<0.5\%$). Anti-thyroidal drugs are not routinely recommended for long-term use because they cannot induce remission in nodular thyroid disease. However, long term anti-thyroidal drug use can be considered when definitive therapy is contraindicated, such as in the elderly or those with limited life expectancy.

Definitive Management

Definitive treatment of toxic multinodular goiter includes surgical resection of the thyroid gland or radioactive iodine. The risks, benefits, and alternatives of each treatment should be discussed with the patient prior to choosing a therapy. Factors that influence the choice of treatment modality are outlined in **Table 2**.

Surgery

Surgery is the preferred treatment option if immediate eradication of hyperthyroidism is desired, if thyroid malignancy is suspected or confirmed, if obstructive symptoms are present due to large goiter with mass effect, or if coexisting hyperparathyroidism exists that requires simultaneous treatment. In contrast, patients with previously operated or irradiated necks, or those with increased surgical risk are not ideal surgical candidates. Relative contraindications to surgery for toxic multinodular goiter include significant comorbidities, limited life expectancy, and pregnancy.

If surgery is chosen as the treatment for a patient with toxic multinodular goiter, pre-treatment with a thionamide $+/-$ beta blockade is recommended to achieve euthyroidism, thus minimizing the risk of intraoperative and postoperative complications from hyperthyroidism. Preoperative iodine should not be administered in this setting due to the risk of exacerbating hyperthyroidism. The preferred surgical procedure for treatment of toxic multinodular goiter is a near-total or total thyroidectomy. Thionamides should be stopped after surgery, while ß-adrenergic blockade should be slowly tapered following the operation. The

Table 2 Factors influencing the choice of treatment modality for toxic multinodular goiter

Factors that favor radioiodine treatment	*Factors that favor surgical treatment*
Small to medium sized goiter	Large goiter or compressive symptoms
Previously operated or irradiated neck	Desire for rapid termination of hyperthyroidism
Increased surgical risk of patient	Suspicion of thyroid malignancy
	Low radioiodine uptake
	Coexisting hyperparathyroidism requiring treatment

risk of treatment failure or need for repeat treatment is <1% following near-total or total thyroidectomy, however the risk of permanent hypothyroidism requiring thyroid hormone replacement is 100%. Potential surgical complications include risk of permanent hypoparathyroidism (<1.0%) or vocal cord paralysis due to recurrent laryngeal nerve injury (<1.0%). Although these complications are rare in the setting of experienced, high volume surgeons, they should be discussed with patients prior to embarking with this treatment option.

Radioactive ^{131}Iodine (RAI)

In patients with contraindications to or a preference for avoiding surgery, RAI therapy can be used to eradicate hyperthyroidism and reduce the thyroid gland volume. Contraindications to RAI use include pregnancy, lactation, coexisting thyroid cancer, or cases where individuals are unable to comply with radiation safety guidelines. In addition, RAI treatment may lead to transient worsening of hyperthyroidism and swelling of the thyroid gland, and should be used with caution in patients at high risk of decompensation from thyrotoxicosis or those at risk of tracheal obstruction.

RAI therapy may exacerbate hyperthyroidism leading to tachyarrhythmias, and in extremely rare cases, thyroid storm (Koornstra *et al.*, 1999). Therefore, in preparation for RAI, pretreatment with beta blockade should be considered in patients with a pre-existing cardiac history or in the elderly. Thionamides may also be used to achieve euthyroidism in patients at high risk of decompensation from worsening hyperthyroidism. However, thionamides may reduce the efficacy of RAI treatment when used in the week before or after RAI administration, therefore, they are routinely held during this interval (Walter *et al.*, 2007; Ross *et al.*, 2016). The recommended RAI activity for treatment of toxic multinodular goiter is based on goiter size, and aims to deliver 150–200 μCi (5.55–7.4 MBq) per gram of tissue corrected for 24-h RAI uptake (Ross *et al.*, 2016).

It should be noted that an elevated or normal TSH at the time of RAI administration will lead to radiation exposure of perinodular normal thyroid tissue. If goiter volume reduction is a goal of treatment, this property may be leveraged to achieve a greater reduction in goiter size at the expense of permanent hypothyroidism. Patients with large goiters should be monitored after administration of RAI for symptoms of compression such as hoarseness, dysphagia, or dyspnea. Significant symptoms such as these can be treated with corticosteroids. The failure rate of RAI in treatment of toxic multinodular goiter is around 15% (Nygaard *et al.*, 1999). The response rate, characterized by alleviation of hyperthyroidism and goiter volume reduction, increases with time and is around 80% by 6 months post-administration of RAI (Nygaard *et al.*, 1999; Kang *et al.*, 2002). The risk of hypothyroidism is 6% at 1 year, and 72% within 26 years following RAI administration for hyperthyroidism (Holm *et al.*, 1982).

Patients who have received ^{131}I ablation should have their thyroid function tests monitored at 1–2 months post treatment, including measurement of serum TSH, free T4, and total T3. Biochemical monitoring should occur every 4–6 weeks for the first 6 months, and annually thereafter (Ross *et al.*, 2016). The long-term management of patients with toxic multinodular goiter is directed at the detection of thyroid dysfunction (hypothyroidism after RAI treatment or relapse of hyperthyroid state), relapse of goiter, and treatment of surgical complications (e.g., calcium and/or vitamin D administration in the case of hypoparathyroidism).

Thyroiditis, Infectious and Subacute☆

Grigoris Effraimidis, Copenhagen University Hospital, Copenhagen, Denmark
Ulla Feldt-Rasmussen, Copenhagen University Hospital, Copenhagen, Denmark

Glossary

Genetic susceptibility Heritable trait based on histocompatibility genes.
Fine needle aspiration biopsy Aspiration of the contents of a thyroid nodule for diagnostic evaluation.
Hypothyroidism Clinical state of hypometabolism characterized by low circulating concentrations of thyroid hormones.
Pyriform sinus fistula Communication between the pyriform sinus and the thyroid gland, most commonly on the left side. It is the most common cause of bacterial thyroiditis.
Radioactive iodine uptake Ability of the thyroid gland to trap iodine.
Thyroiditis Inflammation of the thyroid gland, most often autoimmune in nature (chronic) but may also be caused by infection (subacute and acute).
Thyrotoxicosis Clinical state of hypermetabolism characterized by elevated circulating concentrations of thyroid hormones.

The term thyroiditis is defined as inflammation of the thyroid gland. It is a heterogeneous group of disorders which can be classified according to their symptoms development as acute, subacute and chronic. However, it should be underlined that there is a considerable overlap in their clinical presentation. The acute infectious thyroiditis (caused by pathogenic microorganisms) and subacute thyroiditis (precipitated by viral infection in genetically predisposed individuals) are illustrated in this article.

Infectious Thyroiditis

Infectious thyroiditis, also known as acute suppurative thyroiditis, is a potentially life-threatening disorder caused by invasion of the thyroid by infectious organisms, usually bacterial, fungal, parasitic and mycobacterial infections.

Introduction

Infections of the thyroid are rare, with only about 300 and 100 cases reported in the literature in adults and children, respectively (Yamada *et al.*, 2009). This is due, in large part, to the resistance of the thyroid gland to infection through protective mechanisms, including the rich blood supply to and lymphatic drainage from the thyroid gland; the high glandular content of iodine and peroxidase, which may be bactericidal; and the separation of the thyroid from other structures of the neck by fascial planes and the complete, protective fibrous encapsulation of the gland. The most common predisposing factor to infections of the thyroid appears to be preexisting thyroid disease. Simple goiter, nodular goiter, Hashimoto's thyroiditis, or thyroid carcinoma have been observed in up to two-thirds of women and one-half of men with infectious thyroiditis. The most frequent predisposing factor in children and adolescents is a fistula from the pyriform sinus that extends to the thyroid capsule (Rich and Mendelman, 1987; Sai Prasad *et al.*, 2007). Immunocompromised patients, such as those infected with human immunodeficiency virus or those on immunosuppressive drugs, are particularly at risk for bacterial thyroiditis (Pearce and Farwell, 2003). Thyroidal infections are potentially life threatening, especially if the diagnosis is delayed and appropriate antimicrobial therapy is not instituted, with an overall mortality of up to 12% (Berger *et al.*, 1983; Paes *et al.*, 2010).

Bacterial Infections

Bacterial infections are the most common cause of infectious thyroiditis, comprising about the 75% of cases (Paes *et al.*, 2010; Yu *et al.*, 1998); thus, the presentation, diagnosis, and management of bacterial thyroiditis are discussed in detail. The seminal observation regarding the pathogenesis of bacterial thyroiditis was made in 1979 when Takai *et al.* reported seven cases of infectious thyroiditis due to a fistula originating from the left pyriform sinus (Takai *et al.*, 1979). Subsequently, it has been reported that a pyriform sinus fistula is the most common route of infection in acute suppurative thyroiditis, especially in children and in patients with recurrent episodes. Pyriform sinus fistulae is primarily located in up to 90% on the left side (Miyauchi *et al.*,

☆*Change History*: October 2017. Grigoris Effraimidis and Ulla Feldt-Rasmussen updated the text, tables, further reading and glossary to the entire "Infectious Thyroditis" section and they have written afresh the "Subacute Thyroiditis" section.
This article is an update of Alan P Farwell, Thyroiditis, Infectious, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 505–508.

1990). Additional reports have identified the following routes of thyroidal infection: infected embryonic cysts from the third and fourth brachial pouches, patent thyroglossal duct fistulae, infections of the retropharyngeal space (pharyngitis and tonsillitis) or the lateral pharyngeal spaces (pharyngitis, tonsillitis, parotitis, otitis, and mastoiditis), and perforations in the esophagus. Case reports of hematogenous spread from infections of the skin, lower respiratory tract, urinary tract, and gastrointestinal tract have been described. Hematogenous inoculation occurs more often in adults than in children, usually in the presence of other underlying illnesses. Infectious thyroiditis has also been reported as a complication of thyroid surgery or after fine needle aspiration biopsy (Ünlütürk *et al.*, 2013).

Clinical Presentation and Diagnosis

Bacterial thyroiditis is often preceded by an upper respiratory infection, which may induce inflammation of the fistula and promote the transmission of pathogens to the thyroid (**Table 1**). More than 90% of patients present with thyroidal pain, tenderness, fever, and local compression resulting in dysphagia and dysphonia. Signs and symptoms of systemic toxicity may be present. The thyroid is tender to palpation, with unilateral or bilateral lobar enlargement, firm swelling that moves on swallowing and it is associated with erythema and warmth of the skin. Cervical lymphadenopathy is not a prominent feature unless there is a predisposing pharyngitis.

The differential diagnosis of bacterial thyroiditis can be divided into nonthyroidal and thyroidal causes (**Table 2**). Essentially all of the nonthyroidal causes are infectious in origin and present as discrete painful masses. Subacute thyroiditis is the most common cause of a painful thyroid and often results in both local and systemic symptoms similar to those seen in bacterial thyroiditis. The pain in acute suppurative thyroiditis does not relocate during the clinical course of the disease which can be a key point in the differential diagnosis with subacute thyroiditis.

Thyroid function tests are usually in the normal range in patients with bacterial thyroiditis (**Table 1**), but both thyrotoxicosis and hypothyroidism have been reported (Goldani *et al.*, 2006; Luiz *et al.*, 2013). Thyrotoxicosis is transient due to destruction of the thyroid tissue. Fine needle aspiration biopsy is the best laboratory test in the evaluation of infectious thyroiditis and is diagnostic in most cases, especially when tenderness is limited to a solitary nodule or a localized area and subacute thyroiditis has been ruled out. Gram stain and culture of the fine needle aspirate will reveal the causative organism in the overwhelming majority of the cases. Most imaging studies are adjunctive and are best reserved for patients for whom the diagnosis is unclear.

In adults, *Staphylococcus aureus* and *Streptococcus pyogenes* are the offending pathogens in the majority of cases (Paes *et al.*, 2010; Yu *et al.*, 1998). In children, *S. aureus*, *S. pyogenes*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae* and *Haemophilus influenza* account for most cases. Anaerobic bacteria are also isolated from the infected thyroid and they are usually members of the oropharyngeal flora (Chi *et al.*, 2002).

Management and Prognosis

Once acute suppurative thyroiditis is suspected, the initiation of empiric antibiotic treatment is essential before the culture results are known, taking into consideration the potential mortality of the acute suppurative thyroiditis. In adults antibiotic therapy should cover gram-positive cocci. An antistaphylococcal β-lactam such as nafcillin or cefazolin combined with an aminoglycoside (gentamicin) or monotherapy with a third-generation cephalosporin are appropriate initial regimens (Chow, 2009). In penicillin-allergic patients or if methicillin resistant *S. aureus* is suspected, vancomycin can be chosen. Anaerobic coverage (e.g., clindamycin or β-lactam/β-lactamase inhibitor) should also be included as oral anaerobes may be involved in acute suppurative thyroiditis, especially in pediatric or recurrent cases. For children empiric antibiotic therapy should provide adequate coverage for *S. aureus* and *S. pyogenes* (Schlossberg, 2015). A broader spectrum of antimicrobial therapy should be considered in patients with human immunodefiency virus infection. Empirical antibiotic therapy should be adjusted according to the microbiological susceptibility and modified after the culture results are available.

In patients with compromised airway, an urgent transcutaneous or open-surgical drainage should be considered. In stable patients, therapeutic ultrasound guided fine needle aspiration biopsy may be appropriate.

Since a pyriform sinus fistula is the most common route of infection in bacterial thyroiditis, a barium swallow, computed tomography, or magnetic resonance imaging of the neck should be performed to search for communicating fistulae in most patients, especially in children with the first episode and in all patients with recurrent episodes. Such fistulae must be surgically excised or endoscopically chemo- or electrical-cauterized for definitive cure and prevention of recurrent infection.

With prompt and appropriate treatment, the prognosis of the acute suppurative thyroiditis is excellent unless the diagnosis is delayed and antimicrobial therapy is not initiated during the acute phase.

In survivors, complete recovery is the norm, although there have been reports of transient hypothyroidism, vocal cord paralysis (which may also be transient), and recurrence of infection as sequelae of acute bacterial thyroiditis.

Fungal Infections

Although rare, fungal infections of the thyroid are the next most common cause of infectious thyroiditis, comprising 15% of reported cases (Paes *et al.*, 2010; Yu *et al.*, 1998). The overall fatality rate associated with fungal thyroiditis is high as most

Table 1 Clinical features and the diagnostic tests in the evaluation of infectious thyroiditis and subacute thyroiditis and their comparison

	Characteristic	*Acute thyroiditis*	*Subacute thyroiditis*
History	Fever	Always	Half of the patients
	Thyrotoxicosis	Uncommon	Half of the patients
	Sore throat/preceding upper respiratory infection	Very common	About half of the patients
Physical examination	Left side affected	In about 90% of the cases	Not specific
	Erythema of overlying skin	Very common	Not common
Lab tests	White blood cell count	Usually elevated; nonspecific test	Less than 50% of the patients has leukocytosis; nonspecific test
	Erythrocyte sedimentation rate	Almost always elevated; nonspecific test	Almost always highly elevated >50 mm/h; normal ESR places the diagnosis of subacute thyroiditis in question
	Thyroid function tests	Usually normal; hypothyroidism and thyrotoxicosis can be found	More than 50% of the patients has thyroid function tests indicative of thyrotoxicosis
	Liver enzymes	Usually normal	Common abnormal
	Screening for human immunodeficiency virus	Prudent	Not necessary
Imaging examinations	Fine needle aspiration biopsy	Diagnostic in the vast majority of cases; test of choice; special stains considered necessary	Not necessary
	Radionucleide imaging	Adjunctive test; radioiodine or 99mTc best; provides information regarding overall gland function	Radioactive iodine or 99mTc uptake is always low, usually less than 2% after 24 h; if the radioactive iodine uptake is more than 5% the diagnosis is unlikely
	Ultrasonography	Adjunctive test; might help in the differential diagnosis; unifocal hypoechoic lesions; helpful in identifying pyriform sinus fistulae and/or spread of the infection	Adjunctive test; might help in the differential diagnosis; usually multiple and bilateral lesions in subacute thyroiditis. Not specific
	Neck radiography	Adjunctive test; tracheal deviation; presence of gas indicates abscess with anerobic organisms	Not indicated
	Barium swallow	Adjunctive test; helpful in identifying pyriform sinus fistulae	Not indicated
	Computed tomography	Adjunctive test; helpful in identifying pyriform sinus fistulae and/or spread of the infection	Not indicated
	Magnetic resonance imaging	Adjunctive test; helpful in identifying pyriform sinus fistulae and/or spread of the infection	Not indicated
Clinical Course	Response to glucocorticoid treatment	Transient	Significant clinical improvement within 24 h after the initiation of steroids; absence of rapid improvement would call the diagnosis into question
	Incision and drainage required	Often, especially in patients with compromised airway	Never
	Piriform sinus fistula	The most common route of infection, especially in children and in patients with recurrent episodes	Never

patients with fungal thyroiditis have disseminated fungal infection. The predominant offending organism is Aspergillus species, with the majority of the cases found at autopsy. Virtually all of the affected patients were immunocompromised and had disseminated disease. Asymptomatic infection of the thyroid with *Pneumocystis jiroveci* (former carinii) is found in more cases as the number of immunocompromised patients increase. Case reports of fungal infections of the thyroid have included *Coccidioides immitis, Cryptococcus neoformans, Candida albicans, Histoplasma capsulatum, Pseudallescheria boydii,* and *Nocardia asteroids* (Goldani *et al.*, 2006). There is a tendency of patients with fungal thyroiditis to be hypothyroid (62.5% of the cases) (Yu *et al.*, 1998).

Table 2 Differential diagnosis of the painful neck mass

Nonthyroidal
Infected thyroglossal duct cyst
Infected branchial cleft cyst
Infected cystic hygroma
Cervical adenitis
Cellulitis of the anterior neck
Parathyroid hemorrhage
Thyroidal
Subacute thyroiditis
Infectious thyroiditis
Acute hemorrhage into a cyst or into a benign or malignant nodule
Rapidly enlarging thyroid carcinoma (differentiated, medullary, anaplastic, lymphoma)
Painful Hashimoto's thyroiditis
Radiation thyroiditis
Globus hystericus

Mycobacterial Infections

The true incidence of infection of the thyroid with Mycobacterium tuberculosis has been reported around 10% (Paes *et al.*, 2010; Yu *et al.*, 1998). Infections with atypical mycobacteria, including *M. cheloni* and *M. avium-intracellulare*, have also been described. Mycobacterial thyroiditis had a tendency to cause hypothyroidism (50% of the cases) (Luiz *et al.*, 2013; Yu *et al.*, 1998).

Parasitic Infections

Parasitic agents such as *Echinococcus granulosus* and Cysticercus species have involved the thyroid on rare occasions. If echinococcal infection is suspected, biopsy of the lesion is contraindicated due to spillage and rupture of the cyst contents, and specific serologic testing should be performed. Surgical removal is the preferred mode of treatment, with antiparasitic agents useful as adjunctive therapy and for inoperable cases. Involvement of the thyroid with *Strongyloides stercoralis* has been described only in the setting of disseminated disease in immunocompromised patients.

Viral Infections

The most common infectious organism found in the thyroid at postmortem examination in patients with acquired immune deficiency syndrome is cytomegalovirus, occurring in the setting of disseminated cytomegalovirus infection. However, symptomatic thyroidal infection with cytomegalovirus has not been reported. Thyroiditis has been associated with mumps parotitis, although this is rare.

Subacute Thyroiditis

Subacute thyroiditis is a self-limited inflammatory disorder of the thyroid characterized by neck pain or discomfort, a predictable course of thyroid dysfunction, and disruption of the thyroid follicular cell architecture.

Introduction

Subacute thyroiditis was first described in 1895 by Mygind (1895) in 18 patients with "Thyroiditis akuta simplex." The Swiss surgeon De Quervain described the pathology of the disorder in 1904 and he differentiated it from other forms of thyroiditis (Engkakul *et al.*, 2011). Therefore, the disorder often bears De Quervain's name. It is also referred as subacute granulomatous thyroiditis, subacute thyroiditis, subacute painful thyroiditis, and pseudogranulomatous thyroiditis.

Epidemiology

Subacute thyroiditis is the most common form of painful thyroiditis (Engkakul *et al.*, 2011) and it has been estimated to account for up to 5% of all clinical thyroid abnormalities (Farwell, 2006) and to occur at the rate of 1 case per 5 cases of Graves' disease and in 1 case per 15–20 cases of Hashimoto's thyroiditis (Guimaraes, 2016). Subacute thyroiditis is more common in women (female to male ratio is 3 to 7:1), between the ages of 40 and 50 years and it is rare in children (Carlè *et al.*, 2011; Fatourechi *et al.*, 2003; Nishihara *et al.*, 2008).

Pathogenesis and Etiology

Subacute thyroiditis is presumed to be caused by a viral infection (Fraser and Harrison, 1952) or a postviral inflammatory course in genetically predisposed subjects. The initial hypothesis of a viral or postviral inflammation was supported by epidemiological and clinical data such as a seasonal distribution of the disease (higher in summer), its association with outbreaks of other viral illnesses, the antecedent respiratory infection, the association with viral-type prodrome such as myalgia, malaise and fatigue, and the fact that it is a self-limiting disorder.

The disease was thought to have a higher incidence in summer (Kitchner and Chapman, 1989; Martino *et al.*, 1987; Nishihara *et al.*, 2008) but not all studies confirmed a seasonal variation (Benbassat *et al.*, 2007; Bennedbaek and Hegedus, 1997; Fatourechi *et al.*, 2003). Subacute thyroiditis has been linked to outbreaks of other viral illnesses, including Coxsackievirus, mumps, measles, adenovirus, Ebstein–Barr virus, influenza viruses (H1N1 included), adenovirus and others (Engkakul *et al.*, 2011). There are reports of subacute thyroiditis following influenza vaccination (Altay *et al.*, 2016; Hernán Martinez *et al.*, 2011; Hsiao *et al.*, 2006). Patients with subacute thyroiditis have at least fourfold increase in viral antibodies during the disease course (Desailloud and Hober, 2009; Volpe *et al.*, 1967) or positive viral cultures of the thyroid tissue. However, virological evidence is not present in all subacute thyroiditis patients series (Luotola *et al.*, 1998; Mori *et al.*, 1998).

In addition to the possible viral precipitation of the development of subacute thyroiditis, a genetic predisposition in class I major histocompability antigen status has been suggested. An association between subacute thyroiditis and HLA-Bw35 haplotype has been reported in 72% of the patients with subacute thyroiditis and in different ethnic groups (Nyulassy *et al.*, 1977; Ohsako *et al.*, 1995; Yeo *et al.*, 1981). Genetic susceptibility is suggested in addition by the familial clustering (Kramer *et al.*, 2004; Zein *et al.*, 2007) and the simultaneous development of the disorder in identical twins with HLA-Bw35 (Hamaguchi *et al.*, 2005). Another haplotype, the HLABw67 haplotype, has been reported in Japanese patients, although the association is not as strong as that reported for HLA-Bw35, the disease has a mild course and has been correlated with a seasonal appearance (Ohsako *et al.*, 1995).

It has been proposed that an antigen provided either directly from a virus or from virus-induced host tissue damage binds to HLA molecules on macrophages. The resulting antigen-HLA complex is recognized and activates cytoxic T-lymphocytes that then damage thyroid follicular cells because of molecular mimic. The immune reaction is not self-preserved, like in the autoimmune thyroid disease, and therefore the disease is self-limited.

Although thyroid autoimmunity is not believed to play a central role in subacute thyroiditis, autoimmune abnormalities associated with the disorder have been described. Thyroid antibodies (thyroglobulin and thyroid peroxidase antibodies) have been found in 42%–64% of patients with subacute thyroiditis (Volpe *et al.*, 1967). Those antibodies gradually decrease to low or even undetectable levels after recovery. Antibodies directed against the thyroid stimulating hormone receptor have been reported (Strakosch *et al.*, 1978; Tamai *et al.*, 1991, Wall *et al.*, 1982). It is likely that the thyroid antibodies develop secondary to the tissue damage caused by the viral infection.

Clinical Features

As mentioned previously, a viral prodrome is common, and half of the patients have a history of upper respiratory infection with symptoms such as sore throat, weakness, low-grade fever, myalgias and dysphagia. The clinical manifestation of subacute thyroiditis develops gradually over few days or weeks. Anterior neck pain in the region of the thyroid is predominant in various degrees and is present in up to 96% of the patients (Fatourechi *et al.*, 2003). Pain involves part of a lobe, one lobe or the whole thyroid. It frequently radiates to the upper neck, jaw, throat, ear or even the upper chest. Commonly, the patient initially consults an ear, nose, and throat physician or a dentist because of pain in the area of the throat or mandible. Frequently, the pain will migrate from one side to the opposite thyroid lobe after a few weeks. Exacerbation of the pain occurs by moving the head, swallowing or coughing. Symptoms may be limited in the neck and the head but most patients have systemic symptoms like malaise, myalgia, arthralgia, anorexia and fever that can reach 40°C.

Symptoms of thyrotoxicosis are frequent since thyrotoxicosis occurs in approximately 50% of affected individuals including the typical symptoms of thyrotoxicosis like diaphoresis, nervousness, tremor, heat intolerance, palpitations, tachycardia, and weight loss. Usually the symptoms of thyrotoxicosis are mild-to-moderate and the pain in the neck dominates the clinical picture. Rarely, the clinical presentation of subacute thyroiditis may be so dramatic in onset and so pronounced in severity that obstructive symptoms may develop.

Physical examination may disclose signs of hypermetabolism, with tachycardia, diaphoresis, and tremor. Palpation of the neck generally reveals a slight to moderate enlargement of the thyroid with the one lobe larger than the other. The thyroid gland is very firm to hard, exquisitely tender. Tenderness may be so pronounced that patients may try to prevent palpation by the examiner. The overlying skin is occasionally erythematous.

The inflammation of the thyroid is transient and the illness is self-limited even if the patient is not treated. Transient hyperthyroidism may be followed by a transient hypothyroidism (**Fig. 1**). Recovery is almost always complete but it has been reported that up to 15% of the patients eventually develop permanent hypothyroidism requiring treatment with thyroxine (Fatourechi *et al.*, 2003). Recurrence may occur in 1.3%–4.0% of the patients 6 to 21 years after the first episode (Fatourechi *et al.*, 2003; Iitaka *et al.*, 1996).

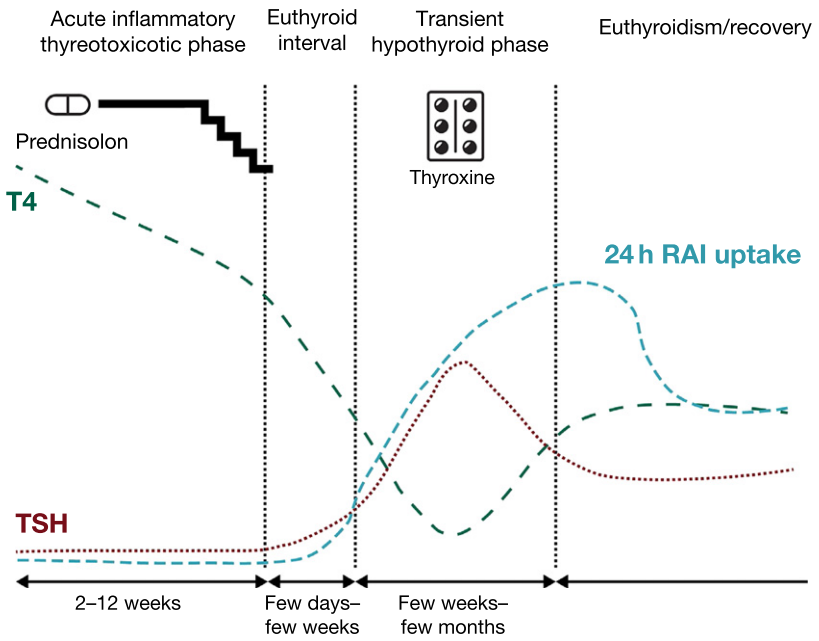

Fig. 1 The clinical course of subacute thyroiditis. The clinical course of subacute thyroiditis generally composed of four phases. The initial, acute inflammatory thyrotoxic phase which is characterized by pain, tenderness, and thyrotoxicosis due to leakage of thyroid hormones from the destruction of the thyroid folicles. The acute phase may last from 2 to 12 weeks. In this phase treatment with glucocorticoids is necessary. Following a euthyroid interval occurs which lasts up to several weeks. A transient hypothyroid phase then follows, which may last from a few weeks to a few months. Rarely, during the hypothyroid phase, levo-thyroxine therapy may be necessary. An asymptomatic recovery phase then follows. Virtually all patients with subacute thyroiditis achieve restoration of normal thyroid function, although permanent hypothyroidism has been reported in up to 15% of patients. In most cases, the entire episode of subacute thyroiditis rarely lasts more than 6 months. Not all patients with subacute thyroiditis progress through all four phases of the disorder since only approximately 50% of patients develop transient hypothyroidism. *RAI*: radionuclide uptake including 99mTc. *TSH*: thyroid stimulating hormone. *T4*: thyroxine.

Laboratory and Imaging Findings

Biochemical thyrotoxicosis with suppressed TSH and elevated levels of free/total T4 and free/total T3 occurs in approximately half of patients with subacute thyroiditis. T3 is not disproportionately elevated as it is in some Graves' patients reflecting the intra-thyroidal T3 and T4 content and the ratio of T4 to T3 in serum is <20. In general, the thyrotoxicosis associated with subacute thyroiditis is mild or at most modest in its severity. The thyrotoxicosis is transient and it is followed by a usually asymptomatic, transient period of overt or subclinical hypothyroidism.

The erythrocyte sedimentation rate is almost always >50 mm/h and may be as high as more than 100 mm/h. A normal sedimentation rate in a patient with a painful anterior neck mass places the diagnosis of subacute thyroiditis in question. C reactive protein may also be elevated, but is less diagnostic than the sedimentation rate. A slightly elevated total white blood cell count is present in half of the patients (Greene, 1971; Niklaus-Müller *et al.*, 1994). Serum thyroglobulin concentration is elevated during the acute phase of subacute thyroiditis, reflecting the destruction of the thyroid follicular architecture and release of thyroglobulin into the circulation. Thyroglobulin measurement should not be part of the routine evaluation of patients with subacute thyroiditis. Other laboratory findings, not routinely needed in order to confirm the diagnosis, are a mild normochromic, normocytic anemia and elevated liver enzymes.

Radioactive iodine uptake is always low, usually less than 2% after 24 h, in contrast to Graves' disease. Indeed, if the radioactive iodine uptake is more than 5% after 24 h, the diagnosis of subacute thyroiditis is unlikely. The absent uptake of iodine by the thyroid is due to destruction of the iodine-trapping mechanism from the inflammatory process as well as from inhibition of TSH secretion by excess circulating thyroid hormone. It is important to perform a radionucleide uptake test in patients with suspected subacute thyroiditis in order to rule out other causes of anterior neck pain as well as other types of thyrotoxicosis. In routine clinical practice a 99mTc-scintigraphy provides similar low uptake and is at the same time associated with lower irradiation to the patient and the environment.

Ultrasonography is not required as part of the evaluation of patients with subacute thyroiditis. Findings show diffuse areas of hypoechogenicity. In the Color Doppler ultrasonography, the thyroid has low-to-normal vascularity in contrast with the hyper vascularity shown in patients with Graves' disease (Bennedbaek and Hegedus, 1997). Fine needle aspiration is not routinely recommended in the evaluation of suspected subacute thyroiditis but may be useful to distinguish patients with unilateral involvement of subacute thyroiditis, acute pyogenic thyroiditis, hemorrhage into a cyst or thyroid cancer. Fine needle aspiration in subacute thyroiditis shows giant cells and pseudogranulomas.

Table 1 summarizes typical clinical and laboratory manifestations of subacute thyroiditis.

Differential Diagnosis

The differential diagnosis of subacute thyroiditis is shown in **Table 2** and includes both thyroid and nonthyroid disorders. Subacute thyroiditis is the most common thyroid etiology of anterior neck pain. Hemorrhage into a cyst or benign nodule is the second most common thyroidal cause of neck pain. Hemorrhage is neither presented by symptoms of infection (such as fever, weakness, myalgias) nor of thyrotoxicosis. In addition, the thyroid pain is predominantly unilateral and hemorrhage is sudden in onset, while subacute thyroiditis develops in days or weeks. The radioactive iodine or 99mTc-uptake in patients with hemorrhage is normal, and a radionuclide scan would reveal a filling defect. Both acute infectious thyroiditis and subacute thyroiditis are characterized by fever, thyroid pain and tenderness. However, in the case of acute infectious thyroiditis the fever is higher and the pain is predominantly unilateral. Very rare infectious thyroiditis may be presented with hyperthyroidism and usually the thyroid function is normal. The white blood cell count in acute infectious thyroiditis is significantly higher than the leucocytosis in subacute thyroiditis and the diagnosis can be confirmed by ultrasonography and fine needle aspiration biopsy. Patients with cellulitis of the anterior neck are not thyrotoxic and they do not have discrete masses on palpation. The patient with an infected thyroglossal duct cyst or branchial cleft cyst are euthyroid and the painful lesion is fluctuant and in more superior (thyroglossal duct cyst) or lateral (branchial cleft cyst) locations.

Rapidly growing thyroid cancer or primary thyroid lymphoma is an unusual cause of thyroid discomfort and anterior neck pain (called also "malignant pseudothyroiditis") (Yang *et al.*, 2006).Those patients do not have clinical features of inflammation and the neck mass is nontender and usually rock hard. In addition, an ultrasound can be helpful in differentiating these conditions vs. subacute thyroiditis.

Radioactive iodine therapy for hyperthyroidism or thyroid cancer or incidental irradiation of the thyroid during external beam radiotherapy to the neck can cause clinical thyroiditis with anterior neck pain and/or swelling. In those cases, the etiology of the inflammation is always obvious.

Treatment and Clinical Course

Treatment of subacute thyroiditis directs toward relief of the thyroid pain and tenderness and the control of thyrotoxic symptoms when present. Patients with mild symptoms may need no treatment.

For the patients who need treatment, anti-inflammatory therapy in form of a nonsteroidal anti-inflammatory drug (NSAID) or prednisolone is indicated. In mild cases, initiating acetylsalicyclic acid (2600 mg daily) or an NSAID like naproxen (500–1000 mg daily divided in two doses) or ibuprofen (1200–3200 mg daily in three to four divided doses) is reasonable. If the NSAID treatment fails and there is no clinical improvement after 2–3 days or in severe cases, prednisolone in a divided daily dose of 30–60 mg (usually 40 mg) should be initiated. Glucocorticoids provide pain relief within hours after their administration. Lack of significant improvement within 24 h after the initiation of steroids is uncommon and the absence of rapid improvement would call the original diagnosis into question. The prednisolone can be tapered after approximately 1 week and once the pain is relieved with a reduction by 5–10 mg every 5–7 days. If the pain and swelling recurs, prednisolone should be resumed. Recurrence of the pain during the prednisolone therapy occurs often in the contralateral lobe, in approximately 20% of patients (Mizukoshi *et al.*, 2001).

Thyrotoxic symptoms may be controlled by the use of beta-blocking agents, with the dose depending on the severity of symptoms. Propranolol in a dose of 40–120 mg or atenolol in a dose of 25–50 mg daily is usually sufficient to control symptoms of thyrotoxicosis, but higher doses may sometimes be needed.

Thionamides are not recommended since the thyrotoxicosis results from release of preformed hormone into the circulation rather than from increased synthesis. Therefore, drugs that inhibit thyroid hormone synthesis, such as thyroid-blocking agents, have no beneficial effect. Sodium iopodate has also been used in the management of the hyperthyroidism of subacute thyroiditis. Thyroidectomy can be employed in cases with prolonged, disabling pain.

It has been reported that patients who have a history of subacute thyroiditis may develop subtle, permanent thyroid abnormalities. It has also been reported that those patients may be sensitive to the inhibitory effects of exogenously administered iodides by exhibiting elevations in serum TSH concentrations, even years after having had subacute thyroiditis (Roti *et al.*, 1990).

Postpartum Thyroid Dysfunction☆

Lakdasa DKE Premawardhana and John H Lazarus, University Hospital of Wales, Cardiff, United Kingdom

Glossary

Antibodies Molecules produced by the immune system, often directed at tissues in the body.
Depression Clinical state of low mood.
Immune Biological process of recognizing self from nonself.
Postpartum Time period of up to 1 year following delivery of a baby.
Screening Performance of a test or procedure in order to detect a specific disease or increased chance of development of disease in a particular group.
Thyroid Butterfly-shaped endocrine gland at the front of the neck.

Historical Background

H. Roberton, a General Practitioner in New Zealand, is credited with the first description of postpartum hypothyroidism as a distinct clinical entity. Thyroid dysfunction was described in the postpartum period more than a century ago, but a possible cause-and-effect relationship to pregnancy and delivery was not clarified until much later. Walfish and Ginsberg first described the thyrotoxic phase, which preceded the hypothyroid phase in the biphasic form of postpartum thyroiditis (PPT). Evidence for changes in thyroid autoimmune markers during pregnancy and the postpartum period (i.e., a decrease in thyroid autoantibodies during pregnancy and an increase after delivery) was obtained later. Amino's work produced a resurgence of interest in the subject, and since then numerous studies from different parts of the world have described the syndrome and its incidence, pathophysiology, and long-term outcome.

Immune Changes During Pregnancy and the Postpartum Period

Normal Women

The immunological changes that occur during pregnancy are directed toward inducing tolerance to the growing fetus. Failure of such tolerance results in rejection and miscarriage. The fetal trophoblast, maternal T cells, and maternal antibody production are all modulated in ways that enhance tolerance and reduce rejection.

The fetal trophoblast enhances tolerance by means of four main mechanisms. First, the failure to express MHC class I/II molecules prevents maternal T cells from mounting a response to paternal antigens. Second, the expression of the HLA-G gene reduces natural killer cell function and activates CD8 T cells, enhancing suppressor function. Third, complement activation is inhibited by the expression of proteins CD46, CD55, and CD59. Finally, Fas ligand is produced, enhancing tolerance.

Maternal T helper cell (Th) cytokine responses shift from a Th1 (γ-interferon and interleukin-2 (IL-2)) to a Th2 (IL-4, IL-5, and IL-10) secretion pattern. Potentially damaging cytotoxic and cytolytic reactions give way to relative immune suppression and tolerance. T-cell subsets that serve a suppressor function increase and natural killer cells decrease during early pregnancy, with postpartum rebound. There has been great interest recently in the role of regulatory T cells (Treg), previously called T suppressor cells, in preventing rejection of the fetal "allograft" in pregnancy. These cells are either thymic or peripheral in origin, and are thought to suppress the activity of immune competent cells (natural killer cells, dendritic cells, B cells, and CD4+ and CD8+ T cells) by various mechanisms. Treg numbers increase during the first and second trimester in both maternal blood and in the uterus, and may be partly estrogen driven. They rapidly decrease during the postpartum period. Although their exact role is currently being clarified, it does not seem to be limited to tolerance induction alone and a more central role is postulated.

The significant hormonal changes that occur during pregnancy have a profound effect on the production of immune tolerance. Placental progesterone is largely responsible for the shift to a Th2 response and may enhance other immune regulators as well. Placental estrogen and growth hormone also make a significant contribution to these changes. Furthermore, increased placental corticotropin-releasing hormone production stimulates the maternal adrenal glands to produce a state of hypercortisolism. There is also an increased production of catecholamines. A moderate increase in 25-hydroxy vitamin D_3 and more significant increases in

This article is an update of L. D. K. E. Premawardhana, A. B. Parkes, John H. Lazarus, Thyroiditis, Postpartum, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 509-514.

 doi:10.1016/B978-0-12-801238-3.04192-1

1,25-dihydroxy vitamin D_3 also occur. Through intermediate mechanisms, all these changes suppress proinflammatory cytokine formation and promote a shift from a Th1 to Th2 response.

Maternal immune mechanisms return to a normal nonpregnant state in the first few months to 1 year after delivery. However, there may be a rebound increase in some elements of the autoimmune reaction which may aggravate existing autoimmune disease or precipitate it for the first time in predisposed women.

Women With PPT

The immune changes that occur in the postpartum period are reminiscent of the recently described phenomenon of "immune reconstitution" that follows treatment with drugs such as alemtuzumab (CAMPATH1) used in multiple sclerosis, and highly active antiretroviral therapy used in HIV disease. It is plausible that pregnancy induced Treg cells, decline in numbers soon after delivery, and their relative insufficiency in relation to preexisting thyroid reactive T cells will set off a "destructive" thyroiditis resembling a Th1 type of reaction, resulting in PPT. The behavior of antibodies to thyroid peroxidase (TPOAb) and thyroglobulin (TgAb) during pregnancy and the postpartum period have been well documented. This "heightened" immune response in the first few months of the postpartum period may be caused by several factors.

Microchimerism

There is a considerable influx of fetal cells into the maternal circulation at the time of delivery. These cells may persist for short or long periods of time in the maternal host. Evidence suggests that these "chimeric" cells may induce an immune reaction in the host by causing a breakdown in immune tolerance. One short-term effect may be the rebound immune enhancement seen in the postpartum period, which may cause an exacerbation or new onset of some autoimmune diseases.

T-Cell Changes

In addition to changes to Treg described earlier, evidence suggests that activation of both circulating and intrathyroidal T cells occurs in PPT. Both Walfish and Stagnaro-Green demonstrated the expression of MHC class II molecules and a higher percentage of increased CD4:CD8 ratios in subjects who developed PPT. In a prospective study of TPOAb-positive women, Kuijpens showed a higher percentage of MHC II-expressing T cells in subjects who subsequently developed PPT compared with those who did not. However, Jansson's group did not demonstrate a difference in circulating subsets of T lymphocytes in thyrotoxic and hypothyroid PPT subjects compared with normal controls. This group demonstrated a relative increase in intrathyroidal B cells and a relative decrease in CD8 cells (resulting in an increased CD4:CD8 ratio) in subjects with PPT.

PPT as an Immune-Mediated Disease

Several features of PPT point to the central importance of immune mechanisms in its pathogenesis (**Table 1**). The majority of women who develop PPT are positive for markers of thyroid autoimmunity (i.e., TPOAb and TgAb). In our experience, all such women have TPOAb during early pregnancy. These TPOAb positive subjects have a 33%–50% chance of developing PPT. Evidence suggests that antibodies with a dual specificity for Tg and TPO may also be found in PPT at a higher prevalence than in normal control subjects. However, several investigators have reported PPT in TPOAb-negative women. In such women, the etiology of PPT is unclear. The histological changes occurring within the thyroid gland, with immune cell infiltration typical of autoimmune thyroid disease, give further credence to the immune pathogenesis of the disease. Fine needle biopsy of the thyroid gland in women with PPT shows lymphocytic infiltration and follicle formation reminiscent of Hashimoto's thyroiditis. Several studies have shown HLA haplotype restrictions in PPT, which are commonly seen in autoimmune thyroiditis such as Hashimoto's and Graves' disease.

The subclasses of TPOAb that are able to activate the complement cascade (IgG_1–IgG_3) increase during the postpartum period (**Fig. 1**) and are associated with both phases of PPT. Jansson reported an increase in IgG_1 in hypothyroid PPT. Hall demonstrated an increase in IgG_2 and IgG_3 in biphasic PPT, with the increase in IgG_3 coinciding with the thyrotoxic phase. Briones-Urbina confirmed the IgG_1 and IgG_2 changes but found low IgG_3 levels. However, these investigators also confirmed that IgG_4, which is incapable of influencing the complement cascade, remains relatively unchanged. This raises the interesting possibility of a

Table 1 Immunohistological features of PPT suggesting an autoimmune etiology

Presence of thyroid antibodies	TPOAb (majority) Thyroglobulin antibodies and antibodies with dual specificity (minority)
Postpartum increase in TPOAb subclasses capable of activating complement	IgG_1–IgG_3
Histological changes	Lymphocyte infiltration and follicle formation within the thyroid gland
HLA haplotype restriction	Similar to autoimmune thyroiditis

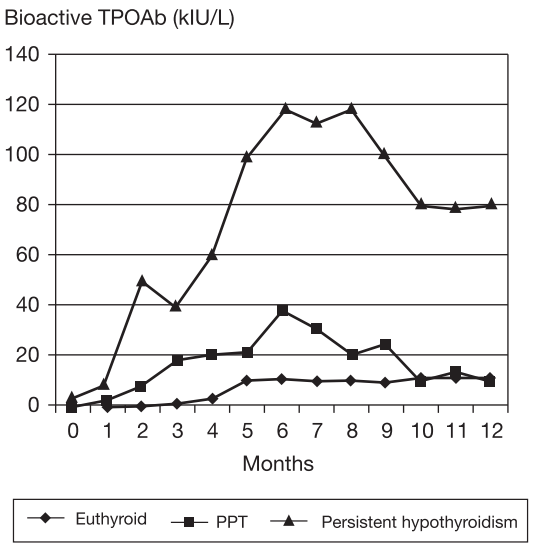

Fig. 1 Biologically active TPOAb levels in antibody-positive women who were euthyroid or had transient or persistent postpartum hypothyroidism. Antibody concentrations returned to normal in those with PPT but remained elevated in subjects with persistent hypothyroidism.

pathogenetic role for these antibodies in PPT, perhaps through complement activation. A sublethal antibody-directed, complement-mediated attack on thyroid cells may result in increased secretion of thyroid hormones, producing the thyrotoxic phase of the disease. However, a more severe complement-mediated attack may produce damage to the follicular architecture of the gland and produce hypothyroidism. Conclusive evidence for such complement activation in PPT is lacking; studies have been unable to demonstrate terminal complement complexes (markers of complement activation) in TPOAb-positive women who developed PPT.

Clinical Features and Management of PPT

Incidence of PPT

There is a wide variation in the reported worldwide incidence of PPT. This variation may be explained by true geographic differences in incidence (reflecting genetic heterogeneity and other factors) or by methodological discrepancies in studies reported from different locations. Variability of factors such as diagnostic criteria, length of follow-up after delivery, frequency of postpartum blood sampling, and differences in hormone assay methodology may have contributed to this variation. An average incidence of 5%–7% is acceptable for unselected pregnant women from most iodine-replete populations.

Predisposition to PPT

Women with TPOAb (and TgAb alone in $<5\%$), type 1 diabetes mellitus, other autoimmune disorders, and previous PPT are at increased risk of developing PPT. Studies from Cardiff show that approximately 50% of women with TPOAb during the early stages of pregnancy develop PPT. Other studies have shown this proportion to vary between 30% and 52%. Therefore, TPOAb is a marker of risk for the development of PPT but remains a weak predictor. There is a higher prevalence of PPT in subjects with type 1 diabetes mellitus. Gerstein followed 40 of 51 pregnant subjects with type 1 diabetes, of whom 10 developed thyroid dysfunction (1 due to Graves' disease), and Alvarez-Marfany followed 28 of 41 similar women, of whom seven developed thyroiditis. Therefore, the incidence is approximately 25% in women with type 1 diabetes mellitus. Recent but limited evidence suggests that gestational diabetes mellitus may also be a risk factor for PPT. The link between other autoimmune disorders and PPT is also significant. Studies have shown that SLE (14%) and chronic viral hepatitis (25%) were associated with a higher incidence of PPT. Similarly, there was a higher incidence of clinical and laboratory features of Sjögren syndrome in subjects with a history of PPT. However, the highest incidence of PPT is found in women who have had a previous episode of the disease. Sixty-nine percent of women who have TPOAb and had PPT following a previous pregnancy will develop PPT during the next pregnancy. However, only 25% who are TPOAb positive and remain euthyroid will develop thyroid dysfunction during the next pregnancy. There is limited evidence that previous autoimmune thyroid disease is also a risk factor for PPT.

There is evidence of a role for environmental factors, such as the presence of a goiter and smoking and a family history of thyroid disease, in the causation of PPT. However, additional studies are needed to confirm this finding.

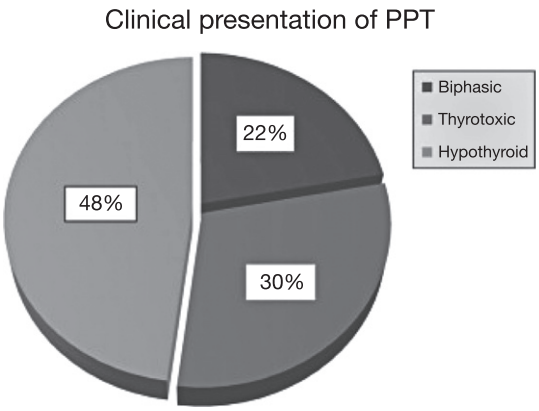

Fig. 2 Clinical types of PPT. The thyrotoxic phase usually precedes the hypothyroid phase.

Types of PPT and Clinical Features

Classically, PPT occurs after a full-term delivery. PPT occurring after early loss of pregnancy between 5 and 20 weeks of gestation has been reported.

PPT is a biphasic disease in about one-fifth of subjects (Fig. 2). A transient thyrotoxic phase is followed by a period of recovery and then a hypothyroid phase. The thyrotoxic phase occurs at a median of 13 weeks postpartum and lasts 1 or 2 months; it is probably due to the release of preformed thyroid hormone resulting from destruction of thyroid follicles. The hypothyroid phase that follows occurs at a median of 19 weeks postpartum, lasts longer (approximately 4–6 months), is accompanied by significant symptoms, and results from autoimmune follicular destruction and reduced hormone synthesis. Some women may require thyroxine replacement therapy during this phase. Rarely, the hypothyroid phase may precede the thyrotoxic phase. In some women, the two phases of PPT may occur independently of each other and either clinical or biochemical evidence of thyrotoxicosis or hypothyroidism alone develops during approximately the same postpartum periods as described previously. Significantly, as many as 30% of women who have TPOAb and PPT may develop permanent hypothyroidism requiring thyroxine replacement therapy by the end of the first postpartum year.

The symptoms of the thyrotoxic phase are mild and self-limiting. Fatigue, palpitations, weight loss, irritability, and heat intolerance are more commonly found in subjects with thyrotoxic PPT than in euthyroid postpartum women. They may also have tremor, nervousness, and psychological symptoms. The mild and nonspecific nature of these symptoms may cause diagnostic confusion, and they may be missed if a high index of suspicion is not maintained.

The hypothyroid phase lasts longer and may cause considerable morbidity. Fatigue, loss of concentration, constipation, muscle and joint pains, and stiffness are common complaints. Some of these symptoms may occur before the abnormalities in biochemical thyroid function become evident and also persist after euthyroidism is achieved. Three out of seven studies reported in the literature demonstrated a relationship between postpartum depression and PPT, that is, only 43%. But the rest did not find a significant relationship. The mechanism of depression in hypothyroid PPT is speculative but may be related to the reduced 5-hydroxytryptamine drive seen in this condition or to known cytokine release associated with this phase, affecting neurotransmission.

Management of PPT

The timing of symptoms in relation to pregnancy and delivery, the presence of thyroid antibodies in the majority of women who develop symptoms, and the pattern and timing of biochemical thyroid dysfunction should alert clinicians to PPT in women at risk. Symptoms and the presence of a goiter are unhelpful in differentiating PPT from other causes of thyroid dysfunction in the postpartum period. The presence of eye signs in the thyrotoxic phase, however, favors a diagnosis of Graves' disease.

The thyrotoxic phase is distinguished from an exacerbation of quiescent or a new onset of Graves' disease relatively easily by radioiodine uptake scanning observing appropriate precautions if breastfeeding. Uptake is consistently low in PPT but high in Graves' disease. When postpartum thyrotoxicosis occurs in women with previously known Graves' disease, a low uptake confirms PPT (on the background of quiescent Graves' disease). However, care needs to be taken in the use of radioiodine as a diagnostic tool in nursing mothers. Technetium scans may be preferable in them. The presence of thyrotrophin receptor antibodies and increased thyroid blood flow on color flow Doppler thyroid ultrasonography favors the diagnosis of Graves' disease. Standard thyroid ultrasonography, thyroglobulin estimation, and IL-6 measurement are of little practical value. Specific antithyroid drug therapy is not required in the thyrotoxic phase because symptoms and biochemical thyroid function return to normal in a few weeks. Occasionally, a beta-blocker may be indicated for symptom relief.

The hypothyroid phase usually follows the thyrotoxic phase in the biphasic form of PPT, and should be anticipated with periodic follow-up. But in a considerable minority (48%), hypothyroidism occurs alone and is the only manifestation of PPT in these women. An elevated TSH level at the appropriate time postpartum in women who are most likely TPOAb positive should alert clinicians to the diagnosis. This phase lasts longer and is associated with considerable morbidity. In a minority, it may result

Table 2 Long-term follow-up of PPT

Author	*Follow-up (years)*	*No. of subjects*	*Thyroid dysfunction (includes subclinical hypothyroidism or abnormal TRH test)*
Nikolai	3	25	6
Vargas	1	42	8
Tachi	5–16	44	10

Lucas	3.3	42	5
Barca	2	49	30

in early permanent hypothyroidism, as described previously. Thyroxine therapy is indicated with a trial of withdrawal at 9–12 months. It is possible to withdraw thyroxine therapy in the majority of women at the end of this period, but a recurrence of symptoms associated with increased TSH levels on follow-up indicates the need for permanent replacement therapy.

Long-Term Outcome Following PPT

The long-term outcome of PPT has been examined in several studies (Table 2). In our series, permanent hypothyroidism occurred as early as 9 months postpartum in approximately 30% of subjects who were TPOAb positive and had PPT. These women required thyroxine replacement therapy to maintain normal clinical and biochemical thyroid function. A review of long-term follow-up studies of PPT from geographically different locations reported a 12%–61% prevalence of permanent hypothyroidism. The variability may in part be due to differences in the definition of PPT and long-term thyroid dysfunction, length of follow-up, and ascertainment. We followed 98 TPOAb-positive women (of whom 48 developed PPT) and 70 TPOAb-negative controls for 66–140 months. Forty-six percent of women who developed PPT were hypothyroid (some subclinically) at the end of the follow-up period compared with only 4% of women who were TPOAb positive but did not develop PPT and 1.4% of women who were TPOAb negative. The rate of conversion to hypothyroidism in women who were TPOAb positive and developed PPT was 7.1% per year, higher than that reported for women in community-based follow-up studies. Investigators from different areas of the world have confirmed a high prevalence of hypothyroidism at the end of variable follow-up periods in women who developed PPT. In a study of Japanese women with a similar length of follow-up after PPT (mean, 8.7 years), Tachi found a 29% prevalence of permanent hypothyroidism. In a Swedish study, Jansson found a 30% prevalence of hypothyroidism at 5 years. In Brazil, Barca found a 61% prevalence of hypothyroidism at the end of a 2-year period of follow-up after PPT. The reason for this high prevalence of relatively early hypothyroidism is unclear.

Women with a high risk for long-term permanent hypothyroidism in these studies (a) had higher TPOAb concentrations and higher TSH levels during the hypothyroid phase of PPT, (b) were older, (c) were multiparous, and (d) had greater hypoechogenicity on thyroid ultrasound scanning during the initial illness.

The nature and mechanism of persistent thyroid damage following the initial episode of PPT remains speculative. Several investigators have indicated the distinct possibility of a persistent but subtle abnormality (probably autoimmune in nature) of thyroid function and morphology in these women. Iodine perchlorate discharge tests were abnormal in 41% of Italian and 64% of Welsh women studied 3 and 7 years, respectively, following PPT, suggestive of a persistent organification defect. Furthermore, we found a significantly higher prevalence of thyroid ultrasound hypoechogenicity (due to autoimmune destruction) at 4–8 weeks postpartum in women who were TPOAb positive and developed PPT (45%) compared with antibody-positive women who did not develop PPT (17%) and to antibody-negative women (1.5%). There was a significantly higher prevalence of persistent abnormalities in the first group after 66–144 months of follow-up (although mildly reduced from the postpartum period), indicative of persistent autoimmune destruction following the initial episode of PPT. It seems likely that a persistent but low-grade immune destructive process severe enough to produce echogenic changes in the thyroid gland continues to occur in these women, although maximal damage occurs at the time of PPT.

These findings indicate the need for long-term follow-up of women who are TPOAb positive and who develop PPT. A relatively high incidence of early permanent hypothyroidism in these women and a higher than normal annual conversion rate to hypothyroidism (compared with that of TPOAb-positive women who do not develop PPT and women from community surveys) indicate the need for long-term follow-up. An increased TSH level with or without symptoms of hypothyroidism on annual (or more frequent) thyroid function testing is an indication for thyroxine replacement therapy.

Screening for PPT and Its Prevention

There is no consensus about screening for PPT. This relates as much to the absence of a highly sensitive and specific marker for prediction as to the lack of appreciation of the clinical problem and the long-term effects of PPT among endocrinologists in

general. The significant morbidity of PPT in the first postpartum year, the likelihood that approximately three-fourths of women who have PPT will have an episode in a future pregnancy, the high prevalence of long-term thyroid dysfunction following PPT, and the availability of effective treatment should make a screening strategy useful. Some authorities recommend a selective screening strategy aimed at only those women who have a high risk of developing PPT (i.e., women with type 1 diabetes mellitus and those who have had PPT in a previous pregnancy). However, a screening strategy should take into account the fact that PPT may also occur in TPOAb-negative women. It is salutary to remember that the prevalence of diseases for which antenatal screening is currently recommended is considerably lower than that of PPT in women of childbearing age.

TPOAb has been proposed as a marker for the prediction of PPT, although the timing of its measurement remains a point of contention. As mentioned previously, when measured in early pregnancy, TPOAb is present in approximately 10% of women. However, only approximately half of these develop PPT, raising questions about the sensitivity of TPOAb as a predictor. Ten studies have examined TPOAb as a predictor of PPT. No firm conclusions can be drawn from these studies for several reasons. Most investigators measured microsomal antibodies, whereas some measured antibodies to TPO (the specific microsomal antigen). The assay methods used and the timing of antibody measurement were variable. Whereas some investigators measured antibodies in the antepartum period, others measured them at delivery and in the postpartum period. These studies, however, showed that thyroid antibodies have a sensitivity of 0.45–0.89 and specificity of 0.91–0.98. Positive predictive value and relative risk were 0.31–0.78 and 20–50.7, respectively. A report confirmed the cost-effectiveness of a screening program. It is not known whether screening will be improved by thyroglobulin estimation, measuring ultrasound thyroid volume or assessment of complement activation.

Although the benefits of preventing PPT seem fairly clear (avoiding symptoms of thyroid dysfunction and preventing permanent hypothyroidism), no single strategy is currently recommended. An early study offering levothyroxine or iodine to TPOAb positive women showed no difference in the incidence of hypothyroidism either in the treatment or control groups. Another study evaluated giving iodine to TPOAb positive women during pregnancy compared with giving iodine during both pregnancy and the postpartum periods. There was no difference in the incidence or severity of PPT between the groups given iodine compared with the group given placebo. The administration of selenium to TPOAb positive women decreased the incidence of PPT and permanent hypothyroidism, and also caused a significant decrease in TPOAb titer in the postpartum period. The effect of radioactive iodine treatment of Graves' disease on the incidence of subsequent PPT was retrospectively studied by Japanese investigators. They found a reduced incidence of PPT in those who received radioactive iodine for Graves' (2.1%) compared with those who had subtotal thyroidectomy (23.6%) and thionamides (55.1%). But both these sets of data are preliminary and need to be replicated in further studies. Therefore, although the benefits of preventing PPT are self-evident, the jury is still out about a specific strategy in doing so.

Conclusion

PPT is a common endocrine disorder affecting young women. The exact mechanisms of cellular damage have not been determined, although the autoimmune destructive nature of the disease has long been recognized. The immune perturbations of pregnancy and the postpartum period account for the modulation of thyroid autoimmunity, which is the hallmark of the disease, and the timing and nature of clinical and biochemical changes. Although the majority of patients have a short and self-limited illness, some have a prolonged and symptomatic disorder that requires specific therapy. The recognition of short- and long-term morbidity, and the need for permanent thyroxine supplementation in a significant minority of subjects following PPT, has raised the important but unsettled issue of screening for PPT, targeted perhaps at those at highest risk. We await the discovery of a sensitive and specific screening tool.

Thyroid and Infertility

Sofie Bliddal, Henriette S Nielsen, and Ulla Feldt-Rasmussen, Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Abbreviations

ART Assisted reproductive technology
FSH Follicle stimulating hormone
ICSI Intracytoplasmic sperm injection
IVF In vitro fertilization
LH Luteinizing hormone
TPOAbs Thyroid peroxidase antibodies

Glossary

Assisted reproductive technology Fertility treatments involving the handling of the woman's eggs and thus does not include isolated stimulation to achieve ovulation or insemination. The most common ART procedure is in vitro fertilization (IVF).
Cretins A person suffering from cretinism, a condition of severely stunted physical and mental growth due to untreated congenital hypothyroidism. Often due to iodine insufficiency during pregnancy and childhood.
FSH Follicle stimulating hormone. Involved in female ovulation and male spermatogenesis.
Gonads Reproductive organs producing sex hormones and cells. In women the ovaries (estrogen, progesterone, and egg cells) and in men the testes (testosterone and sperm cells).
Infertility The inability for a man and a woman of reproductive age to conceive by regular intercourse without use of contraception over a time period of 1 year.
IVF In vitro fertilization. Procedure in which eggs are extracted to be fertilized in the laboratory and after developing for 2–5 days are then transferred to the uterus.
LH Luteinizing hormone. Involved in female ovulation and male testosterone production.
Overt hypothyroidism TSH above reference range and T4 below reference range, or TSH above 10 mU/L.
Subclinical hypothyroidism TSH above upper reference range, but below 10 mU/L, with normal T4 levels.
T4 treatment Replacement of thyroid hormones with synthetic thyroxine.

Introduction

Infertility (the inability for a man and a woman of reproductive age to conceive by regular intercourse without use of contraceptives over a time period of 1 year) affects 10%–20% of couples. Causes are divided into male factor (30%), female factors (35%), both male and female factors (20%) and no known cause (15%). Female factors include endometriosis, tubal factors (often due to previous infection, that is, with chlamydia trachomatis), or ovulatory disorders (hypothalamic/pituitary/ovarian cause). The latter can be due to thyroid disease.

Thyroid hormones are essential to reproduction. Although, many nonthyroidal endocrine abnormalities can lead to infertility (hyperprolactinemia, hypopituitarism, growth hormone deficiency, congenital adrenal hyperplasia to name a few), thyroid disease is common in women of reproductive age. Most often such thyroid disease in young women is concurrent with thyroid autoimmunity representing additional risks to the chance of obtaining and sustaining a pregnancy. Knowledge of the reproductive challenges associated with thyroid disorders and how to diagnose, monitor and treat those, is therefore important to any clinician encountering women of reproductive age.

Key points
- Infertility is defined as the inability for a man and a woman of reproductive age to obtain pregnancy by regular intercourse over a time period of 1 year.
- 10%–20% of all couples in Western Countries experience infertility.
- Thyroid disease increases the risk of infertility.
- Hypothyroidism induces a physiological suppression of the hypothalamic–pituitary–gonadal axis.
- Ovarian hyperstimulation increases the demands for thyroid hormone production, which is difficult to honor in women with low iodine intake or thyroid autoimmunity.
- Thyroid function should be fully restored before initiation of assisted reproductive technology to secure sufficient maternal thyroid hormone supply for fetal development, especially fetal brain development.
- All women attending Fertility Clinics should be screened for TSH level and consulted with an Endocrinologist in case of aberrations.

Mechanisms of Thyroid Function in Fertility

The mechanisms governing the interplay between thyroid dysfunction and infertility are not well understood. A vast range of animal studies have demonstrated an effect of abnormal thyroid hormone levels on gonad maturation, morphology and function. However, results vary between the numerous investigated species and depending on the developmental stage at which thyroid dysfunction occurs.

In rats, it has been shown that thyroid hormones are involved in regulating testicular development by altering expression of enzymes involved in masculinization (increasing activity and expression of type 1 steroid 5-alpha-reductase and androgen receptor and downregulating aromatase (P450arom/cyp19a1) activity and expression) (Castaneda Cortes *et al.*, 2014; Ulisse *et al.*, 1994). During male rat and mice development, levothyroxine (T4) administration led to an early gonadal development with decreased testicular size at maturation (Krassas *et al.*, 2010). Spermatogenic function was unaltered in thyroidectomized rams, while sperm maturation was compromised. This was restored upon administration of T4 replacement in moderate doses (Chandrasekhar *et al.*, 1986). In both male and female rats, thyroidectomy followed by either a hypothyroid or a iatrogenic hyperthyroid state led to a decrease in luteinizing hormone (LH) and follicle stimulating hormone (FSH) levels (Bruni *et al.*, 1975). Normalization of gonadotropin levels were achieved with euthyroidism. In another study of female rats, inducing hypo- or hyperthyroidism led to a significant rise and fall, respectively, of progesterone levels. Both conditions led to lower LH and estradiol levels, and morphological changes in the ovaries, ovarian duct and uterus (Ajayi *et al.*, 2013).

The association between thyroid function and infertility may in some cases be mediated by thyroid disrupting chemicals. In a study of mice exposed to polybrominated diphenyl ethers, a class of brominated flame retardants, reduced thyroid hormone levels were associated with suppressed spermatogenesis (Sarkar *et al.*, 2016). Finally, thyroid autoantibody-presence was demonstrated in human follicular fluid (Monteleone *et al.*, 2011) and was associated with an increased rate of fetal resorption in female rats and mice (Lee *et al.*, 2009; Matalon *et al.*, 2003). While this is suggestive of immune processes being involved in the reproductive challenges posed by autoimmune thyroid disease, thyroperoxidase antibodies (TPOAbs) are generally not considered pathogenic, but rather an epiphenomenon.

In humans, thyroid hormones have been associated with altered peripheral estrogen and androgen metabolism, hyperprolactinemia, serum hormone-binding globulin levels, and abnormal pulsatile release of LH (Krassas *et al.*, 2010). In a study by Jacobs et al., thyrotropin releasing hormone (TRH) was shown to increase prolactin levels (Jacobs *et al.*, 1971). Snyder et al. demonstrated that compared to euthyroid controls, the prolactin response to TRH stimulation was increased in hypothyroid patients and blunted in hyperthyroid patients (Snyder *et al.*, 1973). Treatment with T4 and antithyroid drugs, respectively, normalized prolactin responses in both patient groups (Snyder *et al.*, 1973). As such a significant positive correlation exist between thyroid stimulating hormones (TSH) and prolactin levels explaining at least some of the ovulatory changes occurring in patients with thyroid disease (Fourman and Fazeli, 2015; Honbo *et al.*, 1978). Furthermore, sex-hormone-binding globulin levels are increased in hyperthyroidism being the predominant reason for a reduced metabolic clearance rate of estrogen and thus higher serum levels (Ridgway *et al.*, 1975). Other studies have found normal gonadotropin levels in both hypo- and hyperthyroidism (despite changes in metabolic clearance rate and sex-hormone-binding globulin levels) (Krassas *et al.*, 2010). Finally, altered responses of LH to gonadotropin releasing hormone stimulation indicate an effect of thyroid hormones on the hypothalamic–pituitary–gonadal axis (Gordon and Southren, 1977; Krassas *et al.*, 2010; Tanaka *et al.*, 1981).

Also, local effects of thyroid hormones on reproductive organs are well-substantiated by the findings of thyroid hormones and expression of thyroid hormone receptors, deiodinases and transporters in reproductive organs as illustrated in **Fig. 1** (Vissenberg *et al.*, 2015). These effects are likely governed by an interplay with hormones of the hypothalamic–pituitary–gonadal axis (Catalano *et al.*, 2007).

As such, alterations in thyroid hormone economy directly impact the hypothalamic–pituitary–gonadal axis and function of reproductive organs in both men and women. The following sections will focus on clinical studies, diagnosis, and treatment of thyroid dysfunction in women with infertility before briefly touching upon male infertility.

Thyroid Function and Infertility

Although knowledge of the biologic mechanisms is still expanding it has long been known that thyroid disease is associated with altered fertility. In 1840, Carl Adolph von Basedow described how menstruations ceased in women with protruding eyeballs and swelling of the thyroid gland (Huth and Murray, 2006; von Basedow, 1840). In 1892, a case report was published on ovarian atrophy and amenorrhea in a thyroidectomized woman (Hofmeister, 1892). In the following decades, the understanding of menstrual irregularities alongside with thyroid disorders was broadened. In a case report of irregular menstruation in a 5-year-old girl with overt hypothyroidism (ceasing upon thyroxine replacement), the author commented on the otherwise "well-known fact that puberty is invariably delayed in cretins" (Kendle, 1905; Lederer, 1954).

Overt Hypothyroidism

Overt hypothyroidism is defined as a thyrotropin (TSH) level above accompanied by free T4 (FT4) levels below reference ranges, or a TSH level above 10 mU/L irrespective of FT4 levels. The prevalence is approximately 0.5%–2% in background populations depending on iodine nutritional status (Hollowell *et al.*, 2002; Vanderpump, 2011). Women with overt hypothyroidism are likely to have reduced reproductive capability. In a case series by Scott et al., 56% of 50 patients with clinical hypothyroidism reported of

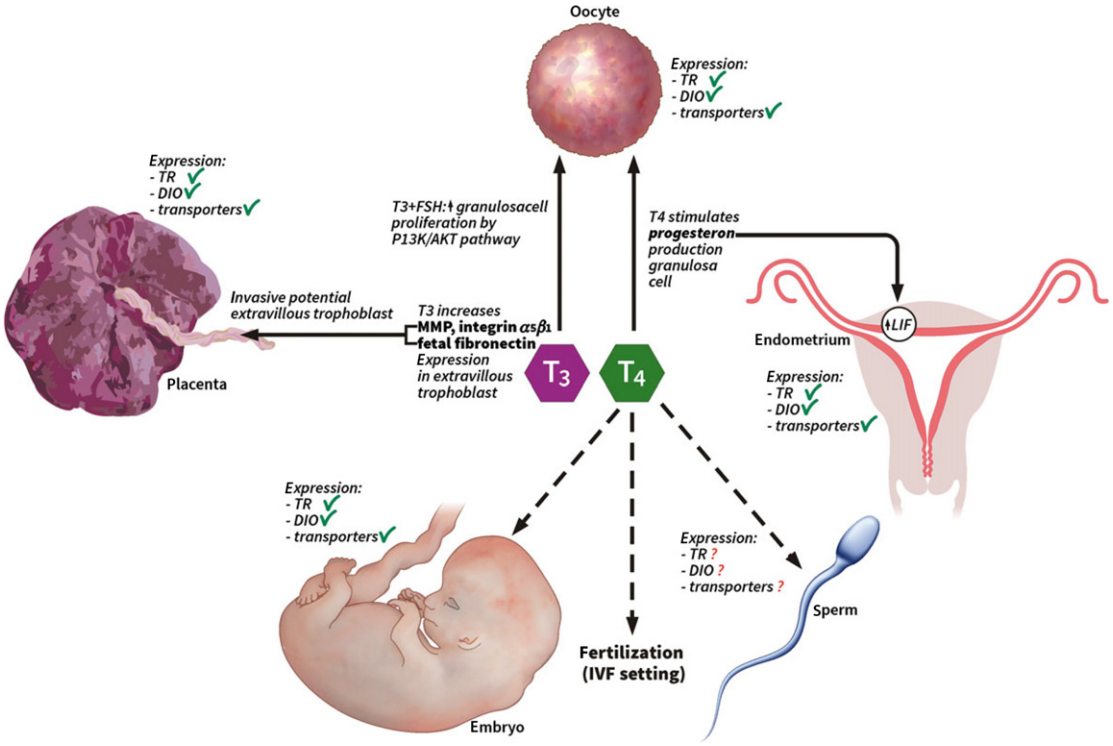

Fig. 1 Thyroid hormone action in reproduction. Multiple local mechanisms of thyroid hormone action have been associated with the reproductive system. *Solid lines* indicate an effect of T4 treatment; dotted lines indicate associations without evidence for causality. Abbreviations: *Akt*, protein kinase B; *DIO*, deiodinases; *IVF*, in vitro fertilization; *LIF*, leukemia inhibiting factor; *MMP*, metalloproteinases; *P13K*, phosphatidylinositol 3′-kinase; *TR*, thyroid hormone receptor. menstrual irregularities most of whom had menorrhagia (Scott and Mussey, 1964). In a controlled study of 178 women referred to a thyroid clinic, normal menstrual patterns were reported by 31.8% of hypothyroid and 35.3% hyperthyroid women as compared to 87.8% of healthy controls ($P < 0.001$) (Joshi *et al.*, 1993). Self-reported reproductive challenges (including infertility) was only significantly more prevalent in hyperthyroid patients, but this was mainly driven by an increased pregnancy loss rate. Interestingly, in many of the patients, menstrual irregularities had preceded other symptoms of thyroid dysfunction (Joshi *et al.*, 1993). The study suffered from a small number of patients and unknown thyroid autoimmunity status. In a larger study by Krassas et al. (1999), significantly more hypothyroid women experienced menstrual disturbances than age- and weight-matched controls (23.4% vs. 8.4%, $P < 0.001$). The severity of menstrual irregularity was associated with higher TSH levels. Upon T4 treatment, there was no difference between the two groups (Krassas *et al.*, 1999). More recently, Quintino-Moro et al. conducted interviews about reproductive history with 193 women with Graves' disease (18–50 years old) and 66 women with Hashimoto's thyroiditis (18–60 years old) (Quintino-Moro *et al.*, 2014). None of the included women had sought fertility treatment. Self-reported infertility rates were 52.3% in patients with Graves' disease and 47.0% in patients with Hashimoto's thyroiditis. However, there were no significant differences in number of achieved pregnancies, pregnancy losses or live births between women reporting of infertility and those who did not (Quintino-Moro *et al.*, 2014).

Among infertile patients, overt hypothyroidism is uncommon and will often have been diagnosed in the primary sector inflicting a bias in studies of thyroid function among patients seeking fertility treatment (Poppe et al., 2008b). In 438 women referred for various reasons of infertility, Poppe et al. only found two women with overt hypothyroidism (both antibody-positive) (Poppe *et al.*, 2002). Although median TSH levels were higher in patients with female infertility compared to controls, the prevalence of TSH above reference range was not different (Poppe *et al.*, 2002). In a Finnish cohort of 299 women seeking fertility treatment for the first time, 3.3% had been diagnosed with overt hypothyroidism prior to referral, and at time of screening a total of 12 women (4%) had elevated TSH levels (Arojoki *et al.*, 2000).

Subclinical Hypothyroidism

Subclinical hypothyroidism is defined as a TSH level above reference ranges (but below 10 mU/L) and FT4 within the reference range. The prevalence in background populations ranges approximately 5%–10% with substantial variations depending on national iodine

status, sex, ethnicity and age (Hollowell *et al.*, 2002; Vanderpump, 2011). Many cases are likely transient as described in follow-up studies illustrating normalization upon repeated measurements in up to 50% of cases (Meyerovitch *et al.*, 2007).

The prevalence of subclinical hypothyroidism in infertile women has ranged from 0.7% to 43% in different studies reflecting variations in study designs, analytical methods and definitions of subclinical hypothyroidism (Poppe et al., 2008b). In a retrospective study of 244 women attending a fertility clinic, Abalovich et al. found subclinical hypothyroidism in 13.9% as compared to 3.9% in fertile controls ($P < 0.002$). Among the infertile women, those with precocious ovarian failure, anovulation, and tubal disturbances had the highest prevalences of subclinical hypothyroidism (40%, 22.2%, and 18.2%, respectively). These results were subsequently recalculated to an increased risk of unexplained subfertility in subclinical hypothyroidism with an odds ratio of 4.0 (95% CI 1.7–9.8) (van den Boogaard *et al.*, 2011). Recently, Orouji et al. (2018) compared TSH levels in 187 women referred for unexplained infertility to 52 women with normal fertility (referred for severe male infertility). The women with unexplained fertility had higher TSH levels in both a priori testing (1.95 vs. 1.66 mU/L, $P = 0.003$) and adjusted analyses taking into account age, BMI and smoking status ($P < 0.01$). Furthermore, the prevalence of TSH above 2.5 mU/L was almost doubled in women with unexplained infertility (26.9% vs. 13.5%, $P < 0.05$).

Several studies of patients in fertility treatment have investigated the association between varying degrees of thyroid hypofunction, that is, increased TSH levels, and treatment outcomes. Thus pregnancy rates were lower in infertile women with an elevated TRH-stimulated TSH response (used as indicator of thyroid hypofunction prior to more sensitive TSH assays) (Gerhard *et al.*, 1991). Cramer et al. showed that higher TSH levels significantly predicted a reduced fertilization rate of oocytes (Cramer *et al.*, 2003). However, in a retrospective study of 627 women, Chai et al. did not find ART outcome (clinical pregnancy, live birth and pregnancy loss rate) to be associated with subclinical hypothyroidism (nor thyroid autoantibody-presence) (Chai *et al.*, 2014). Thus, evidence differs with regards to an impact of smaller aberrations of TSH on fertility treatment outcome.

Hyperthyroidism

In women of reproductive age the most common cause of hyperthyroidism is Graves' disease, an autoimmune disease characterized by low TSH and high T4 levels and pathognomonic TSH receptor stimulating or blocking receptor antibodies.

Krassas et al. investigated 214 premenopausal thyrotoxic women and 214 healthy controls and found menstrual irregularities in 21.5% and 8.4%, respectively (Krassas *et al.*, 1994). This was fewer than in previous studies of thyrotoxicosis where hypomenorrhea, oligomenorrhea or, especially, amenorrhea was found in the majority of patient populations (Goldsmith *et al.*, 1952; Krassas *et al.*, 1994)—possibly reflecting more severe thyroid disease due to less sensitive diagnostic testing. As mentioned above, in a more recent study 52.3% of 193 women with Graves' disease reported of having experienced infertility (Quintino-Moro *et al.*, 2014). Although prevalences vary, little doubt remains that hyperthyroidism affect menstrual frequency and fertility. However, subclinical hyperthyroidism has not been associated with a poor treatment outcome.

Thyroid Autoimmunity

Increasing attention is paid to the role of thyroid autoimmunity in reproduction, especially TPOAbs. Thyroid autoimmunity is common in women of reproductive age and many studies have failed to show an increased prevalence among infertile women (Poppe et al., 2008b). Poppe et al. did find a relative risk of 2.3 (CI: 1.02–5.12, $P = 0.045$) of having thyroid antibodies in women who had a female cause for infertility compared to healthy controls (Poppe *et al.*, 2002). Especially, women with endometriosis were more often thyroid antibody-positive in line with hypotheses of endometriosis being an immunological disorder (Eisenberg *et al.*, 2012). The first controlled study to illustrate increased polyautoimmunity in infertile patients was conducted by Roussev et al. who performed multiple immunological testing of 108 women with reproductive failure (45 with unexplained infertility) (Roussev *et al.*, 1996). Since, thyroid antibodies as a marker of an underlying immunological breach causing reproductive failure has been extensively investigated (Bliddal et al., 2017a; Bliddal and Feldt-Rasmussen, 2014).

A meta-analysis of four studies found subfertility to occur more often in thyroid antibody-positive women (OR 1.5, 95% CI 1.1–2.0) (van den Boogaard *et al.*, 2011). Although there may be an increased prevalence of thyroid autoantibodies among infertile women this did not affect the chance of achieving clinical pregnancy (van den Boogaard *et al.*, 2011). In women undergoing ART, Unuane et al. found the crude cumulative live birth rate after six cycles to be 47% in both 333 TPOAb-positive women and 2019 TPOAb-negative women (Unuane *et al.*, 2016). In a more recent meta-analysis of women in IVF/ICSI treatment (Busnelli *et al.*, 2016), women with thyroid autoantibodies did not differ compared to antibody-negative women in fertilization rate (odds ratio 1.11 (95% CI: 0.97–1.27), $P = 0.13$) nor to clinical pregnancy rate (odds ratio 0.9 (95% CI: 0.77–1.06), $P = 0.22$). However, thyroid antibody-positivity was significantly associated with a higher miscarriage rate (odds ratio 1.44 (95% CI: 1.06–1.95), $P = 0.02$) and reduced live birth rate (odds ratio 0.73 (95% CI: 0.54–0.99), $P = 0.04$) (Busnelli *et al.*, 2016). In 2017, these findings were confirmed by one of the largest to date study of 1468 infertile women (Seungdamrong *et al.*, 2017). Thus, presence of TPOAbs without thyroid dysfunction does not seem to affect the chance of obtaining pregnancy by ART, but rather increase the risk of pregnancy loss.

Thyroid Function Testing in Infertile Patients

Based on the findings described in the above, thyroid function testing of all women seeking fertility treatment is endorsed by multiple international guidelines with the aim of correcting thyroid disease before starting fertility treatment (Alexander *et al.*, 2017; De Groot *et al.*, 2012; Practice Committee of the American Society for Reproductive Medicine, 2015). However, several caveats exist in the interpretation of results.

Pitfalls in Thyroid Function Testing in General

Thyroid function tests are influenced by the presence of concurrent or recent illness, assay interference, biologic variation of TSH secretion and sensitivity, and interindividual differences (Baloch *et al.*, 2003). Acute illness (often severe) can lead to nonthyroidal illness syndrome (transient central hypothyroidism with low TSH in the presence of low triiodothyronine (T3)) giving rise to misinterpretation of an apparently normal TSH level. TSH assays can be obscured by heterophilic antibodies or other interfering antibodies. Thus, repeated measurements by an alternative assay with a minimum of 2 to 3 weeks apart is mandatory for a diagnosis of, especially subclinical, thyroid disease. Noteworthy, TSH reference ranges often span a factor of 10 reflecting the large interindividual differences in the background population. The intraindividual thyroid function fluctuations are much smaller and are to be considered based on an individual biological set-point (Andersen *et al.*, 2002; Feldt-Rasmussen *et al.*, 1980). Comparison with the patient's own previous TSH measurements is a good guidance for correct interpretation.

Affection of Thyroid Function Test During Fertility Treatment

Up to 99% of circulating thyroid hormones are bound to thyroid binding globulin. As estrogen increases the liver's production of globulin, any ART procedure stimulating the ovaries and thus increasing estrogen levels, will affect thyroid function variables. These changes even occur remarkably more abrupt than those seen in normal pregnancy (Feldt-Rasmussen and Mathiesen, 2011). The increase in thyroid binding globulin will result in an increased binding capacity and therefore a transient reduction in the circulating FT4 levels (Muller *et al.*, 2000). By negative feedback, TSH will rise to compensate for this reduction (Gracia *et al.*, 2012; Muller *et al.*, 2000). Poppe et al. demonstrated that in previously euthyroid women, FT4 levels were lower and TSH levels higher after ovarian stimulation, and this was significantly more so in women with thyroid autoantibodies (Poppe *et al.*, 2004). Thus, in women with a latent low thyroid reserve (i.e., low iodine intake, thyroid autoimmunity (Feldt-Rasmussen *et al.*, 2011; Glinoer *et al.*, 1994)), the extra demand for thyroid hormone production during controlled ovarian stimulation can trigger (sub)clinical hypothyroidism (see **Fig. 2**).

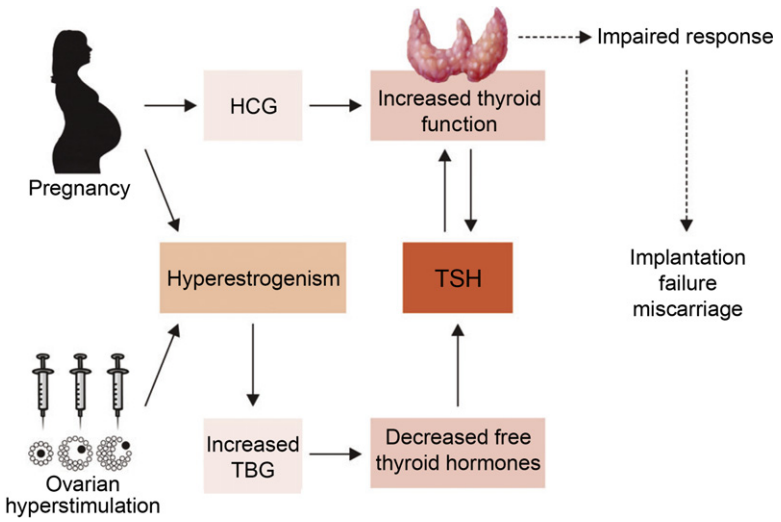

Fig. 2 Thyroid hormone production during pregnancy in ART. In healthy pregnancies, a steep increase in human chorionic gonadotropin levels in the first trimester result in an increased thyroid hormone production by cross-reaction with the TSH-receptor. Ovarian hyperstimulation during ART results in high estrogen levels that stimulate the liver's production of thyroid binding globulin. As a result, more free thyroid hormone is bound and by negative feedback increase pituitary TSH secretion. The combination of physiological pregnancy-adaptation and ovarian hyperstimulation pose high demands on the thyroid's capability of thyroid hormone production. This may be impaired in women with a low iodine reserve or thyroid autoimmunity possibly resulting in an increased risk of implantation failure and miscarriage. Abbreviations: *ART*, assisted reproductive technology; *hCG*, human chorionic gonadotropin; *TSH*, thyroid stimulating hormone. Figure adapted with permission from Colicchia, M. *et al.* (2014). Molecular basis of thyrotropin and thyroid hormone action during implantation and early development. *Human Reproductive Update* **20**, 884–904.

A potentially life-threatening complication of controlled ovarian stimulation is the ovarian hyperstimulation syndrome characterized by cystic enlargement of the ovaries and a risk of shock due to increased capillary permeability and ovarian neoangiogenesis. In two cases, women with known hypothyroidism developed ovarian hyperstimulation syndrome after ART (Poppe et al., 2008a; Skweres *et al.*, 2014). TSH levels steeply increased from normal prepregnancy levels to overt hypothyroidism at the time the women presented with symptoms of ovarian hyperstimulation syndrome. TSH levels normalized after a substantial increase in T4 treatment dose. However, cases of spontaneous ovarian hyperstimulation syndrome in hypothyroidism have also been reported (Borna and Nasery, 2007; Kanza *et al.*, 2013; Sridev and Barathan, 2013).

Screening for TSH and FT4 levels (Baloch *et al.*, 2003) before initiating fertility treatments is thus very important. Should pregnancy be achieved without recognizing low maternal free thyroxine levels, fetal development is at cost.

Special Considerations Related to Pregnancy

In pregnancy, the fertilized egg and (upon implantation) the placenta produces the glycoprotein hormone human chorionic gonadotropin (hCG). The beta-subunit of hCG is capable of binding to the TSH receptor thus stimulating thyroid hormone production. During the first trimester hCG levels steeply increase and thus also thyroid hormone levels, thereby reducing TSH levels by negative feedback. Furthermore, the increased estrogen levels in pregnancy will increase thyroid binding globulin levels and thus total T4 as described in the above (Glinoer, 1999). It is therefore physiological for TSH to decrease to a lower level than prepregnancy and total T4 to increase up to approximately 150% (Alexander *et al.*, 2017). Placental deiodinases involved in transport of maternal thyroid hormones to the fetus, and altered renal clearance of iodine, also affect thyroid hormone status during pregnancy (Glinoer, 1999). In, ART the high level estrogen treatment and subsequent elevation in TSH levels has been shown to exceed pregnancy appropriate targets for TSH, especially in women with preexisting hypothyroidism. The combined stress on the thyroid by ART and pregnancy may thus have important clinical implications for screening and thyroid hormone supplementation (Gracia *et al.*, 2012).

Treatment of Thyroid Diseases During Fertility Treatment

Thyroid hormones play an integral part of fetal development. During pregnancy the fetus rely on a maternal supply of thyroid hormones. This is especially the case in the first and early second trimesters where fetal brain development depends on thyroid hormones, but the fetus has no independent thyroid hormone production (Bernal, 2007). Although unwanted to the woman, the inability to obtain and sustain pregnancy in thyroid disease can therefore be physiologically relevant. Furthermore, it has been hypothesized that even smaller and transient thyroid function impairments may cause implantation failure or miscarriages (Colicchia *et al.*, 2014). Restoring thyroid function before initiating ART is therefore essential to fetal development and will often result in improved fertility. Thus, there is little disagreement on the benefits of treating overt thyroid disease. However, subclinical thyroid disease and isolated thyroid autoimmunity constitute particular challenges, not least due to lack of evidence of benefit.

T4 Treatment in Infertility

Women with known hypothyroidism should increase their T4 dosage before start of ART due to the marked and abrupt changes—in case of spontaneous pregnancy, when becoming pregnant—in order to be able to meet the increased thyroid hormone requirements during pregnancy. Alexander et al. (2004) prospectively followed women with hypothyroidism and concluded that levothyroxine dosage needed to be increased by 50% in the first trimester. A rapid increase in levothyroxine requirements between gestational week 6 and 16 prompted the authors to suggest increments of 30% as soon as pregnancy was confirmed (Alexander *et al.*, 2004). In a small study of 18 infertile women with well-controlled hypothyroidism, Davis et al. compared pregnancies achieved by nongonadotropin and gonadotropin stimulation and found levothyroxine dosage increments to be comparable between groups (30.6% and 32.4%, respectively) (Davis *et al.*, 2007). However, TSH levels were higher in women after controlled ovarian stimulation (3.8 vs. 2.2 mU/L) and lack of significance was likely due to the small number of investigated women. Thus, it is recommended to increase T4 treatment dosage prior to ART and to monitor TSH levels closely in early pregnancy.

T4 Treatment and Outcome of ART

T4 treatment may improve fertility in hypothyroid and subclinically hypothyroid infertile women. Thus Yoshioka found T4 treatment of subclinically hypothyroid women (TSH $>$ 3 mU/L) to improve pregnancy rates and shorten the period of infertility (Yoshioka *et al.*, 2015). In addition to improved fertility, T4 treatment could also improve obstetric outcome of the pregnancies achieved. Abalovich et al. followed 114 hypothyroid women. Women who were not sufficiently treated with T4 during pregnancy experienced pregnancy loss in 60% of cases and preterm delivery in 20% of cases. In comparison none of the euthyroid women had pregnancy loss or premature deliveries (Abalovich *et al.*, 2002). In accordance with this, Busnelli et al. found no difference in pregnancy or delivery rate after ART when comparing 137 hypothyroid women with 274 controls as long as TSH levels were kept below 2.5 mU/L (Busnelli *et al.*, 2013). One study did show a poorer outcome of fertility treatment in women with

hypothyroidism despite sufficient treatment (Scoccia *et al.*, 2012). However, the treatment group more often had competing male factor infertility and a poorer embryo fertilization rate, which could impact results. A randomized controlled trial of the effect of T4 treatment in subclinically hypothyroid women undergoing ART, showed no difference in pregnancy rates, but a reduced pregnancy loss rate (no miscarriages vs. 33.3% in controls, $P = 0.021$) and increased live birth rate ($P = 0.039$) in the treatment group (Kim *et al.*, 2011). Accordingly, a meta-analysis of prospective randomized control trials of T4 treatment in a total of 222 subclinically hypothyroid women undergoing ART found that achieving euthyroidism prior to ovulation induction increased live birth rates (RR 2.76, 95% CI: 1.20–6.44) (Velkeniers *et al.*, 2013).

As part of the ongoing debate on slight thyroid dysfunction in pregnancy is the impact on child neurodevelopment. Observational studies in fertile women found an association between slight maternal thyroid dysfunction and poorer child brain functioning (Haddow *et al.*, 1999; Pop *et al.*, 1999). However, in a large randomized controlled trial on maternal subclinical hypothyroidism or hypothyroxinemia no difference in IQ between the children of treated versus untreated mothers was found in the children at the age of 5 (Casey *et al.*, 2017).

Recommendations for Screening and T4 Treatment in ART

Potentially harmful effects of maternal overtreatment with levothyroxine are not yet clarified, but T4 treatment is generally considered safe. Thus, further studies are needed to define the selection of women who require levothyroxine replacement and to determine the benefits of a predictive dose adjustment strategy. This give rise to discrepancies in guidelines from various scientific societies (Alexander *et al.*, 2017; Lazarus *et al.*, 2014; Practice Committee of the American Society for Reproductive Medicine, 2015). However, due to the possible impact on fertility, obstetric outcome and fetal development, guidelines recommend to screen all patients attending fertility clinics for TSH. The potential downside of this screening strategy is the delay of fertility treatment and overtreatment without clear evidence of benefit (Chan and Boelaert, 2015; Taylor *et al.*, 2014; Velasco and Taylor, 2018). Despite limited evidence showing a benefit of T4 treatment of subclinical hypothyroidism, considering potential benefits, limited side effects, and ART-related thyroid hormone requirements, guidelines recommend T4 treatment for all subclinically hypothyroid women (TSH above upper limit of reference range) in ART. Furthermore, in women with TSH levels between 2.5 and 4.5 mU/L, to perform supplemental TPOAb-measurements and, in case of TPOAb-positivity, T4 treatment (Alexander *et al.*, 2017; Practice Committee of the American Society for Reproductive Medicine, 2015). The treatment goal is a TSH level below 2.5 mU/L in the first trimester of pregnancy (Alexander *et al.*, 2017), although this threshold is somewhat arbitrary (Brabant *et al.*, 2015).

Thyroid Autoimmunity in Euthyroidism

The association between TPOAb-positivity and the risk of pregnancy loss is well substantiated (Alexander *et al.*, 2017; Bliddal and Feldt-Rasmussen, 2014). An increasing amount of evidence also suggests an increased risk of preterm delivery although this finding is less evident (Bliddal et al., 2016, 2017b; Bliddal and Feldt-Rasmussen, 2014; Korevaar *et al.*, 2018). In 2005, Negro et al. conducted a randomized placebo-controlled trial investigating the effect of T4 treatment in TPOAb-positive euthyroid women undergoing ART (Negro *et al.*, 2005). Pregnancy rates were comparable between groups. Euthyroid TPOAb-positive women ($n = 72$) had higher pregnancy loss rates than euthyroid TPOAb-negative women ($n = 412$) (RR 2.01, 95% CI: 1.13–3.56, $P = 0.028$), but there was no difference between the treatment and the placebo group (Negro *et al.*, 2005). However, in a similar trial from the same research group, T4 treatment of euthyroid TPOAb-positive women attending prenatal care had no effect on pregnancy loss rate, but was associated with significantly lower preterm delivery rates (7% vs. 22.4%, $P < 0.05$) (Negro *et al.*, 2006).

In a recently published blinded randomized controlled trial, euthyroid thyroid antibody-positive women undergoing ART were randomized to receive either T4 treatment ($n = 300$) titrated according to continuously monitored TSH levels or placebo ($n = 300$) (Wang *et al.*, 2017). The women underwent the same ART protocol and cases of spontaneous pregnancy were excluded. Approximately one third of women in each group achieved pregnancy and among those, pregnancy loss rates were 10.3% (11 of 107) in the intervention group and 10.6% (12 of 113) in the control group ($P = 0.94$). There were no differences among intervention and control group in terms of live-birth (RR 0.98, 95%CI 0.78–1.24, $P = 0.86$) and risk of preterm delivery (RR 1.13, 95% CI 0.65–1.96, $P = 0.67$) (Wang *et al.*, 2017).

Results are currently awaited from two randomized controlled trials of T4 administration in TPOAb-positive women with infertility or recurrent pregnancy loss; the UK based multicenter TABLET study and the multinational T4life study with preterm delivery and live birth as the respective primary outcomes (T4life Trial, 2017; TABLET Trial, 2017). Meanwhile, the recent ATA guidelines (not taking into account the study by Wang et al.) recommend that "administration of levothyroxine to TPOAb positive, euthyroid women undergoing ART may be considered given its potential benefits in comparison to its minimal risk" (Alexander *et al.*, 2017).

Although, Litwicka et al. found that prednisolone treatment of thyroid antibody-positive women may improve outcome of IVF (Litwicka *et al.*, 2015) this is not recommended by guidelines and neither is treatment with intravenous immunoglobulin therapy (Alexander *et al.*, 2017).

Hyperthyroidism

As with hypothyroidism, treatment of hyperthyroid women normalizes menstrual patterns. Hyperthyroidism should be well controlled before and during pregnancy. In women with Graves' disease, thyroid stimulating or blocking autoantibodies can cross the placenta and affect the fetal thyroid hormone receptors as well. Antithyroid drugs given to the mother also cross the placenta to a higher extent than the maternal thyroid hormones needed for fetal development. Thus, to avoid complications such as iatrogenic fetal hypothyroidism and teratogenic effects of medication this calls for outmost attention from and collaboration between fertility specialists, endocrinologists, obstetricians and pediatricians (Andersen et al., 2017, 2013; Bliddal *et al.*, 2011). Due to the substantial comorbidities related to antithyroid treatment, treatment of subclinical hyperthyroidism is not recommended.

Male Infertility and the Thyroid

Although thyroid dysfunction is far less common in men than in women, both thyroid hypo- and hyperfunction affect male fertility. Clinical studies investigating male thyroid function and fertility suggest an association of both hyper- and hypothyroidism on spermatogenesis, ejaculate volume and erectile function (Krassas *et al.*, 2010). In hypothyroid men with hypogonadotropic hypogonadism, testosterone levels rose and prolactin levels fell when restoring euthyroidism (Donnelly and White, 2000). In hyperthyroid men, erectile dysfunction (prevalent in 78.9%) was ameliorated by restoring euthyroidism (Krassas *et al.*, 2008).

However, thyroid disorders are far less prevalent in men than in women and so far no clinical value has been shown of screening males seeking fertility treatment (Lotti *et al.*, 2016). Instead a targeted case-finding approach in case of suspected hypogonadotropic hypogonadism is advisable.

Conclusion

Thyroid hormones affect the reproductive capability by altering responses of the hypothalamic–pituitary–gonadal axis, changing metabolic clearance of sex hormones and affecting function of local reproductive tissues. Both hypo- and hyperthyroidism in men and women have been associated with infertility. With proper treatment, fertility is restored. Although thyroid autoantibodies constitute an additional risk for infertility they do not seem to reduce chances of obtaining pregnancy by ART, but rather increase the risk of pregnancy loss. Fertility treatment with controlled ovarian stimulation put extra stress on the thyroid gland with a risk of unmasking subclinical cases of thyroid hypofunction. Screening for TSH levels should be performed in all women seeking fertility treatment. However, diagnostic challenges and evolving treatment strategies call for at close collaboration between fertility specialists and endocrinologists. Securing sufficient thyroid hormone economy is detrimental to the chance of achieving and sustaining a healthy pregnancy with an optimal thyroid hormone supply to the fetus.

Jerome M Hershman, Division of Endocrinology, VA Greater Los Angeles Healthcare System, Los Angeles, CA United States

Glossary

Hashimoto's thyroiditis Autoimmune inflammation of the thyroid gland.
Human chorionic gonadotropin (hCG) A hormone secreted by the placenta.
Hyperemesis gravidarum Excessive vomiting during pregnancy.
Hyperthyroidism The condition resulting from the effects of excessive production of thyroid hormone.
Hypothyroidism The condition resulting from the effects of deficient production of thyroid hormone.

Thyroid Size and Function During Pregnancy

An increase in the size of the thyroid gland during pregnancy has been shown in some studies but not others. In regions of adequate iodine intake, the thyroid gland does not typically enlarge during pregnancy, whereas it often enlarges in areas of relative iodine insufficiency.

In regions of Europe where there is reduced iodine intake (average iodine intake of 50–75 μg day^{-1}), such as Belgium and southern France, thyroid volume (as measured by ultrasound) increased approximately 25% in pregnant women. Reevaluation of the thyroid size 1 year postpartum showed that thyroid size was still increased in approximately half of the women. However, pregnant women in southwest France treated with 100 μg iodine per day did not develop thyroid enlargement. Therefore, adequate iodine intake is the most significant factor influencing the size of the thyroid gland.

A number of physiological changes during pregnancy influence thyroid hormone production, transport, and disposal (Table 1). An increase in iodide clearance by the kidney starts in the latter part of the first trimester and continues throughout pregnancy. Serum human chorionic gonadotropin (hCG), which peaks in the first trimester, stimulates thyroid function and size by acting as a thyroid-stimulating hormone (TSH) receptor agonist. Estrogen increases thyroxine-binding globulin (TBG), and thyroid hormone production increases to fill the expanded TBG pool and maintain a normal free thyroxine concentration. Thyroxine disposal is accelerated by type 3 5-deiodinase (D_3) expressed at high levels in the placenta and uterus. There is also an increased volume of thyroid hormone distribution in the plasma. All these factors contribute to an increase in thyroid hormone production during pregnancy that is required to maintain the euthyroid state.

Total serum thyroxine (T_4) and triiodothyronine (T_3) concentrations increase during normal pregnancy due to the estrogen-induced increase of serum TBG, the principal serum-binding protein for both T_4 and T_3. The serum TBG concentration increases early in pregnancy and tends to peak in midpregnancy, approximately 2.5-fold higher than the prepregnancy level. The increase in serum TBG concentration is such a consistent change in early pregnancy that a "normal" serum TBG level in the first trimester is considered an indication of impending miscarriage. The increase in serum TBG concentration is primarily due to an estrogen-induced increase in TBG sialylation that reduces its clearance. The extrathyroidal pool of T_4 must increase more than twofold to maintain normal free T_4 concentration. Free T_4 and T_3 concentrations generally remain within the normal range, although modestly increased or reduced values have been reported. These differences in the results of free hormone measurements may be related to thyroid hormone changes that are a consequence of relative iodine deficiency, the stage of pregnancy, and methodological variables of the free hormone assays used. The regulation of thyroid function by the hypothalamic–pituitary axis is not

Table 1 Physiological changes in pregnancy and their influence on thyroid function tests

Physiologic change	*Serum thyroid test change*
Increased thyroid gland size (women in areas of insufficient iodine intake)	Increased thyroglobulin
Estrogen-mediated increase in serum levels of TBG	Elevated total T_4 and T_3 concentrations
Increased plasma volume	Increased T_4 and T_3 pool
First-trimester elevation in serum hCG	Transient reduction in TSH and probable increase in free T_4 concentrations
Increased expression of type 3 deiodinase (D_3) in placenta and uterus	Accelerated degradation of T_4 and T_3

Abbreviations used: T_4, thyroxine; T_3, triiodothyronine; hCG, human chorionic gonadotropin; TBG, thyroxine-binding globulin.

affected by pregnancy. Alterations of serum TSH in pregnancy reflect changes in thyroid function. The most uniform change during pregnancy is a reduction in serum TSH that corresponds to the peak of serum hCG in the first trimester. Generally, serum TSH remains in the normal range, although subnormal values were reported in approximately 15% of women from an area of relative iodine insufficiency. The reduction of serum TSH is likely the result of an increase in circulating free thyroid hormones at this time. The increase in free T_4 level is most likely mediated by direct stimulation of the thyroidal TSH receptor by hCG.

Hypothyroidism During Pregnancy

The previously described physiological factors that influence thyroid function during pregnancy — increased iodine clearance, increased serum TBG concentration, increased D_3 activity in the placenta and uterus, and increased volume of thyroid hormone distribution in the plasma — are a "stress" on the thyroid gland. Women with normal thyroid glands in iodine-sufficient areas can compensate for these changes, but women in iodine-insufficient areas or those with underlying hypothyroidism may not be able to maintain euthyroxinemia. Although the fetal thyroid gland begins to function at 10–12 weeks of development, maternal thyroid status influences fetal development throughout pregnancy. Up to 40% of the cord blood thyroid hormone concentrations at delivery arise from the mother.

Iodine Deficiency

Iodine deficiency remains an important cause of maternal hypothyroidism in a number of areas throughout the world, including parts of Africa, Asia, and Europe. It is estimated that as many as 500 million people, including up to 30% of school-age children, live in areas of iodine deficiency, despite a worldwide program to eradicate iodine deficiency through universal salt iodization. Approximately 70% of the world's population has access to iodized salt. The World Health Organization recommends that pregnant women receive 250 μg of iodine per day. Since iodine clearance increases during pregnancy, pregnant women in areas of relative iodine insufficiency are at an increased risk of iodine deficiency. In the United States, a survey conducted from 1988 to 1994 indicated that, compared to a similar study conducted from 1971 to 1974, the percentage of women of childbearing age with low urinary iodine (<5 μg dL^{-1}) increased from 4% to 15% and that of pregnant women increased from 1% to 7%. The American Thyroid Association recommends the supplementation of iodine sources from the diet with an oral supplement containing 150 μg iodine during preconception, pregnancy, and lactation.

Hashimoto's Disease

The most common cause of hypothyroidism during pregnancy is chronic lymphocytic thyroiditis, also referred to as Hashimoto's thyroiditis. There is a marked female predominance of Hashimoto's thyroiditis, with a female to male ratio of approximately 7:1. Hypothyroidism can also be seen as a consequence of radioiodine or surgical treatment of Graves' disease, thyroid cancer, or goiter. Transient hypothyroidism in the postpartum period is most often due to postpartum lymphocytic thyroiditis. Hypothyroidism can also occur after external radiation for cervical neoplasms and may also be caused by the medications lithium, amiodarone, or interferon.

Women may first be diagnosed with hypothyroidism during pregnancy. A survey of thyroid function studies of a sample of healthy individuals without known thyroid disease showed a high incidence of undiagnosed hypothyroidism. Thyroid tests were performed from 1988 to 1994 and showed that 4.3% of the group had undiagnosed subclinical hypothyroidism and 0.3% had undiagnosed overt hypothyroidism. Positive anti-thyroid peroxidase antibodies were found in 11.3% of the population without known thyroid disease. The incidence of abnormalities was significantly higher in women than in men. Approximately one-fourth of hypothyroid women have menstrual irregularity, with oligomenorrhea more common than hypomenorrhea and menorrhagia.

Complications

A variety of maternal and fetal complications of pregnancy have been associated with hypothyroidism. Although severe hypothyroidism can interfere with conception, women have become pregnant even when profoundly hypothyroid. Correction of subclinical hypothyroidism with thyroxine replacement has been associated with conception in women with ovulatory defects. Although complications of pregnancy are not uniformly seen in hypothyroidism, a number of complications are observed with a higher frequency in women who are hypothyroid during pregnancy. Among women who experience a miscarriage, a high percentage have positive anti-thyroid antibodies, and some have mild or overt hypothyroidism. Although it is possible that reduced thyroid hormone levels and thyroid autoantibodies play a pathogenic role in miscarriage, it is more likely that thyroid autoantibodies are a marker for antibodies to other fetal or placental components that result in miscarriage. Other complications of pregnancy associated with hypothyroidism include placental abruption, pregnancy-induced hypertension, and preterm delivery. In a study of 150 pregnancies complicated by overt or subclinical hypothyroidism, the incidence of miscarriage and preterm delivery was much higher in patients with incompletely treated hypothyroidism than in those receiving adequate thyroxine

replacement. Term deliveries were seen in approximately 20% of women with inadequately treated hypothyroidism and approximately 95% of women receiving adequate thyroxine replacement at the time of delivery. Table 2 summarizes the effects of hypothyroidism on pregnancy and fertility.

Increased Thyroxine Dose

In women known to be hypothyroid, the thyroxine dose should be titrated to a low-normal TSH prior to conception, if possible. A number of studies suggest that maternal euthyroxinemia is important in early gestation, prior to fetal thyroid gland functioning at 10–12 weeks. Approximately 50–70% of hypothyroid women require an increase in thyroxine dose during pregnancy. Women who are completely athyreotic (as a consequence of radioiodine therapy or surgical thyroidectomy) have the least thyroid reserve and are likely to need the greatest increase in thyroxine dose. Women with some thyroid reserve will need only a small increment or no change in thyroxine dose. The average required increase in thyroxine dose is approximately 50 μg. Women should generally be advised to increase their thyroxine dose by 30% immediately upon confirmation of pregnancy, perhaps by taking two extra tablets of thyroxine each week.

It is also important to caution women about taking calcium and iron supplements simultaneously with thyroxine since this may interfere with thyroxine absorption. Many women may take such supplements for the first time during pregnancy. Thyroid function should be evaluated in the first trimester with subsequent monitoring every 4–6 weeks, with dose adjustments as necessary to keep the serum TSH within the pregnancy-specific ranges (first trimester, 0.1–2.5 mIU L^{-1}; second trimester, 0.2–3.0 mIU L^{-1}; third trimester, 0.3–3.0 mIU L^{-1}). The dose can be returned to the prepregnancy dose immediately after delivery.

Fetal Development

The influence of hypothyroidism on fetal development is controversial. When identified and started on thyroxine replacement soon after birth, infants with congenital hypothyroidism have generally been found to have normal intellectual and neurological development. Some investigators have identified subtle defects of cognitive function in treated hypothyroid children. The placenta does not usually allow thyroxine to cross between mother and fetus. In congenital hypothyroidism, however, there is evidence that in the presence of a large maternal-to-fetal gradient, thyroxine will cross. This permits sufficient thyroxine for the fetus for development. The intellectual development of the offspring of hypothyroid mothers is thought by some to be modestly reduced. One study showed a small but significant reduction in the IQ of 8-year-old children born to mothers with untreated hypothyroidism.

The potential benefits and cost-effectiveness of antenatal thyroid function screening during pregnancy has been controversial. One study of nearly 22,000 women did not demonstrate a difference in the IQ of 3-year-old children born to women who were screened and treated for hypothyroidism (as determined by either TSH, FT_4, or both) if found, compared to children of hypothyroid women whose hypothyroidism was not treated. In contrast, another study based on a large population-based cohort in the Netherlands reported that hypothyroxinemia during pregnancy was associated with increased risks of expressive language and cognitive delays when evaluated in infants age 18–30 months.

Hyperthyroidism During Pregnancy

Graves' disease is the most common clinically recognized cause of hyperthyroidism in pregnant women. The majority of patients have previously identified Graves' disease, although it can also develop for the first time during pregnancy. Most women with hyperthyroidism have oligomenorrhea or amenorrhea.

Table 2 Hypothyroidism and fertility/pregnancy

Maternal complications	*Fetal complications*
Ovulatory dysfunction	Low birth weight
Miscarriage (highly associated with positive anti-TPO antibodies regardless of thyroid status)	Perinatal mortality (some studies show a small increase; others show no difference)
Pregnancy-induced hypertension	Increase in congenital anomalies (studies vary, with some showing a small increase and others no difference)
Placental abruption	Intellectual development (some studies show a small reduction in IQ at 8 years of age)
Preterm delivery	

TPO, thyroid peroxidase.

Table 3 Hyperthyroidism and pregnancy

Maternal complications	*Fetal complications*
Preeclampsia	Low birth weight
Preterm labor	Increased perinatal mortality
	Neonatal hypothyroidism (due to excessive treatment of mother with antithyroid drugs)
	Neonatal hyperthyroidism (due to transplacental passage of maternal thyroid-stimulating immunoglobulin)

Complications

Graves' disease is associated with a variety of complications during pregnancy (Table 3). There can also be significant fetal complications as a consequence of antithyroid drug treatment. Preterm labor and infants small for gestational age are associated with Graves' disease. Approximately 1 in 100 infants from mothers with Graves' disease will have neonatal Graves' disease. Since this results from maternal thyroid-stimulating immunoglobulin (TSI) crossing the placenta, the fetus is at risk even if the mother has been definitively treated with radioiodine or surgery. Some advocate measuring maternal TSI levels in the serum at 26–28 weeks gestation to determine the risk of neonatal Graves' disease, although the predictive value of this measurement is uncertain.

Treatment

There is controversy regarding the appropriate treatment for Graves' disease in anticipation of pregnancy, and the recommendations vary with the severity of disease and the region of the world. Some advocate definitive treatment of Graves' disease with radioiodine prior to pregnancy. This eliminates the possibility of Graves' disease complicating pregnancy, although the thyroxine dose during pregnancy must be carefully monitored and adjusted. Some endocrinologists recommend against radioiodine treatment in women of reproductive age because of fear of radiation dose to the ovaries. Although limited data are available, in follow-up of a small group of women treated as children with high-dose radioiodine for thyroid cancer, there was no increase in the incidence of congenital anomalies. In another study, radioiodine use for thyroid cancer was associated with a delay in childbearing in women across most of the reproductive lifespan.

In most cases of mild to moderate Graves' disease in women of reproductive age, treatment with antithyroid drugs is used. Most authorities recommend a treatment goal of keeping the free T_4 level at the upper normal to slightly elevated level, rather than normalization of the serum TSH level. Studies that have correlated fetal thyroid hormone levels with maternal levels indicate that when the mother is treated to euthyroidism, there is a much greater risk of fetal hypothyroxinemia. The total dose of antithyroid drug should be limited to restrict its transplacental passage. The choice of drug is controversial. A limited number of studies suggest that propylthiouracil (PTU) has less transplacental passage and is found in the breast milk to a lesser extent than methimazole, although PTU has also been associated with rare acute livery injury. However, methimazole therapy has been associated with aplasia cutis, a rare congenital defect manifest as loss of cutaneous structures in the crown of the head, and other more severe embryopathies. In Europe, the most popular drug is carbimazole, which is metabolized to methimazole and has not been associated with aplasia cutis. The American Thyroid Association guidelines for the management of thyroid dysfunction in pregnancy recommend the use of PTU during the first trimester to minimize the risk of embryopathies, and this should then be switched to methimazole during the second and third trimesters to minimize the risk of PTU-induced liver injury.

In general, Graves' disease becomes less active during pregnancy as general immunosuppression occurs in the later stages of gestation. The dose of medication required for treatment is often considerably less in the second and third trimesters. During the postpartum period, however, there can be a flare of Graves' disease, as is seen with many other autoimmune diseases. Some women may have their first manifestation of Graves' disease in the postpartum period. This must be differentiated from postpartum thyroiditis. Although a radioiodine uptake study can distinguish between these conditions, this cannot be easily performed in women during lactation, due to the risk of transmitting radioiodine to the nursing infant. Serum TSH receptor antibodies can be tested to support a diagnosis of Graves' disease. Sequential thyroid function tests show spontaneous improvement or transition to a hypothyroid state in those with thyroiditis, whereas those with Graves' disease have persistent hyperthyroidism.

Human Chorionic Gonadotropin (hCG)-Associated Hyperthyroidism

There is an exponential increase in serum hCG concentrations during the first trimester of pregnancy, with peak levels occurring at 10–12 weeks of pregnancy. *In vitro* studies using cells transfected with the human TSH receptor demonstrate that hCG binds the TSH receptor and activates adenylate cyclase. This is likely responsible for the reduction in serum TSH seen in most women in the first trimester of pregnancy. There are also a number of clinical manifestations of excess hCG (Table 4).

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by prolonged and severe nausea and vomiting in early pregnancy and is associated with a loss of 5% body weight, dehydration, and ketosis. It occurs in approximately 1–1.5% of pregnancies, is more prevalent in Asian

Table 4 Spectrum of hCG action in pregnancy

Nature of hCG elevation	*Clinical consequences and changes in thyroid function*
Physiologic elevation in first trimester	Mild elevation of serum free T_4, mild reduction in serum TSH concentration
Exaggerated first-trimester hCG elevation (commonly seen with multiple gestations)	Greater increase in serum free T_4 and greater reduction in serum TSH concentration; associated with hyperemesis gravidarum
Pathologic elevation from hydatidiform mole or choriocarcinoma	Marked elevation in serum free T_4 and free T_3 concentrations; suppression in serum TSH; clinical thyrotoxicosis observed in some patients
Increased "sensitivity" to hCG due to a TSH receptor mutation	Gestational thyrotoxicosis

Abbreviations used: hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

women than in Caucasians, and is more common with multiple gestations. Abnormalities of serum chemistries include hyponatremia, hypokalemia, hypochloremic alkalosis, and abnormalities of liver function. There is a positive correlation between the severity of vomiting and serum hCG level.

The majority of hyperemesis patients have a suppressed serum TSH level and increased free thyroxine concentration. Free thyroxine and TSH levels normalize when the hyperemesis resolves in the second trimester. In general, these patients do not have clinical features of hyperthyroidism or goiter. The hyperthyroidism is most likely due to a less sialylated hCG, which stimulates the TSH receptor to a greater extent, although it has a reduced serum half-life.

In most patients, the increased thyroid function of hyperemesis gravidarum is self-limited and subsides with the disappearance of vomiting. In a small percentage of patients, however, there is clear clinical evidence of hyperthyroidism; this has been termed transient hyperthyroidism of hyperemesis gravidarum or gestational thyrotoxicosis. In these situations, the diagnosis of Graves' disease should be excluded. Treatment with antithyroid drugs does not influence the course of hyperemesis gravidarum, even when associated with elevated thyroid function tests. If they are used, these drugs should be discontinued as soon as thyroid function tests return to normal and the vomiting subsides.

Trophoblastic Tumors

Clinical thyrotoxicosis has been associated with excessive hCG produced by trophoblastic tumors, hydatidiform mole, and choriocarcinoma. The hCG produced by these tumors is used as a marker for the diagnosis and management of these patients. The serum concentration of hCG in affected patients may be several-fold higher than the peak levels of normal pregnancy. Molar pregnancies are estimated to occur in approximately 1 in 1500 pregnancies in the United States and 1 in 1000 pregnancies in the United Kingdom, and they are significantly more common in Asian and Latin America populations.

Molar pregnancies are usually diagnosed before 20 weeks of gestation because of abnormal vaginal bleeding. Toxemia and hyperemesis gravidarum may also occur in molar pregnancy with greater frequency than in normal pregnancy. Thyroid function abnormality ranges from subclinical hyperthyroidism to increased free thyroxine levels with minimal clinical features of hyperthyroidism and even to severe thyrotoxicosis causing atrial fibrillation and congestive heart failure. In general, the manifestations of hyperthyroidism probably depend on the severity and duration of the increased thyroid hormone levels, which are in turn proportional to the hCG level, and the hCG level is proportional to the mass of the tumor.

TSH Receptor Mutation Sensitive to hCG

A very rare but informative cause of gestational thyrotoxicosis has been reported. In this case, a women and her mother both had a similar history of hyperemesis and hyperthyroidism during pregnancy. The TSH receptor had an A-to-G heterozygous mutation at codon 183 in exon 7, resulting in substitution of arginine for lysine in the middle portion of the extracellular domain of the TSH receptor. *In vitro* studies indicated that cells transfected with the mutant TSH receptor were much more sensitive to hCG than those expressing the wild-type TSH receptor. The hyperthyroidism during pregnancy in this family is most likely due to activation of this mutant TSH receptor by hCG.

Thyroid Disorders in the Elderly☆

Vafa Tabatabaie and Martin I Surks, Albert Einstein College of Medicine, Bronx, NY, United States

Epidemiology

Thyroid disorders are common in the general population, and their prevalence increases with age. Based on data from NHANES III it is estimated that 10.4 million people in the United States have thyroid disease, goiter, or take thyroid medication, and an additional 8.7 million have biochemical evidence of thyroid dysfunction (Hollowell *et al.*, 2002). In NHANES III, 4.6% of participants had hypothyroidism, and 1.3% had hyperthyroidism. Measuring serum thyroid stimulating hormone (TSH), Bagchi *et al.* screened more than 900 community dwelling older adults in Detroit, MI and found increased prevalence of hypothyroidism (defined in this study as TSH >6 mU/L) and hyperthyroidism (TSH <0.1 mU/L) compared with the general population: 6.9% and 2%, respectively. The prevalence was higher in subjects older than 75 years as compared to the 55- to 64-year age group (Bagchi *et al.*, 1990). Increased incidence of hypothyroidism or raised TSH with age has also been reported from Great Britain (Vanderpump *et al.*, 1995), in more than 25,000 participants in state health fairs in Colorado(Canaris *et al.*, 2000) and in a population wide study including $>300{,}000$ residents of Tayside, Scotland (Flynn *et al.*, 2004).

Diagnosis of Thyroid Disease in the Elderly

In the presence of an intact hypothalamic-pituitary axis, serum TSH remains the most reliable means of assessing thyroid function. As for most other laboratory parameters, clinicians rely on a reference range, derived from population studies, to determine whether an individual's thyroid function is within the reference range and thus can be considered "normal." In recent years, published reports have shown that the TSH reference range might be different in the elderly population, therefore adding to the complexity of diagnosis of thyroid disease in this age group. Using data from two NHANES surveys, Surks and Hollowell showed that the TSH distribution curve shifts toward higher concentrations with age, suggesting that an increase in the TSH reference limits, especially its upper limit, might be appropriate in the elderly (Surks and Hollowell, 2007). This finding was later confirmed in population studies from Australia (Bremner *et al.*, 2012; Yeap *et al.*, 2017) and Scotland (Vadiveloo *et al.*, 2013). Investigators of the Cardiovascular Health Study also showed that in more than 800 adults with mean age of 85 years who were followed for 13 years, TSH increased over time and it was not associated with increased or decreased risk of mortality (Waring *et al.*, 2012). Other investigators have shown increased serum TSH levels in healthy centenarians (Atzmon *et al.*, 2009) and decreased risk of all-cause mortality in elderly individuals with TSH values of 5–10 mIU/L (Selmer *et al.*, 2014). These findings raise concern about assuming that small increases in TSH in the elderly, up to 8 mIU/L, represent hypothyroidism as well as routinely treating this group with levothyroxine. These findings together imply that subclinical hypothyroidism may be significantly over diagnosed in the elderly when the conventional upper TSH limit is employed. If so, treating mild elevations of TSH with levothyroxine in advanced age may be inappropriate unless an age-specific reference limit was employed. This is of particular concern since 20–40% of elderly people treated with levothyroxine have decreased serum TSH, indicating over-treatment, especially when the risks of adverse events due to iatrogenic hyperthyroidism are taken into account (Mammen *et al.*, 2015).

Another important consideration in diagnosis of thyroid disease in this age group is the higher prevalence of concurrent illness and use of medications which can lead to thyroid dysfunction, for example, amiodarone and iodinated contrast agents, or affect interpretation of thyroid tests, for example, steroid hormones and antiseizure medications. Careful consideration of recent illnesses and exposures is essential for accurate interpretation of test results and before treatment, which is often life long, is started.

Hypothyroidism

In Iodine sufficient areas, Hashimoto's thyroiditis is the most common cause of hypothyroidism. Prevalence of hypothyroidism due to Hashimoto's disease is higher in women than men and increases with age. Overt hypothyroidism is diagnosed when TSH is higher than 10 mIU/mL and concentration of free thyroxine is lower than the lower reference limit (Garber *et al.*, 2012). The classic symptoms and signs of hypothyroidism, including constipation, cold intolerance, dry skin, fatigue, and muscle cramps can be subtle or attributed to aging, side effect of medication, or concurrent illness. Hypothyroidism may thereby not be diagnosed unless free T4 and TSH are determined.

☆*Change History:* September 2017. V Tabatabaie and MI Surks updated the text in the chapter.

This article is an update of Jerome M. Hershman, Thyroid Disorders in the Elderly, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 422–425.

 doi:10.1016/B978-0-12-801238-3.95832-X

Elderly patients with hypothyroidism should be treated with levothyroxine (Garber *et al.*, 2012). Based on expert opinion, for patients without evidence of coronary artery disease, a starting dose of 50 mcg daily is recommended. If coronary artery disease is possible, reducing the starting dose to 12.5–25 mcg daily is appropriate. After either starting treatment or a change in levothyroxine dosage, serum TSH should be measured after 6–8 weeks and the dosage adjusted appropriately.

Hyperthyroidism

In contrast to young hyperthyroid patients who often present with classic sign and symptoms such as heat intolerance, tremor, palpitations, and anxiety, manifestations of hyperthyroidism in the elderly are often subtle and can go unnoticed for prolonged periods of time. Apathy, depression, weight loss, and fatigue often predominate in the elderly and can be attributed to the normal process of aging or intercurrent illness. Cardiovascular manifestations are also more common in this age group, with many patients first being diagnosed with hyperthyroidism when they present with cardiac arrhythmias, particularly atrial fibrillation (Boelaert *et al.*, 2010).

Effect of hyperthyroidism on cardiovascular and bone health in the elderly deserves special attention. Atrial fibrillation, a known complication of untreated hyperthyroidism, is much more common in the elderly hyperthyroid population than in young people (Osman *et al.*, 2007). Furthermore, elderly hyperthyroid patients are at increased risk for mortality due to cardiovascular causes. Franklyn *et al.* showed that after ablative doses of radioactive iodine and starting thyroid hormone replacement, this increased mortality risk returned to that of the background population (Franklyn *et al.*, 2005). The effect of hyperthyroidism in increasing bone turnover is also well recognized, especially in elderly postmenopausal women. A history of hyperthyroidism has been shown to be associated with increased risk of hip fracture in women (Cummings *et al.*, 1995).

Subclinical Thyroid Disorders

Effect of subtle changes of thyroid function in the elderly has been long debated. In recent years a number of population-based and retrospective studies have contributed to our understanding of the importance of subclinical hypothyroidism and subclinical hyperthyroidism in the elderly.

Subclinical Hypothyroidism

Subclinical hypothyroidism is defined as a serum TSH that is higher than the upper limit of the reference range, but lower than 10 mIU/mL, in the presence of normal free T4. Most experts agree that individuals with serum TSH higher than 10 mIU/mL are more likely to progress to overt hypothyroidism than if TSH is raised but <10 mIU/L. If TSH >10 mIU/L is a stable finding over time, or progressively increases, treatment with levothyroxine is generally recommended, even when free T4 remains within the reference range. Milder subclinical hypothyroidism, that is, when TSH is higher than upper reference limit but <10 mIU/L, has not been consistently shown to affect metabolic or cognitive health or mortality risk in elderly patients.

As part of Cardiovascular Health Study, Cappola *et al.* studied 679 patients with subclinical hypothyroidism at least 65 years old and showed no association between persistent subclinical hypothyroidism and coronary heart disease, heart failure, and cardiovascular death (Hyland *et al.*, 2013). In a pooled analysis of close to 50,000 individual participants with subclinical hypothyroidism, investigators in Thyroid Studies Collaboration showed an increased risk of stroke and fatal stroke in participants 18–64 years of age, but not in those older than 65 (Chaker *et al.*, 2015). These investigators also showed no association between subclinical hypothyroidism with TSH up to 9.9 mIU/L and risk of heart failure, although this risk increased when TSH exceeded 10 mIU/L (Gencer *et al.*, 2012). In contrast, Tseng *et al.* studies Taiwanese adults with subclinical hypothyroidism, defined in their study as TSH 5–19.96 mIU/L and showed increased mortality as compared to euthyroidism regardless of age; surprisingly this association was seen only in those with smaller elevations of TSH (5–9.99 mIU/L), and not in those with higher TSH values (10–19.96 mIU/L) (Tseng *et al.*, 2012).

Similarly, no association between subclinical hypothyroidism and frailty (Virgini *et al.*, 2015), risk of MI in older women (LeGrys *et al.*, 2013), impairment of cognitive function or increased incidence of depression (Yeap *et al.*, 2012) has been demonstrated.

Subclinical Hyperthyroidism

Subclinical hyperthyroidism is defined as a serum TSH that is lower than the reference range, with free thyroxine and T3 concentrations that are within the reference range. Several studies have shown an association between subclinical hyperthyroidism and adverse cardiovascular and skeletal effects in the elderly; this association seems to be more robust when TSH concentration is <0.1 mIU/L).

In a recent pooled study of individual participant data from 13 prospective cohorts, investigators in Thyroid Studies Collaboration demonstrated an increased risk of hip and other fractures, particularly when TSH levels was <0.1 mIU/L (Blum *et al.*,

2015). The same group also demonstrated an increased risk of heart failure in older individuals with TSH values of <0.1 mIU/L (Gencer *et al.* 2012). Subclinical hyperthyroidism has also been show to be associated with increased risk of atrial fibrillation, with a higher attributable risk seen in individuals older than 65 years of age as compared to younger people (Selmer *et al.*, 2012). Other groups have shown that subclinical hyperthyroidism in the elderly is associated with higher incidence of heart failure (Nanchen *et al.*, 2012).

Conclusion

Disorders of the thyroid are common and their diagnosis and treatment pose specific challenges in the elderly. Before making therapeutic decisions, which are often life long, healthcare providers should familiarize themselves with considerations specific to this vulnerable age group.

Drug Effects and Thyroid Function☆

Ulla Feldt-Rasmussen and Åse K Rasmussen, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark

Glossary

Amiodarone Medication used to prevent disturbances of heart rhythm. It is high in iodine content and has multiple side effects, including several affecting the thyroid.

Check point inhibitors Anti-PD-1/PD-L1 are a novel class of inhibitors that function as a tumor suppressing factor via modulation of immune cell–tumor cell interaction. These checkpoint blockers are rapidly becoming a highly promising cancer therapeutic approach that yields remarkable antitumor responses with limited side effects.

Deiodinase Family of tissue enzymes that catalyze the removal of an iodine atom from thyroid hormones, as in the conversion of thyroxine to triiodothyronine (T3), an activating step, or the further deiodination of T3, an inactivating step.

Furosemide Diuretic that is a potent inhibitor of thyroxine and triiodothyronine binding to thyroxine-binding globulin.

Heparin Anticoagulant that releases tissue lipases into the circulation. After blood sampling, lipases can lead in vitro to an increased concentration of nonesterified fatty acids, which can displace thyroxine and triiodothyronine from thyroxine-binding globulin.

Lithium Medication that is used for bipolar or manic–depressive illness and that can impair thyroid hormone release, leading to goiter and/or hypothyroidism.

Nonesterified fatty acids (NEFA) Family of hydrophobic products of triglyceride hydrolysis that circulate at a concentration of 0.5–2.0 mmol/L, of which only a minute fraction is unbound, the rest being carried predominantly on albumin. At concentrations >3 mmol/L (see heparin), NEFA can displace thyroxine and triiodothyronine from thyroxine-binding globulin.

Phenytoin (diphenylhydantoin, Dilantin) Anti-epileptic medication that competes for thyroxine and triiodothyronine binding to thyroxine-binding globulin, accelerates the clearance of thyroid hormones, and influences the secretion of thyroid-stimulating hormone.

Thyroid-stimulating hormone (TSH) Two-chain glycoprotein from the anterior pituitary that increases iodide trapping, increases hormone synthesis and release, and stimulates thyroid growth. It is regulated by negative feedback from the circulating concentration of free thyroxine.

Thyroxine (T4) Major secretory product from the thyroid gland, which normally produces approximately 0.1 mg/day. T4 circulates at a total concentration of 50–150 nmol/L, of which 99.97% is protein bound. It is the standard medication used for thyroid hormone replacement.

Thyroxine-binding globulin (TBG) α2-Globulin of hepatic origin that carries approximately 70% of circulating thyroxine (T4) and triiodothyronine (T3). Its concentration is normally approximately 300 nmol/L, being about one-third occupied. Its concentration and capacity is increased by estrogen and several other medications. A wide range of substances can displace T4 and T3 from TBG.

Triiodothyronine (T3) Major metabolically active thyroid hormone that circulates in a total concentration of 1–3 nmol/L, of which 99.7% is protein bound. It is secreted directly from the thyroid gland, but formed mainly from peripheral monodeiodination of thyroxine, by deiodinases in liver, kidney, brain, pituitary.

Introduction

The effects of drugs can be complex, because some agents, for example, amiodarone, glucocorticoids, and diphenylhydantoin, can influence the pituitary–thyroid axis in several ways. There have been significant advances in the understanding of the thyroid-related effects of cytokines, monoclonal antibodies, heparin, phenytoin, amiodarone, and inhibitors of hormone binding to plasma proteins. Importantly and often neglected, abnormal thyroid function, either thyrotoxicosis or hypothyroidism, can influence the effect and potential toxicity of a wide range of therapeutic agents, predominantly by altering their metabolism or clearance.

Altered Release of Thyroid Hormone From the Gland

Iodide at a high dosage acutely decreases the release of thyroid hormone from the gland, apparently by inhibition of proteolysis of thyroglobulin (Bürgi, 2010). This effect is occasionally used in the management of complicated thyrotoxicosis, when standard

 doi:10.1016/B978-0-12-801238-3.96002-1

Table 1 Principal medications that influence thyroid hormone or TSH levels

Agents inhibiting thyroid hormone production
Antithyroid drugs, amiodarone, lithium, iodide (large doses), iodine containing contrast media
Agents altering the extrathyroidal metabolism of thyroid hormone

– Inhibit conversion of T4 to T3
Propylthiouracil, glucocorticoids, propranolol, amiodarone, iodine-containing contrast media
– Stimulate T4 and T3 degradation
Carbamazepine, barbiturates, rifampicin, phenytoin, sertralin

Agents altering binding of T4 and T3 to plasma proteins

– Increase concentration of TBG
Estrogen, heroin, methadone, clofibrate, 5-fluorouracil, perphenazine
– Decrease concentration of TBG
Glucocorticoids, androgens, L-asparaginase, nicotinic acid
– Displace T4 and T3 from binding proteins
Furosemide, (**Fig. 1**), salicylates, phenytoin, fenclofenac, heparin (**Fig. 2**)

Agents inducing thyroiditis
Amiodarone, interleukin-2, interferon-α, interferon-β, γ-interferon, sunitinib, monoclonal antibody therapy (the check point inhibitors: nivulomab, pembrolizumab, ipilimimab)
Agents affecting TSH secretion

– Increase serum TSH concentration
Lithium, dopamine receptor blockers, L-dopa inhibitors, cimetidine, clomiphene, amiodarone, amphetamine
– Decrease serum TSH concentration
Thyroid hormones, dopamine, L-dopa, glucocorticoids, growth hormone, somatostatin, octreotide, interferon-α

Agents impairing absorption of ingested T4
Aluminum hydroxide, ferrous sulfate, cholestyramine, calcium carbonate, calcium citrate, calcium acetate, iron sulfate, colestipol, sucralfate, soya preparations, kayexalate, ciprofloxacin, sevelamer, or proton pump inhibitors

TSH, thyrotropin; *T4*, thyroxine; *T3*, triiodothyronine; *TBG*, thyroid hormone binding globulin.

anti-thyroid drugs cannot be used or are insufficient. Iodine containing contrast agents e.g. those used in coronary angiography can have similar effect due to iodine load (Bonelli *et al.*, 2017), and lithium also inhibits thyroid hormone release as a result of decreased proteolysis of thyroglobulin (Lazarus, 2009).

Inhibition of 5′-(Outer Ring) Deiodination of T4

The outer ring deiodinase, or 5′-deiodinase, present predominantly in liver, kidney, thyroid, and heart, designated type 1, is a selenoprotein that catalyzes the peripheral conversion of T4 to triiodothyronine (T3) and reverse T3 (rT3) to 3,3′T2. This activity is markedly diminished by caloric deprivation and in catabolic states. Activity of this enzyme is also inhibited by numerous drugs (**Table 1**), resulting in decreased T3 and increased rT3 serum concentrations. Several iodinated compounds, including amiodarone (Rosene *et al.*, 2010), also inhibit the pituitary 5′-deiodinase type 2, an effect that results in decreased formation of T3 in the pituitary, leading to a slight increase in serum TSH, generally within the normal reference range (Harjai and Licata, 1997).

Beta-blockers differ from one another in their effect on 5′-deiodination. Propranolol in high doses diminishes the production of T3, an effect due to a quinidine-like membrane stabilizing effect, rather than specific beta-blockade (Wiersinga, 1991). This T3-lowering effect is not seen with other beta-blockers, such as atenolol, metoprolol, or labetalol. The symptomatic benefit of beta-blockers in thyrotoxicosis is independent of their influence on serum T3. A subnormal serum T3 concentration is a normal response to illness or caloric deprivation that is potentially beneficial; this acute response should not be interpreted as hormone deficiency (Van den Berghe, 2014), although measurements of free T4 may be indicative of such condition in a number of commercially available free T4 assays (Sapin *et al.*, 2000). An experimental model of this non-thyroidal illness condition using infusion of salsalate in healthy volunteers found that an acute release of T4 and T3 from circulating transport proteins, induced by this inhibitor of binding, can result in large and rapid redistribution of T4 and T3 into tissue compartments associated with transiently reduced peripheral tissue 5′-monodeiodination and deranged TSH regulation (Wang *et al.*, 1998). Thus, during non-thyroidal illness, or with the use of medications that can lower serum T3 (Van den Berghe *et al.*, 1994), the possibility of thyrotoxicosis should not be dismissed on the grounds of normal serum T3, if this diagnosis is supported by T4 excess and suppression of TSH.

Enhanced Thyroid Hormone Metabolism and External Loss

There is usually little effect from medications that enhance thyroid hormone clearance if the pituitary–thyroid axis is normal, but effects may be profound when an individual is dependent on exogenous T4. Hepatic T4 and T3 metabolism is enhanced by numerous agents that stimulate the cytochrome P450 system, among others rifampicin, phenytoin, carbamazepine, and barbiturates (Curran and DeGroot, 1991). External loss of protein as in severe proteinuria in nephrotic syndrome or severe protein loosing enteritis includes loss of thyroid hormones bound to TBG and thus the major circulating reservoir mainly of T4. These patients also require higher dosages of T4 if on replacement therapy, and they may even require commencement of T4 if decompensating to hypothyroidism with prior euthyroidism before the protein loss (Chandurkar *et al.*, 2008).

Altered Concentration of Plasma-Binding Proteins

Estrogens, whether endogenous or exogenous, commonly affect tests of thyroid function by increasing total serum T4 and T3 due to an increase in the serum concentration of thyroxine-binding globulin (TBG), but free T4 and T3 remain normal. Estrogens increase the glycosylation of TBG, which slows its clearance, leading to a higher serum concentration, or binding capacity, with normal binding affinity. Transdermal estrogens do not show this effect to the same extent, because they have less influence on hepatic proteins. In pregnancy, the mean total serum T4 concentration is increased by approximately 30%–50%, with over 40% of values above the normal reference range in the second and third trimesters (Feldt-Rasmussen and Mathiesen, 2011). This estrogen induced increase in TBG can result in a higher requirement of T4 replacement dose in women treated for hypothyroidism (Arafah, 2001). Conversely, antiandrogen therapy for breast cancer can decrease this requirement (Arafah, 1994). It is not certain whether other drugs that alter the serum concentration of TBG (**Table 1**) increase the synthesis or retard the clearance of TBG.

Competition for Thyroid Hormone Binding to Plasma Proteins

Thyroid hormone-binding proteins show wide cross-reaction with various drugs (**Table 1**; Lim *et al.*, 1988). In contrast, the binding proteins for corticosteroids, vitamin D, and the sex hormones are more specific for a single family of ligands. Substances that interfere with T4 and T3 binding are themselves bound to albumin. Because of differences in relevant total therapeutic concentration and albumin binding, the hierarchy of drug competitor potency in vivo in undiluted serum differs markedly from the rank order of drug affinity for isolated TBG (Stockigt, 2001; Surks and Sievert, 1995).

Serum dilution and albumin concentration need to be clearly defined in the interpretation of in vitro drug competition studies, because the concentrations of free ligand and competitor(s) and the number of unoccupied binding sites do not maintain the relationship that exists prior to serum dilution.

Therapeutic concentrations of phenytoin and carbamazepine induce an artifact with an increased free fraction of T4 by 40%–50% in undiluted serum, but no increase in free T4 when assayed in diluted serum (Surks and Defesi, 1996). Similarly, the T4-displacing effect of furosemide is most obvious (**Fig. 1**) in methods with the lowest sample dilution (Hawkins, 1998).

Any substance that shares albumin-binding sites with a competitor can influence the free concentration of that competitor. Indoles and furans that accumulate in renal failure can displace drugs from albumin and may thus indirectly accentuate drug

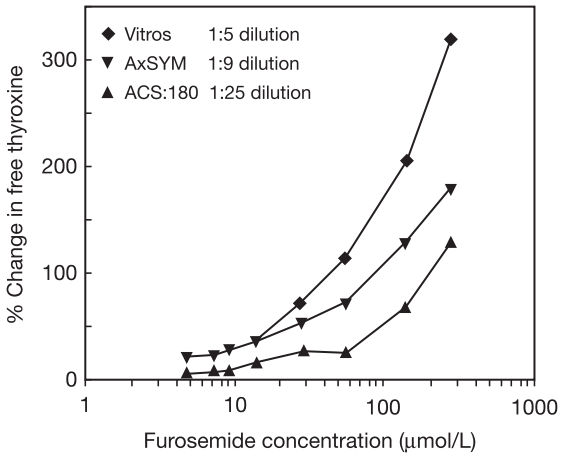

Fig. 1 Effect of furosemide on estimates of serum free T4 by three methods, showing that T4 displacement is progressively lost with increasing sample dilution. The least diluted serum sample most closely reflects the in vivo effect. Redrawn from Hawkins, R. C. (1998). Furosemide interference in newer free thyroxine assays. *Clinical Chemistry* **44**, 2550–2551.

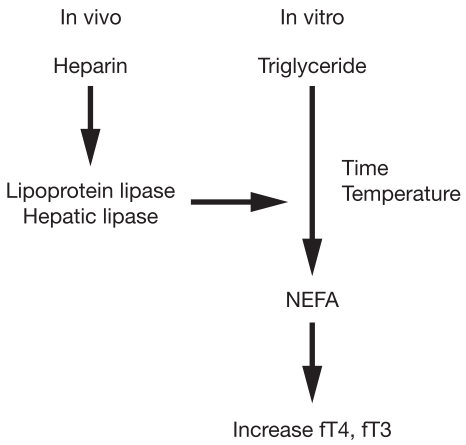

Fig. 2 Heparin-induced changes can markedly increase the apparent concentration of serum free T4. Heparin in vivo (left) liberates lipoprotein lipase from vascular endothelium. Lipase acts in vitro (right) to increase the concentration of free fatty acids to >3 mmol/L, which displaces T4 and T3 from TBG. Generation of non-esterified free fatty acids (NEFA) is increased by sample storage or incubation and by high serum triglyceride. The T4-displacing effect is accentuated at low albumin concentrations. Concept from Mendel, C. M., Frost, P. H., Kunitake, S. T. and Cavalieri, R. R. (1987). Mechanism of the heparin-induced increase in the concentration of free thyroxine in plasma. *Journal of Clinical Endocrinology and Metabolism* **65**, 1259–1264.

effects on hormone binding; i.e., the free hormone concentration can be influenced by substances that have little direct effect on hormone binding (Lim *et al.*, 1993).

The effect of heparin on increasing the apparent free T4 concentration in vitro is an example of spurious competition. Heparin treatment causes an in vivo release of lipases, followed by generation of non-esterified free fatty acid during sample storage or incubation in vitro, leading to much higher non-esterified free fatty acid concentrations in the assay tube than were present in vivo (see Fig. 2). Heparin doses as low as 10 units can cause this effect after prolonged sample incubation, especially if serum triglyceride is increased. Low-molecular-weight heparin preparations have a similar effect. This artifact may account for reports of method-dependent increases in apparent free T4 concentrations in hospitalized subjects who are often exposed to heparin (Mendel *et al.*, 1987).

Agents That Modify Immune Function and Induce Thyroiditis

Treatment of hepatitis C with interferon-α is frequently associated with thyrotoxicosis or hypothyroidism, sometimes in a sequence that suggests thyroiditis; the abnormalities are often transient, with resolution occurring over several months after treatment is ended. The prevalence of this effect has been estimated at 15%–30%, with greater frequency in females and those with positive thyroid peroxidase antibodies (Hsieh *et al.*, 2000). In contrast, thyroid dysfunction is less common during interferon-β treatment of neurological disorders, such as multiple sclerosis (Durelli *et al.*, 2001; Coles *et al.*, 1999).

Monoclonal antibody treatment for multiple sclerosis may lead to persistent autoimmune thyroid dysfunction. Six to thirty months after treatment, one-third of previously euthyroid patients who received a 5-day course of the humanized anti-CD52 monoclonal antibody developed antibodies against the TSH receptor (Shang *et al.*, 2017). Check point inhibitors act by promotion of the effector T cell response to tumors. The drugs enhance effector T cells by blockade of programmed cell death protein (PD-1) (Shang *et al.*, 2017) and its ligand PD-L1 (pembrolizumab, nivulomab) or cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) (ipilimumab). The drugs have endocrinological side-effects because of exacerbation of autoimmunity, and thyroiditis is reported in up to 43% of patients treated with nivulomab, but much rarer after treatment with pembrolizumab and ipilimumab (Barroso-Sousa *et al.*, 2017; Abdel-Rahman *et al.*, 2016). The check point inhibitors can also induce autoimmune conditioned hypothyroidism or Graves' hyperthyroidism (Shang *et al.*, 2017).

Altered Secretion of Thyroid-Stimulating Hormone

Glucocorticoids, either endogenous or exogenous, are potent inhibitors of thyroid-stimulating hormone (TSH) secretion (Haugen, 2009). Dopaminergic drugs, even at doses that do not influence blood pressure, cause profound inhibition of TSH secretion; after cessation of dopamine infusion, there is a rapid reversal of TSH suppression within a few hours (Haugen, 2009; Van den Berghe *et al.*, 1994).

Cytokines directly affect TSH secretion (Pang *et al.*, 1993). For example, infusion of interferon-α in normal volunteers results in a 60%–70% decrease in serum TSH within 8–12 h, prior to any significant change in serum thyroid hormone concentrations

Table 2 Medications with multiple effects on the pituitary–thyroid axis

Glucocorticoids
Inhibit TSH secretion
Impair thyroid hormone release from the gland
Inhibit 5′-deiodination of T4 and rT3
Decrease concentration of TBG
Amiodarone
Delivers iodine load
Iodine-induced thyrotoxicosis (Jod-Basedow)
Iodine-induced hypothyroidism
Causes unique form of thyrotoxicosis due to thyroiditis
Retards T4 clearance
Inhibits 5′-deiodination (type 1 and type 2) of T4 and rT3
Augments TSH secretion
Phenytoin
Inhibits T4 and T3 binding to TBG
Accelerates T4 clearance and metabolism

TSH, thyrotropin; *T4*, thyroxine; *T3*, triiodothyronine; *rT3*, reverse triiodothyronine; *TBG*, thyroid hormone binding globulin.

(Corssmit *et al.*, 1995). In addition, cytokines can induce or aggravate autoimmune thyroid dysfunction (McLachlan and Rapoport, 2014).

During long-term amiodarone therapy, TSH tends to be high in relation to serum free thyroxine (T4), because this drug, or its active metabolite, desethylamiodarone, acts as an antagonist at thyroid hormone receptors (Rosene *et al.*, 2010). Heavy amphetamine abuse can result in higher than normal levels of serum TSH and may cause TSH-induced hyperthyroxinemia.

Impaired Thyroxine Absorption

Numerous agents (**Table 1**) can impair the absorption of ingested T4, some probably by binding T4 in the bowel lumen by e.g. complex formation with the drug (Mersebach *et al.*, 1999). Such agents have little effect if the pituitary–thyroid axis is intact, but they may make fixed oral T4 dosage inadequate in hypothyroid patients who have no capacity to increase T4 production. This effect can generally be minimized by avoiding concurrent ingestion of T4 and potential inhibitors of absorption or use liquid formulations of levothyroxine preparations (Vita *et al.*, 2017).

Clinical Issues With Particular Drugs

Amiodarone

Amiodarone affects thyroid status in a complex manner (**Table 2**). Benign euthyroid hyperthyroxinemia, with high total and free T4, normal or subnormal serum T3, and increased serum rT3, occurs in up to one-third of amiodarone-treated subjects. This abnormality requires no treatment—the diagnosis of amiodarone-induced thyrotoxicosis should not be based on T4 excess alone.

In iodine-replete regions, the predominant amiodarone-induced thyroid problem is hypothyroidism, which is especially likely to occur on a background of thyroid autoimmunity. Routine replacement with T4 is effective, but therapy may need to be modified because of associated heart disease.

The most difficult abnormalities that result from amiodarone therapy are two unpredictable forms of thyrotoxicosis, one due to iodine excess and the other attributed to a unique form of persistent thyroiditis with specific intracellular inclusion bodies. Severe life-threatening thyrotoxicosis can occur rapidly, without premonitory abnormalities of thyroid function. Weight loss, deterioration of cardiac function, and severe myopathy are the important clues to this diagnosis. There can be poor correlation between circulating thyroid hormone levels and the clinical features of amiodarone-induced thyrotoxicosis, perhaps because of interaction of this drug, or its active metabolite desethylamiodarone, with thyroid hormone receptors.

A distinction between these two forms of amiodarone-induced thyrotoxicosis by color Doppler flow studies has been reported. If blood flow is increased (Easton *et al.*, 2002) the thyrotoxicosis may be directly due to iodine excess; standard anti-thyroid drugs, with the possible addition of potassium perchlorate, may be appropriate first-line therapy. In contrast, glucocorticoids are generally preferred in the thyroiditis variant that shows markedly decreased thyroid blood flow. Emergency thyroidectomy may be necessary in some cases of severe amiodarone-induced thyrotoxicosis that cannot be controlled medically.

At the other end of the spectrum, short-term amiodarone for atrial fibrillation after catheder ablation gave only a very transient change of thyroid function (Diederichsen *et al.*, 2016).

Iodine-Based Contrast Agents

Most used contrast agents in radiology for CT scans and angiographies are iodine-based, and may thus put the thyroid function at risk. In current practice, nonionic low or isoosmolar preparations are used almost exclusively for intravascular injections (Beckett *et al.*, 2015; Thomsen, 2011). Iodine based contrast agents for an average examination contain free iodine equal to around five times the daily recommended dose for intake of iodine (Thomsen, 2011). Yet, for some CT scans approximately 500–600 mg of iodine per kilogram of bodyweight is recommended to obtain adequate imaging of hepatic parenchymal enhancement (Spampinato *et al.*, 2017).

It is generally considered, that patients with normal thyroid function are not at risk (Thomsen, 2011), even though urinary iodine can be increased (Lee *et al.*, 2015a,b). However, thyroid dysfunction after exposure to iodine-based contrast media has been described in persons with completely normal thyroid function and no apparent abnormality in their thyroid glands (Lee *et al.*, 2015a,b). The effect on the thyroid gland can be both one of hypo- and hyperthyroidism as for other iodine compounds (Thomsen, 2011; Lee *et al.*, 2015a,b). In a group of 810 consecutive patients with ischemic heart disease undergoing cardiac angiography, 58 (7.2%) had hyperthyroidism before the procedure, but more patients developed hyperthyroidism after the iodine load (10%) (Bonelli *et al.*, 2017).

In another study (Vassaux *et al.*, 2017) the thyroid perturbing effect from iodine-based contrast agents seemed to be unrelated to the free iodine content, but rather an iodine unrelated direct effect on the sodium iodide receptor (NIS), causing a dramatic drop in their numbers.

Independent on the amount of contrast media used, patients with untreated Graves' disease and/or multinodular goiter and thyroid autonomy, the elderly, and those living in areas where dietary iodine deficiency is common should be identified, and the risk of inducing thyrotoxicosis through excess iodine absorption should be reduced (Beckett *et al.*, 2015). Use of iodinated contrast agents should be avoided immediately before planned radioactive iodine imaging or therapy, because the iodine may reduce radioactive iodine uptake. It is also advised that consultation with an endocrinologist may be beneficial before administration of an intravenous contrast agent (Thomsen, 2011; Beckett *et al.*, 2015).

Lithium

This agent, widely used in the management of manio–depressive illness, has several effects on the pituitary–thyroid axis, the most important being the effect of inhibiting thyroglobulin hydrolysis and hormone release. Lithium exacerbates, or may possibly cause, autoimmune thyroid disease of the Hashimoto type, leading to eventual primary hypothyroidism, often with goiter. Women with positive anti-peroxidase antibodies are especially likely to be affected. Among 690 lithium-treated Scottish patients, 14% of women and 4.5% of men developed various grades of thyroid failure (Lazarus, 1998, 2009). There are also reports of lithium-induced thyrotoxicosis of probable autoimmune origin.

It is generally recommended that TSH, T4, and anti-peroxidase antibodies be assessed before commencement of lithium therapy, with serial evaluation of thyroid status every 6–12 months during treatment or if a goiter develops. Thyroxine replacement is recommended if there is TSH excess.

Phenytoin

This anti-epileptic drug commonly results in subnormal serum total T4, with an apparent lowering of free T4, not accompanied by the anticipated increase in TSH. Such findings are not easily distinguishable from central hypothyroidism due to pituitary deficiency. The effect on free T4 may be spurious, because the T4-displacing effect of phenytoin is poorly reflected by assays that use diluted serum, leading to an underestimate of the free T4 concentration.

It remains difficult to make an accurate assessment of thyroid status in hypopituitary patients who are taking T4 together with phenytoin or carbamazepine; serum TSH is not useful and free T4 estimates can be misleading. Phenytoin accelerates T4 clearance by induction of cytochrome P450 enzymes (Curran and DeGroot, 1991), so that the replacement dose may need to be increased. Treatment with phenytoin or carbamazepine can make previously optimal treatment of primary hypothyroidism inadequate or may unmask diminished thyroid reserve.

Effects of Thyroid Status on Drug Effects

In general, thyrotoxicosis increases drug clearance, whereas hypothyroidism may markedly retard drug disposal. During thyrotoxicosis, standard drug dosage may be ineffective, as, for example, in the reputed "insensitivity" of thyrotoxic patients to digitalis preparations. A higher than normal dosage may be required, but as the thyrotoxicosis comes under control, digitalis toxicity can occur unless dosage is adjusted.

Severely hypothyroid subjects are abnormally sensitive to narcotics, sedatives, and analgesics, due to diminished clearance of these substances. This may be recognized as prolonged respiratory depression after anesthesia, when hypothyroidism has not been previously recognized (O'Connor and Feely, 1987).

Anticoagulant therapy is an exception to this rule (Kellett *et al.*, 1986). Consumption of coagulation factors tends to be more rapid in active thyrotoxicosis, with a tendency toward increased responsiveness and lower coumarin dose requirements. An increase in dosage may be required as control of thyrotoxicosis is achieved.

Lithium☆

John H Lazarus, Institute of Molecular and Experimental Medicine, Cardiff, United Kingdom

Introduction

In the first half of the 20th century, lithium was used as a salt substitute in patients with cardiac failure, but severe toxicity prevented its acceptance. In 1949, during an investigation into the role of uric acid in manic patients, Australian psychiatrist J. F. J. Cade noticed that guinea pigs that had been given lithium urate became less startled. This led to the trial administration of lithium in manic depressive patients and then to the widely acclaimed studies of Schou and colleagues from Denmark defining the clinical effectiveness of this ion in psychiatry. It is the most effective mood stabilizer for the treatment of bipolar disorder, but it is toxic at only twice the therapeutic dosage and has many side effects. The endocrine effects of lithium may be regarded as comprising effects of lithium on cell function as well as on the influence of the ion on specific endocrine glands or systems.

Cell Function

The transport of lithium has been studied extensively in red cells. There are four separate pathways of lithium transport: the sodium–lithium countertransport system, the bicarbonate pathway, the sodium–potassium ouabain-sensitive pump, and the so-called passive leak pathway. These systems contribute variably to total lithium transport. The intra- to extracellular concentration ratio, which is a steady-state distribution ratio, is most dependent on the countertransport pathway, although both passive leak and the bicarbonate pathways make a contribution, at least in humans. Lithium inhibits the formation and action of the adenylate cyclase cAMP system in many tissues, but the precise mode of action is unclear. This may have adverse effects in many endocrine and other systems. For example, the immunological modulatory effects of lithium are thought to be mediated at least in part by its inhibitory action on lymphocyte cAMP. Lithium also affects the signal transduction system involving inositol phospholipids. The effect on phosphatidyl inositol may influence the calcium supply to a cell, thereby affecting function. Attention has also been directed to the action on regulator network GSK3 (glycogen synthase kinase 3). The action through inositol monophosphatase is intriguing but to date no small molecule antagonists are available. It has been reported that ebselen (an antioxidant) inhibits the enzyme and exhibits lithium-like actions at many levels, including enzymatic, inositol recycling, and animal behavior. This drug lowers inositol concentrations in human brain suggesting that this may be an important action of lithium. Lithium may also affect cellular endocrine function by separate actions on membrane transport and intracellular enzyme function.

At the neuronal level, lithium reduces excitatory (dopamine and glutamate) but increases inhibitory (GABA) neurotransmission. Lithium also appears to reduce the oxidative stress that occurs with multiple episodes of mania and depression. These actions of lithium are complex and interrelated in defining the therapeutic action of the drug.

Lithium and the Thyroid

Administration of lithium to humans causes inhibition of thyroidal hormone release and, to a lesser extent, inhibition of intrathyroidal biosynthesis of thyroxine. In patients already possessing thyroid antibodies (thyroid peroxidase or antithyroglobulin), lithium exposure leads to an increase in titer of these antibodies and early onset of hypothyroidism. The clinical effects of lithium are characterized by goiter without antibodies and euthyroidism, antibody-negative goiter with accompanying hypothyroidism, euthyroid goiter with positive antibodies, and the development of autoimmune thyroiditis with hypothyroidism. Screening thyroid function and thyroid antibodies is recommended before beginning lithium therapy.

Lithium increases iodine retention and inhibits thyroid hormone release. It has therefore been evaluated as an adjunct in the radioiodine treatment of Graves' and toxic nodular hyperthyroidism. The likelihood of cure was significantly greater in those patients receiving adjuvant lithium and this supports its use in improving the efficacy of radioiodine in the therapy of Graves' disease and the management of toxic nodular goiter. It has beneficial effects in the management of some patients with thyroid cancer.

Some patients receiving lithium have developed thyrotoxicosis with or without positive thyroid-stimulating hormone receptor-stimulating antibodies. There is no consensus that lithium causes this hyperthyroidism immunologically or in any other way.

☆*Change History:* September 2017. Abstract, body part of the text, and the reference list have been updated and some older references have been removed. J.H. Lazarus updated text and references.

This article is an update of John H. Lazarus, Lithium, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 197-198.

 doi:10.1016/B978-0-12-801238-3.04169-6

Lithium and Calcium

Lithium alters the calciostat and renders the parathyroid cell less sensitive to calcium. It can stimulate the release of human parathyroid hormone in vitro which may account for the increase in set point in response to calcium. Some patients develop parathyroid adenomas accompanied by an increase in serum calcium and immunoreactive parathyroid hormone. Parathyroid hyperplasia has also been described more often than expected but of patients who do develop hyperparathyroidism more than half have single adenomas.

Other Endocrine Effects

Diabetes insipidus (DI) occurs in up to 40% of patients within a few days of beginning lithium therapy. DI is usually nephrogenic, with high circulating concentrations of arginine vasopressin and an impairment of the renal response to this hormone. Aquaporins are water channels inside of proteins expressed in renal tubules and collecting ducts. The greater the activation of aquaporins, the greater water reabsorption in renal collecting ducts, reducing the volume of urine. When the expression of aquaporins is inhibited, polyuria ensues. The binding of antidiuretic hormone (ADH) to the V2 receptor stimulates the expression of aquaporins in the kidney. Lithium inhibits the expression of these aquaporins in the renal collecting duct, mainly aquaporin 2 (AQP2), by mechanisms still not fully understood. Lithium may also inhibit antidiuretic hormone release from the posterior pituitary, leading to central DI but this only occurs in a few cases.

The clinical effect of lithium on adrenal function is minimal, although urinary aldosterone concentration increases soon after starting the drug. An increase in body weight is commonly seen in patients receiving lithium. The effects of the drug on glucose metabolism are not thought to be of clinical significance.

Glossary

Action potential Changes in the plasma membrane during depolarization and the subsequent repolarization of cardiomyocytes. The duration of the action potential is reflected by the QT time of the electrocardiogram (interval between the start of the QRS-complex and the end of T-top). Class III anti-arrhythmic drugs (such as amiodarone) act via prolongation of the action potential.

Colloid Proteinaceous substance in thyroid follicles, containing sizable quantities of iodine, thyroglobulin, and thyroid hormone.

Deiodination Enzymatic removal of iodine atoms from organic compounds.

Euthyroidism Normal thyroid function.

Lysosome A membranous bag of hydrolytic enzymes; this organelle is used for the intracellular digestion of macromolecules.

Organification The incorporation of iodine atoms in organic compounds.

Thionamides Class of anti-thyroid drugs (such as carbimazole, methimazole, and propylthiouracil) that inhibit thyroid hormone synthesis by interfering with organification.

Thyroid hormone receptor Protein that, after binding of triiodothyronine (T3), binds to specific DNA sequences in the promoter region of T3-dependent genes, thereby modulating the transcription of these genes.

Wolff-Chaikoff effect Decreasing yield of organic iodine from increasing doses of inorganic iodide.

Amiodarone is a potent antiarrhythmic drug, widely used in the treatment of atrial fibrillation as well as of life-threatening ventricular or supra-ventricular arrhythmias and to prevent sudden death in selected patients. However, the drug has side effects on several tissues, including the thyroid gland.

Pharmacology

Amiodarone is highly lipophilic; this explains its tissue distribution, with the highest concentrations in the adipose tissue, liver and lung, and to a lesser content the thyroid gland (**Table 1**). A daily dose of amiodarone results in urinary iodine of approximately 14,000 μg in 24 h, largely exceeding the recommended daily dose of 200 μg. Amiodarone metabolism occurs mainly through N-dealkylation, leading to formation of the main active metabolite, desethylamiodarone (DEA). Other metabolic pathways of amiodarone include deiodination and glucuroconjugation; excretion is mainly through biliary excretion; the average half-life of amiodarone and DEA is 40 days and 57 days, respectively, accounting for their long-lasting effects (Wiersinga *et al.*, 1997).

Antiarrhythmic Properties

Amiodarone is a class III antiarrhythmic drug, mostly acting through the inhibition of myocardial Na-K ATPase activity, which eventually increases the refractory period. However, amiodarone also has class I (decrease in conduction velocity through blockade of Na channel), class II (antiadrenergic effect reducing β-adrenergic receptor) and class IV (suppression of Ca-mediated action potentials) actions. Owing to its multiple antiarrhythmic effects, amiodarone is used in patients with supraventricular and ventricular tachyarrhythmias, atrial fibrillation (when other therapies are ineffective) and to prevent sudden cardiac death in selected patients.

Effect of Amiodarone on Thyroid Function Tests

Euthyroid patients under amiodarone therapy undergo to changes of thyroid function tests (**Table 2**). Within 2 months after starting amiodarone therapy, a transient increase in serum TSH concentrations occurs, whereas serum thyroid hormone concentrations remain unaffected. During chronic ($\geq$3 months) amiodarone therapy, TSH usually normalizes, serum free T_4 (FT_4)

 doi:10.1016/B978-0-12-801238-3.96000-8

Table 1 Tissue distribution of amiodarone (A) and desethylamiodarone (DEA) in human autopsies

Tissue	*A (μg/g)*	*DEA (μg/g)*	*A/DEA*
Adipose tissue	316	76	4.2
Liver	391	2354	0.12
Lung	198	952	0.21
Kidneys	57	262	0.22
Heart	40	169	0.24
Muscle	22	51	0.43
Thyroid	14	64	0.22

Table 2 Effect of amiodarone on thyroid function tests in euthyroid patients

	Short-term	*Long-term*
Thyroxine (T4)	Increased	Normal to Increased
Triiodothyronine (T3)	Reduced	Normal to Reduced
Reverse T3 (rT3)	Increased	Increased
Thyrotropin (TSH)	Increased	Usually normal

and reverse T_3 (T_3) concentrations increase and serum free T_3 (FT_3) levels decrease. These changes are due to an inhibitory effect of amiodarone on intracellular T_4 transport and pituitary D2 activity, with a consequent reduction in intracellular T_3 generation, and thyroid hormone binding to its cognate pituitary receptor, whereas in the chronic therapy an inhibitory effect of amiodarone on hepatic D1 activity prevails (Martino *et al.*, 2001). These changes, however, do not indicate a thyroid disease.

Effects of Amiodarone at the Molecular Levels

Amiodarone is a benzofuranic iodine-rich drug with a molecular structure resembling that of thyroid hormones (**Fig. 1**); amiodarone DEA, exert thyroid hormone receptor (TR)-mediated thyromimetic effects. These participate in the developing some hypothyroid-like effects occurring in euthyroid subjects under amiodarone therapy. Amiodarone causes down-regulation of myocardial genes, including sarcoendoplasmic reticulum calcium ATPase-2 (SERCA2a) and α-myosin heavy chain (αMHC), and increased expression of β-myosin heavy chain (βMHC), all features observed in hypothyroidism. In addition, downregulation of the hepatic LDL receptor, leading to an increase in serum cholesterol concentrations, has been attributed to a direct effect of amiodarone on the LDL receptor gene expression CA. These effects are the consequence of the competitive binding of amiodarone and DEA with thyroid hormone to TRβ (Martino *et al.*, 2001).

Amiodarone and Thyroid Dysfunction

Amiodarone-induced thyroid dysfunctions are due to the excessive iodine load or to the drug itself. The iodine load is responsible for the occurrence of amiodarone-induced-hypothyroidism (AIH) and for amiodarone-induced thyrotoxicosis type 1 (AIT-1), whereas the intrinsic property of the drug is linked to the amiodarone-induced thyrotoxicosis type 2 (AIT-2) (Newman *et al.*, 1998).

Effects of Iodine Load

A normal thyroid gland responds to iodine load through an intrinsic autoregulatory mechanism, which acutely blocks thyroid hormone synthesis (Wolff-Chaikoff effect) and causes an increase in serum TSH concentration. The normal thyroid gland then escapes this block by reducing iodine transport and intrathyroidal concentrations to levels insufficient to maintain the Wolff-Chaikoff effect. Amiodarone can inhibit iodide transport into the thyroid by either an iodine-independent mechanism or a decrease in the sodium-iodide symporter mRNA expression (Bogazzi *et al.*, 2012).

Failure to escape from the Wolff-Chaikoff effect may occur in patients with an apparently normal thyroid gland thus causing amiodarone-induced hypothyroidism (AIH). In these patients AIH may be a transient phenomenon, and the drug withdrawal,

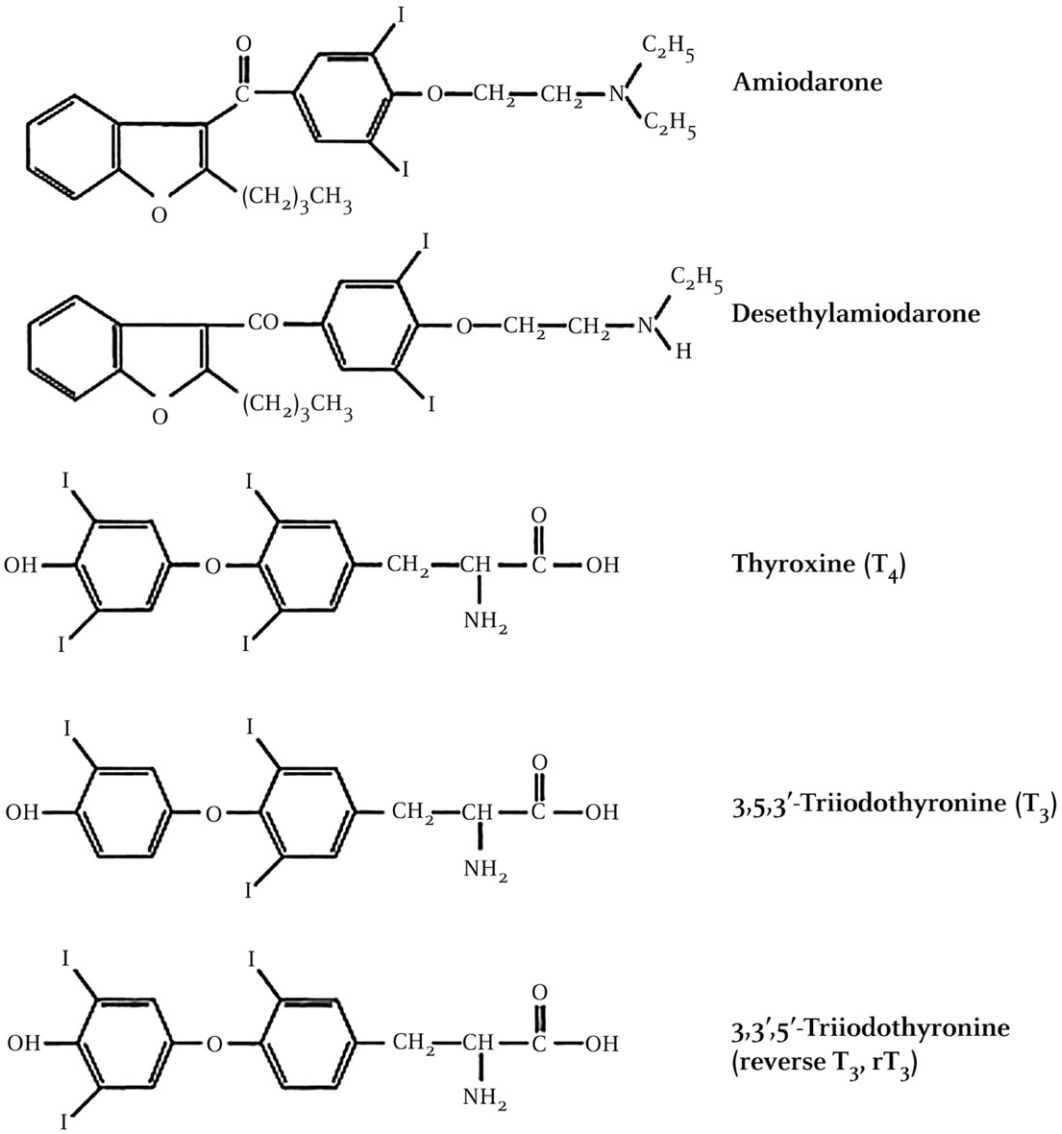

Fig. 1 Molecular structure of amiodarone, desethylamiodarone, and thyroid hormone.

when feasible, may restore euthyroidism. On the other hand, the huge iodine load caused by amiodarone may accelerate the progression towards hypothyroidism in euthyroid patients with preexisting chronic autoimmune thyroiditis. In these patients, hypothyroidism is usually permanent (Bogazzi *et al.*, 2012).

Excessive iodine is the cause of type 1 amiodarone-induced thyrotoxicosis (AIT), a form of iodine-induced hyperthyroidism, in which iodine load unveils underlying thyroid autonomy or latent Graves' disease and triggers the occurrence of hyperthyroidism (Jod-Basedow phenomenon).

Effects Intrinsic to the Molecular Structure

Amiodarone and DEA have proapoptotic and direct cytotoxic effects on thyroid follicular cells. Histopathological studies, both in animal models and in patients with AIT submitted to total thyroidectomy, showed disruption of thyroid structure, including follicular damage, a reduced number of mitochondria, an increased number of lysosomes and dilation of endoplasmic reticulum. The above findings are in keeping with drug-induced damage of the thyroid gland, resembling those occurring in other thyroid-destructive processes, such as subacute thyroiditis.

While, as mentioned above, type 1 AIT is a true form of iodine-induced hyperthyroidism, type 2 AIT is a destructive thyroiditis usually occurring in a substantially normal thyroid gland. Further evidence lending support to this notion is its self-limiting outcome, the usually prompt response to glucocorticoids, and the absence of thyroid hyperfunction.

Epidemiology of Amiodarone-Associated Thyroid Dysfunction

Prevalence of amiodarone-induced thyroid dysfunction is influenced by environmental iodine supply: hypothyroidism is relatively more frequent in iodine-sufficient areas, thyrotoxicosis in iodine-deficient areas. A proportion of 2% and 12% of patients under chronic amiodarone therapy may develop thyrotoxicosis in areas with high or low iodine intake, respectively. Conversely, hypothyroidism ranges from 13% (high iodine intake) to 6% (low iodine intake) (Trip *et al.*, 1991).

Amiodarone-Induced Hypothyroidism

Underlying chronic autoimmune thyroiditis and female gender are predisposing risk factors for developing AIH; each factor carries on average a relative risk of 7. Because chronic autoimmune thyroiditis has a much higher prevalence in women, the relative risk of AIH in women with chronic autoimmune thyroiditis is 13. In these patients, hypothyroidism is permanent despite amiodarone withdrawal, and requires levothyroxine (L-T_4) replacement.

Clinical features of AIH do not differ from those of patients with hypothyroidism of different causes, although goiter is rare. Diagnosis is confirmed by low serum FT_4 and elevated serum TSH concentrations.

AIH is easily managed by L-T_4 replacement. Serum TSH should be maintained in the upper third of the normal range. Amiodarone therapy can be continued, if needed, irrespective of the presence or absence of an underlying thyroid disorder. Hypothyroidism does not remit after drug discontinuation in patients with chronic autoimmune thyroiditis. Conversely, amiodarone withdrawal results in the restoration of euthyroidism in most patients without underlying thyroid autoimmunity.

Amiodarone-Induced Thyrotoxicosis

Over the years, proportion of patients with type 1 and type 2 AIT has changed, at least in Italy: while the number of patients affected by type 1 AIT did not change, the number and proportion of type 2 AIT patients increased. The practical consequence is that, for the time being, endocrinologists will face mainly with amiodarone-induced destructive thyroiditis; consensus exists on the differentiation of the two main forms of AIT, although mixed forms may exist.

Differentiation of the two main forms of AIT is crucial, although challenging, because therapeutic options and outcome greatly differ. The available different diagnostic procedures are aimed to reveal a thyroidal increased hormonal synthesis or an increased released of preformed hormones (Type I and Type II, respectively), often, performed in a rapid sequence in the same patient (**Table 3**) (Bogazzi *et al.*, 2010).

Clinical features of AIT are variable and indistinguishable from those of patients with spontaneous hyperthyroidism or other forms of thyrotoxicosis. However, some peculiar manifestation may herald AIT: apathetical hyperthyroidism, unexplained worsening of the underlying cardiac disease, or an unexplained increased sensitivity to warfarin.

Management of AIT patients is challenging. Based on the different pathogenic mechanisms, type 1 and type 2 AIT should be managed using different medical therapies. In the therapeutic management of AIT, first of all, the underlying heart disease and the cardiovascular compensation should be considered. If cardiovascular conditions are not critical, a medical therapy can be considered.

In type 1 AIT treatment should control the increased thyroid hormone synthesis, using thionamides. Since an iodine replete thyroid gland is less responsive to thionamides, higher doses than those usually prescribed in spontaneous hyperthyroidism are necessary (40–60 mg methimazole); perchlorate, when available, can be added during the first weeks of treatment (no >1 g/day for 4–6 weeks) to reduce the intrathyroidal iodine load. However, type 1 AIT patients usually have an underlying thyroid disorder,

Table 3 Characteristics of amiodarone-induced thyrotoxicosis Types I and II

	Type I	*Type II*
Underlying thyroidal functional autonomy	Yes	No
Pathogenetic mechanism	Excessive thyroid hormone synthesis due to iodine excess	Excessive thyroid hormone release due to destructive thyroiditis
Goiter	Usually diffuse or nodular goiter	Occasionally small diffuse goiter
Thyroid radioiodine uptake	Low, normal, or high	Low
Anti-thyroid antibody	Sometimes present	Sometimes present
FT4/FT3 ratio	<4	>4
Onset after Amio initiation	Short	Dealayed
Spontaneous remission	Less likely	More likely
Preferred drug treatment	Thionamides	Glucocorticoids
Subsequent hypothyroidism	Unlikely	Possible

which may require a definitive therapy. This may be relevant, because thyroid ablation may make continuation of amiodarone therapy (if needed from the cardiac standpoint) perfectly feasible. Radioiodine therapy is not feasible in the short run due to the persistently high intrathyroidal iodine content, whereas, total thyroidectomy may be programmed, once euthyroidism has been restored (Martino *et al.*, 2001; Bogazzi *et al.*, 2010, 2012, 2018; Trip *et al.*, 1994).

In type 2 AIT, the primary goal of medical therapy is to abate the destructive and inflammatory process damaging the thyroid gland. This is usually achieved by the use of oral glucocorticoids (starting dose, prednisone 0.5 mg/kg/day, or equivalent doses of other synthetic glucocorticoids). In type 2 AIT time to restore euthyroidism may occasionally be exceptionally long. Overall, the time required to restore euthyroidism during glucocorticoid therapy is a function of thyroid volume (estimated with standard echography) and serum concentrations of free thyroxine at the diagnosis of AIT; those two parameters may be considered surrogate of the grade of thyroid damage (Bogazzi *et al.*, 2012). Glucocorticoid therapy may be continued for several weeks to months if cardiac conditions are stable; however, deterioration of the cardiovascular function should dictate a re-evaluation of the therapeutic options. Under these circumstances, thyroid ablation by total thyroidectomy represents a valid option also in type 2 AIT.

Amiodarone-induced thyrotoxicosis (AIT) occurs in patients with preexisting cardiac disease and may represent an emergency condition because of the detrimental effects of excess thyroid hormone on underlying heart abnormalities. When AIT represents an imminent risk for cardiac function, it should be managed without delay, because the late resolution of thyrotoxicosis is associated with a high mortality rate. Under these circumstances, emergent thyroidectomy may represent the most effective and rapid way for resolving thyrotoxicosis (Bogazzi *et al.*, 2018).

Thyroid Disease and Bone

Bente L Langdahl, Aarhus University Hospital, Aarhus, Denmark

Glossary

Bone mineral density (BMD) The mineral content in bone measured by DXA (dual energy X-ray absorptiometry) or quantitative computer tomography (qCT).

Bone remodeling A coupled process of bone resorption followed by bone formation, which maintains skeletal integrity throughout adulthood. After peak bone mass is reached at age 20–30 years, bone resorption usually exceeds bone formation and this imbalance leads to age-related bone loss.

Osteoblast The bone forming cell.

Osteoclast The bone resorbing cell.

Osteocyte The mature osteoblast embedded on bone matrix. The osteocyte is the major controller of bone remodeling and responds to hormones, strain, and microdamage.

Osteoporosis Osteoporosis is a systemic skeletal disease, characterized by reduced bone mass and deteriorated bone architecture resulting in an increased risk of fractures. Osteoporosis is defined by WHO as BMD more than 2.5 standard deviations below peak bone mass (T-score < -2.5).

TSH Thyroid stimulating hormone.

T3 and fT3 Triiodothyronine and free triiodothyronine. The biologically active thyroid hormone.

T4 and fT4 Thyroxine and free thyroxine. The thyroid prohormone, which is secreted by the thyroid gland and subsequently converted to T3.

Effects of Thyroid Hormones on Bone

The thyroid hormone transporter MCT8 and the thyroid receptor alpha are present in osteoblasts (Bassett and Williams, 2016). In vitro studies have shown that T3 stimulates proliferation of osteoblasts, the bone forming cell (Kassem *et al.*, 1993). The same studies also showed that T3 stimulates the early phases of osteoblast differentiation. Bone resorption is also influenced by thyroid hormone; however, it is less clear if there is a direct effect of thyroid hormone on osteoclasts, the bone resorbing cell or if the effect is indirect through the osteoblast or the osteocyte (Bassett and Williams, 2016). Osteocytes are difficult to investigate in vitro and therefore the effect of thyroid hormones on osteocyte function is still unknown.

If T3 is administered to healthy women in high doses for a week, rapid and pronounced increases are seen in bone turnover (Langdahl *et al.*, 1996d, 1997). The most pronounced effects were seen on markers of osteoclast activity, but also markers of bone formation were affected.

In healthy postmenopausal women with thyroid hormones and thyroid stimulating hormone (TSH) within the normal ranges included in an observational study of the prevalence of osteoporotic fractures (Murphy *et al.*, 2010), it was demonstrated that the level of free thyroxine (T4) in the circulation was negatively associated with Bone Mineral Density (BMD) at the hip and with changes in BMD at the hip over time. Regression analyses demonstrated that higher levels of free triiodothyronine (T3) and T4, although still within the normal ranges were associated with an increased risk of non-vertebral fractures. Similarly, higher levels of TSH were associated with decreased risk of non-vertebral fractures. These findings have subsequently been confirmed by a recent meta-analysis that found that higher free T4 and lower TSH within the normal reference ranges were associated with 22%–25% increased risk of hip fractures (Aubert *et al.*, 2017).

In recent years, there have been speculations whether TSH had an effect on bone independent of T3 or T4. Animal and in vitro studies have suggested that TSH inhibits bone remodeling directly. To investigate the importance of TSH in humans, patients with Graves's disease where thyroid hormone as well as TSH signaling is increased because TSH receptor antibodies stimulates the TSH receptor and increase T4 and T3 production have been examined. The studies have showed that patients with Graves's disease lose bone to the same extent as patients with nonautoimmune causes of hyperthyroidism, suggesting that stimulation of the TSH receptor does not protect against T4/T3 induced bone loss and therefore probably plays a minor, if any role in humans (Bassett and Williams, 2016).

Childhood Thyroid Disease Affects Bone Development

Hypothyroidism in childhood is associated with growth retardation, delayed skeletal development and subsequently short stature due to defective osteochondral ossification (Bassett and Williams, 2016). The impaired osteochondral ossification results in delayed closure of the fontanelles, skull sutures and in severe cases epiphyseal dysgenesis. Initiation of substitution therapy leads to rapid bone growth and skeletal maturation and normal adult height is achieved in most cases (Salerno *et al.*, 2001).

Hyperthyroidism in children stimulates bone growth and accelerates ossification of both intramembranous and endochondral bone. This may in severe cases lead to premature fusion of growth plates and thereby early cessation of growth and permanent short stature. Closure of the cranial sutures may result in craniosynostosis. Craniosynostosis may also be seen as a consequence of untreated hyperthyroidism during pregnancy (Bassett and Williams, 2016).

Hypothyroidism

Hypothyroidism in adults leads to a low bone turnover state in the skeleton. Remodeling of the skeleton is less frequent than in euthyroid individuals and the balance between bone resorption and the subsequent bone formation is in favor of bone formation (Eriksen *et al.*, 1986). These changes would tend to increase BMD to a level above age-matched normal, however, since turnover is reduced it would take years for the changes to become measurable. Most studies therefore find that patients with hypothyroidism have normal BMD (Vestergaard and Mosekilde, 2002). There is no documented increased fracture risk in patients with hypothyroidism.

Substitution with T4 and/or T3 restores bone turnover. No long-term studies of the effect of substitution therapy in hypothyroidism has been conducted. Short term studies have not shown significant changes in bone mass (Ross, 1993; Boeving *et al.*, 2011; Cole *et al.*, 1997; Celi *et al.*, 2011). Cross-sectional studies of patients who have been on long-term substitution therapy have shown that these patients have BMD indistinguishable from healthy controls (Langdahl *et al.*, 1996a; Salerno *et al.*, 2004).

Cross-sectional population based studies have demonstrated an increased risk for fracture in hypothyroid patients substituted with thyroid hormones (Vestergaard and Mosekilde, 2002; Flynn *et al.*, 2010) and this increased risk has been suggested to be associated with overtreatment (Ko *et al.*, 2014).

The effect of subclinical hypothyroidism on fracture risk has been investigated and a recent meta-analysis did not find an increased risk for fracture in patients with subclinical hypothyroidism (Blum *et al.*, 2015).

Goiter

If goiter is not associated with hyperthyroidism or suppressed TSH, goiter is not associated with changes in bone metabolism or bone mass. Treatment of goiter may, however, affect the skeleton. Treatment of goiter with radioactive iodine does not affect the skeleton, whereas treatment with T4 may affect the skeleton negatively (Wesche *et al.*, 2001; Knudsen *et al.*, 1998). Goiter associated with subclinical hyperthyroidism; normal T3 and T4, but suppressed TSH, is associated with bone loss that can be prevented by treatment with radioiodine (Faber *et al.*, 1998).

Hyperthyroidism

Hyperthyroidism is associated with increased bone turnover (Pantazi and Papapetrou, 2000) and a negative balance at each remodeling site (Eriksen *et al.*, 1985). The increased bone turnover is restored to normal when hyperthyroidism is treated, independently of whether the treatment is radioiodine, surgical or medical (Pantazi and Papapetrou, 2000; Langdahl *et al.*, 1996b,c).

The increased bone turnover and the negative remodeling balance lead to bone loss (Vestergaard and Mosekilde, 2003). Bone mass increases when hyperthyroidism is treated (Vestergaard and Mosekilde, 2003) and patients who have had normal thyroid function for more than 4 years have similar bone mineral density as healthy controls (Langdahl *et al.*, 1996b,c).

Hyperthyroidism is associated with increased risk of fractures (Vestergaard and Mosekilde, 2003). This risk seems to decrease after treatment, however remains above the risk found in the background population (Vestergaard *et al.*, 2000). The studies have not been able to show if it is the loss of BMD, the high bone turnover, or the thyroid disease itself which cause the increased risk of fracture. The BMD losses are usually less than 10%, but the increases in bone turnover may be significantly higher and it is well-known that high bone turnover leads to thinning of trabeculae and loss of trabeculae and to cortical porosity and thinning of the cortex. These changes will destabilize bone and compromise bone strength. If the patient is young the majority of these changes may be reversible, but in postmenopausal women loss of trabecular connectivity and cortical thinning are predominantly irreversible. It is therefore likely that the high bone turnover is more important than the loss of BMD for the increased fracture risk.

Population based investigations have demonstrated that history of hyperthyroidism is an important risk factor for future fractures (Cummings *et al.*, 1995) (**Table 1**).

Subclinical Hyperthyroidism

Subclinical hyperthyroidism is defined as circulating concentrations of T3 and T4 within the normal reference ranges and circulating TSH below the reference range.

Table 1 Bone turnover, bone mineral density, fracture risk and management of bone health in patients with thyroid disease

Treatment	*Bone turnover*	*Bone mineral density*	*Fracture risk*	*Management of bone health*
Hypothyroidism	Normal/ reduced	Normal/ increased	Normal/low	As in euthyroid patients
Goiter	Normal	Normal	Normal	As in euthyroid patients If long-term T4 therapy, consider DXA
Subclinical hyperthyroidism (suppressed TSH)	Increased/ normal	Reduced/ normal	Increased	If long-term lasting, consider DXA
Hyperthyroidism	Increased	Reduced	Increased	Treat hyperthyroidism and advise on bone friendly lifestyle Consider DXA when euthyroid for 6 months
TSH suppression therapy	Normal/ increased	Normal/ decreased	Normal/increased (post-menopausal women)	Advise on bone friendly lifestyle Reduce TSH suppression to minimum Consider DXA

Subclinical hyperthyroidism is associated with bone loss and increased risk of fractures. A recent meta-analysis found that TSH below 0.01 mU/L is associated with a two-fold increase in hip fractures and a 3.5-fold increase in vertebral fractures (Blum *et al.*, 2015). In a large Danish register based study excluding patients with a history of thyroid or pituitary diseases or use of any kind of thyroid medication, it was demonstrated that a single measurement of TSH below the normal reference range was associated with increased risk of hip fractures (Abrahamsen *et al.*, 2014). The duration and severity of the suppression of TSH was associated with increased risk of both hip and major osteoporotic fractures.

TSH Suppressive Therapy

TSH suppression therapy is used in patients thyroidectomised due to thyroid cancer. This is a situation similar to mild hyperthyroidism or subclinical hyperthyroidism and therefore associated with increased bone turnover. There is some controversy if TSH suppressive therapy leads to bone loss as some studies did not demonstrate this (Reverter *et al.*, 2005) whereas others did (Sugitani, 2005). The differences may be related to the women included in the studies as Sugitani *et al.* demonstrated that bone loss was only seen in postmenopausal women. This was later confirmed in a meta-analysis that also included a few studies in men and found no bone loss in men receiving TSH suppressive therapy (Quan *et al.*, 2002).

Management of Patients With Thyroid Diseases

Hypothyroidism

Patients with untreated hypothyroidism have low risk of osteoporosis. Patients receiving replacement therapy have low risk of osteoporosis, however, may have an increased risk of fractures during the first years of treatment or if oversubstituted. Therefore, general screening for osteoporosis in this group of patients is not recommended, however, DXA may be considered in postmenopausal women and elderly men if other risk factors for osteoporosis are present.

Hyperthyroidism

Patients with hyperthyroidism have high bone turnover and lose bone mass. The risk of developing osteoporosis and fractures depends on age, gender and menopausal status.

The most important intervention is treatment of hyperthyroidism. In addition, the patient should be advised about bone healthy lifestyle measures; avoid smoking, physical activity and sufficient intake of calcium and vitamin D. In postmenopausal women and elderly, it is advised to consider DXA when the patient has had normal thyroid function for 6 months.

Subclinical Hyperthyroidism or Suppressed TSH Found on Routine Biochemical Screening

Individuals with suppressed TSH may have increased risk of fractures, however, the risk depends on many other risk factors. DXA may be considered as part of the work-up that should be done in these patients.

TSH Suppressive Therapy

Patients receiving suppressive therapy probably have an increased risk of developing osteoporosis and fractures, however the risk depends on the level of suppression of TSH, age, gender, menopausal status, and other risk factors. The suppression of TSH should therefore be the least acceptable in the context of the cancer disease and performing DXA should be considered in postmenopausal women.

Treatment of Osteoporosis in Patients With Thyroid Diseases

Treatment of osteoporosis comprises general measures; secure sufficient calcium and vitamin D intake, avoid smoking, and be physical active and engage in exercise and specific treatment. Medical treatment of osteoporosis can be divided into antiresorptive and anabolic treatment and choice of initial treatment and long-term management follows the general recommendations for treatment of osteoporosis as there are no clinical trials specifically investigating treatment of osteoporosis in patients with thyroid diseases.

Conclusion

Thyroid status affects bone status. Individuals with thyroid function in the upper end of the normal reference range have lower BMD and increased risk of fragility fractures compared with individuals with thyroid function in the middle or lower end of the reference range.

Hypothyroidism generally does not pose a risk to bone health, only long-term over substitution with thyroid hormones may lead to increased risk of fractures.

Overt hyperthyroidism is accompanied by increased bone turnover, bone loss, and increased risk of fractures. The risk of fractures may not be completely reversible in postmenopausal women and elderly men and therefore it is recommended to perform DXA when the patient has been euthyroid for 6 months.

Subclinical hyperthyroidism is also associated with bone loss and increased risk of fractures and should therefore be treated. Similarly, TSH suppression therapy in patients with thyroid cancer is associated with bone loss, especially in postmenopausal women and bone friendly lifestyle should be advised and DXA considered. Osteoporosis in patients with thyroid disease should be managed in accordance with general guidelines.

Thyroid Function and Depression☆

Martin B Jørgensen and Ulla Feldt-Rasmussen, University of Copenhagen, Copenhagen, Denmark

Glossary

Apathetic thyrotoxicosis Hyperactivity of the thyroid gland in which the classic signs and symptoms are subtle; occurs chiefly in middle-aged and elderly persons.

Bipolar disorder Psychiatric syndrome with both episodes of mania and depression. Formerly called manic-depressive illness.

Depression Psychiatric syndrome with decreased mood, loss of interest and lack of energy.

Dysphoria Decreased mood, bad mood.

Hyperthyroidism A condition of excessive functional activity of the thyroid gland and excess secretion of thyroid hormones marked by goiter, tachycardia or atrial fibrillation, widened pulse pressure, palpitations, fatigability, nervousness and tremor, heat intolerance and excessive sweating, ocular signs, and emotional lability.

Hypothyroidism Deficiency of thyroid activity that, in adults, is most common in women and is characterized by a decrease in basal metabolic rate, tiredness and lethargy, depression, sensitivity to cold, and menstrual disturbances.

Levothyroxine Monosodium salt of the levoisomer of the thyroid hormone thyroxine; used for replacement therapy in reduced or absent thyroid function; administered orally.

Liothyronine Synthetic levoisomer of the thyroid hormone triiodothyronine, which is more potent and has a more rapid action than thyroxine; used for thyroid replacement or supplementation in hypothyroidism and nontoxic goiter; administered orally.

SSRI Selective serotonine reuptake inhibitor.

Tca Tricyclic antidepressant.

Thyroid gland Endocrine gland normally situated in the lower part of the front of the neck and consisting of two lobes, one on either side of the trachea and joined in front by a narrow isthmus; secretes, stores, and liberates (as necessary) the thyroid hormones, which require iodine for their elaboration and which play the major endocrine role in regulating the metabolic rate.

Thyrotropin A glycoprotein hormone of the anterior pituitary that has affinity for and specifically promotes the growth of, sustains, and stimulates the hormonal secretion of the thyroid gland.

Thyrotropin-releasing hormone A tripeptide elaborated by the paraventricular nucleus of the hypothalamus or obtained by synthesis that stimulates release of thyrotropin from the anterior pituitary gland.

Thyroxine A crystalline iodine-containing hormone, considered the major hormone elaborated by the thyroid gland, that is formed from thyroglobulin and transported mainly in the blood serum by thyroxine-binding globulin; chief function is to increase the rate of cell metabolism.

Triiodothyronine An organic iodine-containing compound liberated from thyroglobulin by hydrolysis and thought to be formed by the conjugation of one molecule each of monoiodotyrosine and diiodotyrosine and by the partial deiodination of thyroxine intrathyroidally and in the periphery; has several times the biological activity of thyroxine; thought to be the "tissue-active" form of thyroid hormone.

Introduction

In 1888, a committee appointed by the Clinical Society of London established that thyroid hormone is important for central nervous system (CNS) development and function. Although early investigations suggested that adult brain tissue was not responsive to thyroid hormone due to its failure to increase the consumption of oxygen, thyroid hormone receptors have been demonstrated in the neonatal and adult brain (Dezonne *et al.*, 2015). Furthermore, it has been shown that thyroid hormone regulates normal neuronal growth and synaptogenesis (Stenzel and Huttner, 2013). The fact that hypothyroidism could lead to depression and be reversed by thyroid hormone administration was established by Asher in 1949 (Asher, 1949). Since then, attention has shifted to the potential role of thyroid hormone, particularly liothyronine (T_3), as adjuvant therapy for euthyroid patients who have depression. T_3 has been reported to influence the effect of antidepressants either by hastening the onset of response or by converting a nonresponder into a responder (Joffe, 2011). Although it has been given as adjuvant therapy for refractory depression for more than four decades, efficacy is moderate, and it is paramount to find biomarkers to identify preferential responders (Joffe, 2011).

Clinical Manifestations of Depression and Thyroid Disease

Major depression affects on average 5% of the population across all countries (Kessler and Bromet, 2013). The diagnosis is made in those who present with a depressed or irritable mood, and have a lack of interest or pleasure and reduced energy for at least 2 weeks in combination with accompanying symptoms (**Table 1**). The initial episode of depression most frequently occurs during the fourth or fifth decade of life but may occur at any age. If left untreated, the duration of an episode can vary greatly, from a few months to 1 or more years. Occasionally, it will persist as chronic depression. A family history of mood disorders is common (McIntyre, 2016).

As in thyroid disease, depression occurs more often in women than in men, with peak incidence varying between countries and across ages (Bromet *et al.*, 2011). The prevalence of autoimmune thyroid disease is highest among women more than 40 years of age (Ajjan and Weetman, 2015). Most individuals presenting with depression do not have biochemical evidence of thyroid dysfunction; despite this, depression and thyroid dysfunction share many clinical features (see **Table 2**). In those cases where patients present with depression and findings that suggest thyroid dysfunction, it may be difficult to distinguish clinically which entity is the cause of the symptoms.

Regulation of the Hypothalamic–Pituitary–Thyroid Axis

The fundamental actions of the hypothalamus–pituitary–thyroid axis are based on stimulation of the pituitary thyrotrophs balanced by a negative feedback inhibition. The hypothalamus regulates the synthesis and release of thyrotropin (TSH) through the secretion of thyrotropin-releasing hormone (TRH). TRH is produced in the paraventricular nucleus of the hypothalamus and transported to the specialized nerve terminals in the median eminence before being liberated into the hypophyseal portal blood. The basophilic cells of the anterior pituitary produce TSH in response to TRH. TSH is liberated in the circulation and stimulates the thyrocytes to produce thyroid hormones via the thyrotropin receptor. Once thyroxine (T_4) and T_3 are liberated, they exert a negative feedback inhibitory effect on TSH and TRH secretion (see **Fig. 1**). Apart from thyroid hormones, there are other inhibitors of TSH secretion, including somatostatin, dopamine, glucocorticoids, and certain cytokines (see **Table 3**), while α-adrenergic agonists stimulate the thyrotrophs (Persani, 2012).

Table 1 Associated symptoms of major depression

- Reduced self-esteem and self confidence
- Feelings of worthlessness or guilt
- Recurrent thoughts of death or suicide
- Decreased concentration and attention
- Motor agitation or retardation
- Insomnia or hypersomnia
- Appetite or weight change

- Anhedonia
- Constipation
- Lethargy
- Anergia
- Decreased libido
- Dysphoria
- Fatigue
- Somnolence
- Melancholia
- Weight gain or weight loss

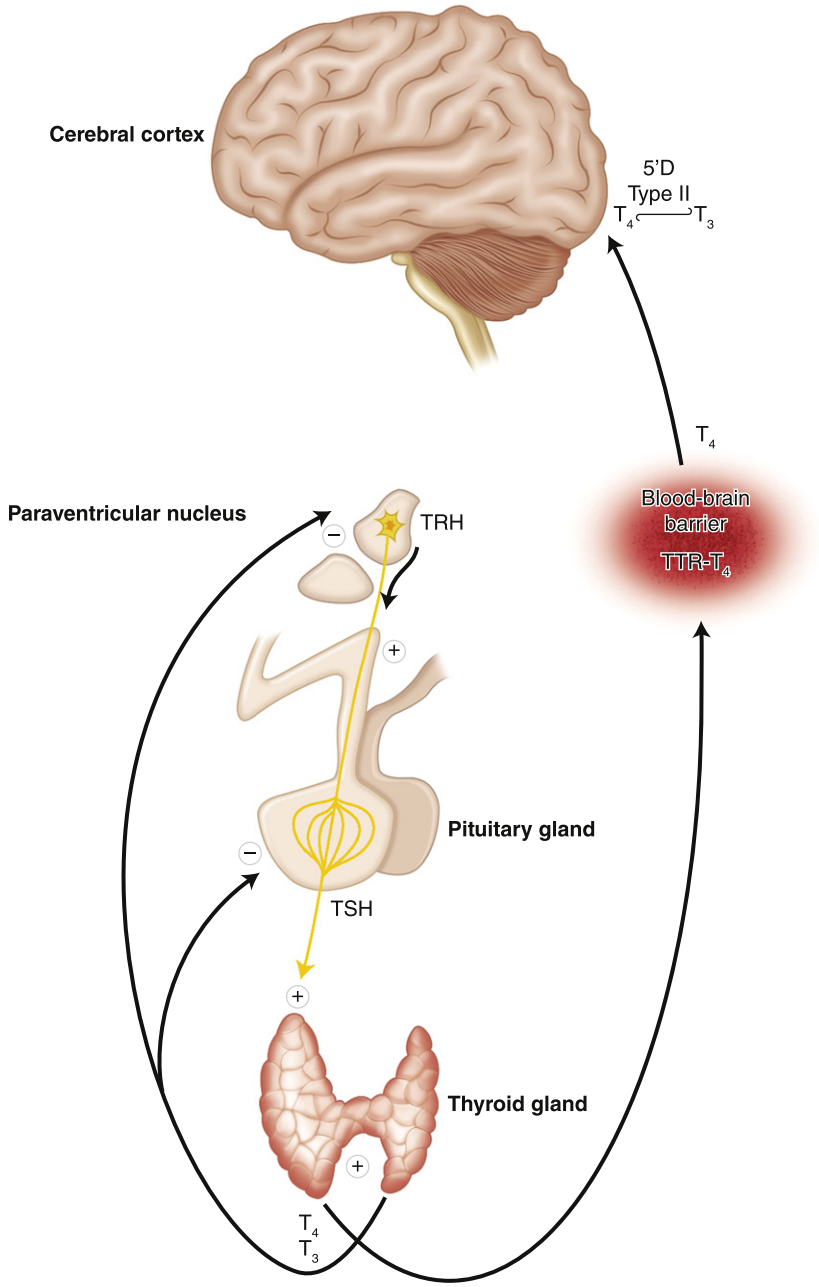

Fig. 1 The hypothalamic–pituitary–thyroid axis. Once T_4 is in the circulation, it crosses the blood–brain barrier with the aid of transthyretin. In the cerebral cortex, T_4 is converted into T_3 by 5′-deiodinase type II. Finally, T_3 is inactivated by 5-deiodinase (5D) into diiodothyronine (T_2). T_3 is the active thyroid hormone at the cellular level.

The most abundant thyroid hormone produced by the thyroid gland is T_4. The monodeiodination of T_4 in extrathyroidal tissues gives rise to 80% of the T_3 in the peripheral circulation, with the remainder being derived from direct thyroid gland secretion. Within the CNS, local deiodination activity in the brain is of great importance because it enables the CNS to maintain an optimal T_3 content. Type II 5′-deiodinase and 5-deiodinase are the major mediators of this process. The former, which is responsible for the conversion of T_4 to T_3, is found in the cerebral cortex, pituitary, and hypothalamus. The latter is also found in the cerebral cortex but not in the anterior pituitary. It results in degradation of T_3 and inactivates T_4, yielding reverse triiodothyronine (rT_3). In addition, 5-deiodinase activity predominates in the euthyroid state, and the rT_3 produced plays a role in the regulation of local deiodination (see Fig. 1). The cortex has the highest level of activity of these enzymes, followed by the midbrain, pons, hypothalamus, and brainstem (in that order).

Table 3 Conditions with a blunted TSH response to exogenous TRH (Persani, 2012)

- Dopamine
- Phenytoin
- Somatostatin
- Fasting
- Nonthyroidal illness

Alterations of the Hypothalamic–Pituitary–Thyroid Axis in Depression

Patients with depression can present many abnormalities of the hypothalamic-pituitary-thyroid axis (see **Fig. 2**). The most widely recognized disturbance is blunting of the TSH response to TRH stimulation (Arem and Cusi, 1997;Duval *et al.*, 2015). Defined as a TSH rise of less than 5 mU/L, this phenomenon occurs in 25%–30% of depressed individuals. Normalization of this response is noted once clinical recovery ensues. It differs from thyrotoxicosis in which the TSH response is flat and the circulating T_3 levels are elevated, and may rather be caused by central hypothalamic suppression, as seen during fasting and in nonthyroidal illness. A blunted TSH response is therefore not unique to depression but occurs in other clinical settings (Persani, 2012) (see **Table 3**).

Another common abnormality of the hypothalamic–pituitary–thyroid axis is held to be an increase in total and/or free thyroxine (FT_4) levels, although still within the conventional normal range, that regress after successful treatment of depression (Jackson, 1998). It has been reported that some patients admitted with acute psychosis, including depression, manifest a transient elevation above normal levels of T_4 and/or FT_4 and occasionally TSH. These findings usually resolve spontaneously within 2 weeks (Roca *et al.*, 1990).

In a fetal rat hypothalamic culture system, Luo and Jackson demonstrated an increase in TRH gene expression by glucocorticoid exposure (Luo and Jackson, 1999). This effect is notable because human depression is characterized by hypercortisolemia, which we believe leads to activation of the TRH neuron and, consequently, thyroid function. The hypercortisolemia of depression probably results from impaired function of the hippocampus, a locus for glucocorticoid negative feedback of the hypothalamic–pituitary–adrenocortical axis (MacQueen and Frodl, 2011). Although glucocorticoids generally inhibit the thyroid axis in humans and rats in vivo, a "functional" disconnection of the hypothalamus from the rest of the brain (as is postulated to occur in depression) would remove this inhibitory influence from the hypothalamus. Indeed, a fornical lesion that severs the hypothalamus from hippocampal regulation will increase thyroid function (Shi *et al.*, 1993). In many ways, the hypothalamus in culture is analogous to a deafferentated hypothalamus in vivo. Luo and Jackson hypothesized that the direct stimulation of the TRH neuron by glucocorticoids seen in vitro is overridden in vivo by an inhibitory influence emanating from the hippocampus in the normal human or rat but not in some persons with clinical depression. In these individuals, activation of the TRH neuron could lead to increased hypothalamic TRH secretion with down-regulation of the TRH receptors. This could result in a blunted TSH response to exogenous TRH and spillover of TRH into the cerebrospinal fluid (CSF), increased levels of which have been reported. In addition, Jackson and Lou have explored a direct effect of antidepressants on the TRH neuron to explain the reversal of hyperthyroxinemia with successful treatment of clinical depression. The results showed that the selective serotonin reuptake inhibitors (SSRIs) and the tricyclic antidepressants (TCAs) inhibit TRH secretion (Jackson and Luo, 1998). These studies suggest that the fall in circulating T_4 levels seen with antidepressant medication might reflect a direct effect on the TRH neuron and consequent reduced activation of the thyroid axis. Antidepressants may also be clinically efficacious by enhancing T_4-to-T_3 conversion in the CNS (Bauer *et al.*, 2008).

As mentioned previously, T_3 is the active thyroid hormone in the brain. It has been hypothesized that depression leads to inhibition of type II deiodinase, possibly due to the elevated cortisol levels in this disorder (Bauer *et al.*, 2008). Therefore, T_4 is converted to rT_3 by 5-deiodinase. This would explain the elevated levels of rT_3 in the CSF of individuals with unipolar depression.

Transthyretin, a T_4 transport protein, is synthesized by the choroid plexus and accounts for up to 25% of the protein in the CSF. It has a relative binding affinity of 39.3% for T_4 and of only 1.4% for T_3; thus, it is unlikely that transthyretin plays a significant role in the transport of T_3 across the blood–brain barrier. Interestingly, in a study of eight patients with refractory depression, CSF levels of transthyretin were much lower when compared with nine patients with neurological disease but without depression. The authors of this study proposed that low levels of TTR could give rise to "brain hypothyroidism" with normal peripheral thyroid hormone concentrations in depression (Sullivan *et al.*, 2006).

Autoimmune thyroiditis is found in 7% of depressed patients (Gold *et al.*, 1981; Haggerty, *et al.* 1997) and may be associated with an exaggerated response to TRH stimulation, indicating a subtle subclinical hypothyroidism. In bipolar patients the

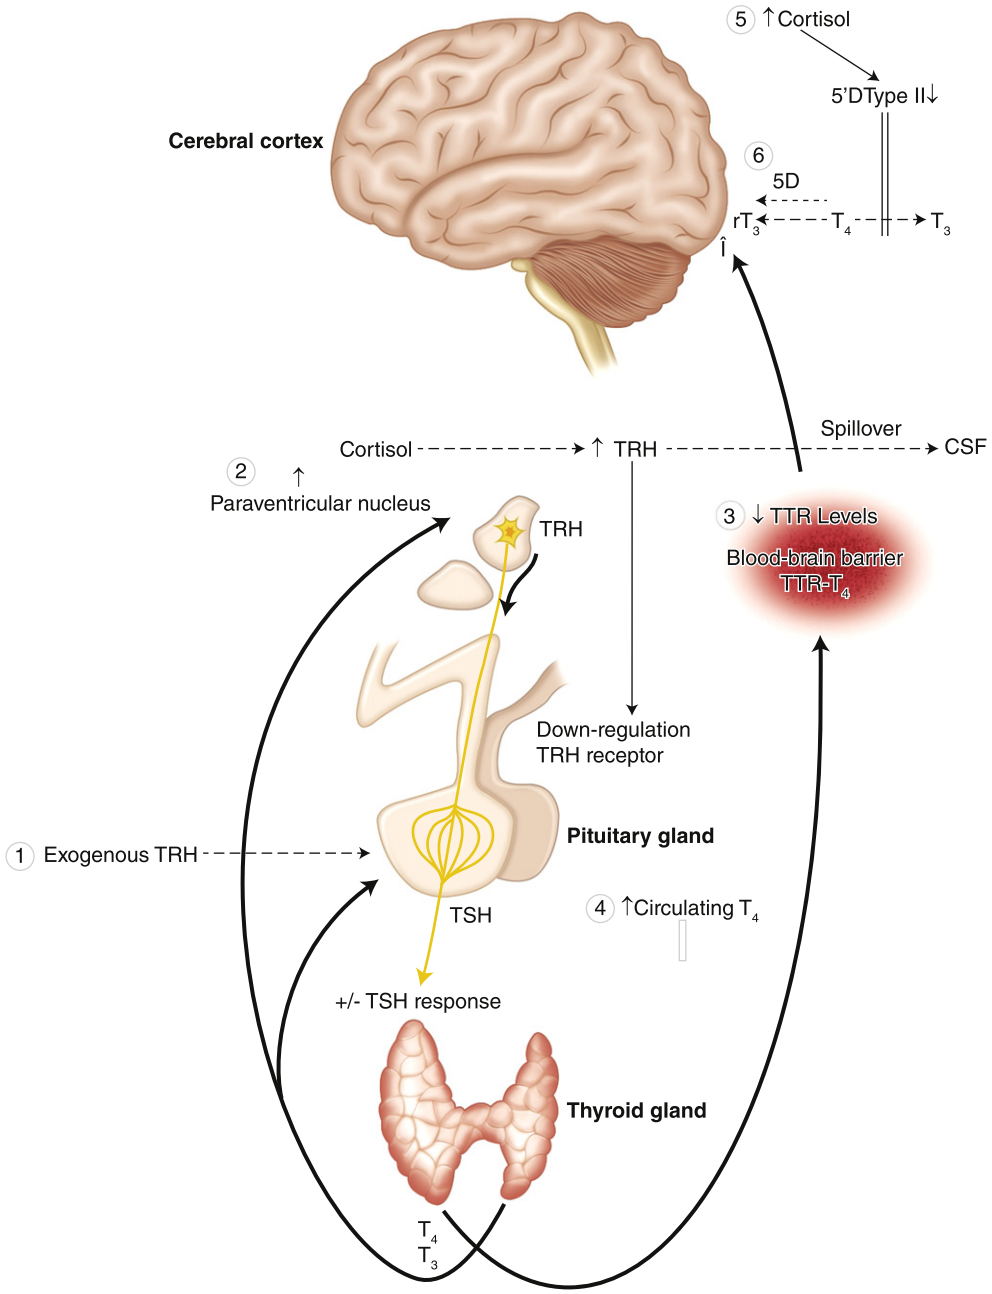

Fig. 2 Alterations of the hypothalamic–pituitary–thyroid axis in depression: (1) Blunted (+/−) thyrotropin (TSH) response to exogenous thyrotropin-releasing hormone (TRH) administration (Haggerty, *et al.* 1993). (2) Elevated cortisol levels activate the TRH neuron, which can lead to down-regulation of the TRH receptor (Jackson, 1998; Tsigos and Chrousos, 2002). (3) Decreased levels of transthyretin (TTR), a thyroxine (T_4) transport protein, have been found (Hatterer *et al.*, 1993; Sullivan *et al.*, 2006). (4) Circulating T_4 levels have been found to be elevated (Jackson, 1998). (5) Inhibition of 5′-deiodinase type II (5DType II) occurs, possibly due to elevation of cortisol, resulting in decreased triiodothyronine (T_3) (Bauer *et al.*, 2008; Brouwer *et al.*, 2006). (6) T_4 is converted into reverse T_3 (rT_3), resulting in higher rT_3 levels in the CSF (Bauer *et al.*, 2008).

prevalence of autoimmune thyroiditis is higher with 28% carrying anti-TPO antibodies (Kupka *et al.*, 2002) and up to 50% in one series of patients with i rapid cycling bipolar disease (four or more episodes of manic depression per year) (Bauer *et al.*, 1990). Furthermore, women with postpartum thyroiditis often suffer from depression. In a study of 145 women with presence of antithyroid antibodies, 47% had significant depressive symptoms. When these women were compared with a control group, with negative titers to antithyroid antibodies, only 32% presented with depressive symptoms regardless of the thyroid function abnormalities. Among the antibody-positive individuals, 62 had episodes of thyroid dysfunction; a total of 27 had signs of hypothyroidism, 11 had signs of hyperthyroidism, and 24 showed biochemical evidence of hyperthyroidism followed by hypothyroidism (Harris *et al.*, 1992). A recent systematic review (Barbuti *et al.*, 2017) found evidence of increased circulating

thyroid autoantibodies in depressed and mixed episode bipolar patients and pointed at a study on bipolar twins that suggests that autoimmune thyroiditis is related to the genetic vulnerability to develop bipolar disease rather than to the disease process itself.

Alterations in the circadian rhythm of TSH have been described, including absence of the normal nocturnal TSH surge that may result in an overall diminution of thyroid hormone secretion (Bartalena *et al.*, 1990). This suggests that there may be a degree of central hypothyroidism in some patients with depression. Furthermore, sleep deprivation, which has an antidepressant effect, leads to restoration of TSH and an elevation in the levels of T_4 and T_3 (Parekh *et al.*, 1998).

Depression in Thyroid Disease

Hypothyroidism

Hypothyroidism indicates any degree of thyroid hormone deficiency. The epidemiology and causes of this are described in the chapter on Hypothyroidism. Studies on adult patients with hypothyroidism have demonstrated decreased cerebral blood flow and consumption of oxygen and glucose (27% below normal) (Bauer *et al.*, 2009; Kinuya *et al.*, 1999). Results from positron emission tomography (PET) studies indicate that TSH levels correlate inversely with global and regional blood flow as well as cerebral glucose metabolism. In addition, when PET studies were performed in individuals with severe hypothyroidism of short duration, the brain activity was globally reduced without the regional modifications observed in primary depression. As noted previously, T_3 in the brain is derived from deiodination of T_4 and intracerebral generation of T_3 increases as serum concentrations of T_4 decline, to maintain the intracellular T_3 concentrations until serum T_4 has been depleted. Depression has been described in all grades of hypothyroidism (Thomsen *et al.*, 2005). The occurrence of depression is believed to be higher in those who have a history of a first-degree relative with depression, but it has not been studied if this also relates to first degree relatives more often having thyroid autoimmunity. One study showed that the presence of thyroid autoimmunity may be more important for depression than hypothyroidism per se (Watt *et al.*, 2012), which may be related to an occurrence of Hashimoto's encephalopathy in some patients (Montagna *et al.*, 2016). Up to 10% of patients admitted for treatment of depression are found to have subclinical or frank hypothyroidism. However, in a large study of patients with subclinical hypothyroidism depression was not associated with increased depressive symptoms among older adults at high cardiovascular risk (Blum *et al.*, 2016). Clinical manifestations are indistinguishable from non-thyroid-related depression. Response is usually refractory to antidepressants alone; on certain occasions, it has also been resistant to thyroid hormone replacement.

Hyperthyroidism

Hyperthyroidism can be seen in up to 3% of individuals over 60 years of age. Typically, Graves' disease is still the most common cause of thyrotoxicosis in the elderly in some populations, but toxic multinodular goiter or adenomas are more frequent than they are in young people, and very prevalent in populations with current or recent low iodine intake (Laurberg *et al.*, 2006). The classic findings of hyperthyroidism are not always seen in the elderly. The term "apathetic thyrotoxicosis" has been used to address such a condition, which may be associated with depressive symptoms (see **Table 4**), that are relieved by antithyroid treatment. The laboratory data show a suppressed TSH with or without frank elevation of T_4 and T_3. In studies of patients with thyrotoxicosis, depression has been documented in up to 30%–60% of the cases, although such a high prevalence is controversial. Other studies showed much lower prevalence (Bove *et al.*, 2014), and subclinical hyperthyroidism with suppressed TSH and normal circulating thyroid hormones did not seem to have a higher depression tendency in one study (Almeida *et al.*, 2011), but probably in another (Blum *et al.*, 2016).

Thyroid Hormone Supplementation in Depression

In the evaluation of thyroid hormone as adjuvant therapy for depression, there is a need to exclude patients with borderline TSH elevation as well as those with detectable antithyroid antibodies. This population may respond favorably to thyroid hormone

Table 4 Manifestations of apathetic thyrotoxicosis

- Anorexia
- Apathy
- Depression

- Weight loss
- Constipation
- Atrial fibrillation
- Angina exacerbation
- Muscle atrophy

supplementation simply because of underlying hypothyroidism. In addition, when variables of thyroid function are evaluated, the antithyroid peroxidase (anti-TPO) antibody should be included. It is conceivable that patients with evidence of autoimmune thyroid disease might benefit from treatment with levothyroxine because the treatment corrects a cryptic underlying decrease in thyroid function. Patients with rapid cycling bipolar disease may benefit from pharmacological doses of levothyroxine. Such cases may reflect an aberrant expression of hypothyroidism. In studies involving thyroid hormone as adjuvant therapy in depression, T_3 has been used more broadly than T_4 (Joffe, 2011). Cooke and colleagues reported that T_3 augmented the response to antidepressant therapy in T_4-replaced hypothyroid patients in a randomized controlled trial during a 3-week period (Cooke *et al.*, 1992). Joffe found T_3 to be significantly more effective than T_4 in patients with depression who did not respond to TCAs. However, because T_4 equilibrates in tissues more slowly than does T_3, 6–8 weeks of T_4 therapy may be required for adequate comparison of its efficacy with the more rapidly acting T_3 (Joffe and Singer, 1990).

Thyroid Hormone Use to Hasten or Enhance Antidepressant Response

When the hormone is added to the antidepressant at the outset of the study (and the patients therefore are not selected as nonremitters) it is conceptualized as an enhancement study (Joffe, 2011).The therapeutic response of antidepressants is delayed up to 1 month. Therefore there is a tradition for attempts to hasten this effect. All such studies on thyroid hormones and TCAs are more than 40 years old and employed T_3 as accelerator of a response. The studies included small number of patients, poorly defined patient groups and suboptimal dosing but showed promising results (Joffe, 2011). The four published studies on SSRIs point in different directions with one showing a hastened effect (Posternak *et al.*, 2008), two showing an enhanced effect (Cooper-Kazaz *et al.*, 2007; Posternak *et al.*, 2008) and two studies showing no effect (Appelhof *et al.*, 2004; Garlow *et al.*, 2012).

Thyroid Hormone Use to Augment the Effect of Antidepressants

After 1st line treatment for depression slightly less than one third remit and less than half of the patients respond (Trivedi *et al.*, 2006b). With a second line strategy of either shift or augmentation only further 25% receive remission or response (Rush *et al.*, 2006; Trivedi *et al.*, 2006a). As a consequence, there is much interest in the possibility that augmentation therapy. As mentioned T_3 has been the most widely used in doses from 20 to 50 μg daily. In 8 of 11 open label studies more than 50% of the patients showed response (Joffe, 2011). In only 3 of the studies fewer patients responded—one on inpatients were all 14 patients showed no response (Birkenhager *et al.*, 1997), one with only 5 of 20 patients resistant to imipramine and interpersonal therapy responded (Thase *et al.*, 1989) and one with 7 of 20 responding (Iosifescu *et al.*, 2005). In one blinded add-on of T_3 study on patients nonresponsive to amitriptyline or imipramine 8 of 12 patients showed marked response (Goodwin *et al.*, 1982). One of the largest randomized studies published to date, took 51 nonresponders to TCAs and added either T_3, lithium, or placebo to the antidepressant and found that 10 of 17 subjects responded to T_3, nine of 17 responded to lithium and three of 16 responded to placebo (Joffe *et al.*, 1993). The largest study was part of the STAR*D trial, on 142 patients who had not achieved remission or who were intolerant to an initial prospective treatment with citalopram and a second switch or augmentation trial (Nierenberg *et al.*, 2006). They were randomly assigned to augmentation with lithium ($N = 69$) or with T_3 ($N = 73$) for up to 14 weeks. It was found that remission rates with lithium and T(3) augmentation were modest and did not differ significantly (16% and 25% respectively). But the lower side effect burden and ease of use of T_3 augmentation suggest that it has slight advantages over lithium in this patient group. Another double blind cross over study failed to find difference between T_3 and placebo (Gitlin *et al.*, 1987). However, it only included 16 patients who showed no responsiveness to just 4 weeks of imipramine whereafter T_3 was added for only 2 weeks before cross over, which can make it difficult to interprete the response.

Studies on T_4 as augmenting agent are few, they are carried out on few patients of different subtypes of depression with doses of T_4 of 100–500 μg daily. They all showed some antidepressant effect (Joffe, 2011). In a study by Stamm *et al.* (2014) 62 bipolar depressed patients were randomized to levothyroxine or placebo adjunctive to continuing treatment with mood stabilizer and/or antidepressant medication. The T_4 group did numerically but not statistically better than the placebo group.

Moreover, studies have focused on whether a relationship can be detected between the swiftness in reaching a clinical remission or the risk of recurrence and the baseline thyroid hormone levels. Cole *et al.* (2002) observed that both lower values of free T_4 and higher values of TSH were significantly associated with longer times to remission, that is, slower response to treatment in bipolar depressed patient. Correspondingly, Amann *et al.* (2017) in a study on comorbidity found that particularly hypothyroidism was associated with an increased risk of manic relapse in bipolar disorder. The authors questioned whether adjuvant therapy with thyroid hormone may optimize the management of patients presenting in the depressive phase of bipolar disorders. Joffe and colleagues (Joffe and Marriott, 2000) looked at the relationship between basal thyroid hormone levels and the life course of depressive illness in 75 outpatients with unipolar major depressive disorder. The significant positive predictors of recurrence were comorbid anxiety, number of previous episodes of depression, prolonged course of episodes, and level of T_3. An increase in T_3 was associated with a 22% decrease in the risk of recurrence.

Although adjuvant therapy may help nonremitters, observers must be cautious about this conclusion for many reasons. First and most important, we do not know with certainty which clinical and/or biochemical variables determine the subset of depressed patients who will benefit from adjuvant treatment. Second, the clarification of the thyroid status was not universally reported in

the studies that are available, and unrecognized "subclinical" hypothyroidism or autoimmune thyroid disease could have led researchers to overestimate the therapeutic response to T_3. Third, the relationship between T_3 dose and clinical response is unclear. Fourth, because the longest duration of T_3 administration in studies has been only a few weeks, the extent of treatment remains imprecise, although it has been recommended by some investigators that thyroid augmentation be discontinued 8–12 weeks after a response and then reinstituted if symptoms recur. Fifth, studies regarding long-term side effects from use of thyroid hormones in depressed patients are not available, and when instituting this form of therapy, the potential effect of thyroid hormone over-replacement on risk of heart arrhythmias, osteoporosis and muscle loss/myopathy has to be strongly taken into account, as indicated in recent recommendations on safety monitoring (Rosenthal *et al.*, 2011; Touma *et al.*, 2017). Finally, longer and larger randomized, double-blind, placebo-controlled trials are needed.

Use of Thyrotropin-Releasing Hormone in Refractory Depression

The therapeutic use of TRH in mood disorders is based on the fact that this hormone has direct effects on the CNS independent of pituitary and thyroid stimulation. High-affinity receptors to TRH are found throughout the brain especially, in the amygdala and the hippocampus, and modulate the effects of serotonin and dopamine. In addition, in some studies the concentrations of TRH in the CSF of untreated individuals with mood disorders were elevated. It remains unclear whether this corresponds to a natural compensatory mechanism or to a pathological occurrence. Marangell *et al.* (1997) administered 500 μg of TRH intrathecally in a double blinded fashion to eight drug-free patients with refractory depression compared to sham spinal punctures a week apart. Five patients had a clinically significant, rapid, and robust but short-lived improvement in mood after TRH infusion, but not after the sham puncture. Systemic thyroid function was unaltered. Intrathecal TRH might thus be a positive modulator of mood, but this has not been pursued in further studies.

Conclusions

Hypothyroidism predisposes patients to depression that may be wholly reversed by thyroxine replacement. When first seen for depression, most patients have normal circulating TSH, T_3, and T_4. However, 15% may have subclinical hypothyroidism and have a TSH hyper-response to TRH stimulation. Another 10%–15% may show evidence of autoimmune disease. In this setting, thyroxine may alleviate depressive symptoms alone or in combination with antidepressants. The clinical features of depression often resemble those of hypothyroidism and may reflect brain hypothyroidism despite systemic euthyroidism. The mechanism may be related to impaired conversion of T_4 to T_3 in the brain due to inhibition of type II 5′-deiodinase, possibly by increased levels of circulating cortisol and/or reduced transport of T_4 across the blood–brain barrier. Another possibility is a functional polymorphisms in type 1 deiodinase, DIO1-C785T, which was associated with efficacy of T3 but not placebo supplementation, and at baseline a lower serum T3 was found (Cooper-Kazaz *et al.*, 2009). This would provide a possibility for predicting a positive response of adjuvant T3 therapy in individual depressed patients. Adjuvant therapy with T_3 for patients receiving antidepressant medication has been postulated to augment responsiveness to therapy in about a quarter of cases of refractory depression, possibly by correcting brain hypothyroidism. TCAs and SSRIs have been reported to inhibit TRH gene expression in vitro, a fact that might explain the normalization of serum T_4 levels following treatment; TCAs also enhance the conversion of T_4 to T_3 in the brain, providing another potential explanation for their therapeutic efficacy in depression. A possible role of intrathecal TRH administration as modulator of mood requires further studies.

Measuring Impact of Benign Thyroid Diseases on Quality of Life

Torquil Watt, Copenhagen University Hospital, Copenhagen, Denmark

Glossary*

GO-QLS Graves' ophthalmopathy quality of life scale
GO-QOL Graves' orbitopathy quality of life instrument
Item A question (including any introductory legends) and its associated response options, within a PRO
Multi-item scale A condensation of responses to a number of items. Most often a simple summation of arbitrary numerical weights associated with each response option
Patient-reported outcome (PRO) and Patient-reported outcome measure (PROM) Any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else (FDA 2009)
QOL Thyroid eye disease quality of life scale
Quality of life (QoL) The subjective assessment of the impact of disease and its treatment across the physical, psychological, social, and somatic domains of functioning and well-being (Revicki *et al.* 2000)
Short Form (36) Health Survey (SF-36) The most widely used instrument for measuring generic quality of life (or rather: health status), that is, independent of any specific disease or condition
ThyDQoL Underactive thyroid-dependent quality of life questionnaire
ThyPRO Thyroid-related patient reported outcome
ThyPRO-39 Thyroid-related patient reported outcome, 39-item version
ThySRQ Thyroid symptom rating questionnaire
ThyTSQ Thyroid treatment satisfaction questionnaire

Introduction

In recent years, a paradigm shift has occurred in medical care. Patient-centered care has become the goal in most clinical settings and the value of an intervention is increasingly judged by its ability to maximize health, with an emphasis on the degree to which longevity and health-related quality of life (QoL) are impacted. QoL assesses the patient's point of view concerning how they feel and what they are able to do in everyday life. It has been defined as the subjective assessment of the impact of disease and its treatment across the physical, psychological, social, and somatic domains of functioning and well-being (Revicki *et al.*, 2000, Barofsky, 2012). QoL is measured by standardized questionnaires (patient-reported outcomes, PRO), where responses to questions are converted to and summarized in numeric values that quantify the attributes being measured. Typically, multi-item scales are used, where several items measuring the same construct are summarized into one scale, to reduce random measurement error and to simplify reporting. Findings are generally ordered within three main domains: physical, mental and social/participation, in accordance with the definition of health-related QoL (Ware, 2003).

For QoL assessments to be valid, it is essential to apply tools with appropriate measurement properties for the population and research question under study. The International Society of Quality of Life Research recently recommended minimum requirements for PROs used in patient-centered outcomes and comparative effectiveness research (Reeve *et al.*, 2013). The definitions and recommendations are presented in **Table 1**.

There are two broad categories of QoL measures, disease specific and generic measures. Disease specific QoL measures typically emphasize evaluation of symptoms, functioning and patient perceptions that relate to a narrowly defined disease or condition. Generic measures assess broad categories of functioning and well-being that can be affected by a multitude of conditions, and enable comparisons between the relative burdens of diseases and their treatment benefits. Both types of measures have been widely used to quantify QoL. However, because generic QoL measures favor broad functional health and well-being concepts over symptoms and problems that are more specific, they are sometimes found to be less sensitive to differences among clinically relevant groups and to be less responsive to small changes in health (Guyatt *et al.*, 1999, Patrick and Deyo, 1989).

Thyroid diseases affect QoL (Bianchi *et al.*, 2004, Watt *et al.*, 2006, Elberling *et al.*, 2004, Mishra *et al.*, 2013, Cramon *et al.*, 2015, Bove *et al.*, 2014), work role function (Nexo *et al.*, 2014, Nexo *et al.*, 2015), as well as morbidity and mortality (Brandt *et al.*, 2012, Thvilum *et al.*, 2013). A model of the theoretical relationships between thyroid pathophysiology and QoL impact is illustrated in **Fig. 1**. Pathophysiological mechanisms lead to physical and mental symptoms and impair functioning and well-being, which leads to impaired participation in life and overall QoL.

Generic measures can be applied in patients with thyroid diseases; for example, the Short Form (36) Health Survey (SF-36) has been applied in a number of studies. This may be advantageous, when comparison with other patient groups is

Please also see Table 1 for descriptions of concepts concerning measurement properties.

 doi:10.1016/B978-0-12-801238-3.64960-7

Table 1 Measurement properties: patient-reported outcomes measurement properties—definitions and recommended minimum requirements

Measurement property	*Definition*	*Recommendation*
Conceptual and measurement model	The conceptual model provides a description and framework for the targeted construct(s) to be included in a PRO measure. The measurement model maps the individual items in the PRO measure to the construct	A PRO measure should have documentation defining and describing the concept(s) included and the intended population(s) for use. In addition, there should be documentation of how the concept(s) are organized into a measurement model, including evidence for the dimensionality of the measure, how items relate to each measured concept, and the relationship among concepts included in the PRO measure
Reliability	The degree to which a PRO measure is free from measurement error	The reliability of a PRO measure should preferably be at or above 0.70 for group-level comparisons, but may be lower if appropriately justified. Reliability can be estimated using a variety of methods including internal consistency reliability, test–retest reliability, or item response theory. Each method should be justified
Internal consistency reliability	The degree of the interrelatedness among the items in a multi-item PRO measure	
Test–retest reliability	A measure of the reproducibility of the scale, that is, the ability to provide consistent scores over time in a stable population [2]	
Validity	The degree to which a PRO instrument measures the PRO concept it purports to measure	
Content validity	The extent to which the PRO measure includes the most relevant and important aspects of a concept in the context of a given measurement application	A PRO measure should have evidence supporting its content validity, including evidence that patients and experts consider the content of the PRO measure relevant and comprehensive for the concept, population, and aim of the measurement application.
Construct validity	The degree to which scores on the PRO measure relate to other measures (e.g., patient-reported or clinical indicators) in a manner that is consistent with theoretically derived a priori hypotheses concerning the concepts that are being measured	A PRO measure should have evidence supporting its construct validity, including documentation of empirical findings that support predefined hypotheses on the expected associations among measures similar or dissimilar to the measured PRO
Criterion validity	The degree to which the scores of a PRO measure are an adequate reflection of a "gold standard."	
Responsiveness	The extent to which a PRO measure can detect changes in the construct being measured over time	A PRO measure for use in longitudinal research study should have evidence of responsiveness, including empirical evidence of changes in scores consistent with predefined hypotheses regarding changes in the measured PRO in the target population for the research application
Interpretability of scores	The degree to which one can assign easily understood meaning to a PRO measure's scores	A PRO measure should have documentation to support interpretation of scores, including what low and high scores represent for the measured concept
Minimal important difference (MID)	The smallest difference in score in the outcome of interest that informed patients or informed proxies perceive as important, either beneficial or harmful, and that would lead the patient or clinician to consider a change in the management	
Burden	The time, effort, and other demands placed on those to whom the instrument is administered (respondent burden) or on those who administer the instrument (investigator or administrative burden)	A PRO measure must not be overly burdensome for patients or investigators. The length of the PRO measure should be considered in the context of other PRO measures included in the assessment, the frequency of PRO data collection, and the characteristics of the study population.
Translation of the PRO measure		A PRO measure translated to one or more languages should have documentation of the methods used to translate and evaluate the PRO measure in each language. Studies should at least include evidence from qualitative methods (e.g., cognitive testing) to evaluate the translations

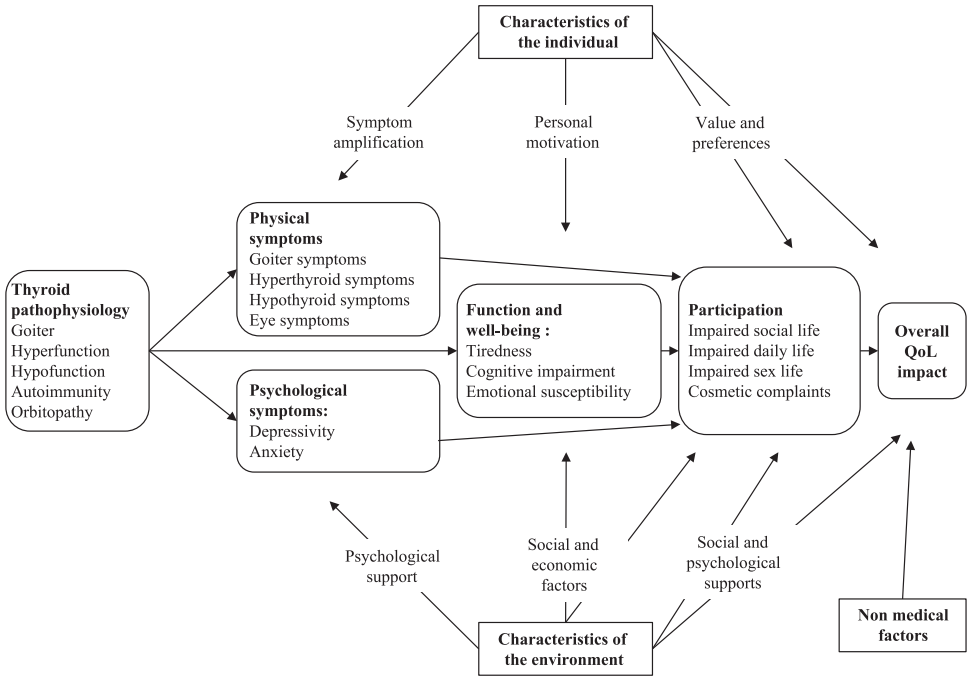

Fig. 1 Conceptual Model linking clinical pathophysiological variables and thyroid-relevant aspects of QoL. Based on Wilson, I. B. and Cleary, P. D. (1995). Linking clinical variables with health-related quality of life. A conceptual model of patient outcomes. *The Journal of the American Medical Association* **273**, 59–65.

important, for example, in descriptive studies quantifying impact on QoL of thyroid diseases overall. However, a thyroid-specific measurement has been found more sensitive to change than a generic measure (Watt *et al.*, 2014a), and such measurements thus are more relevant in studies evaluating effect of treatment and course of disease as well as when comparing clinically different groups of thyroid patients.

Focus in this article is thus on the properties of existing thyroid-specific PRO measures.

Thyroid-Specific PRO Measures

Instruments for Patients with Hyperthyroidism

The Hyperthyroidism Complaint Questionnaire (HCQ) measures "somatic and mental discomfort … typical for patients suffering from hyperthyroidism" (Fahrenfort *et al.*, 2000) and consists of 31 dichotomous items requiring a dual response: currently present and formerly present; two overall summary measures are generated: Past and Present Complaints, respectively. Eleven items concern physical symptoms, 6 are about emotional distress, 6 evaluate fatigue, 3 concern cognitive functions whereas existential problems, sleeping problems, anxiety, sexual function and social function were covered by one item each. The development was based on interviews with a small sample of patients (not documented). In a study including 303 patients previously treated for hyperthyroidism, internal consistency reliability (**Table 1**), was 0.93 for both scales. Item-total correlations were generally low, some were 0.21, questioning the justification of the overall summary score. A relationship between overall score and degree of self-reported thyroid dysfunction was found, but no further description of the validity of the instrument has been provided. The HCQ has not been used in any subsequent study.

Instruments for Patients with Graves' Orbitopathy

The Graves' Orbitopathy Quality of Life Questionnaire (GO-QOL) is a disease specific QOL-instrument for patients with Graves' orbitopathy (Terwee *et al.*, 1998, 1999, 2001). The development was based on a review of existing eye QOL-measures, as well as open-ended questionnaires from 24 patients and was pretested in 8 patients. Detailed description of these content validity studies have not been published. The GO-QOL consists of 16 items summarized in two scales: "Visual Functioning" and "Cosmetic Complaints"; that is, two distal QoL-concepts, albeit not as distal as "overall QoL". No proximal concepts such as physical symptoms are measured. Subsequent studies comprising 70–164 well-described patients have shown excellent test-retest and internal consistency reliability (Terwee *et al.*, 1998, 1999) and have supported its construct validity (Terwee *et al.*, 1998, 1999, 2001) in terms of exploratory factor analyses and examinations of con- and divergent validity. Further, good responsiveness was found (Terwee *et al.*, 2001). Modern psychometric methods have not been applied. According to the European Group of Graves' Orbitopathy (EUGOGO) website, the GO-QOL is available in 15 languages (www.

eugogo.eu). The Korean version has been clinically (not cross-culturally) validated (Choi *et al.*, 2012). GO-QOL has been applied in numerous subsequent clinical studies (Terwee *et al.*, 2002, Marcocci *et al.*, 2011, Kashkouli *et al.*, 2011, Park *et al.*, 2004, Wickwar *et al.*, 2015, Prummel *et al.*, 2004, European Group on Graves' Orbitopathy (EUGOGO) *et al.*, 2009, Ponto *et al.*, 2011, 2015, Fichter *et al.*, 2013, Jellema *et al.*, 2014, Lin *et al.*, 2013, Bartalena *et al.*, 2012, Dickinson *et al.*, 2004, Wemeau *et al.*, 2005). Cross-cultural validity does not seem to have been quantitatively assessed, but a forthcoming validation of the English version is described in a published trial protocol (Rajendram *et al.*, 2008). A non-validated modified version has also been applied in one clinical study (Finamor *et al.*, 2004).

In an attempt to develop a measure with high correlation with clinical variables, Yeatts developed the nine-item *GO-QLS* questionnaire (Yeatts, 2005). The development was based on analyses of responses from 256 patients to 105 existing generic and eye-specific items. The best discriminating items fitting a one-factor analysis were selected. The resulting nine-item measure does not seem to have been implemented in subsequent clinical studies yet.

Recently, a three-item Graves' orbitopathy-specific PRO has been developed, the TED-QOL (Fayers and Dolman, 2011). It consists of three visual analogue scale-like single items measuring overall QoL impact, interference with daily activities and satisfaction with appearance, respectively. The development was very briefly described, test-retest reliability was found to be good, convergent and discriminant validity was confirmed, compared with similar or dissimilar aspects from GO-QOL and GO-QLS and meaningful correlation with clinical variables were found. It has been translated and validated (not cross-culturally though) in Korean (Son *et al.*, 2014), but clinical studies applying the measure or studies reporting other important aspects of validity such as responsiveness, have not yet been published.

Instruments for Patients with Hypothyroidism

For the purpose of detecting patients developing hypothyroidism in a follow-up system after radioiodine-treatment, Barker and colleagues used a patient-completed questionnaire about nine classical symptoms of hypothyroidism (Barker and Bishop, 1969, Gardner and Barker, 1975). The evaluation of the instrument focused on its screening abilities, that is, ability to detect biochemical hypothyroidism. As with the Zulewski index, a simple summation of the number of symptoms were as effective as more complex weighting and scoring systems and if patients with five or more symptoms was referred to further diagnostic procedures, this would include 70% of the hypothyroid and 40% of the euthyroid patients.

For the analysis of the relationship between symptoms and biochemical thyroid status, Canaris and colleagues developed a 16–17 item hypothyroid symptom index (Canaris *et al.*, 1997), sometimes referred to as the *Colorado Thyroid Symptom Survey*. The questionnaire was developed on the basis of a combination of a literature study and expert evaluation. It was tested for readability and with regards to its ability to discriminate between hypothyroid and euthyroid patients. A modest correlation with TSH was found.

A modified version of the questionnaire was used in the large Colorado Thyroid Disease Prevalence Study (Canaris *et al.*, 1997) and in a subsequent screening study (Canaris *et al.*, 2013). Generally, low discriminating properties of individual symptoms were found. The proportion of hypothyroid patients increased with increasing number of symptoms present and with increasing weighted score; the total score had moderate discriminative power.

The *Chronic Thyroid Questionnaire (CTQ)* is a hypothyroidism *and* patient-specific QOL-questionnaire. It consists of 104 items, each representing a specific complaint, covering four domains: "Physical Complaints," "Mood and Emotions," "Energy and General Well-Being," and "Cognitive Complaints" (Jaeschke *et al.*, 1994, 1996). The development of the CTQ was quite thorough. Based on a literature review, a list of symptoms or problems related to hypothyroidism, potentially responsive to treatment and likely to influence the QoL of the patients, was generated (Jaeschke *et al.*, 1994). This list was expanded through interviews with endocrinologists and patients. The scoring of the CTQ is unusual: Of the 104 complaints, each patient identifies applicant items and rates the degree of discomfort represented by these items. Thus, for a patient with two of the 104 complaints, the instrument consists of two items, whereas a patient with 22 complaints rates 22 items. This approach increases the potential sensitivity of the measure to improvements in the individual patient, but it makes between-patient comparisons and interpretations of what is actually measured difficult and new complaints arising from intervention are ignored in longitudinal studies. The CTQ has not been validated in any subsequent studies, but applied in one subsequent study (Jorde *et al.*, 2006). A modified version was applied in two other studies ((Clyde *et al.*, 2003, Hoang *et al.*, 2013); however, the modifications were not described.

The *Thyroid Symptom Questionnaire (TSQ)* consists of 12 items: 6 items on cognitive complaints, 5 items on physical symptoms and 1 item on fatigue, summarized in one overall score (Saravanan *et al.*, 2002). The items were selected on the basis of patient-responses to a notice in the British Thyroid Foundation newsletter, inviting patients to tell about persisting complaints despite replacement therapy with L-thyroxine. Moderate correlations with the generic QOL-questionnaire General Health Questionnaire (GHQ-12) were found, but no other evidence of validity has been presented. The measure does not seem to have been adopted in subsequent clinical studies.

The *Underactive Thyroid-Dependent Quality of Life Questionnaire (ThyDQoL)* (McMillan *et al.*, 2004). ThyDQoL is a 20-item questionnaire measuring impact of hypothyroidism on various domains of QOL: overall QoL (2 items), limitations in usual activities (6 items), social function (4 items), fatigue (2 items), emotional well-being (2 items), sexual function, cosmetic complaints, weight problems, and bodily discomfort (1 item each). Items are scored individually in a two-step procedure: both impact and importance of the items are rated, and the item score is derived by multiplication of these two ratings. An average weighted impact score is obtained by summing all applicable weighted domain scores (i.e., not the two overall QoL items), divided by number of domains applicable to the individual. Content validity was ensured through interviews with 38 hypothyroid

patients, as part of the development process (McMillan *et al.*, 2004). In a subsequent validation study, appropriate internal consistency reliability was found. Construct validity in terms of scale validity as evaluated by exploratory factor analyses was also examined. Although the authors conclude that an identified two-factor solution was un-interpretable, it could be argued, that a picture of one set of items clustering around an aspect of participation and another around symptoms and well-being within the patient, was indeed drawn (Table 3 in McMillan *et al.* (2008)); but a one-factor solution also seems well justified. Criterion validity was not explicitly addressed, but a tendency towards worse perceived negative impact on QoL was observed among patients with overt hypothyroidism, compared to patients with subclinical disease. One problem with the two-step importance rating approach is the reduced inter-individual comparability of the measure and the susceptibility to a confounding effect of coping. These results regarding validity have been reproduced for the German version (Quinque *et al.*, 2013). In that study, also criterion validity was evaluated (correlation with clinical variables), and only partial support for criterion validity was found; of note, however, only 25 patients and 27 healthy controls were included in the criterion validation study. ThyDQoL has been applied in a clinical study evaluating effect of L-thyroxine on subclinical hypothyroidism (Razvi *et al.*, 2007) and in a study of impact of transient hypothyroidism among patients with thyroid cancer (Smith *et al.*, 2015). In the latter, scores worsened during hypothyroidism, supporting the clinical validity of the measure. Also, it is specified as an outcome in a published trial protocol (Wilkes *et al.*, 2013).

During the development of the ThyDQoL, symptoms related to hypothyroidism were extracted into a separate instrument, the *Thyroid Symptom Rating Questionnaire, ThySRQ* (McMillan *et al.*, 2004). The motivation was the observation, that the symptoms were "too specific in nature to be important for many aspects of life, for example, voice problems, or because some patients were unsure whether they were attributable to hypothyroidism." ThySRQ consists of 15 items, covering both physical, psychological, and functional (tiredness, cognition) symptoms. Items are reported separately, since factor analyses could not support summation (McMillan *et al.*, 2008). Similarly to ThyDQoL, items are completed in a two-step procedure: first, whether it is experienced, then, the extent to which it causes distress. To the authors' surprise, high internal consistency reliability was found. Along with ThyDQoL, it was applied in patients with subclinical hypothyroidism (Razvi *et al.*, 2007) and is included as outcome in a published trial protocol (Wilkes *et al.*, 2013). A simplified version was applied in a study in Brazil; no information regarding method of translation or validation thereof was presented (Vigario Pdos *et al.*, 2013). In a third study applying the measure, an average sum-score was analyzed and reported, despite the evidence against the validity of such an approach (Smith *et al.*, 2015).

In parallel with ThyDQoL and ThySRQ, a *Thyroid Treatment Satisfaction Questionnaire*, the *ThyTSQ*, was developed (McMillan *et al.*, 2004). The questionnaire has two parts: seven items measuring satisfaction with present treatment and four items with past treatment, each rated from 6 (very satisfied) to 0 (very dissatisfied). In a validation study, excellent internal consistency reliability, good acceptance and evidence of unidimensionality, justifying reporting as a single summated scale, for the two multi-item scales (Past and Present Satisfaction) (McMillan *et al.*, 2006). It has been applied in the abovementioned L-thyroxine study (Razvi *et al.*, 2007) and in a published study protocol (Wilkes *et al.*, 2013).

Instrument for all Benign Thyroid Diseases

The *Thyroid-related quality of life patient-reported outcome (ThyPRO)* is 85-item instrument covering all benign thyroid diseases summarized in 13 multi-item and one single-item scale(s): 4 scales measuring physical symptoms (goiter symptoms (11 items), hyperthyroid symptoms (8 items), hypothyroid symptoms (4 items) and eye symptoms (8 items)), 2 scales measuring mental symptoms (anxiety (6 items) and depressivity (7 items)), 3 scales measuring well-being and function (emotional susceptibility (9 items), cognitive complaints (6 items) and tiredness (7 items)), 4 scales measuring aspects of impaired participation (impaired social life (4 items), impaired daily life (6 items), impaired sex life (2 items) and cosmetic complaints (6 items)) and overall QOL impact (1 item). It takes 14 min to complete, on average, and each items is rated on a 5-point Likert scale from no symptoms/problems $=0$ to severe symptoms/problems $=4$. The average score of items in a scale is divided by four and multiplied by 100 to yield thirteen 0–100 scales, with higher scores indicating worse health status. The development was based on a literature review (Watt *et al.*, 2006), interviews with 15 thyroid experts and 80 thyroid patients (Watt *et al.*, 2007) and qualitatively validated and refined in 6 rounds (4–10 patients each round, 31 in total) of cognitive interviewing (Watt *et al.*, 2008). Subsequently it was substantially validated using classical (Watt *et al.*, 2009, Rasmussen, 2016) and modern (Watt *et al.*, 2014c, Watt *et al.*, 2014b) psychometric methods as well as clinimetrics (Watt *et al.*, 2010, Watt *et al.*, 2014a) which found good internal consistency and test-retest reliability, appropriate construct validity and measurement invariance, as well as good discriminant validity and ability to detect relevant clinical change. As the only thyroid-related PRO, cross-cultural validity has been approved (Watt *et al.*, 2015a) and by October 2017 linguistically validated versions are available in 19 languages and undergoing adaptation in another 11 languages. ThyPRO (or its short-form ThyPRO-39, see below) is or has been in use in more than 60 clinical trials world-wide (personal communication). Published studies includes cross-sectional, longitudinal and interventional studies in patients with autoimmune hypothyroidism (Winther *et al.*, 2016, Watt *et al.*, 2012, Stott *et al.*, 2017), cross-sectional and longitudinal studies of hyperthyroidism (Cramon *et al.*, 2016, Bove *et al.*, 2014, Bukvic *et al.*, 2015, Taieb *et al.*, 2016), cross sectional, longitudinal as well as interventional studies on non-toxic goiter (Cramon *et al.*, 2015, Bukvic *et al.*, 2014, Mishra *et al.*, 2013, Zivaljevic *et al.*, 2015, Fast *et al.*, 2014, Graf *et al.*, 2011) and two published randomized clinical trial (RCT) protocols (Winther *et al.*, 2014, Watt *et al.*, 2013). Due to the coverage across all benign thyroid diseases, the instrument is rather lengthy.

The *Short form thyroid-related quality of life patient-reported outcome (ThyPRO-39)* was extracted from the 85-item ThyPRO, based on previous patient interviews, validation studies and item response modeling (Watt *et al.*, 2015b). It consists of 39 items, summarized in the same scales as the 85-item version, except for impaired sex life, which was omitted. In addition, mental symptoms, well-being and function and participation scales were further summarized in one overall composite score. High level of agreement between the two versions was found and good measurement properties were preserved, when repeating the psychometric and clinimetric analyses described above. Although the extracted version had appropriate measurement properties, it has not yet been validated as a stand-alone measure.

Comparison of Instruments

Of the identified instruments, only few have been developed in accordance with current standards, as shown in **Table 2**: Three instruments for patients with Graves' orbitopathy: GO-QOL, GO-QLS, and TED-QOL and one triplet of instruments for patients with hypothyroidism, ThyDQoL, ThySRQ and ThyTSQ and ThyPRO/ThyPRO-39, for patients with any benign thyroid disease, and thus the only PRO validated for use among patients with non-toxic goiter and hyperthyroidism.

[a]Not based on patient-interviews.
[b]A total score was not fully justified by factor analyses.
[c]No significant relationship with clinical variables, but study design not specifically aimed at criterion validity.
[d]PRO scores correlated in a meaningful direction with some clinical variables. Criterion validity only partially supported.
[e]MID has been published as a conference paper and responsiveness data as well as general population norms offer interpretability-information.
[f]Cross-cultural validity not yet quantitatively assessed.
[g]Only applicable to patients currently receiving treatment.
[h]High level of agreement, repetition and nestedness allows extrapolation from the full version validation studies.
Description of development and validation, including number of associated studies published, in accordance with the terminology presented in Table 1.

Spectrum of Concepts Measured by Thyroid-Specific PROs

As evident from Table 2, some instruments focus on very specific manifestations of disease impact, for example, physical symptoms (Barker and Canaris indices, for example), whereas other focus on broader aspects of QoL, for example, impact on social functioning (TED-QLS, for example). These broader aspects may also be termed "distal" concepts (corresponding to the right, "downstream" part of the theoretical QOL-model (Fig. 1)), whereas aspects more closely associated with a particular condition may be referred to as" proximal" aspects (corresponding to the left part of the QOL-model). Disease- or condition-specificity of an instrument may in fact be obtained with both categories. Proximal outcomes may do so by selecting symptoms specific for, or very relevant to, a specific condition. Distal outcomes may acquire specificity by attributing the concept in focus to the relevant condition. As an example of the former approach, the Canaris index measures symptoms characteristic of hypothyroidism. In contrast, the TED-QLS asks about impact of eye-disease on overall QoL, daily function and well-being, using only one item for each of these. This latter approach is tempting, due to the ease of administration, and because it can easily be applied to a wide variety of diseases, using the same format. However, with this approach, precision and reliability is a concern. Moreover, the standard approach for ensuring content validity may be less suited in this situation: In a study comparing TED-QLS with GO-QOL and GO-QLS, patients were asked if the items covered their situation. Since the questions are so broad, it is difficult to bring up an issue, which cannot be categorized under one of these aspects. In such a situation, a more elaborate approach is needed, to evaluate content validity. For example, in-depth cognitive interviewing, exploring whether patients truly consider all relevant subaspects, when they formulate their replies to such broadly formulated questions. Proximal items offer the advantage of providing cues for comprehension and retrieval to the respondent. ThyPRO includes both proximal and distal aspects, reported separately. Proximal aspects are administered first, to stimulate retrieval, and distal aspects are administered in the end of the questionnaire. Aspects measured by other instruments not covered by ThyPRO are "treatment satisfaction" and "positive effects of the disease", measured in ThyDQoL and ThyTSQ, respectively. Thus, studies focusing on treatment satisfaction among patients with hypothyroidism could use the ThyTSQ.

Future Directions

Availability of a validated PRO for patients with thyroid diseases enables studies evaluating currently unresolved clinical questions. For example, studies evaluating if treatment of mild or subclinical thyroid disease improves QoL, including the question of whether certain subgroups (e.g., various strata of TSH-elevation) benefit more than others.

It could also be argued, that the role of thyroxine/thyronine combination therapy for patients not satisfactorily treated with standard thyroxine supplementation alone is not clarified yet. A pragmatic RCT, testing the treatment approach suggested by the European Thyroid Association (Wiersinga *et al.*, 2012), or a new slow-release combination tablet, could be set up, including clinical and genetic biomarkers (e.g., deiodinase gene polymorphisms), preferably in a multi-cultural setting.

A study evaluating if various TSH-targets lead to differences in QoL would also provide important clinical insights into a previously debated and studied issue (Jonklaas *et al.*, 2014, Walsh *et al.*, 2006, Wartofsky and Dickey, 2005, Surks *et al.*, 2005).

Ideally, QoL-outcome of the various treatment modalities available for Graves' disease (including titration vs. block-replacement (Abraham *et al.*, 2005)) should also be evaluated in RCTs in analogy to a previous unique Swedish study (Torring *et al.*, 1996).

No studies on routine clinical use of PRO assessments among patients with thyroid diseases have been published.

Several features of thyroid diseases could make routine PRO assessments particularly well suited for these patients: (1) Thyroid hormones affect many organ systems and have profound effect on the central nervous system and thereby mental health. (2) QoL-issues have major influence on choice of intervention (e.g., physical symptoms and cosmetic concern in non-toxic goiter). (3) Some patients experience reduced QoL despite adequate thyroid function on treatment and may experience lack of congruence between the focus of the endocrinologist and themselves (Nexo *et al.*, 2015). (4) The diseases are often chronic and occur in all ages, including during working life. (5) Thyroid diseases are rarely life-threatening, and thus focus on and relevant addressment of QoL-issues may have relatively large impact. In contrast, most research on routine use of PRO have been among patients with cancer, who face a life-threatening disease, serious adverse effects, potential disease progression and treatment failure.

From a scientific point of view, thyroid diseases may also be an advantageous group for studies of the effect of PRO-implementation in clinical practice. For example, independent markers of management (e.g., TSH) exist and can be used as independent effect markers. Also, the existence of different, yet linked, thyroid diseases allows for comparison of effects among the different diagnostic groups.

As regards ThyPRO, several features position it as a good candidate for a PRO-implementation trial. First, it is relevant to patients and clinicians (Watt *et al.*, 2007), easy to understand and complete (Watt *et al.*, 2008), framed within a clinical and theoretical understanding (Watt, 2008; Watt *et al.*, 2014b) and with good measurement properties, including responsiveness to treatment. Second, it encompasses both proximal (symptoms) and distal (participation, overall QoL) aspects, enabling analyses of differing effects and uses of such. Third, despite being disease-specific, general population norms are available for interpretation-optimization.

PROs have become a natural, integral part of clinical research. Although the optimal use in routine clinical practice still has to be identified, clinical implementation for descriptive purposes seems well justified at present. Thereby data regarding usual course of disease and treatment can be described and possibly predictors for reduced QoL after treatment can be identified. Such data

could improve other patient-engaging activities, such as shared decision-making, for which a tool has recently been developed (Brito *et al.*, 2015). More detailed information about impact on QoL can improve such tools.

Further patient-engagement, also in design of clinical trials, is recommended.

DEDICATION

Professor Luciano Martini, 1927–2017

The other Editor in Chief of the Encyclopedia, Professor Luciano Martini, passed away on July 13th, 2017. He was an internationally acclaimed authority in the field of endocrinology, in particular neuroendocrinology, a brilliant and imaginative scientist, and an impressive and erudite scholar.

Luciano achieved the venerable age of 90, and his long career was full of outstanding scientific achievements, leadership positions in academia and in scientific societies, academies, and committees.

Luciano received his MD degree from the University of Milan in 1950. He then rapidly progressed through junior academic ranks up to the position of Professor and Chairman of the Department of Pharmacology at the University of Perugia in 1968, and subsequently, in 1972, he returned to his *alma mater*, the University of Milan, as full Professor and Chairman of the Department of Endocrinology, a post he held until 2001. He served in Milan as director of the training and research program entitled Physiology of Reproduction for nearly 20 years and attracted to his team top-class Italian and foreign scientists to address his main research interests of neuroendocrine regulation of reproductive functions.

Scientific severity, ethical integrity, fine perception, and deep farsightedness describe best Luciano's character as a scientist. He created in his institute a scientific research group devoted to experimental endocrinology, which grew over the years in size and visibility and became widely recognized internationally. Luciano published more than 400 peer-reviewed and highly cited papers mainly in the fields of neuroendocrinology, endocrine oncology, physiology of reproduction, and steroid and energy metabolisms.

Luciano was a prolific editor of scientific books and journals, which include the two volumes of *Neuroendocrinology* and the nine biennial volumes of *Frontiers in Neuroendocrinology*. He was Editor in Chief of *Comprehensive Endocrinology* published in 12 volumes and the first Edition of *Encyclopedia of Endocrine Diseases*. He served as President in many national and international scientific societies including the International Society of Neuroendocrinology, the Italian Society of Endocrinology, the International Society of Endocrinology, and the European Federation of Endocrine Societies. For his scientific achievements Luciano received honorary doctorates in the universities of Liège, Santiago de Compostela, Pécs, and Milan, and he was the recipient of numerous scientific awards and invited academy memberships.

Luciano's portrait could not be complete if one forgets to mention his life-time passion for music. He was a well-trained and accomplished pianist, a passionate music listener, and an enthusiastic connoisseur of all types of music. He also was an amateur in visual arts and deeply interested in history.

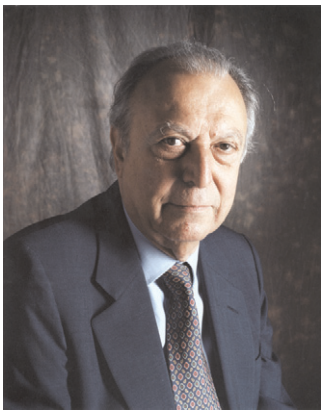
All of us who knew Professor Luciano Martini deeply mourn the loss of a great scientist and friend, the real "Il Maestro", teacher, colleague, and pioneer of modern neuroendocrinology. I trust Luciano would have been proud of this new edition of the Encyclopedia of Endocrine Diseases, and all of us having worked on its production would like to dedicate it to his memory.

Ilpo Huhtaniemi

Editor in Chief
Encyclopedia of Endocrine Diseases, 2nd edition

EDITORS IN CHIEF

Ilpo Huhtaniemi received his MD and PhD at University of Helsinki, Finland, did postdoctoral training in United States (UC San Francisco and NIH, Bethesda), and has been on sabbatical leave in Germany, United States and Scotland. In 1986–2002 he held the post of Professor and Chairman of Physiology at University of Turku, Finland. He moved in 2002 to UK to a Chair in Reproductive Endocrinology at Imperial College London, from which position he retired in 2015. He has received several national and international honors, amongst them a fellowship of The Academy of Medical Sciences, United Kingdom, and a Doctor Honoris Causa at the Medical University Łódź, Poland, and University of Szeged, Hungary. He was the Chief Managing Editor of *Molecular and Cellular Endocrinology* 1999-2017, has served in the Editorial Board of *Endocrinology and Endocrine Reviews* and is/has been the Editor or Editorial Board Member of several other scientific journals (e.g., *European Journal of Endocrinology*, *Clinical Endocrinology*, *Human Reproduction Update*, *Journal of Endocrinology*, *Molecular Human Reproduction*, *Reproduction*, *Asian Journal of Andrology*). He has extensive experience as Official of international scientific organizations (e.g., Past President of International Society of Andrology). His research interests include clinical and basic reproductive endocrinology, in particular the function of gonadotrophins and male reproductive endocrinology. He also has long-term interests in development of male contraception, hormone-dependent cancer, and the endocrinology of aging. He has authored about 700 peer-reviewed research articles and reviews, and his H-factor is 78.



Luciano Martini was born on May 14, 1927, in Milan, Italy. He obtained the degree of Medical Doctor "summa cum laude" on November 24, 1950, from the Faculty of Medicine of the University of Milan, Italy. He was Emeritus Professor of Pharmacology of the University of Perugia, Italy, and Emeritus Professor of Endocrinology of the University of Milan, Italy. He was Doctor Honoris Causa in Medicine of the Universities of Liège, Belgium, Santiago de Compostela, Spain, and Pécs, Hungary, and Doctor Honoris Causa in Biotechnological Sciences of the University of Milan, Italy. He was an author of more than 400 peer-reviewed scientific publications in the fields of endocrinology, neuroendocrinology, pharmacology, physiology of reproduction, steroid biochemistry, and basic oncology. He was elected member of the Accademia Nazionale dei Lincei (Italian National Academy) and of the American Academy of Arts and Sciences (Honorary Foreign Member).

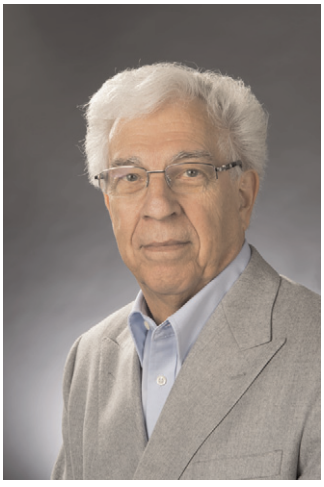
Luciano Martini acted as Editor in Chief of the journal *Frontiers in Neuroendocrinology* from 1990 to 2001, and was a Member of the Editorial Board of *Endocrinology* (Foreign Consulting Editor, 1961–65), as well as of several other speciality journals, such as *Experimental and Clinical Endocrinology*, *Biochemistry*, and *Steroids*. He has acted as Editor of several textbooks (e.g., *Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1966–67, and *Clinical Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1977–82) as well of a series of books under the name *Comprehensive Endocrinology* (13 volumes), Raven Press, New York, 1979–84. He acted as Editor in Chief for the first edition of *Encyclopedia of Endocrine Diseases* (4 volumes), Academic Press-Elsevier, San Diego, 2004.

EDITORIAL BOARD

SECTION EDITORS

Professor **Jean-Jacques Body** has been trained as an endocrinologist and a medical oncologist. He was Head of the Department of Medicine at University Hospital Brugmann in Brussels and Full Professor of Medicine (Internal Medicine) at the Free University of Brussels, (ULB), Brussels, Belgium. He was previously Head of the Internal Medicine Clinic at Institute J. Bordet (Cancer Center of ULB). He has also developed the "Supportive Care Dept" at the same Institute. His particular research interests are osteoporosis and bone metastases. He has a long-standing interest for bone metabolism and turnover in osteoporosis and tumor bone diseases. He has authored or co-authored more than 250 international peer-reviewed papers and he counts more than 200 invited lectures for international meetings.

Felipe F. Casanueva is Professor of Medicine at University of Santiago de Compostela and Head of Department of Endocrinology and Nutrition at University Hospital Santiago. He has been President of the scientific societes, such as: European Federation of Endocrine Societies (EFES), The Pituitary Society, International Society of Endocrinology (ISE) and, Sociedad Española para el Estudio de la Obesidad (SEEDO). Has written more than 50 chapters in international books and published more than 700 papers in international journals. He has received several awards for research at national and international level, such as: Rey Jaime I to the Medical Research, Geoffrey Harris Prize in Neuroendocrinology, Fundación Lilly of Bio-medical Research Clinic, Fundacion Danone – Professional Career – Dr Carlos Martí Hennberg, European Hormone Medal by the European Society for Endocrinology (ESE); he has been named Honorary Doctorate in Medicine of the University of Łódź, Erciyes, and Belgrade, and Honorary Member of the European Society of Endocrinology.



Dr. **Jean-Louis Chiasson** is currently Full Professor of Medicine at the University of Montreal. He is Head of the Research Group on Diabetes and Metabolic Regulation at the Research Center of the Centre hospitalier de l'Université de Montréal (CRCHUM).

Dr. Chiasson obtained his MD at Laval University in Quebec City in 1967. He did his specialty training in Internal Medicine at Laval Univesity and in Endocrinology at McGill University. He then did a research Fellowship in Diabetes at Vanderbilt University in Nashville, Tennessee. In 1974–76 and 1978–80, he was appointed Assistant Professor in the Department of Medicine and Physiology respectively at Vanderbilt University. In 1980, he returned to Montreal as Assistant Professor in the Department of Medicine at the University of Montreal and as Endocrinologist at Hotel-Dieu Hospital, now merged into the Centre hospitalier de l'Université de Montréal.

Dr. Chiasson's research interests include the regulation of carbohydrate metabolism in health and diabetes, as well as the development and evaluation of new strategies for the treatment and prevention of diabetes and its vascular complications. He has contributed over 250 scientific publications and lectures nationally and internationally on various topics on diabetes mellitus, its pathogenesis, its treatment, and its prevention. His scientific contribution puts him in the prestigious club of the 100 most cited publications in the world in the field of diabetes.

Sophie Christin-Maitre received her MD at University of Paris XI and her PhD at University Paris VI, Pierre and Marie Curie, France. She did a postdoctoral training in United States (Massachusetts General Hospital, Harvard University, Boston); she specialized in reproductive medicine. She holds the post of Professor of Endocrinology at University of Sorbonne, Paris, France. She has been the head of the Adult Endocrine Unit, in Hôpital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, since 2011. She is a member of the INSERM research unit UMR S_933, specialized in identifying new genes in reproductive disorders. Her interests include clinical and basic reproductive endocrinology, in particular the management of patients with Turner syndrome, patients with primary ovarian insufficiency, patients with hypogonadisms, and patients with abnormalities of sex development. She has authored approximately 150 peer-reviewed research articles and reviews.

Ulla Feldt-Rasmussen is Professor at Copenhagen University and Chief of Medical Endocrinology, National University Hospital. Her research interests involve the thyroid gland and autoimmunity, as well as pituitary and adrenal dysfunction.

She has published more than 410 papers in peer-reviewed journals on e.g., thyroid hormones and body composition, thyroid autoimmunity and cancer, cytokines as regulators of endocrine cells, influence of thyroid disrupting chemicals on thyroid cells, growth hormone deficiency related to body composition, bone metabolism and other pituitary axes, and transition from adolescent to adult care, as well as several aspects of Fabry disease. In recent years her group has embarked on studies on pituitary function after traumatic brain injury in a nationwide setting, and focusing on diagnostic accuracy of pituitary testing procedures. She has further authored numerous proceedings, textbook chapters, and other publications; as well as organized numerous international meetings and postgraduate courses, and has led several European projects and other collaborations within many areas of endocrinology.

Professor Feldt-Rasmussen reviews for international journals, and is an editorial board member of several endocrine journals. She belongs to many international professional organizations, including the Endocrine Society, ETA, ATA, ENEA, and GRS; she has served as Secretary-Treasurer of ETA and as President of the ETA Cancer Research Network.

Professor Feldt-Rasmussen serves on the advisory boards of several ad hoc endocrine committees, and has received many prestigious prizes including the Mayo Clinic's Haynes Lecturer's Award and ETA's Pinchera Research Prize.

Wouter W. de Herder M.D. Ph.D. (1960) is Professor of Endocrine Oncology at the Erasmus MC in Rotterdam, the Netherlands. In this University Hospital he is chairman of a multidisciplinary group for endocrine oncology (tumorwerkgroep endocriene tumoren) and he is head of the ENETS centre of excellence for neuroendocrine tumors. His major research interests are neuroendocrine and endocrine tumors.

Professor de Herder received his M.D. in 1985 and his Ph.D. in 1990 from the Erasmus University in Rotterdam, the Netherlands.

He is a member of several international and Dutch national societies, such as the Dutch Society for Endocrinology (NVE), the Endocrine Society (USA), the European Society of Endocrinology (ESE), European Neuroendocrine Tumor Society (ENETS) and the North American Neuroendocrine Tumor Society (NANETS). He served as a board member of the Dutch Society for Endocrinology (NVE) (2009–14). He served as chairman (2006–08) and vice-chairman of ENETS (2008–10) (European Neuroendocrine Tumour Society). He is member of the advisory boards of ENETS and NANETS.

Professor de Herder has (co-)published over 400 peer-reviewed papers and book chapters and is a reviewer for many international journals.

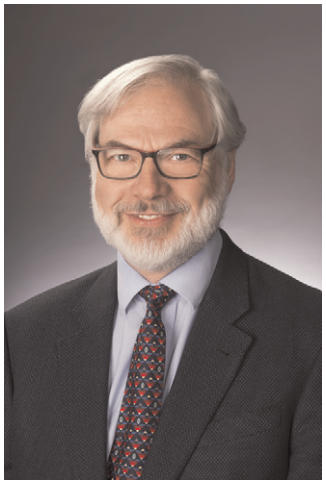
He is a member of the editorial boards of *Neuroendocrinology; Endocrinology, Diabetes & Metabolism Case Reports; Clinical Endocrinology*, and *Endocrine-Related Cancer*.

Professor de Herder has given over 200 invited presentations at Dutch national and international meetings.

Ieuan Hughes is currently Emeritus Professor of Pediatrics at the University of Cambridge and Honorary Consultant Pediatrician at Cambridge University Hospitals NHS Foundation Trust and Cambridge Biomedical Campus. He is the author of more than 300 papers and chapters across the whole range of paediatric endocrinology. His particular expertise is in disorders of sex development for which he coordinated the International Consensus on the approach to the investigation and management of this broad topic. Research interests focus on steroid enzyme deficiencies and molecular mechanisms of androgen action.
Professor Hughes has served on the editorial boards of several journals, including *Clinical Endocrinology*, *Journal of Clinical Endocrinology*, and *Metabolism* and *Archives of Disease in Childhood* where he was also the Associate Editor. He is Past-Secretary and President of the European Society for Pediatric Endocrinology and a recipient of the highest award of the Society, the Andrea Prader Prize. Professor Hughes is a James Spence Medallist of the Royal College of Pediatrics and Child Health for outstanding contributions to paediatric knowledge. He is a Fellow of the Academy of Medical Sciences, a Council Member of the Learned Society of Wales and a Trustee of two charities. The chapter on Disorders of Sex Development in *Williams Textbook of Endocrinology* (now in its 14e) by Hughes and co-authors is considered to be a definitive and up to date regular review of this topic, specific and key to pediatric endocrinology.

Dr. **Gregory Kaltsas** MD FRCP (Lon) is Professor in General Medicine and Endocrinology at the National and Kapodistrian University of Athens, Greece. He was trained in General Medicine in Athens, Greece and London, UK, and in Endocrinology at the Middlesex and St Bartholomew's Hospital, London, UK. He developed a particular interest in neuroendocrinology (pituitary and neuroendocrine tumors) and adrenal physiology and diseases. Upon returning to Greece he established a neuroendocrine network and he is currently running the European Neuroendocrine Tumor Society (ENETS) Center of Excellence at Laiko Hospital in Athens, Greece. He has served as a member of the advisory board of ENETS and of the Executive Committee of the European Neuroendocrine Association (ENEA) and he has been elected in the Executive Committee of the International Society of Endocrinology. He has recently been elected as a representative of the European Society of Endocrinology in the ExCo of the International Society of Endocrinology. He has published more than 300 original papers, reviews, and chapters and serves on editorial boards and as associate editor in several endocrine journals.

Jean-Marc Kaufman obtained his MD and PhD degrees at the Ghent University, Belgium. He was a Senior Postdoctoral Research Fellow (1982–84) in reproductive physiology at the University of Texas Medical School at Houston. He is board certified in Endocrinology and in Nuclear Medicine. In 1985 he joined the staff of the Ghent University Hospital; he headed the department of Endocrinology from 2003 to 2014 and the Laboratory for Hormonology from 1995 to 2014. He was appointed in 1993 Professor of Medicine at the Ghent University (1993) and is past Chair of the Department of Internal Medicine at the Ghent University (2010–14). From October 1st 2014 he is Professor Emeritus at the Ghent University where he is pursuing clinical and research activities. Main research interests are in the assessment, regulation, and action of sex steroids with focus on their role in health, disease, and aging in men, and in osteoporosis in men. He is (co)author of over 300 publications in international peer-reviewed journals.



André Lacroix, MD FCAHS is Professor of Medicine, Division of Endocrinology at Centre hospitalier de l'Université de Montréal (CHUM). His areas of interest include the mechanisms of adrenal Cushing syndrome, primary aldosteronism, adrenal tumorigenesis, the role of aberrant adrenal hormone receptors in adrenal overfunction, as well as new drugs in the therapy of Cushing disease, primary aldosteronism and adrenocortical cancer.
He was trained at the University of Montreal followed by fellowships in Endocrinology and research at Vanderebilt University and National Institutes of Health, USA. He was Chairman of Medicine and Director of Academic Affairs at CHUM. Former President of the Canadian Society of Endocrinology and Metabolism, he is currently chairperson of the International Society of Endocrinology (2016–20), Editor, Adrenal Section of UpToDate and *Encyclopedia of Endocrinology*, Senior Editor of the *European Journal of Endocrinology*. Fellow of the Canadian Academy of Health Sciences since 2008 and Foreign member of the National Academy of Medicine of France since 2016.

Franco Mantero received his MD at the University of Padua, Italy, did postdoctoral training in Switzerland (Clinique Medicale Therapeutique, Hopital Cantonal, University of Geneva) and in United States (University of California, San Francisco), and has been on sabbatical leave in United Kingdom, United States, and France. He held a post of Associate Professor in Medicine at the Institute of Semeiotica Medica, University of Padua (1981–86). In 1986 he moved to the University of Catania to the Chair of Andrology and Endocrinology, in 1992 to the University of Ancona, and in 2000 to the University of Padua to the Chair of Endocrinology and Chief of the Endocrinology Unit of the Department of Medicine. He has received national and international honors, including a Doctor Honoris Causa at the Semmelweis University, Budapest, Hungary.
He has been Editorial Board Member of several scientific journals (e.g., *Clinical Endocrinology*, *Endocrinology*, *Journal of Hypertension*, *Journal of Endocrinology Investigation Steroids*)
He has served as Member of the Council of several international scientific societies (including International Society of Endocrinology, International Aldosterone Conference, Journee Klotz d'Endocrinologie Clinique, ENS@T) and one of the founders of the European Network for the Study of Adrenal Tumors. His research interests include clinical and basic endocrinology of the adrenal gland and endocrinology of hypertension, in particular pathophysiology of mineralocorticoids and primary aldosteronism. He has authored approximately 500 peer–reviewed articles and edited several books and proceedings.

Jorma Toppari, MD, PhD, is Professor of Physiology at the University of Turku and Chief Physician of Pediatric Endocrinology at Turku University Hospital, Turku, Finland. He is also Adjunct Professor in the Department of Growth and Reproduction at the University of Copenhagen, Denmark. He has served as chief editor of International Journal of Andrology (2001–09), and has been on editorial boards of several endocrinological journals, including currently *Endocrinology* and *Journal of Clinical Endocrinology and Metabolism*. He is the past President of the European Academy of Andrology. He has made numerous contributions to the studies on endocrine disruption in the past 20 years. He has published approximately 400 articles on endocrinology.

Jacquetta Trasler is a James McGill Professor in the Departments of Pediatrics, Human Genetics, and Pharmacology and Therapeutics at McGill University and a Senior Scientist at the Research Institute of the McGill University Health Centre (RI-MUHC). She received her MD and PhD degrees from McGill University followed by postdoctoral training in reproductive molecular biology at Tufts University in Boston. She has served as Director of the McGill University MD-PhD Program, Scientific Director of the Montreal Children's Hospital Research Institute (and simultaneously as Deputy Director/CSO of the RI-MUHC), President of the Canadian Fertility and Andrology Society, Member of the Institute Advisory Board for the Canadian Institutes of Health Research (CIHR) Institute of Genetics and currently serves on the CIHR Stem Cell Oversight Committee and College of Reviewers. Her research focuses on epigenetics and epigenomics to better understand the molecular and cellular targets for drug effects on germ cells with implications for the resulting offspring. She has been involved in scientific program organization for numerous meetings in the field of reproductive biology and medicine and is collaborating with national and international colleagues in clinical studies to examine how assisted reproductive technologies, infertility, drug treatment, and folate deficiency and supplementation impact the human epigenome including that of future generations.

Christina Wang, MD is Professor of Medicine, Assistant Dean at the David Geffen School of Medicine at UCLA, and Associate Director for Clinical and Translational Science Institute and a faculty member of the Division of Endocrinology, Department of Medicine, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, California.

Dr. Wang has been involved in many funded basic and clinical research studies. Her current clinical research studies include androgen replacement therapy, hormonal male contraceptive development, late onset hypogonadism, accurate assessment of serum androgens, and diet and androgen metabolism. Her basic research studies focus on the regulation of spermatogenesis and mitochondrial derived peptides in spermatogenesis.

She has authored over 300 peer-reviewed publications, 67 chapters and reviews mainly on male reproductive biology including characterization of the pharmacokinetics and efficacy of androgens in men, trials of hormonal male contraceptive, regulation of germ cell apoptosis, and reproductive aging. Dr. Wang served on the Executive Council, several committees and was the President of the American Society of Andrology (2006–07). She also served the International Society of Andrology as Secretary (2001–05) and Chair of the Program Organizing Committee (2005–09). She was President of the International Society of Andrology (2009–13). She is a member of the Research Group on Methods for the Regulation of Male Fertility of the World Health Organization since 1984 and Chairperson (1991–2002).

She has mentored many physician and scientist and is an advocate of young investigators. Dr. Wang has been invited speaker and distinguished lecturer at many national and international endocrinology, reproductive endocrinology, and andrology conferences.

LIST OF CONTRIBUTORS

Bo Abrahamsen
University of Southern Denmark, Odense, Denmark; and Holbæk Hospital, Holbæk, Denmark

Catarina Abreu
Hospital of Santa Maria, Lisbon, Portugal

O. Addison
University of Maryland School of Medicine, Baltimore, MD, United States

Zaida Agüera
Carlos III Institute of Health, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Enrico Agabiti-Rosei
University of Brescia, Brescia, Italy

Carlo Aggiusti

University of California Los Angeles, Los Angeles, CA, United States

Lorenza Macrina
IRCCS San Raffaele Scientific Institute, Milan, Italy

Filippo Maffezzoni
University of Brescia, Brescia, Italy

Mario Maggi
University of Florence, Florence, Italy; and Istituto Nazionale Biostrutture e Biosistemi, Rome, Italy

M. Maghnie
University of Genova, Genova, Italy

Amita Mahajan
University of Calgary, Calgary, AB, Canada

Eamonn R. Maher
Cambridge Biomedical Campus, Cambridge, United Kingdom

Virginie Maillard
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Katharina M. Main
University of Copenhagen, Copenhagen, Denmark

Gabriel M. Makhlouf
Virginia Commonwealth University, Richmond, VA, United States

Konstantinos Makris
KAT General Hospital, Athens, Greece; and University of Athens, Athens, Greece

Willy J. Malaisse
Free University of Brussels, Brussels, Belgium

J. Maletkovic
UCLA School of Medicine, Los Angeles, CA, United States

Federico Mallo Ferrer
Biomedical Research Center (CINBIO), University of Vigo, Vigo, Spain

Núria Mallorquí-Bagué
Carlos III Health Institute, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Meera Mallya
Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom

Giuseppe Mancia
University of Milan-Bicocca, Monza, Italy

Jacqueline Mandelbaum
Tenon Hospital, Paris, France; and Pierre and Marie Curie University, Paris, France

Massimo Mannelli
University of Florence, Florence, Italy

Franco Mantero
University of Padua, Padua, Italy

Paolo Manunta
University Vita-Salute San Raffaele, Milan, Italy

Claudio Marcocci
University of Pisa, Pisa, Italy; and University Hospital of Pisa, Pisa, Italy

Roxana Marino
Hospital de Pediatría Garrahan, Buenos Aires, Argentina

Gabriel V. Markov
Sorbonne University, Banyuls-sur-Mer, France

Laura Marroquí
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Gary R. Marshall
University of Pittsburgh School of Medicine, Pittsburgh, PA, United States

Ritzén E. Martin
Karolinska Institute, Stockholm, Sweden

Laetitia Martinerie
University Paris-Sud, University of Paris-Saclay, Le Kremlin-Bicêtre, France; Service d'Endocrinologie Pédiatrique, Hôpital Robert Debré, Paris, France; and Paris Diderot University, Paris, France

Antoine Martinez
CNRS, INSERM, Clermont Auvergne University, Clermont-Ferrand, France

Daniel B. Martinez-Arguelles
McGill University, Montreal, QC, Canada

Sergio Martinez-Hervas
University of Valencia, Valencia, Spain; and CIBERDEM-Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, ISCIII, Madrid, Spain

Enio Martino
University of Pisa, Pisa, Italy

Katia Maruca
IRCCS San Raffaele Scientific Institute, Milan, Italy

George Mastorakos
National and Kapodistrian University of Athens, Aretaieion Hospital, Athens, Greece

Yuji Matsuzawa
Sumitomo Hospital, Osaka, Japan

Gherardo Mazziotti
Carlo Poma Hospital, Mantova, Italy

Eugene V. McCloskey
MRC Arthritis Research UK Centre for Integrated Research in Musculoskeletal Aging, Metabolic Bone Center, Northern General Hospital, Sheffield, United Kingdom; University of Sheffield, Sheffield, United Kingdom; and University of Sheffield Medical School, Sheffield, United Kingdom

Timothy McClure
Lefrak Center for Robotic Surgery, Weill Cornell Medicine, New York, NY, United States

Ken McElreavey
Institut Pasteur, Paris, France

Bruce S. McEwen
Rockefeller University, New York, NY, United States

Serge McGraw
University of Montreal, Montreal, QC, Canada

Christian Meier
University Hospital Basel, Basel, Switzerland

Onno C. Meijer
Leiden University Medical Center, Leiden, The Netherlands

Berenice B. Mendonca
University of São Paulo, São Paulo, Brazil

Gabriele Mertes
Mülheim, Germany

Gemma Mestre-Bach
University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Boyd E. Metzger
Northwestern University Feinberg School of Medicine, Chicago, IL, United States

Ralph G. Meyer
Utah State University, Logan, UT, United States

Heino F.L. Meyer-Bahlburg
New York State Psychiatric Institute, New York, NY, United States; and College of Physicians & Surgeons of Columbia University, New York, NY, United States

Mirella L. Meyer-Ficca
Utah State University, Logan, UT, United States

Dragan Micic
University of Belgrade, Belgrade, Serbia

Jesús E. Millán Núñez-Cortes
Gregorio Marañon University General Hospital, Madrid, Spain; and Complutense University of Madrid, Madrid, Spain

Joaquín J. Millán Pérez
Complutense University of Madrid, Madrid, Spain

Paul D. Miller
University of Colorado Health Sciences Center, Denver, CO, United States

Geltrude Mingrone
Catholic University, Rome, Italy; and Guy's Campus, King's College London, London, United Kingdom

Katrina M. Mirabito Colafella
Erasmus MC, Rotterdam, The Netherlands; and Monash University, Melbourne, VIC, Australia

Alexander D. Miras
Imperial College London, London, United Kingdom

Philippe Monget
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Danielle Monniaux
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Silvia Monticone
University of Turin, Turin, Italy

Rebecca J. Moon
Southampton Children's Hospital, Southampton, United Kingdom

Stefano Mora
IRCCS San Raffaele Scientific Institute, Milan, Italy

G. Morana
University of Genoa, Genoa, Italy

Rachel C. Morgan
Indiana University School of Medicine, Indianapolis, IN, United States

Alberto Morganti
Centro Fisiologia Clinica e Ipertensione, Policlinico Hospital, Milan, Italy; and University of Milan, Milan, Italy

Luigi Mori
University of Brescia, Brescia, Italy

A. Ross Morton
Queen's University, Kingston, ON, Canada

Howard A. Morris
University of South Australia, Adelaide, SA, Australia

Giovanna Motta
University of Turin, Turin, Italy

Pierre Mouriquand
Hôpital Mère-Enfant – Claude-Bernard University, Lyon, France

Miguel Muñoz
Virgen del Rocío University Hospital, Sevilla, Spain

Maria Teresa Muñoz
University Hospital Niño Jesús, Institute of Investigation La Princesa, Madrid, Spain; and Center for Biomedical Research in Network on the Pathophysiology of Obesity and Nutrition (CIBEROBN), Carlos III Health Institute, Madrid, Spain

Araceli Muñoz-Garach
Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Maria Lorenza Muiesan
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Dick Mul
Diabeter, Center for Pediatric and Adolescent Diabetes Care and Research, Rotterdam, The Netherlands

Manfred J. Müller
University of Kiel, Kiel, Germany

Beat Müller
Medical University Clinic, Kantonsspital Aarau, Aarau, Switzerland; and University Hospital Basel, Basel, Switzerland

Paolo Mulatero
University of Turin, Turin, Italy

Tayane Muniz Fighera
Federal University of Rio Grande do Sul, Porto Alegre, Brazil

K.S. Murthy
Virginia Commonwealth University, Richmond, VA, United States

Marina Muzza
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Angel Nadal
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Y. Nagayama
Nagasaki University, Nagasaki, Japan

Bimota Nambam
Louisiana State University, Shreveport, LA, United States

Ruta Navardauskaite
Lithuanian University of Health Sciences, Kaunas, Lithuania

M.-L. Névoret
Impeto Medical, San Diego, CA, United States

Markella Nezi
National and Kapodistrian University of Athens, Aretaieion Hospital, Athens, Greece

Brian T. Nguyen
Keck School of Medicine of University of Southern California, Los Angeles, CA, United States; and Los Angeles Biomedical Research Institute and Harbor-UCLA Medical Center, Torrance, CA, United States

Atossas Niakan
University of Tennessee Health Science Center, Memphis, TN, United States

Nicolas C. Nicolaides
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Claus H. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Henriette S. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Lynnette K. Nieman
National Institutes of Health (NIH), Bethesda, MD, United States

Sarah M Nikkel
University of British Columbia, Vancouver, BC, Canada

Charlotte M. Niznik
Northwestern University Feinberg School of Medicine, Chicago, IL, United States

James D. Nobles
Leeds Beckett University, Leeds, United Kingdom

Pavel Nockel
National Cancer Institute, Bethesda, MD, United States

Ruben Nogueiras
CIMUS, USC, IDIS, Santiago de Compostela, Spain; and Carlos III Health Institute, Madrid, Spain

Ruben Nogueiras
CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain; and University of Santiago de Compostela (USC), Santiago de Compostela, Spain

Anna Nordenström
Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

M. Nowak
Medical University of Lublin, Lublin, Poland

Tsuneo Ogawa
University of Ottawa, Ottawa, ON, Canada

Onyebuchi Okosieme
Cardiff University, Cardiff, United Kingdom

Wilma Oostdijk
Leiden University Medical Center, Leiden, The Netherlands

Jacques Orgiazzi
Lyon 1-Claude Bernard University, Lyon, France

Andrés E. Ortiz-Flores
University Hospital Ramón y Cajal, Madrid, Spain; University of Alcalá, Madrid, Spain; Ramón y Cajal Institute for Health Research IRYCIS, Madrid, Spain; and Biomedical Research Network Center in Diabetes and Related Metabolic Diseases CIBERDEM, Madrid, Spain

Nantia Othonos
University of Oxford, Oxford, United Kingdom

Susan M. Ott
University of Washington, Seattle, WA, United States

Karel Pacak
University of Connecticut Health Center, Farmington, CT, United States; and National Institutes of Health, Bethesda, MD, United States

Stephanie T. Page
University of Washington, Seattle, WA, United States

Uberto Pagotto
Alma Mater Studiorum University of Bologna, Bologna, Italy

Anna Paini
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Stefano Palomba
Grande Ospedale Metropolitano of Reggio Calabria, Reggio Calabria, Italy

George Paltoglou
Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Alessandra Panarotto
University of Brescia, Brescia, Italy

Amit V. Pandey
University of Bern, Bern, Switzerland

Vassilios Papadopoulos
University of Southern California, Los Angeles, CA, United States

Ralph Papas
University of Balamand, Beirut, Lebanon

Theodora Pappa
National and Kapodistrian University, Athens, Greece

Anne-Simone Parent
University of Liège, Liège, Belgium; and CHU de Liège, Chênée, Belgium

Gabriele Parenti
Endocrine Unit, Careggi Hospital, Florence, Italy

Ralf Paschke
University of Calgary, Calgary, AB, Canada

Leena Patel
The University of Manchester, Manchester, United Kingdom; and Royal Manchester Children's Hospital, Manchester University Hospitals NHS Trust, Manchester Academic Health Science Centre, Manchester, United Kingdom

Heather B. Patisaul
North Carolina State University, Raleigh, NC, United States

G. Patti
University of Genova, Genova, Italy

Michael A. Patton
St Georges University of London, London, United Kingdom

L.J. Pelliniemi
University of Turku, Turku, Finland

Bas Penders
Maastricht University, Maastricht, The Netherlands

Alberto M. Pereira
Leiden University Medical Center, Leiden, The Netherlands

Paola Perotti
University of Turin, Turin, Italy

Luca Persani
University of Milan, Milan, Italy

Luca Persani
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Panagiota Pervanidou
National and Kapodistrian University of Athens Medical School, Athens, Greece

Felice Petraglia
University of Florence, Careggi University Hospital, Florence, Italy

Cindy Pham
Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Eliana Piantanida
University of Insubria, Varese, Italy

Jean-Yves Picard
Pierre and Marie Curie University, Paris, France

Marie-Eve Piché
Quebec Heart and Lung Institute, Quebec City, QC, Canada; Laval University, Quebec City, QC, Canada;

and Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom

Axelle Pintiaux
Free University of Brussels (ULB), Brussels, Belgium

Rosario Pivonello
University of Naples Federico II, Naples, Italy

Rosario Pivonello
Federico II University of Naples, Naples, Italy

T.M. Plant
University of Pittsburgh School of Medicine, Pittsburgh, PA, United States; and Magee-Womens Research Institute, Pittsburgh, PA, United States

P-F. Plouin
Hôpital Européen Georges Pompidou, Paris, France; and Paris-Descartes University, Paris, France

Genevieve Plu-Bureau
Paris-Descartes University, Paris, France

Paul Poirier
Quebec Heart and Lung Institute, Quebec City, QC, Canada; and Laval University, Quebec City, QC, Canada

Snezana Polovina
University Business Academy, Novi Sad, Serbia

Constantin Polychronakos
Research Institute of the McGill University Health Centre, Montréal, QC, Canada

Maguelonne Pons
Hôpital Mère-Enfant – Claude-Bernard University, Lyon, France

Giulia M. Pontesilli
Alma Mater Studiorum University of Bologna, Bologna, Italy

Callum Potts
Inova Fairfax Hospital, Falls Church, VA, United States

Aleksander Prejbisz
Institute of Cardiology, Warsaw, Poland

Lakdasa D.K.E. Premawardhana
Cardiff University, Cardiff, United Kingdom; and University Hospital of Wales, Cardiff, United Kingdom

Morton P. Printz
University of California San Diego, San Diego, CA, United States

Tomas Prior
Queen Charlotte's and Chelsea Hospital, London, United Kingdom; and Imperial College London, London, United Kingdom

Soraya Puglisi
University of Turin, Turin, Italy

Shrey Purohit
Duke University, Durham, NC, United States

Lechosław T. Putowski
Medical University of Lublin, Lublin, Poland

Ivan Quesada
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Ingrid Quevedo Wanichi
University of São Paulo, São Paulo, Brazil

Rémi Rabasa-Lhoret
Montreal Clinical Research Institute, Montreal, QC, Canada; University of Montreal, Montréal, QC, Canada; and Montreal Diabetes Research Center, Montréal, QC, Canada

Naila Rabbani
University of Warwick, Coventry, United Kingdom

Jacob Rajfer
David Geffen School of Medicine, Los Angeles, CA, United States

Ewa Rajpert-De Meyts
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Stuart H. Ralston
University of Edinburgh, Edinburgh, United Kingdom

S. Ramaswamy
University of Pittsburgh School of Medicine, Pittsburgh, PA, United States; and Magee-Womens Research Institute, Pittsburgh, PA, United States

Amarnath Rambhatla
Wayne State University, Detroit, MI, United States

Oliver J. Rando
University of Massachusetts Medical School, Worcester, MA, United States

Elena Rapizzi
University of Florence, Florence, Italy

Åse Krogh Rasmussen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Joanne Rasschaert
Free University of Brussels, Brussels, Belgium

Giulia Rastrelli
University of Florence, Florence, Italy

Verdiana Ravarotto
University of Padua, Padova, Italy

Gérald Raverot
Groupement Hospitalier Est, Bron, France

José T. Real
University of Valencia, Valencia, Spain; and CIBERDEM-Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, ISCIII, Madrid, Spain

Dafydd Aled Rees
University Hospital of Wales, Cardiff, United Kingdom; and Cardiff University, Cardiff, United Kingdom

Jean-Yves Reginster
WHO Collaborating Center for Public Health Aspects of Musculoskeletal Health and Aging, Liège, Belgium; and University of Liège, Liège, Belgium

Ian R. Reid
University of Auckland, Auckland, New Zealand

Giuseppe Reimondo
University of Turin, Turin, Italy

Martin Reincke
Ludwig Maximilian University of Munich, Munich, Germany

Rodolfo A. Rey
R. Gutierrez Children's Hospital, Buenos Aires, Argentina

Caroline Reynaud
INSERM, Faculty of Medicine Lyon East, Lyon, France

Luigi Ricciardiello
Alma Mater Studiorum University of Bologna, Bologna, Italy

Guido Rindi
Catholic University – IRCCS Fondazione Policlinico Universitario A. Gemelli, Roma, Italy

Scott A. Rivkees
University of Florida College of Medicine, Gainesville, FL, United States

William B. Rizzo
University of Nebraska Medical Center, Omaha, NE, United States

René Rizzoli

Stephan Zipfel
Medical University Hospital Tübingen, Tübingen, Germany

PREFACE

The first Edition of the *Encyclopedia of Endocrine Diseases* was published in 2004. Because of the enormous development in the field it was found important to produce a completely revised and updated Second Edition of the Encyclopedia. The new Edition is a must-have one-stop reference covering every aspect of the physiological background, pathogenesis, clinical diagnostics, and therapeutic aspects of the wide array of endocrine and related metabolic diseases.

The functional balance of the body (homeostasis) is maintained by two regulatory circuits, i.e., the nervous and the endocrine systems. Among the most complex constructs in the body, the endocrine system comprises a group of glands that secrete hormones directly into the bloodstream, where they reach their specific receptors in other parts of the body, evoking specific intracellular signaling pathways leading to their biological effect. Many classically non-endocrine organs (e.g., the heart) have also turned out to have endocrine functions. The endocrine system maintains and regulates the body's homeostasis by using hormones to control metabolism, temperature, biological cycles, internal fluid volume, reproduction, growth, body composition, and development. The system is a marvel when functioning optimally, i.e., maintaining the body homeostasis. Unfortunately, there is a myriad of ways these processes, actions, and functions can go awry, resulting in various endocrine and metabolic diseases, which form the over-arching theme of the Encyclopedia.

The Encyclopedia is not meant as a primer on the subject of endocrinology, but instead intended to provide a comprehensive reference work on the extensive spectrum of diseases and disorders that can occur within the endocrine and metabolic system. The updated version of this groundbreaking encyclopedia is especially timely, as it covers the dramatic discoveries in the field of endocrinology and metabolism over the past 10 years, particularly with respect to novel diagnostic techniques and treatment approaches. In particular, there have been tremendous advancements in our understanding of the molecular basis of endocrine and metabolic diseases (mutations, epigenetics, signaling), as well as pathogenesis and therapy of the common forms of these diseases (e.g., diabetes, obesity, and endocrine malignancies).

The Encyclopedia offers a unique source of up-to-date information for the physicians and basic scientists working in the field. It is an essential resource for every clinician diagnosing and treating endocrine patients. The Encyclopedia also offers the prime source of information for students of medicine and science around the world, as well as basic research workers in academia, the pharma industry, and in other areas in need of information on endocrinology and metabolism. It also offers useful information for the lay public about normal and abnormal functions of hormones.

The Encyclopedia is intended to serve as a useful and comprehensive source of information spanning the many and varied aspects of the endocrine and metabolic system. The chapters have been written to be accessible to both clinical and nonclinical readers. The articles have been formatted in similar fashion and each is intended as a stand-alone presentation. Each article begins with a glossary list defining key terms that may be unfamiliar to the reader and are important for understanding the article. The body of the article begins with a brief introduction to the subject under discussion, bold headings lead the reader through the text, and figures and tables explain and illuminate most articles. The main text is followed by referenced citations to provide the reader with access to additional information on the topic, and cross-references lead the reader to related entries in the encyclopedia. The relatively short stand-alone articles have allowed us to recruit the best experts available for each topic.

Unlike the first Edition, where the articles were arranged in alphabetical order, the 2nd Edition is arranged in organ-based thematic order, where each organ-based group of diseases is presented as cluster of articles in the first four volumes. The fifth volume is a stand-alone compilation of all articles on pediatric endocrinology. The thematic organization gives the reader a better general view of the coverage of articles on a specific endocrine organ or disease type.

The Second Edition of the Encyclopedia builds of the first edition. Nevertheless, to bring a major reference work with such a broad scope from initial conception to final publication involved a great deal of planning and organization, together with the efforts of innumerable individuals. The authors of the first edition were invited to update their earlier texts. If this was not possible, the Section Editors invited another expert in the topic either to update the previous text or to write a de novo text; the latter happened in most of these cases. Hence, the Second Edition contains to a large extent totally new information, or at least the fluency of all texts has been scrutinized. Furthermore, all manuscripts have undergone peer-review arranged by the Section Editors.

Assembling a large volume of articles with the purpose to cover all essential topics of endocrine diseases posed multiple challenges. Coverage was a significant problem: on one hand some redundancy of the topics was almost impossible to avoid in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these gaps in future editions. We also note that as can be expected for a large multi-author compilation the individual articles do differ in detail and approach. We considered it more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines.

Most of the editing work of the Encyclopedia has been carried out by a highly competent board of 16 Section Editors, each of them internationally renowned experts in their respective field within clinical endocrinology. First, the broadest possible list of topics was compiled, aiming at the best possible coverage. Throughout the editorial process, the Section Editors supervised their subject area of expertise, recommended and corresponded with fellow editors and article contributors, reviewed the manuscripts, and continuously helped to refine the final list of topics. This has made the task of the Editor in Chief easy, mainly entailing the supervision of smooth progress of the project.

The Section Editors and their fields deserve being listed here: *Jean-Jacques Body* (Belgium, bone endocrinology), *Felipe F. Casanueva* (Spain, metabolism and obesity), *Richard N. Clayton* (United Kingdom, pituitary gland), *Jean-Louis Chiasson* (Canada, diabetes), *Sophie Christin-Maitre* (France, female reproduction), *Wouter W. de Herder* (The Netherlands, neuroendocrinology), *Ulla Feldt-Rasmussen* (Denmark, thyroid gland), *Ieuan Hughes* (United Kingdom, pediatric endocrinology), *Gregory Kaltsas*, Greece, and *Martin O. Weickert*, United Kingdom, (gastrointestinal hormones), *Jean-Marc Kaufman* (Belgium, endocrinology of aging), *André Lacroix* (Canada, adrenal cortex), *Franco Mantero* (Italy, adrenal medulla and endocrine hypertension), *Jorma Toppari* (Finland, endocrine disruptors), *Jacquetta Trasler* (Canada, endocrine epigenetics) and *Christina Wang* (United Kingdom, male reproduction).

The Elsevier editorial staff, *Will Smaldon*, *Laura Escalante Santos*, and *Kate Miklaszewska-Gorczyca*, have been of enormous help to the editors at every step during this long project. I admire the professionalism of everyone and am deeply indebted to all for their dedication and hard work to make the Encyclopedia the leading reference book of clinical endocrinology.

The authors of the individual chapters, more than 450 in total, were specifically selected by the Section Editors to represent the best available knowledge on the topic available. They all should be thanked for their dedication and the excellent quality of their contributions.

Ilpo T. Huhtaniemi
Editor in Chief

Introduction to the volume lxiii

VOLUME 1 – General Principles of Hormone Production and Action, Diabetes, Lipid Metabolism and Atherosclerosis, Obesity, Gastrointestinal Hormones, Multi-Organ Endocrine Diseases, Endocrinology of Aging, and Endocrine toxicology and EDCs

General Principles of Hormone Production and Action

History of Endocrinology *Wouter W de Herder* 1
Statistics in Endocrinology: Meta-Analysis Advantages and Pitfalls *Olaf M Dekkers* 11
Evolution of Hormonal Mechanisms *Vincent Laudet and Gabriel V Markov* 16
General Principles of Endocrine Genetics *Constantin Polychronakos* 23
Endocrine Epigenetics, Epigenetic Profiling and Biomarker Identification *Virginie Bertrand-Lehouillier, Lisa-Marie Legault, and Serge McGraw* 31
Protein and Peptide Hormone Synthesis *Johannes Hofland and Frank H de Jong* 36
Protein and Peptide Hormone Action *Frank H de Jong and Johannes Hofland* 43
Roles of Plasma Binding Proteins in Modulation of Hormone Action and Metabolism *Geoffrey L Hammond, Lesley A Hill, and Phillip W Round* 51
Dynamic Endocrine Rhythms *Thomas J Upton and Stafford Lightman* 61
Growth Factors *Uxía Fernandez, Luisa M Seoane, and Ruben Nogueiras* 69

Diabetes

Normal Glucose Physiology *Mazen Alsahli and John E Gerich* 72
Glucose Metabolism and Hormonal Regulation *Keith Tornheim* 87
Insulin Secretion: Functional Biochemical Aspects *Willy J Malaisse* 95
Insulin Action; Post-Receptor Mechanisms *Ashok K Srivastava, Preeti Bajpai, and Ashish Jain* 100
Diagnosis and Classification of Diabetes Mellitus *Jean-Marie Ekoé* 105
Type 1 Diabetes *Bimota Nambam, William Winter, and Desmond Schatz* 110
Type 2 Diabetes *Susan L Samson and Alan J Garber* 116
Diabetes Mellitus and Pregnancy *Emily D Szmuilowicz, Charlotte M Niznik, and Boyd E Metzger* 122

Diabetes Mellitus; Diagnosis and Treatment in the Elderly *Odilia I Bermudez* 133
Carbohydrate Metabolism: Diabetes Mellitus, Genomic Aberrations *RK Semple* 141
Lifestyle Diabetes Prevention *Ahmad Alkhatib and Jaakko Tuomilehto* 148
Hyperglycemic Hyperosmolar State *J Maletkovic and A Drexler* 160
Hypoglycemia *Darleen A Sandoval, Elizabeth M Lamos, Lisa Younk, Maka S Hedrington, and Stephen N Davis* 163
Glycation- and/or Polyol Pathway-Inducing Complications *Naila Rabbani and Paul J Thornalley* 170
Hypertension and Diabetes *Atossas Niakan and William C Cushman* 180
Dyslipidemia in Diabetes *Savitha Subramanian and Alan Chait* 186
Ocular Manifestations Associated With Diabetes *S Lauhon, MS Stem, and PE Fort* 199
Kidney Disease in Diabetes *Stephanie Toth-Manikowski and Mohamed G Atta* 202
Diabetic Nerve Disease; Neuropathy *Jean-Marie Ekoe* 207
Neurological Disease and Diabetes, Autonomic *Aaron I Vinik, Tomris Erbas, M-L Névoret, and C Casellini* 210
Foot Disease in Diabetes *Jean-Marie Ekoé, Benjamin A Lipsky, and David G Armstrong* 216
Cardiovascular Disease in Diabetes *Marie-Eve Piché and Paul Poirier* 219
Treatment: Alpha Glucosidase Inhibitors *Markolf Hanefeld and Gabriele Mertes* 238
Insulin Pumps and Artificial Pancreas *Nadine Taleb, Véronique Gingras, and Rémi Rabasa-Lhoret* 245
Transplantation: Pancreatic and Islet Cells *Anissa Gamble, Antonio Bruni, and AM James Shapiro* 259
Hypoglycemic State, Nondiabetic *Pierre J Lefèbvre and André J Scheen* 270

Lipid Metabolism and Atherosclerosis

Classification of Hyperlipidemias and Dyslipidemias *Jesús E Millán Núñez-Cortes and Joaquín J Millán Pérez* 275
Atherosclerosis *Jesus A Araujo and Aldons J Lusis* 282
Atherogenesis *L Badimon and V Llorente-Cortés* 289
Epigenetics, the Vascular Wall, and Atherosclerosis *Gertrud Lund and Silvio Zaina* 303
Primary Mixed Dyslipidemias *Rafael Carmena* 314
Hypercholesterolemia *Sergio Martinez-Hervas and Juan F Ascaso* 320
Low HDL and High HDL Syndromes *Shizuya Yamashita and Yuji Matsuzawa* 327
Hypertriglyceridemias and Their Treatment *José T Real* 340

Obesity

Genetic Basis of Obesity *Dolores Corella and Oscar Coltell* 346
Gut Microbiota; Its Importance in Obesity *Araceli Muñoz-Garach, Isabel M Cornejo-Pareja, and Francisco J Tinahones* 353
Regulation of Food Intake *Albert Lecube and Carolina López-Cano* 363
Adipose Tissue *Xabier Unamuno, Gema Frühbeck, and Victoria Catalán* 370
Comorbidities of Obesity *Vettor Roberto and Di Vincenzo Angelo* 385

Hypothalamic Control of Food Intake and Energy Homeostasis *Luisa M Seoane, Miguel López, and Ruben Nogueiras* 393

Gastrointestinal Hormones and Their Regulation of Food Intake *Luca Busetto, Marco Rossato, and Roberto Vettor* 398

Body Composition *Manfred J Müller, Corinna Geisler, and Anja Bosy-Westphal* 406

Obesity and Food Addiction *Fernando Fernández-Aranda, Trevor Steward, Gemma Mestre-Bach, Susana Jiménez-Murcia, and Ashley Gearhardt* 414

Leptin *Rachel C Morgan and Robert V Considine* 420

Lifestyle and Nutrition *Dragan Micic and Snezana Polovina* 428

Physical Activity and Exercise *Federico Mallo Ferrer* 436

Treatment of Obesity with Bariatric Surgery *Maitane Izaguirre, Gema Frühbeck, and Victoria Catalán* 442

Metabolic Surgery; Indications and Outcomes *Lidia Castagneto-Gissey, James Casella-Mariolo, and Geltrude Mingrone* 459

Treatment: New Drugs *Silvia Garelli, Nicola Salituro, Giulia M Pontesilli, Luigi Ricciardiello, Valentina Vicennati, and Uberto Pagotto* 464

Binge-Eating, Bulimia, and Other Eating Disorders *Zaida Agüera, Núria Mallorquí-Bagué, María Lozano-Madrid, Andreas Stengel, Stephan Zipfel, and Fernando Fernández-Aranda* 473

Lipodystrophy *Marta Giralt, Francesc Villarroya, and David Araújo-Vilar* 482

Gastrointestinal Hormones

GI Hormone Development (Families and Phylogeny) *Anders H Johnsen* 496

GI Tract: General Anatomy (Cells) *George Kontogeorgos* 501

GI Hormones Outside the Gut: Central and Peripheral Nervous Systems *Graham J Dockray* 515

GI Tract: General Pathology of Neuroendocrine Growths *Guido Rindi, Frediano Inzani, and Enrico Solcia* 520

Gastrin *Graham J Dockray* 525

Cholecystokinin (CCK) *Nori Geary* 529

Pancreatic Polypeptide (PP) *Dana K Andersen and F Charles Brunicardi* 534

Peptide YY (PYY) *Peter Holzer and Aitak Farzi* 546

Glucagon and Glucagon-Like Peptides *Daniel M Kemp and Joel F Habener* 555

Glucagon Like Peptide 2 (GLP-2) *Georgios K Dimitriadis and Alexander D Miras* 561

Enterochromaffin-Like Cells *Apostolos V Tsolakis* 565

Substance P *Miguel Muñoz and Rafael Coveñas* 571

Gastrointestinal Hormones in Cancer *Inbal Uri, Kristallenia Alexandraki, and Simona Grozinsky-Glasberg* 579

Somatostatin Receptor Expression in Gastrointestinal Tumors *Eleftherios Chatzellis and Gregory Kaltsas* 587

Gastrointestinal Neuroendocrine Tumor Syndromes (GI NETS) *Robert T Jensen* 597

Gastrinomas *Robert T Jensen* 617

Pancreatic Islet Cell Tumors *Ulrich Knigge, Mikkel Andreassen, Birgitte Federspiel, Carsten Palnæs Hansen, Andreas Kjær, and Seppo W Langer* 626

Peptide Neurotransmitters and Smooth Muscle in the Gut *JR Grider, KS Murthy, and GM Makhlouf* 635

Multi-Organ Endocrine Diseases

Pituitary Tumors Associated With Multiple Endocrine Neoplasia Syndromes *Liliya Rostomyan, Adrian F Daly, and Albert Beckers* 642

Endocrinology of Aging

Aging and Longevity of Human Populations *Diana van Heemst* 648

Animal Models for Aging *EC-H Lee, B Rogina, L Haynes, and GA Kuchel* 653

Oxidative Stress and Aging *Arthur K Balin and RG Allen* 659

Immunology and Aging *Victor Appay* 664

Premature Aging Syndromes *Fabio Coppedè* 669

Hormonal Circadian Rhythms and Sleep in Aging *Georges Copinschi and Anne Caufriez* 675

Circadian Clock, Epigenetic Regulators (Sirtuins), and Metabolism *Mirella L Meyer-Ficca and Ralph G Meyer* 690

Somatotropic Axis in Human Aging *Sabrina Chiloiro, Antonio Bianchi, Antonella Giampietro, and Laura De Marinis* 700

Abnormalities in Water Homeostasis in the Elderly *Laura E Cowen and Joseph G Verbalis* 708

Body Weight, Body Composition, and Aging *Odessa R Addison and Alice S Ryan* 713

Lipid Disorders in the Elderly *Wilbert Aronow* 719

Gonadotropins and Testicular Function in Aging *Fiona Yuen, Peter Y Liu, Ronald Swerdloff, and Christina Wang* 723

Hypogonadism and Testosterone Therapy in Elderly Men *Bu B Yeap* 729

Sexual Function in Aging Men *Giulia Rastrelli, Giovanni Corona, and Mario Maggi* 739

Osteoporosis in the Oldest Old *Evelien Gielen* 748

Aging and the Thyroid Gland *Leonidas H Duntas* 758

Endocrine toxicology and EDCs

Introduction to Endocrine Toxicology and Endocrine Disruption *Jorma Toppari* 762

Toxic Effects of Common Environmental Pollutants in Pancreatic β-Cells and the Onset of Diabetes Mellitus *Paloma Alonso-Magdalena, Eva Tudurí, Laura Marroquí, Ivan Quesada, Robert M Sargis, and Angel Nadal* 764

Endocrine Disruptors and Obesity *Sigal A Willner and Bruce Blumberg* 776

Endocrine Disruptors and Thyroid Function *Josef Köhrle* 787

Neuroendocrine Disruption of Reproduction *Julie Fudvoye, Jean-Pierre Bourguignon, and Anne-Simone Parent* 793

Association of Endocrine Disrupting Chemicals With Male Reproductive Health *Helena E Virtanen, Katharina M Main, and Jorma Toppari* 802

Endocrine Disrupting Chemicals and Behavior *Sheryl E Arambula and Heather B Patisaul* 812

VOLUME 2 – Neuroendocrinology, Pituitary Gland and Diseases, Female Reproduction, and Male Reproduction

Neuroendocrinology

Corticotropin-Releasing Hormone (CRH) *Nicolas C Nicolaides and George P Chrousos* 1

Neurotensin *Arthur Shulkes* 10

Carcinoid Syndrome *Marina Tsoli and Gregory Kaltsas* 13

Catecholamines *Graeme Eisenhofer and Jacques WM Lenders* 21

Pineal Tumors *María-José Barahona and Susan M Webb* 25

Vasopressin *Aoife Garrahy and Christopher J Thompson* 29

Effects of Steroid Hormones on Brain *Anne-Sophie CAM Koning, Russell D Romeo, Bruce S McEwen, and Onno C Meijer* 36

Memory and Epigenetics: Role of Estrogen *Jennifer J Tuscher, Ashley M Fortress, and Karyn M Frick* 42

VIPoma, Glucagonoma, and Somatostatinoma *Wouter T Zandee and Wouter W de Herder* 52

Insulinoma *Wouter T Zandee and Wouter W de Herder* 58

Melatonin *J Arendt* 63

Overview of Neurotransmitters *Floyd E Bloom* 75

Pituitary Gland and Diseases

Anatomy of Hypothalamus *Béla Halász* 81

Pituitary Gland Anatomy and Embryology *Béla Halász* 90

Hypothalamic Disease *Sylvia L Asa and Shereen Ezzat* 97

Diabetes Insipidus *Gary L Robertson* 107

Growth Hormone (GH) *Rikke Hjortebjerg, Gerhard Baumann, and John J Kopchick* 116

Natural and Synthetic Growth Hormone Secretagogues *Giovanna Motta, Stefano Allasia, Marco Zavattaro, Ezio Ghigo, and Fabio Lanfranco* 127

Luteinizing Hormone (LH) *Livio Casarini, Daniele Santi, Gary R Marshall, and Manuela Simoni* 142

Follicle-Stimulating Hormone (FSH) *Daniele Santi, Livio Casarini, Gary R Marshall, and Manuela Simoni* 149

Prolactin: Regulation of Secretion and Action *Filippo Maffezzoni, Gherardo Mazziotti, and Andrea Giustina* 157

Molecular Pathogenesis of Pituitary Tumors *Shereen Ezzat and Sylvia L Asa* 165

Classification of Pituitary Neuroendocrine Tumors (PitNets) *Jacqueline Trouillas, Alexandre Vasiljevic, Emmanuel Jouanneau, and Gérald Raverot* 176

Genetic Causes of Familial Pituitary Tumors *Maria Manuel Costa and Márta Korbonits* 185

Clinical Features of Acromegaly *I Ilie and M Korbonits* 212

Diagnosis of Acromegaly *I Ilie and M Korbonits* 223

Therapy for Acromegaly *Philippe Chanson* 230

ACTH-Secreting Pituitary Tumors *Rosario Pivonello, Maria Cristina De Martino, Davide Iacuaniello, Chiara Simeoli, and Annamaria Colao* 248

TSH-Secreting Pituitary Adenomas *Olympia Koulouri and Mark Gurnell* 261

Surgery for Pituitary Tumors *Pamela Jones and Brooke Swearingen* 267

Clinical Features, Diagnosis, and Management of Nonfunctioning Tumors of Pituitary *Athanasios Fountas and Niki Karavitaki* 271

Surgical Treatment of Nonfunctioning Pituitary Tumors *Michael Buchfelder and Yining Zhao* 281

Pituitary Radiotherapy *Frederic Castinetti and Thierry Brue* 289

Diagnosis and Clinical Management of Aggressive Pituitary Tumors *Gerald Raverot, Emmanuel Jouanneau, and Jacqueline Trouillas* 294

Hypopituitarism, Causes, Diagnosis, Management and Mortality *Athanasios Fountas and Niki Karavitaki* 301

Diagnosis of Prolactinoma and Causes of Hyperprolactinemia *James Ahlquist* 314

Prolactinomas: Clinical Manifestations and Therapy *Anna Scholz and Dafydd Aled Rees* 319

Hypophysitis *Federica Guaraldi, Olivera Casar-Borota, and Marie-Lise Jaffrain-Rea* 325

Radiology of the Pituitary *Jane Evanson* 339

Hyponatraemia *Aoife Garrahy and Christopher J Thompson* 349

Pituitary Disorders Following Traumatic Brain Injury *Anne Marie Hannon and Christopher J Thompson* 365

Female Reproduction

Folliculogenesis *Danielle Monniaux, Véronique Cadoret, Frédérique Clément, Rozenn Dalbies-Tran, Sébastien Elis, Stéphane Fabre, Virginie Maillard, Philippe Monget, and Svetlana Uzbekova* 377

Human Menstrual Cycle *Sophie Christin-Maitre* 399

Implantation *Lechosław T Putowski and M Nowak* 404

Pregnancy Endocrinology *Stefano Palomba and Jessica Daolio* 408

Placental Epigenetics and Outcomes in Children *Patricia Fauque* 418

Endocrinology of Delivery *Silvia Vannuccini and Felice Petraglia* 425

Premenstrual Syndrome (PMS) *M Link* 432

Amenorrhea *Sophie Christin-Maitre* 436

Congenital Hypogonadotropic Hypogonadism in Females *Jacques Young* 439

Functional Hypothalamic Amenorrhea *Sarah L Berga* 444

Polycystic Ovary Syndrome *Stephen Franks* 451

Polycystic Ovary Syndrome: Implications for Cardiovascular, Endometrial, and Breast Disease *HF Escobar-Morreale* 456

Ovarian Androgen-Producing Tumors *Michael DiMattina and Callum Potts* 458

Sport and Menses *Angelica Lindén Hirschberg* 461

Primary Ovarian Insufficiency *Luca Persani* 471

Adult Care of Turner Syndrome *Claus H Gravholt, Mette Viuff, Kirstine Stochholm, and Niels H Andersen* 482

Initial Evaluation of the Infertile Couple *Jean-Marie Antoine and Jacqueline Mandelbaum* 490

Endometriosis *Alain Audebert* 498

Epigenetics of Endometriosis *Daniel Vaiman* 506

Uterine Fibroids and Infertility *Jacques Donnez, Olivier Donnez, Pablo Arriagada, and Marie-Madeleine Dolmans* 513

Environmental Factors and Female Reproduction *Patrick Fénichel and Charlotte Rougier* 525

Miscarriages *Hervé Fernandez and Perrine Capmas* 538

Obesity and Reproduction *Andrés E Ortiz-Flores and Héctor F Escobar-Morreale* 543

Developmental Epigenetics and the Contribution of Parental Diet to Offspring Outcomes *Oliver J Rando and Rebecca A Simmons* 553

Anti-Müllerian Hormone (AMH) in Adults *Agathe Dumont, Geoffroy Robin, Sophie Catteau-Jonard, and Didier Dewailly* 556

Ovarian Stimulation with Clomiphene Citrate *J Gianfortoni* 567

Ovulation Induction With Gonadotropins *Aude Bruyneel, Ralph Papas, and Anne Delbaere* 570

Ovarian Hyperstimulation Syndrome *Basil C Tarlatzis, Julia K Bosdou, and Efstratios M Kolibianakis* 581

Fertility and Pregnancy in Patients With 21-Hydroxylase Deficiency *Virginie Grouthier, Carine Courtillot, Jérôme Dulon, Philippe Touraine, and Anne Bachelot* 588

In Vitro Fertilization (IVF) *Renato Fanchin* 595

Ovarian Failure Treatment Strategies: Egg Donation *Pedro N Barri* 599

Fertility Preservation in Women *Julie Benard, Alexandra Benoit, Charlotte Sonigo, and Michael Grynberg* 603

Female Hormonal Contraception *Genevieve Plu-Bureau* 615

Progesterone Receptor Modulators: Current Applications and Perspectives *Kamila Kolanska, Axelle Pintiaux, Philippe Bouchard, Emile Daraï, and Nathalie Chabbert-Buffet* 622

Diagnosis of Menopause *Tommaso Simoncini, Marta Caretto, Andrea Giannini, and Andrea R Genazzani* 628

Menopausal Treatment *Anne Gompel* 634

Hormonal Treatment of Breast Cancer *Stéphanie Bécourt and Marc Espié* 646

Hormonal Treatment of Male to Female Transgender *Alessandra D Fisher and Louis Gooren* 656

Male Reproduction

Testes Embryology: Cellular Molecular Changes *T Svingen and LJ Pelliniemi* 664

Spermatogonial Physiology and Regulation of the Niche *Stefan Schlatt and Swati Sharma* 670

Male Germ Cell Differentiation *My-Thanh Beedle and Michael D Griswold* 678

Endocrine Control of Spermatogenesis *TM Plant, S Ramaswamy, and Karel De Gendt* 684

Gonadotropin-Releasing Hormone (GnRH) Development and Actions *Margaret E Wierman* 692

Genes and Gene Defects Affecting Gonadal Development and Sex Determination *Dagmar Wilhelm and Stefan Bagheri-Fam* 695

Mutations of the Gonadotropin-Releasing Hormone Receptor Gene *Alfredo Ulloa-Aguirre, Teresa Zariñán, and Saúl Lira-Albarran* 704

Androgen Biosynthesis and Gene Defects *Adina F Turcu and Richard J Auchus* 713

Reproductive and Nonreproductive Actions of Testosterone *Shalender Bhasin and Ravi Jasuja* 721

Hormone Replacement Therapy in Men *Cindy Pham, Christina Wang, and Ronald S Swerdloff* 735

Male Hormonal Contraception *Brian T Nguyen, Ronald S Swerdloff, Frederick CW Wu, and Christina Wang* 741
Estrogen and the Male *Agnė Kadusauskienė and Jonas Čeponis* 751
Gynecomastia *Glenn D Braunstein* 763
Male Sexual Dysfunction *Amarnath Rambhatla and Jacob Rajfer* 767
Androgens and Benign Prostatic Hyperplasia *Maritza Farrant and Stephanie T Page* 775
Prostate Cancer *Timothy McClure, Spyridon P Basourakos, Jaspreet S Sandhu, Peter N Schlegel, and James J Colt* 784
Insulin-Like Peptide 3 (INSL3) *Ravinder Anand-Ivell and Richard Ivell* 793
Epididymis *Maria Christina W Avellar and Barry T Hinton* 807
Fertility in Men With Spermatogenesis Abnormalities *Katherine Rotker and Mark Sigman* 814
Genetics of Male Infertility *Csilla Krausz and Francesca Cioppi* 821
Testicular Tumors *Ewa Rajpert-De Meyts* 831
Male Oncoinfertility *Bernard Robaire and Peter T Chan* 840

VOLUME 3 – Adrenal Glands and Hypertension

Adrenal Glands and Hypertension

Adrenal Cortex; Physiology *Fady Hannah-Shmouni and Christian A Koch* 1
Adrenal Cortex; Development *Typhanie Dumontet and Antoine Martinez* 8
Corticotropin-Releasing Hormone Peptide Family *David W Hogg, Mia Husic, and David A Lovejoy* 16
Regulation of POMC and ACTH Secretion *Dongyun Zhang and Anthony P Heaney* 27
ACTH, Melanocortin Receptors, and MRAP Accessory Proteins *Robert M Dores* 38
Adrenocorticotropic Hormone (ACTH): Physiology and Its Involvement in Pathophysiology *George Mastorakos and Athanasios Antoniou-Tsigkos* 48
Adrenal Steroidogenesis *Daniel B Martinez-Arguelles and Vassilios Papadopoulos* 56
Overview of Glucocorticoids *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 64
Stress and Endocrine Physiology *Nicolas C Nicolaides, Panagiota Pervanidou, and George P Chrousos* 72
Hypothalamic–Pituitary–Adrenal Suppression *Nicolas C Nicolaides and George P Chrousos* 83
Glucocorticoid Metabolism and Activation *Nantia Othonos and Jeremy Tomlinson* 90
Glucocorticoid Receptor *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 104
Glucocorticoids and Immunity *Karen E Chapman* 112
Corticotropin-Releasing Hormone and Inflammation *Markella Nezi, Evangelia Zapanti, and George Mastorakos* 121
Adrenal Insufficiency: Etiology and Diagnosis *Nicolas C Nicolaides and Evangelia Charmandari* 131
Primary Adrenal Hypoplasia and ACTH Resistance Syndromes *Ioannis Kyrou and Constantine Tsigos* 139
Impact of Glucocorticoid Receptor Polymorphisms on Glucocorticoid Action *Mesut Savas and Elisabeth FC van Rossum* 147

Glucocorticoid Resistance Syndromes and States *Nicolas C Nicolaides and George P Chrousos* 157

X-Linked Adrenoleukodystrophy/Adrenomyeloneuropathy *William B Rizzo* 166

INTRODUCTION TO VOLUME 5

Pediatric Endocrinology transcends the whole of endocrinology as it relates to infants, children, and adolescents. Hence the decision to devote a standalone volume to the subject in this second edition of the Encyclopedia. In the first edition, topics such as congenital hypothyroidism, delayed puberty, and Turner syndrome were scattered throughout the encyclopedia based on using an alphabetical system. Now there is logic in collating topics uniquely specific to pediatrics together with those of an endocrine organ nature where the adult counterpart covered in addition in relevant sections of the other four volumes.

Growth, puberty, and disorders of sex development are completely within the purview of the pediatric endocrinologist and are covered in detail in this volume. Thereafter, chapters are more organ-specific (thyroid, adrenal, pituitary) and coupled with reference to further relevant information in the cognate adult chapter. There are also a number of chapters describing endocrine-related syndromes. A few topics are missing, such as rarer adrenal enzyme deficiencies but in particular, topics rela
ted to pediatric diabetes. Some aspects are covered in the adult diabetes section, but this omission will be rectified in due course by posting some chapters on line using the Reference Module system.

I acknowledge the support of the Editor in Chief, Ilpo Huhtaniemi, for allowing me the freedom to compile this volume, the authors for their excellent contributions, my fellow Section Editors for their ready collaboration, and the aforementioned Elsevier staff for their guidance and patience.

Ieuan Hughes

Control and Monitoring of Fetal Growth

Tomas Prior and Christoph Lees, Queen Charlotte's and Chelsea Hospital, London, United Kingdom; and Imperial College London, London, United Kingdom

Introduction

A favorable in utero environment facilitating adequate fetal growth is critical, not only for fetal and neonatal wellbeing, but also as a determinant of long term health. In the absence of other reliable measures, assessment of fetal growth has been the mainstay of fetal monitoring for over 100 years. Alfred Lewis Galabin, in his 1886 "Manual of midwifery," published charts of symphysio-fundal height (SFH) measurement, a measure that is still used to this day as a screening tool to identify the growth restricted fetus.

Over the last 40 years, ultrasound assessment has been established as the gold standard technique for monitoring fetal growth. Initially, assessment of fetal growth consisted of fetal biometry and calculation of an estimated fetal weight (via any one of a number of accepted formulae), with a comparison of these parameters to published longitudinal nomograms. The dilemma, that in part remains to this day, is distinction of the pathologically growth restricted fetus, failing to meet its genetic growth potential, from the physiologically small fetus. This distinction was made somewhat easier in 1984, when Schuman et al. observed that fetuses that were small for gestational age had significantly higher umbilical artery resistance indices (Schulman *et al.*, 1984), and Doppler ultrasound assessment of fetal blood flow is now a key component of any assessment of fetal growth.

Fetal Doppler has become ubiquitous as a monitoring tool in fetal growth restriction, with abnormalities in flow velocity waveforms from a number of fetal vessels being employed as triggers for delivery in the context of the premature and growth restricted fetus. However, even small fetuses with normal Doppler indices are at increased risk of requiring operative delivery during labour, when compared to appropriately grown fetuses (Danielian *et al.*, 1992). Furthermore, within a cohort of appropriately grown fetuses, mean birthweights and birthweight centiles are significantly lower in babies that develop signs of compromise in labour (Prior *et al.*, 2013), suggesting evaluation of fetal weight remains an important indicator of fetal wellbeing.

Control of Fetal Growth

Fetal growth is influenced by genetic, environmental and hormonal influences. It is beyond the scope of this article to describe all of these influences in detail, and instead will briefly discuss endocrine controls.

Perhaps the most important endocrine regulator of fetal growth is the IGF system (Gicquel and Le Bouc, 2006). This system acts through the interaction of two growth factors (IGF-I and IGF-II), the actions of which are influenced by up to six other binding proteins (IGFBP). While the IGF system does have endocrine effects, its actions are principally autocrine. Both IGF-1 and IGF-II play a role in fetal growth throughout gestation, however, IGF-I dominates in later gestation while IGF-II is the primary growth factor in the embryonic period. IGF-I concentrations correlate far more closely with fetal weight than do IFG-II (Fowden, 2003), which in turn has a greater influence on placental growth (Fowden and Forhead, 2009). The IGF system interacts with other growth influencing hormones, IGF-I production being increased by insulin (Fowden and Forhead, 2004), however, in contrast to the neonatal period, GH is not a strong facilitator of IGF action in utero. While IGF gene defects are rare in humans, the important role of the IGF system in determining fetal growth has been demonstrated in animal experiments. Baker et al. demonstrated in 1993 that mice fetuses lacking the IGF-I or IGF-II genes grow to around 60% of normal size, and the growth retarding effect is potentiated if both genes are lacking (Baker *et al.*, 1993).

The IGFs are mitogens and influence cell proliferation and differentiation, with the latter particularly prominent in late gestation with development of adult cell types. IGF-I appears to act to promote fetal growth through increased amino acid utilization and protein synthesis throughout the body. In contrast to IGF-II, IGF-I plasma levels are correlated with glucose and oxygen concentrations, leading to suggestions that IGF-I may act to ensure fetal growth responds appropriately to nutritional supply (Fowden and Forhead, 2009).

The other important endocrine controller of fetal growth is insulin. Metabolically insulin is an anabolic hormone, and its influence on fetal growth is clearly evidenced by the increased fetal growth observed in fetuses of diabetic mothers. Deficiency of insulin, as would be expected, results in fetal growth restriction (Fowden *et al.*, 1989). Insulin acts by increasing cellular uptake and utilization of glucose and amino acids. In doing so, insulin also reduces circulating concentrations of these metabolites and facilitates transfer across the placenta via an increased concentration gradient (Fowden and Hay, 1988).

Pathogenesis of Fetal Growth Restriction

Placental Etiology

For some time, the widely accepted model of placental dysfunction precipitating both fetal growth restriction, and the frequently associated pre-eclampsia, has centered around a failure of trophoblastic invasion (Burton *et al.*, 2009). In this model, failed trophoblastic invasion prevents adequate transformation of the uterine spiral arteries, and as a result, the placenta retains a high resistance circulation. This in turn precipitates release of mediators into the maternal circulation and subsequent endothelial dysfunction (Borzychowski *et al.*, 2006). While this hypothesis neatly explains the pathogenesis of fetal growth restriction, sub optimal trophoblastic invasion is also seen in 40% of normal pregnancies (Aardema *et al.*, 2001) and pre-eclampsia may also occur in the absence of fetal growth problems, suggesting other factors also play a role.

Maternal Cardiovascular Function and FGR

While early onset pre-eclampsia is frequently associated with fetal growth restriction, a growing body of evidence suggests that the late onset variant of the disease (after 34 weeks gestation and less often associated with growth restriction) is likely to have a different etiology. These two pre-eclampsia phenotypes may be distinguished both by placental pathology, but also by maternal cardiovascular parameters, leading to suggestions that maternal haemodynamics may be instrumental in the development of fetal growth restriction. Indeed, it has been shown that pregnancies affected by fetal growth restriction demonstrate a failure of maternal cardiovascular adaptations to pregnancy, with a significantly lower increase in cardiac output in the first trimester (Duvekot *et al.*, 1995). Since this observation, a litany of research has suggested that fetal growth restriction is associated with a particular maternal cardiovascular phenotype, that of a high peripheral resistance and low cardiac output state (Valensise *et al.*, 2008).

If the maternal cardiovascular system is instrumental in the development of fetal growth restriction, it raises the tantalizing prospect of not only better identification of pregnancies at risk of growth restriction, but also that interventions or therapies designed to alter this haemodynamic phenotype may be beneficial in pregnancies at risk of fetal growth restriction.

Genetic Factors

In contrast to fetal growth restriction, where a fetus fails to reach its genetic growth potential, often due to placental dysfunction, some fetuses have a reduced potential growth due to intrinsic genetic factors. The genetic influences on fetal growth are of course numerous and diverse, but the following examples give some indication of how genetic and epigenetic changes may influence fetal growth potential.

Russel Silver syndrome is characterized by both intrauterine and postnatal growth restriction. This phenotype is suspected to occur due to increased expression of maternal genes via a number of genetic pathways. Maternal uniparental disomy of chromosome 7 accounts for around 10% of cases, while imprinting errors on chromosome 11 account for up to 60% of cases. In general, maternally expressed genes inhibit growth while paternally expressed ones enhance growth. Chromosome 11 contains a group of paternally expressed genes including IGF-II. Imprinting errors may therefore result in under expression of IGF-II resulting in reduced in utero growth (Mascarenhas and Ayyar, 2012). Consequently, the growth retardation of Russel Silver syndrome can be significantly ameliorated with postnatal growth hormone therapy.

Triploidy is a chromosomal abnormality in which the fetus has 69 pairs of chromosomes and three sex chromosomes. Two distinct genotypes of triploidy have been reported, diandric where the fetus has an extra set of paternally derived chromosomes, and digynic where the fetus possesses an extra set of maternally derived chromosomes. These genotypes give rise to two distinct phenotypes, the digynic one being associated with marked asymmetrical growth restriction and relative macrocephaly, potentially due to over expression of maternal genes that impair fetal growth.

The most common chromosomal abnormalities are the trisomies, particularly trisomy 13, 18, and 21. While fetal growth restriction may be present in all three but is particularly prominent in trisomy 18. The precise etiology behind this is poorly understood, but it has been suggested that cell cycle times in trisomic fetuses may be prolonged, with a subsequent impact on fetal growth (Paton *et al.*, 1974).

Placental Morphology

As the organ facilitating fetal nutrition and gaseous exchange, the placenta has a fundamental role in fetal growth. It may therefore seem reasonable that examination of the placenta would yield valuable information. However, the value of morphological assessment of the placenta continues to be disputed. What is clear, is that as the placenta ages, there is increasing calcification within it, and it is premature appearance of this calcification that has in some studies been linked to a restriction in fetal growth (Patterson *et al.*, 1983).

Placental aging is most frequently assessed via the Grannum classification system, which grades placental maturity from 1 to 3 based on a subjective assessment of the degree of calcification and of indentation of the chorionic plate. However, much of the published data examining the relationship between placental aging and fetal growth has been limited by a lack of distinction between isolated placental calcification, and calcification associated with other causative factors of fetal growth restriction, such as cigarette smoking. Also, many studies of placental morphology were conducted some time ago, using ultrasound technology that has since been superseded. A more recent study conducted in 2010 did suggest that isolated premature placental calcification was indeed associated with a number of adverse neonatal outcomes, including low birth weight, but only when calcification appeared prior to 32 weeks gestation (Chen *et al.*, 2011). This supports the assertion that placental calcification is predominantly a physiological aging process in the placenta, rather than pathological, and the value of placental grading in clinical practice remains limited.

As well as examination of placental aging, a number of morphological sub-types of placenta have been described.

A *bilobed placenta* describes a placenta that is separated into two equally sized lobes. If one of the lobes is significantly smaller, this is termed a *succenturiate lobe*. Neither a bilobed or succenturiate lobe placenta has any consequence for fetal growth.

A circumvallate placenta describes a placenta in which the chorionic plate is small and as a consequence the edges of the placenta have a "folded in" appearance, with detachment from the myometrium and doubling back toward the centre of the placenta.

A velamentous cord insertion is when the umbilical cord inserts into the chorion-amniotic membrane, beyond the margin of the placenta. The vessels from the cord then travel within the membrane to the placenta. This affects 1% of singleton pregnancies but as many as 10% of twin pregnancies. Both velamentous cord insertion and circumvallate placenta have been associated with an increased risk of fetal growth restriction and therefore warrant increased surveillance of fetal growth.

Monitoring Fetal Growth

In an ideal world, the pathologically growth restricted fetus would be identified by comparing its growth to a known target, or genetic growth potential. However, determining an individual fetus' genetic growth potential is challenging, and therefore a surrogate marker for pathological growth must be utilized. Numerous definitions exist for fetal growth restriction, but the most common used clinically are as follows (Unterscheider *et al.*, 2013; Lees *et al.*, 2013; Gordijn *et al.*, 2016):

Small for gestational age—EFW <10th centile for gestation or AC <10th centile.

Fetal growth restriction—EFW <10th centile for gestation or AC <10th centile, AND Umbilical artery PI >95th centile.

At present, no effective treatment has been demonstrated to improve fetal growth or neonatal outcomes in cases of fetal growth restriction. With acknowledgement that growth restricted fetuses are exposed to a sub-optimal in utero environment, associated with chronic fetal hypoxia and increased risk of fetal death, but also that prematurity poses huge challenges to the newborn, timing of delivery is of paramount importance to achieve optimal neonatal outcomes. Careful monitoring of the growth restricted fetus is therefore critical to ensure delivery occurs before the risks of continued conservative management outweigh the benefits.

Fetal Biometry

Assessment of fetal biometry is the most basic element of fetal growth surveillance. Generally speaking, fetal biometry refers to the assessment of fetal growth via measurement of four different parameters; the bi-parietal diameter, the head circumference, the abdominal circumference, and the femur length. A number of formulae exist to use these parameters to generate a fifth, the estimated fetal weight. A rigorous approach to ultrasound assessment is essential in order to assess fetal biometry accurately, and minimize intra and inter-observer variability. Standardized international guidelines are published by the International society for ultrasound in obstetrics and gynecology in order to facilitate this (Salomon *et al.*, 2011).

It is crucial that any assessment of fetal growth is undertaken in the context of an accurately dated pregnancy. If the pregnancy has not been accurately dated, small for gestational age fetuses may be incorrectly assumed to be appropriately grown. Fortunately, in most developed healthcare settings, accurate pregnancy dating is achieved via assessment of the crown-rump-length (CRL) in the 1st trimester. CRL is considered the most accurate method of dating a pregnancy up to 84 mm/13 + 6 weeks, following which head circumference (HC) is preferred. If not dated via CRL measurement, two serial scans should be performed in order to assess growth velocity and ensure that a growth restricted fetus is not overlooked.

As well as assessment of fetal size at one point in time, the pattern of fetal growth may also be indicative of pathology. Fetal growth velocity refers to the change in fetal growth over a period of time, and may identify the fetus with pathological growth that has already achieved an appropriate weight. There is no international consensus as to what constitutes a pathological growth velocity, however, persistent deviation from an established growth centile should prompt concern. It should be noted that assessment of fetal growth velocity is particularly sensitive to intra and inter-observer error, and this is amplified if assessments are performed with short time intervals (Chang *et al.*, 1993). A number of published longitudinal nomograms exist for fetal biometry, however, there is considerable controversy as to whether such nomograms should be standardized or customized according to individual parameters such as maternal ethnicity, height etc. Two landmark and conflicting studies

have attempted to address this issue, but their conflicting results mean staunch proponents of each method remain. The intergrowth study, published in 2016, examined fetal weights in women with optimal health and antenatal care, in differing regions around the world. This study demonstrated no significant difference in fetal weights across the regions. Those who advocate against the use of customized charts argue that they risk "controlling out" pathology, and that the differences in fetal weight observed in different populations is manifest of differing rates of fetal growth restriction, not differing physiological fetal growth. These findings conflict with those of a large World Health Organization funded study, which did find growth disparity between different regions (Kiserud *et al.*, 2017).

Fetal Doppler

Doppler ultrasound utilizes the effect described by and named after Austrian physicist Christian Doppler in 1842, which describes the change in frequency between a transmitted electromagnetic wave and its reflection.

In 1977, Fitzgerald and Drumm reported a novel non-invasive technique, Doppler ultrasound, used to image the umbilical vein and umbilical artery (FitzGerald and Drumm, 1977). Until this time, assessment of fetal size had been the predominant method for assessing fetal wellbeing. By utilizing the Doppler effect, Doppler ultrasound allows assessment of flow velocities in fetal vessels in real time, and evaluation of blood flow velocity changes throughout the cardiac cycle. In 1984, Schulman et al. observed that small for gestational age fetuses had increased resistance to flow in the umbilical artery and suggested a potential role for umbilical artery Doppler assessment in clinical practice (Schulman *et al.*, 1984). Since then, numerous parameters, derived from the flow velocity waveform elicited using Doppler ultrasound, have been described but the pulsatility index is perhaps the most commonplace in contemporary clinical practice. The pulsatility index is a useful measure as it is considered independent of the angle of insonation of the Doppler waveform (the disparity between the direction of blood flow in the target vessel and that of the ultrasound beam). If this angle is >30 degree, the accuracy of blood flow velocity measurement via Doppler ultrasound is significantly compromised.

The pulsatility index is a measure of the variance of blood flow velocity within the vessel throughout the cardiac cycle and is calculated as follows:

$$\text{Pulsatility index (PI)} = \frac{\text{Peak systolic velocity} - \text{Trough diastolic velocity}}{\text{Mean blood flow velocity}}$$

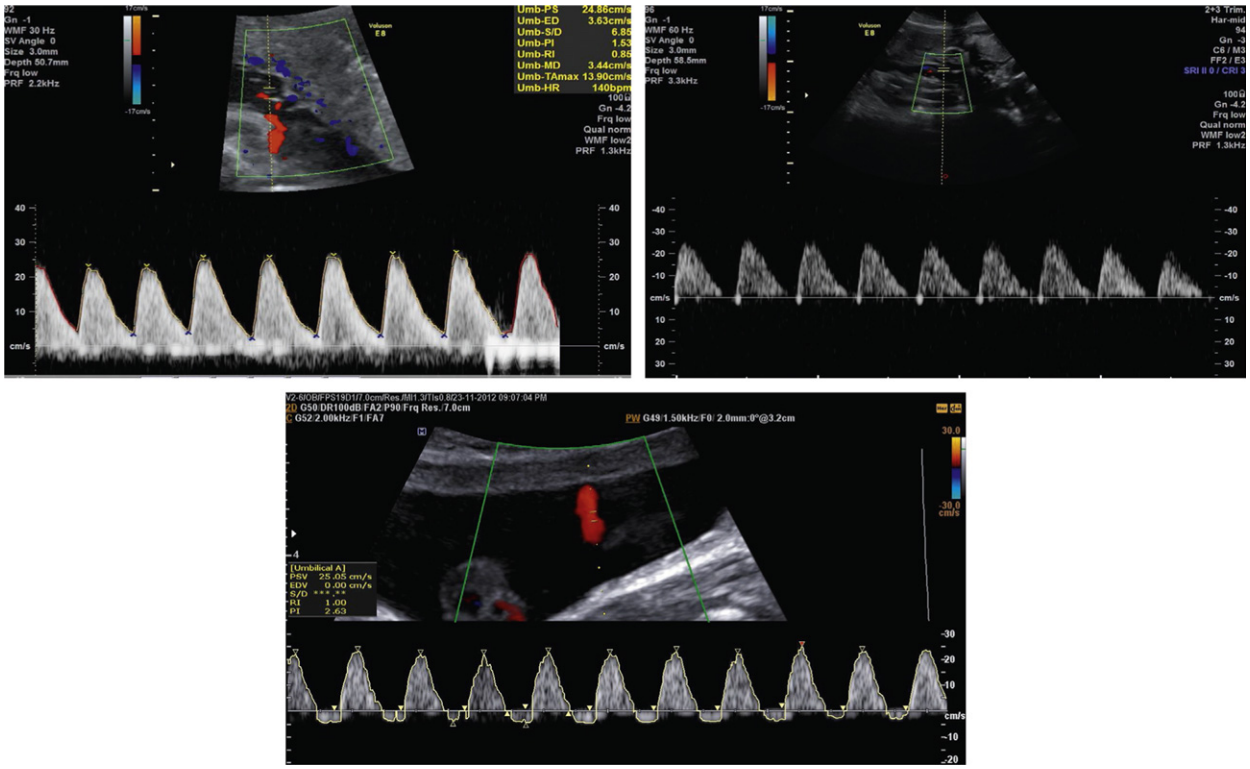

Fig. 1 Progression from raised umbilical artery PI to absent and then reversed EDF.

Doppler assessment of the umbilical artery, middle cerebral artery, and the ductus venosus have established roles in fetal monitoring. Assessment of these vessels can facilitate optimal timing of delivery in the context of fetal growth restriction.

Umbilical Artery

In a structurally normal fetus, two umbilical arteries carry blood from the fetus to the placenta for gaseous and nutrient exchange. Resistance to blood flow in the umbilical arteries is thus descriptive of resistance within the placenta.

Doppler assessment of the umbilical artery has been reported at a number of locations, including the placental cord insertion, paravesical, or more frequently at a free loop. The location of sampling is important to maximize reproducibility, as the resistance falls along the length of the cord, being lowest at the placental end and highest at the fetal end. Acquisition of flow velocity waveforms using Doppler ultrasound should take place in the absence of fetal movements or breathing movements, and ideally from a free loop of cord with the umbilical artery running parallel to the ultrasound beam, and certainly with an angle of insonation <30 degree. At least three consecutive waveforms should be recorded and the average pulsatility index calculated.

A progressive pattern of abnormal flow in the umbilical artery has been observed in growth restricted fetuses (see **Fig. 1**). Initially a raised pulsatility index is observed due to reduced diastolic blood flow associated with increasing resistance to flow in the vessel. If resistance increases sufficiently, diastolic flow ceases all together, a finding termed "absent end diastolic flow (AEDF)." Further progression may result in reversal of blood flow in the umbilical arteries during diastole (reversed EDF). By monitoring umbilical artery Doppler over serial ultrasounds, progression along this pathological pathway can be identified, and used to facilitate timely delivery of the fetus. The use of umbilical artery Doppler has been demonstrated to reduce the incidence of perinatal death (Alfirevic *et al.*, 2010) and to predict fetal/neonatal compromise (Morris *et al.*, 2011). Critically, undiagnosed SGA babies are four times more likely to die than those monitored with umbilical artery Doppler (Lindqvist and Molin, 2005). In general, if the umbilical artery has positive diastolic flow, it is reasonable to continue to manage the pregnancy conservatively until 36 weeks gestation. If there is absent or reversed diastolic flow, delivery is indicated after 32 weeks and should be considered between 30 and 32 weeks. Prior to 30 weeks, timing of delivery is based on assessment of the ductus venosus, which will be discussed later in this article.

The value of umbilical artery Doppler assessment in the appropriately grown fetus is less clear. Conventional thinking has considered umbilical artery Doppler of little use when fetal growth is appropriate for gestational age. However, over the last 10 years, a number of published studies have contributed to a growing consensus that umbilical artery Doppler may be descriptive of placental function, and thus fetal wellbeing, even in the context of an appropriately grown fetus. This suggestion is not new, with authors as far back as 1991 reporting higher rates of Caesarean delivery for fetal compromise, within a low risk cohort, in babies with abnormal umbilical artery waveforms (Arduini *et al.*, 1991). More recently, increased resistance in the umbilical artery, particularly when combined with reduced resistance in the middle cerebral artery, has been associated with fetal compromise in labour (Prior *et al.*, 2013). However, whether umbilical artery Doppler should be used as part of routine fetal monitoring remains contentious, with a systematic review in 2010 demonstrating no benefit in an unselected low risk population (Alfirevic *et al.*, 2010). Furthermore, there are concerns relating to the potential for false positives and associated increased rates of intervention. Such an approach to fetal monitoring would also have significant health economic implications.

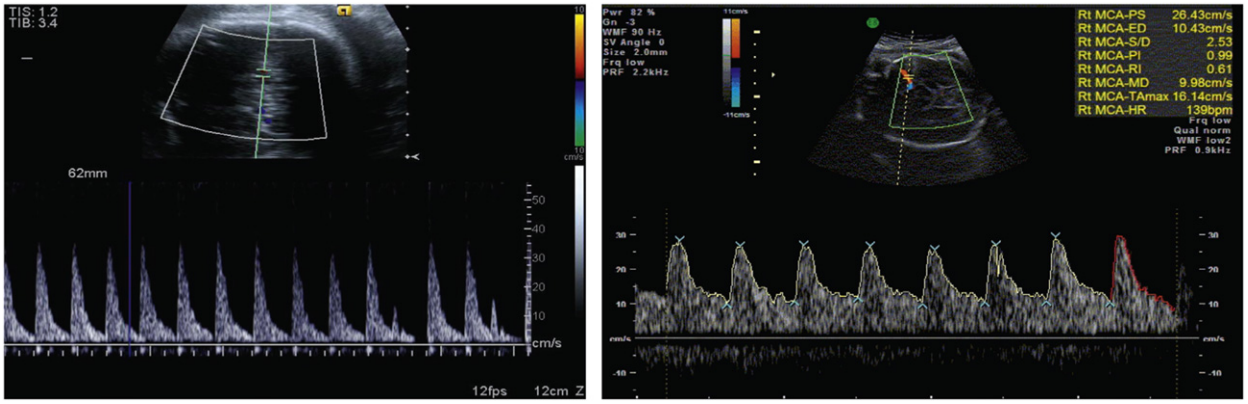

Fig. 2 MCA Doppler from a normal fetus, showing little end diastolic flow, and a growth restricted fetus, with cerebral redistribution demonstrated by increased end diastolic flow.

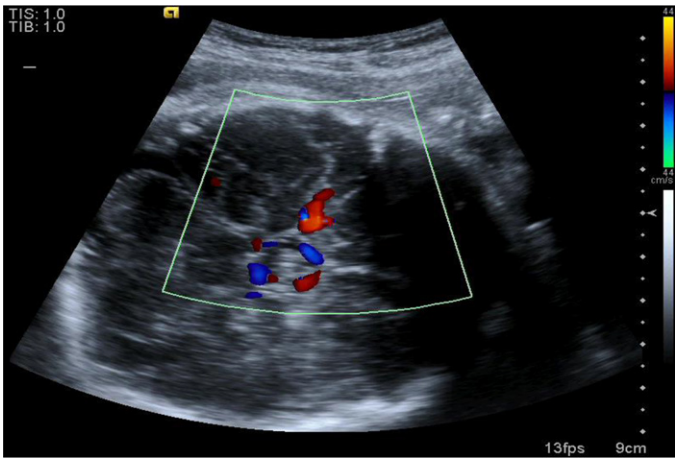

Fig. 3 The middle cerebral artery imaged using color Doppler.

Middle Cerebral Artery

In 1991, Thornburg et al. reported that in response to stress, fetuses redistribute blood flow preferentially toward the brain, cardiac muscle, and adrenal glands, at the expense of other organs considered less "vital" (Thornburg, 1991). What was later termed 'brain sparing' was initially demonstrated in growth restricted fetuses by Doppler assessment of the internal carotid artery. However, the middle cerebral artery became established as the vessel of choice for assessment of cerebral perfusion due to its ease of access and favorable anatomical path, which lends itself to an angle of insonation close to 0 degree and thus acquisition of accurate flow velocity waveforms. Despite this, careful acquisition remains critical as Doppler parameters are influenced both by the segment of the middle cerebral artery sampled, but also the pressured applied to the fetal head using the ultrasound probe.

Initial studies examining the use of middle cerebral artery Doppler in the assessment of fetal growth were conflicting, with some suggesting resistance was reduced in cases of fetal growth restriction (Ishimatsu *et al.*, 1989), while others found no change (Veille and Cohen, 1990). Further investigation however confirmed that while evidence of brain sparing was not present in all growth restricted fetuses, its presence was associated with an increased risk of adverse neonatal outcome (Arduini and Rizzo, 1992) (**Fig. 2**).

The middle cerebral artery branches from the circle of Willis and runs laterally just superior to the wing of the sphenoid bone. It is imaged by taking a transthalamic plane of the fetal head and using color Doppler to identify the circle of Willis (**Fig. 3**).

Ductus Venosus

The ductus venosus completes the triad of fetal vessels used in monitoring fetal growth in high risk cases. The ductus venosus branches from the left umbilical vein and acts as a shunt allowing freshly oxygenated blood to bypass the fetal liver and flow directly into inferior vena cava. Around 50% of blood takes this path, with the proportion decreasing with advancing gestation. In physiological pregnancy the ductus venosus has a triphasic waveform, incorporating two velocity peaks (ventricular systole and diastole), followed by a reduction in velocity with atrial systole.

The ductus venosus can be imaged either in a mid-sagittal plane, or an oblique transverse plane, and is identified as a branching vessel from the umbilical vein with turbulent flow on application of color Doppler.

With severe placental dysfunction, there is preferential redistribution of blood to the fetal brain and myocardium, achieved in part by reducing resistance to flow in the cerebral circulation, but also via increased resistance to flow in the peripheral vasculature. This increases afterload on the right ventricle, which if progressive can result in tricuspid regurgitation and the concomitant changes observed in the ductus venosus waveform. These changes are particularly treacherous for the fetus, as they further reduce the flow of oxygenated blood from the umbilical vein to an already compromised myocardium (Kaponis *et al.*, 2011). Progressive changes in the ductus venosus can be observed in growth restricted fetuses, typically commencing with a reduction in blood flow during atrial systole and a correspondent increase in the pulsatility index. The presence of absent or reversed flow in the ductus venosus during atrial systole (absent/reversed a-wave) is associated with poor perinatal outcomes and implies failure of fetal compensatory mechanisms to preferentially supply vital organs with well oxygenated blood (Baschat *et al.*, 2003). Absent or reversed a-wave in the ductus venosus thus identifies fetuses at the highest risk of in utero demise.

The Cardiotocograph

The fetal cardiotocograph (CTG) is most frequently used for fetal monitoring in the intra-partum period. However, its use in the antenatal period is also commonplace, particularly in growth restricted fetuses, where abnormalities of fetal heart rate rhythm may prompt delivery. CTG may be interpreted by a trained observer, or using computerized analysis—computerized CTG (cCTG).

When interpreted by an observer, the CTG is analyzed according to its five constituent parts, before these are combined to give an overall assessment. While this form of CTG is commonplace, it has been criticized for a high inter-observer variability rate. Computerized CTG aims to eliminate this, by providing a computerized assessment of the fetal heart rate rhythm according to preset criteria.

The five criteria analyzed during CTG interpretation are as follows:

Baseline rate—This describes the fetuses normal heart rate and should be anywhere between 110 and 160 bpm.

Variability—Variability is a description of the variation in fetal heart rate. A normal fetal heart rate has a variability of 5–25 bpm and is descriptive of the interplay between the sympathetic and parasympathetic nervous system. A reduction in variability is thus an ominous sign.

Accelerations—These are short periods of elevation of the fetal heart arte above the baseline rate by >15 bpm for >15 s. Accelerations are frequently associated with fetal movement and are thus indicative of a functioning somatic nervous system and are reassuring.

Deceleration—These are short periods of reduction in the fetal heart rate, below the baseline rate by 15 bpm for 15 s. There are numerous different types of decelerations observed during labour, and not all are pathological, however decelerations occurring in the antenatal period in the absence of precipitating uterine contractions are nearly always a sign of fetal compromise.

Short term variation—Short term variation (STV) examines the variability of the fetal heart rate from beat to beat, and cannot be interpreted by observer visual analysis. This parameter is only available with computerized CTG. A reduced STV (<3.0 msec) has been reported to correlate with stillbirth and severe fetal acidaemia (Dawes *et al.*, 1991).

Timing Delivery of the Growth Restricted Fetus

In the UK, the RCOG has issued national guidelines to facilitate optimal timing of delivery of growth restricted fetuses, to maximize the benefits of conservative management with the concomitant reduction in the complications of prematurity, but also attempting to avoid in utero demise (Royal College of Obstetricians and Gynaecologists, 2013) (RCOG green top Small for Gestational age). Until a gestation of 30 weeks, delivery, particularly of the growth restricted fetus, may be associated with significant risk of cerebral palsy as well as other adverse neurodevelopmental outcomes. There are also other significant complications of prematurity such as respiratory and gastrointestinal sequelae. As such, delivery at these gestations is only indicated in cases where fetal compensatory mechanisms are failing and the risk of in utero demise is considered high with continued conservative management. At gestations <30 weeks, it is therefore reasonable to continue with conservative management as long as the ductus venosus a-wave remains positive. Between 30 and 32 weeks, delivery should be considered in the context of absent or reversed end diastolic flow in the umbilical artery. After 34 weeks, the risks of prematurity are lower, though not inconsequential, and thus the delivery may be indicated in the context of a growth restricted fetus with a raised umbilical artery PI.

While the above recommendations are followed in many obstetric units, evidence for the best triggers for delivery, particularly in the context of early onset growth restriction, is limited. Most studies have reported only short term neonatal outcomes limiting their value. One randomized trial, the GRIT study (GRIT Study Group, 2003), allocated patients with early onset growth restriction to either early or delayed delivery, and reported no significant difference in outcomes for either group. More recently, the TRUFFLE group (Lees *et al.*, 2013) have tried to address this question by randomizing women with early onset growth restriction to delivery based on either reduced computerized CTG short term variation, early Doppler changes in in the ductus venosus (raised pulsatility index), or late Doppler changes in the ductus venosus (absent or reversed a-wave). The authors reported that delivery based on late Doppler changes in the ductus venosus may be associated with an improvement in developmental outcomes at 2 years of age, however, this may be associated with an increased rate of antenatal fetal death. The study also demonstrated that outcomes for survivors, even at gestations of 26–28 weeks gestation, were better than anticipated, with over 70% of survivors having normal outcomes in all three monitoring groups.

Summary

While there is now a good understanding of many of the mechanisms controlling fetal growth, interventions to improve fetal growth in cases of fetal growth restriction remain out of reach. In lieu of treatment, we must optimize the timing of delivery to maximize the benefits of conservative management whilst minimizing its risks. To this aim, clear national guidelines now exist to facilitate the use of fetal Doppler in a consistent manner, and optimize neonatal outcomes in cases of fetal growth restriction.

Physiology of Growth Hormone in Fetus and Child

Vijayarangan G Kannian and Fiona J Ryan, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom

Historical Perspective

Even before there was a written history, dwarfs appeared in the artwork of many cultures. It was in the 19th century, individuals with growth stunting were defined as "dwarfs" if disproportionate and as "midgets" if proportionate. In the early 20th century the term "ateliosis" was created by an English physician, Hastings Gilford, to describe patients with proportional short stature. He further subdivided ateliosis based on with and without sexual maturation.

Charles S. Stratton, was the most famous likely growth hormone (GH) deficient individual better known by his stage name "General Tom Thumb". He achieved great fame as a performer under circus pioneer and distant relative P T Barnum. Born (January 4, 1838) to parents of medium height who were first cousins, Charles was relatively large baby weighing 9 pounds and 8 ounces (4.3 kg) at birth. He grew steadily until 18 months of age; thereafter his height did not progress as expected and reached an adult height of 3 ft. 2 in. Charles was married to Lavinia Warren Bump, she as well a likely growth hormone (GH) deficient lady, who started her career as a school teacher and switched to circus performer after learning about Charles S Stratton's nationwide success. Lavinia was born (October 31, 1842) to normal parents, who were third cousin and she grew normally until the age of 1 year and then her growth was slowed down reaching an adult height of 2 ft. 8 in. Due to their proportionate short stature, normal birth weight and height, growth retardation starting in the first year of life, normal intelligence, and normal sexual development, it is assumed that both Stratton and Bump had autosomal recessive growth hormone deficiency.

Introduction

Growth in childhood is an overall indicator of health and development. Human linear growth can be divided into three phases—infancy, childhood, and puberty. The infancy phase is the continuation of fetal growth and it is nutritionally driven, childhood phase is mostly dependent on growth hormone (GH), whilst the pubertal phase depends on the combination GH and sex steroids (Tse *et al.*, 1989).

GH production begins in early fetal life and GH is secreted from the anterior pituitary gland in a pulsatile fashion. The levels of GH vary during childhood and peak during the pubertal growth spurt. The GH pulse frequency and the amplitude is influenced by a number of factors including age, gender, sleep, nutrition, exercise, and pubertal status. Apart from the linear growth, GH also play an important role in the intermediary metabolism of glucose, fats, and proteins.

Human Growth Hormone (GH) also known as somatotropin, is a 191-amino acid single—chain polypeptide that is synthesized, stored and secreted by somatotrophs of the anterior pituitary gland. In the fetus, growth hormone production begins as early as 7 weeks of gestation, reaches the maximum level at 20–24 weeks of gestation and continues thereafter throughout life, although at a progressively lower rate (Root, 1976). Growth hormone exerts its growth promoting and metabolic activities by interacting with a cell surface GH receptor (GHR). The majority of the growth promoting effects of GH are mediated via the production of IGF-1.

The Growth Hormone Gene

The human growth hormone (GH) gene family comprises of five distinct genes which are pituitary GH, *GH-N*; placental GH variant, *GH-V*, and the placenta expressed CS genes, *CS-A*, *CS-B*, *CS-L* all located on the long arm of chromosome 17 at position 23.3 (**Fig. 1**).

These five Growth Hormone (GH) genes are closely related, share 90%–99% nucleotide sequence similarity, and are believed to have evolved by gene duplication (Chen *et al.*, 1989). The pituitary GH gene encodes two alternatively spliced mRNA products and as a result two growth hormones are translated, the full length transcript 191 amino acid, 22-kDA protein that makes up

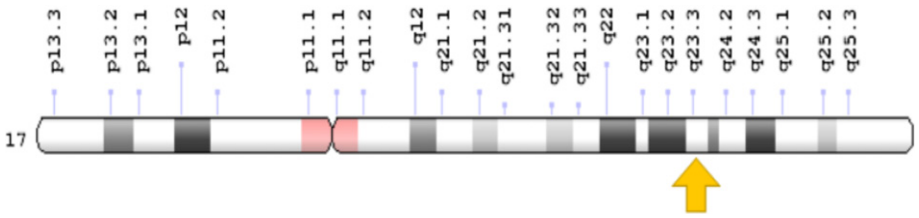

Fig. 1 The growth hormone gene.

 doi:10.1016/B978-0-12-801238-3.65221-2

majority (80%–95%) of the circulating pituitary GH and the 20-kDA protein which lacks amino acids 32–46 and this account for the remaining 5%–15% of the circulating GH.

PIT1 is a pituitary-specific transcription factor which belongs to the POU family of transcription factors that regulate mammalian development. The binding of PIT1 to the specific HS 1/2 (Hypersensitive sites) of the human growth hormone locus control region (LCR) is an important step in the expression of *h*GH-N gene, and that defines the somatotroph cells. However the Pit1 protein also plays an important role in the expression of prolactin-producing lactotrophs and thyroid stimulating hormone producing thyrotroph (Yang *et al.*, 2010).

Deletion and splice site mutation of the GH gene results in various forms of isolated growth hormone deficiency (IGFD). *HESX1*, a member of the homeobox family of genes plays a crucial part in the early determination and differentiation of the pituitary gland. Heterozygous mutations of *HESX1 gene* have been identified in children with various forms of hypopituitarism and SOD. Mutations in *Prop-1 gene* and in the *POU1F1 (Pit-1) gene* also account for rare cases of GH deficiency that are usually accompanied with other pituitary hormone deficiencies (Dattani, 2005).

Growth Hormone Structure

The major structural feature of the GH molecule is the three-dimensional fold of a four-helical bundle protein with an unusual connectivity. Cytokines such as prolactin, erythropoietin and many interleukins share similar structural configuration. The NH2 and COOH-terminal helices (helices 1 and 4) are longer than the other two helices (helices 2 and 3). Crystal structure analyses indicate that these helices run in a unique up-up-down-down pattern, in contrast to the more usual pattern of up-down-up-down. A long crossover connection (consisting residues 35–71) links helix 1 and helix 2 and a similar connection (residues 129–154) is found between helices 3 and 4. Of the two disulphide bonds, one links the N-terminal and C-terminal regions (Cys 53-Cys 165) and the second disulphide bond is located at the C-terminus (Cys 182-Cys189) (de Vos *et al.*, 1992). The other important feature of the hGH is the two zinc ($Zn2+$) binding sites which is identified at residues His 44 and Glu 200. The binding of $Zn2+$ is critical for facilitating GH dimerization and aggregation in the secretory granules biogenesis of the anterior pituitary gland. This is the process through which growth hormone is stored and released readily into the circulation upon appropriate stimulation without necessitating de novo protein synthesis (Cunningham *et al.*, 1991) (**Fig. 2**).

Growth Hormone Receptor (GHR)

The growth hormone receptor GHR is a homo-dimeric single pass transmembrane receptor belonging to the cytokine/haemopoietin receptor superfamily. The receptor consist of an extracellular ligand binding domain (ectodomain), a single pass membrane-spanning domain (transmembrane domain) and a cytoplasmic signaling component (cytoplasmic domain) which recruits and activates JAK-2 and subsequent intracellular signaling cascades. For a long time it was understood that the GH induced the dimerization of monomeric GHR polypeptide and this was based on receptor dimerization model of Fuh et al. More recent studies suggests that the full length GHR dimerization occurs in the absence of ligand (GH) and subsequent binding of one molecule of GH induces GHR conformational and rotation changes that activate the GHR signaling cascades via JAK-2.

Extensive mutational and crystal structure analysis has revealed two essential binding sites within the GH protein which interact with each monomer of the dimeric GHR. Although the two binding sites on GH have no structural similarity, the residues on both the monomers that interact with these sites are largely the same. The ectodomain of the GHR can be proteolytically cleaved to circulate as a monomeric GH binding protein (GHBP). The GHBP binds the circulating GH in a 1:1 ratio and this association provides as a dynamic reservoir for bound and free GH (**Fig. 3**).

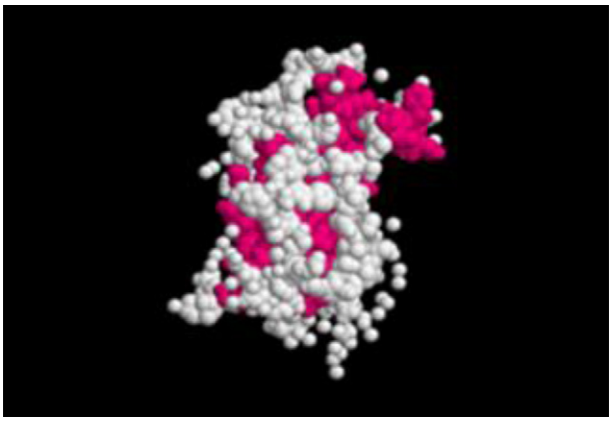

Fig. 2 Structure of GH (wikipedia).

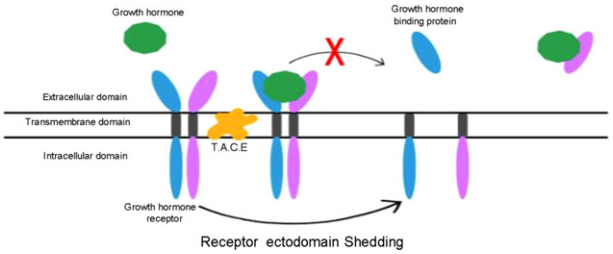

Fig. 3 Growth hormone receptor.

The Regulation of Growth Hormone Secretion

The secretion of growth hormone is pulsatile in nature rather continuous release in all species. GH secretion is controlled by many factors/influences that make it one of the more complex regulated hormones in the body. The hypothalamic neuropeptides, growth hormone-releasing hormone (GH-RH) and somatotropin release-inhibiting factor (SRIF, Somatostatin) secrete and inhibit growth hormone respectively. The hypothalamic stimulatory influence on GH secretion was first suggested by Reichlin and later by Frohman who demonstrated reduced plasma GH levels on destruction of the ventromedial hypothalamus and on electrical stimulation of the ventromedial and arcuate nuclei of hypothalamus caused acutely increased GH release in young rat models (Goldenberg and Barkan, 2007). Growth hormone is secreted relatively more during the early to mid-adolescence years, about 700 μg/day which is almost double the levels when measured in adulthood (approx. 400 μg/day). Because of the pulsatile pattern of GH secretion, the serum concentration of GH is quite variable and usually low when measured on healthy individuals (Burgess *et al.*, 2002).

Growth Hormone-Releasing Hormone (GHRH)

Growth hormone-releasing hormone, also known as GH-releasing factor (GRF) is a 44-amino acid peptide produced in the ventromedial and arcuate nuclei of the hypothalamus. The stimulatory hypothalamic neuropeptide, GHRH was first originally isolated from extrahypothalamic/extrapituitary (pancreatic) tumor cells of a Turner's syndrome patient with acromegaly (Thorner *et al.*, 1982). Studies in animal models and humans have unequivocally documented that GHRH as the primary GH pulse generator as well as exert a positive effect of somatotrope proliferation. Further studies have confirmed the direct relationship of GH pulsatile with increased concentration of GHRH in the portal blood (Burgess *et al.*, 2002). The GHRH receptor (GHRH-R) present on the anterior pituitary somatotroph cells belongs to the family of the G protein-coupled receptors. Upon stimulation by GHRH results in the production cyclic adenosine monophosphate and this leads to increased GH synthesis and secretion. GH secretion is greater in the childhood and adolescence age range than in adulthood. This age related attenuation of GH secretion (somatopause) is due to diminished GHRH secretion and perhaps the pituitary responsiveness to GHRH remains intact. At all ages, the effect of GHRH on GH secretion is partially blocked by the administration of somatostatin which inhibits GH secretion and controls the GH pulse frequency (Backeljauw and Hwa, 2016).

Ghrelin (S)

Ghrelin is a peptide hormone primarily expressed in gastric cells and ghrelin mRNA has also been identified in hypothalamus. It is 28 amino acid molecule and circulates in two forms: the active form octanoylated peptide and the inactive form deoctanoylated peptide. A number of synthetic analogues of ghrelin (GHS) have been discovered, capable of stimulating GH secretion. These peptides act on the receptors differently to GHRH. This distinct receptor is known as the GH secretagogue receptor and also belongs to the G protein-coupled receptor family (Smith *et al.*, 1999). Administration of GHS results in immediate release of GH but when administered along with the GHRH results in massive release of GH suggesting the synergistic effect of hypothalamic GHRH that is essential for their action (Bowers *et al.*, 1991). There is no increased level of ghrelin during fasting when there is increased GH secretion and no correlation of ghrelin levels to GH pulses (Avram *et al.*, 2005).

Somatostatin or Somatotropin Release-Inhibiting Factor (SRIF) (I)

Somatostatin, also called somatotropin release inhibiting factor, is a 14 amino acid molecule (tetradecapaptide) secreted from the neuroendocrine cells located in the ventromedial nucleus of the hypothalamus. Through the hypothalamo-portal network, somatostatin reaches the anterior pituitary gland, where it inhibits the secretion of GH from the somatotroph cells. At this level, it has a dominant effect over GHRH on GH release. It inhibits the basal as well as the stimulated GH secretion (amplitude of GH pulse) but not the GH pulse frequency and the diurnal rhythm of GH secretion (Dimaraki *et al.*, 2003). With the "shortfeedback" loops which operates at the hypothalamus level, somatostatin secretion is directly stimulated by GHRH and GHRH secretion is inhibited by somatostatin (Yamauchi *et al.*, 1991). At the same level, pituitary GH inhibits hypothalamic GHRH secretion and

stimulates somatostatin release from the hypothalamic neurons. This overall complex pathway plays an important role in the creation of pulsatile GHRH and somatostatin secretion pattern and ultimately the GH release from the pituitary in a pulsatile pattern (Chomczynski *et al.*, 1988; Chihara *et al.*, 1981). The classic negative feedback mechanism to GH secretion is mainly due to the increased serum concentration of GH and IGF-1 which stimulates the release of the somatostatin from the hypothalamic neurons. There are five subtypes of somatostatin receptors (SSTR-1—SSTR-5) of which four subtypes are expressed in somatotrophs. Somatostatin preferentially acts on SSTR-2 and SSTR-5 receptor to suppress the secretion of pituitary GH by inhibiting the intracellular adenylate cyclase activity and thereby reducing the intracellular calcium.

Other Regulators

Insulin-like growth factor-1 (IGF-1) which mediates most of the peripheral actions of GH inhibits the secretion of GH through the classic negative feedback mechanism. Although the exact mechanism is not known it acts both directly at the level of pituitary gland and indirectly at the level of hypothalamus to lower the GH concentration and the pulse amplitude (Ceda *et al.*, 1987).

Sex steroids (estrogen and androgen) cause increased secretion of GH during puberty with increased concentration of serum GH and IGF-1. Although the exact regulatory mechanism of GH by sex steroid is not known, it acts differently in both males and females.

Sleep appears to increase the GH secretion and this has been well documented in both animal and human studies.

Nutrition influences GH secretion and it varies between fasting and fed conditions. Hypoglycaemia causes acute rise in GH secretion that is dependent on both the severity and the rate of glucose fall. Insulin induced hypoglycaemia has been demonstrated to show acute rise in GH secretion and this has been long been used as part of assessment of growth hormone deficiency. Hyperglycaemia causes suppression of GH secretion and again this has been demonstrated in oral glucose tolerance test to assess the individual ability to suppress the GH secretion after administration of a fixed amount of glucose.

Growth Hormone in Fetal Life

Growth hormone has relatively little effect on fetal growth, as GH receptors are generally expressed at very low levels in the fetal tissues. Fetal growth is a complex, dynamic process which primarily depends upon fetal genetics, nutrient supply and various growth factors and hormones of maternal, fetal and placental origin.

The IGF system that comprises of two ligands (IGF-1, IGF-2), two receptors and six binding proteins (IGFBPs) plays the crucial role in the regulation of fetal and placental growth. IGF-1 stimulates and ensures fetal growth that is appropriate for the available nutrient supply, whilst IGF-2 plays a key role in the placental growth and nutrient transfer. Both IGF-1 and IGF-2 are expressed in fetal tissues as early as from pre-implantation to final phase of tissue maturation before birth. In fetus, the IGFs are thought to act in an autocrine fashion and the endocrine-systemic actions occur in the latter half of the gestation. Most studies have found no correlation between IGF-2 concentration and birth weight but there is strong association between IGF-1 concentration and birth weight, and this has been shown with decreased concentration of IGF-1 in utero and at birth with the fetuses displaying intrauterine growth retardation (Fowden, 2003).

Fetal GH is produced by the pituitary gland from the end of the first trimester (Kaplan *et al.*, 1972). In the placenta, the syncytiotrophoblast cells expresses the GH-V gene that encodes human placental growth hormone (PGH). Like GH, the protein sequence of PGH contains 191 amino-acid residues but differs by 13 amino-acid. The regulation of PGH is less understood, secreted in a rather non-pulsatile fashion and predominates in the third trimester of pregnancy when the GH levels are low. The serum PGH concentration during normal pregnancy vary, it is detected in the serum as early as at 5 weeks of gestation and reaches its peak value in week 34–37. After this gestational age, studies have shown slight decline in PGH levels (Chellakooty *et al.*, 2004) but other studies have shown no consistent changes in the level of PGH (Frankenne *et al.*, 1988; Wu *et al.*, 2003).

The serum PGH level start to decline immediately as the placenta, which is the source is removed from the uterus. Several studies have shown a positive correlation between serum PGH and IGF-1 levels both in cross-sectional and longitudinal studies. Thus the IGF-1 secreted in response to PGH ensures appropriate fetal growth (Caufriez *et al.*, 1990, 1993) (**Fig. 4**).

Insulin Like Growth Factor-1 (IGF-1)

It was in 1957, works from Salmon and Daughaday, showed that the actions of GH was mediated by a factor which they initially named as sulfation factor because they found that the uptake of organic phosphate by cartilage was not affected by addition of GH. Later they proposed the factor as somatomedin as it mediates the action of somatotropin (GH). The present name insulin like growth fator-1 (IGF-1) was designated to indicate the chemical structural similarity to insulin and it is the major mediator of growth hormone (GH) stimulated somatic growth, as well as GH-independent anabolic responses in many cells and tissues (Lindholm, 2006).

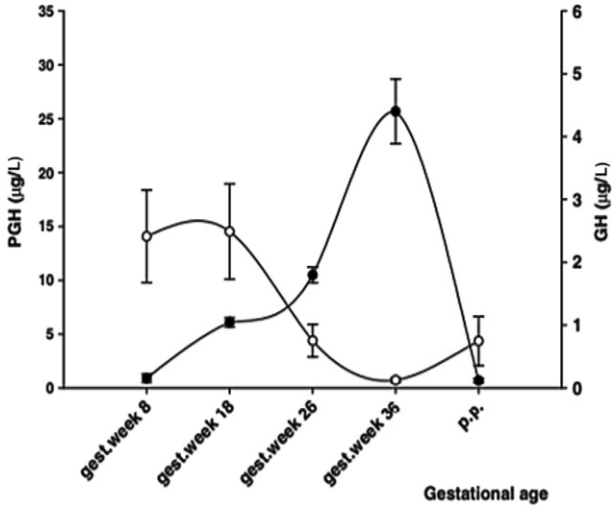

Fig. 4 Serum PGH (*filled circles*) and GH (*open circles*) during pregnancy in healthy subjects. Notice the different scalings on the *y*-axes for PGH and GH.

Synthesis and Structure of IGF-1

IGF-1 is synthesized by various mesenchymal cell types. The IGF-1 synthesized by the liver and secreted into the circulation is under the control of GH and this mediates the balanced growth among multiple organs and tissues. This accounts for around 75% of the circulating IGF-1. The remaining IGF-1 which is synthesized in an autocrine/paracrine way in the peripheral tissues, is also under the control of GH and by factors that are secreted locally in the surrounding tissues. This autocrine/paracrine IGF-1 is responsible for local, unbalanced growth independent of GH. Examples of this type of growth are bone remodeling, wound healing and growth of contralateral kidney after unilateral nephrectomy (Wang *et al.*, 2013).

The IGF-1, IGF-2 and the insulin gene all belong to the same family. All three peptides contain A, B, and C domains, but IGF-1 and IGF-2 are secreted with D domain extensions of six to eight amino acid that are not cleaved.

IGF-1 Receptor

The IGF-1 receptor is found in multiple cell types and tissues, and this account for the IGF-1 to mediate balanced growth. The presence IGF-1 receptor is regulated by GH and thyroxine (T4) and also other growth factors such as platelet derived growth factor (PDGF) and fibroblast growth factor (FGF). The binding of IGF-1 to the alpha subunit of the IGF-1 receptor triggers a conformational change in the transmembrane beta subunit and a cascade of intracellular events followed by phosphorylation of tyrosine by tyrosine kinase activity. The final activation of mitogen-activated protein kinase pathway (MAP kinase) is important for stimulation of cell growth by IGF-1 (**Fig. 5**).

IGF- Binding Proteins (IGFBP)

There are six high affinity IGF-binding proteins in the plasma that bind IGF-1 and IGF-2 with different affinities. The effects of IGF-1 and IGF-2 are modulated by these six different IGFBPs, named IGFBP1—IGFBP6. Most of the IGFs (75%–80%) in the circulation form ternary complex containing IGF-1 or IGF-2, IGFBP3 and an acid labile subunit (ALS); the remaining 20%–25% of IGF is bound to one of the IGFBP forming a binary complex and less than 1% of IGF in plasma is in free form.

Of all the IGFBPs, the IGFBP3 is the most abundant form in the plasma and more than 75% of IGF-1 is bound to this protein. Exogenous administration of GH increases the concentration of IGFBP3 and thereby functions as the carrier of IGF-1 and IGF-2. In the plasma, the formation of ternary complex helps to stabilize IGF-1 binding and prolongs its half-life to 16 h.

IGFBP2 is the second most abundant form of IGFBPs in the plasma. It's affinity for IGF-1 is relatively less than that of IGFBP3 and has shorter half-life of 90 min. IGFBP2 has important function in that it regulates the available free IGF-1 in plasma to enter into the extravascular space and bind to the receptors in peripheral tissues.

IGFBP1 is regulated by insulin. IGFBP1 level fluctuates throughout the day, with fasting its level increases, which inhibits insulin secretion and the levels fall with feeding and insulin administration. It has also been found that the level of IGFBP1 increases progressively in individuals who develop type 2 diabetes and in those with insulin resistance (Kotronen *et al.*, 2008).

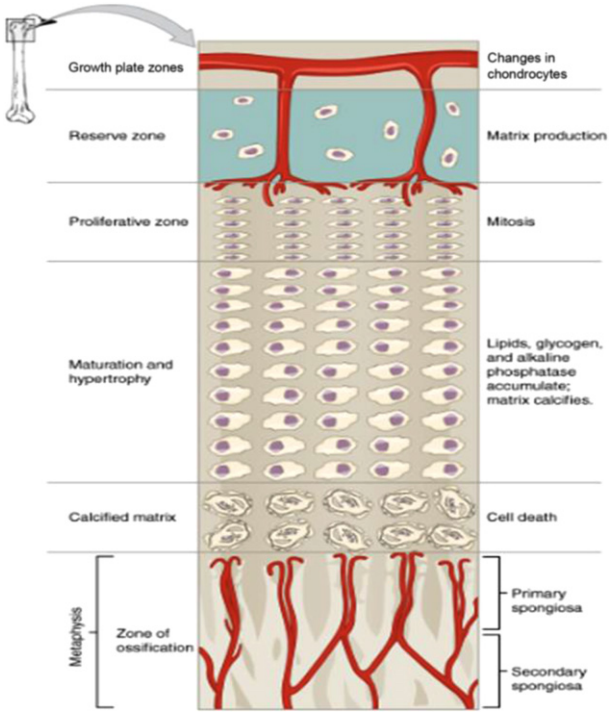

Fig. 6 The growth plate.

IGFBP 4, 5 and 6 are present in much smaller concentration in the plasma. Its actions are not fully understood but IGFBP4 is regulated by protease pregnancy associated plasma protein (PAPP) and parathyroid hormone (PTH). IGFBP5 can also form a ternary complex with acid labile subunit and its plasma concentration is regulated by GH.

Effects of GH and IGF-1 on Tissues and Growth Plate

GH is the major growth factor in the linear growth of children. It mediates many of its biological actions via IGF-1, which acts on the epiphyseal plates of long bones also known as the growth plates. Chondrocytes in the growth plates which are regarded as stem cells, under the influence of GH/IGF-1 and other growth factors, undergo cell proliferation and maturation that results in the linear growth of children.

Recent studies has shown the role of suppressor of cytokine signaling 2 (SOCS2) as a key modulator of GH at the growth plate. The SOCS proteins are a family of negative regulatory proteins that are expressed in response to activation of cytokine and growth factor signal cascades, particularly those utilize JAK/STAT signaling system (Greenhalgh *et al.*, 2005).

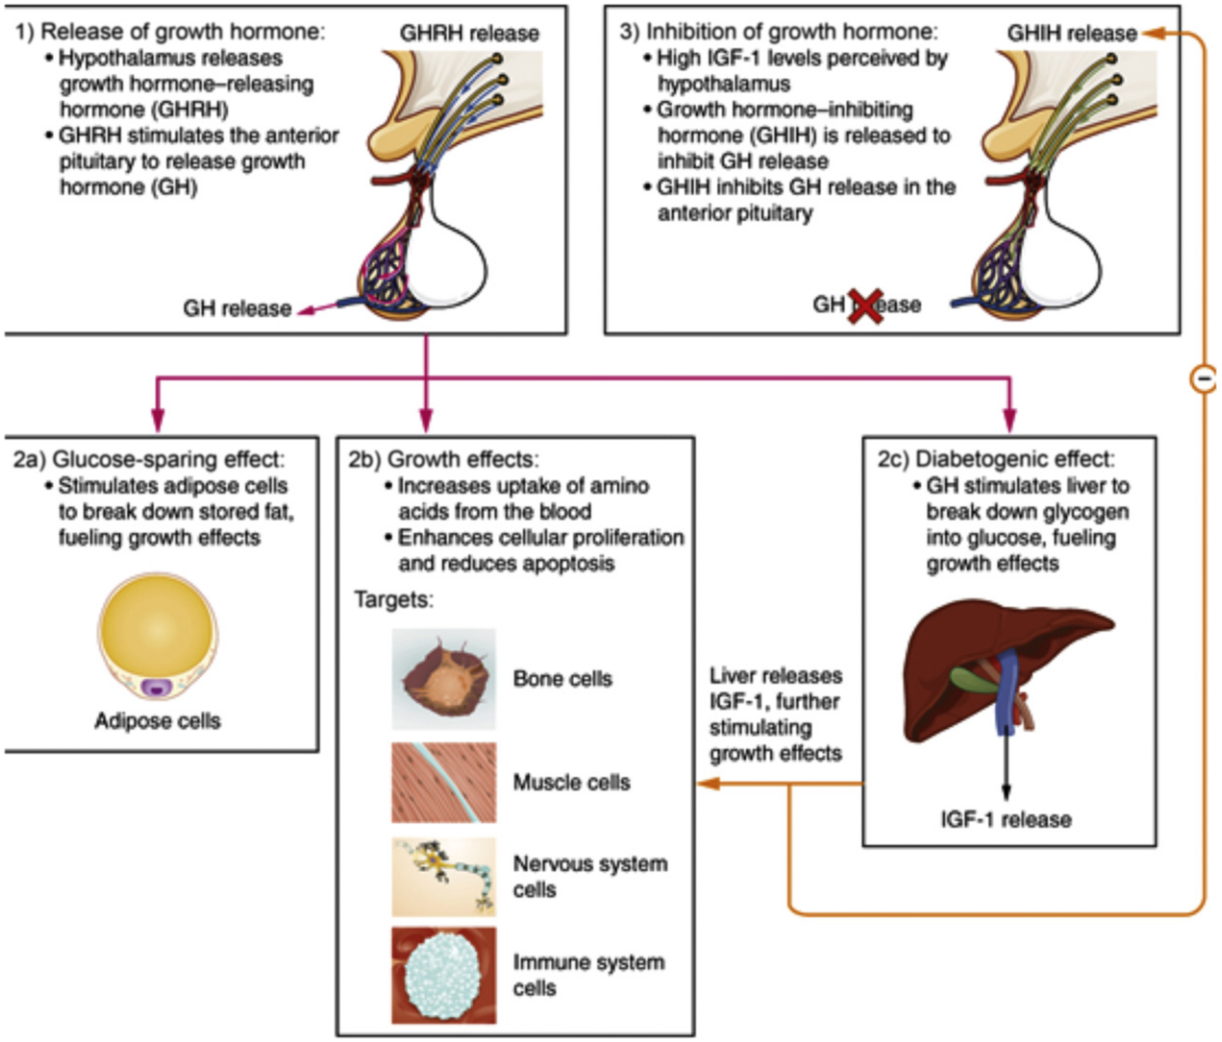

Fig. 7 Summary of actions of GH and IGF1.

Excess GH levels in pre-pubertal children where the epiphyses are yet to fuse results in uncontrolled linear growth, termed as gigantism. Whereas, acromegaly results in individuals whose epiphyses are fused with excess secretion of GH.

In addition to linear growth, GH also has other potent effects—including modulation glucose, lipids and nitrogen metabolism; promotion of lipolysis, increase amino acid uptake and protein synthesis and decrease in protein breakdown (Press, 1988).

Growth Plate

The growth plate, also known as the epiphyseal plate is a thin layer of cartilage that lies between the epiphyses and metaphyses, and is where the growth of long bones takes place. Such longitudinal bone growth occurs here through the mechanism of endochondral ossification, with formation of cartilage and then remodeling into bone tissue (Fig. 6).

The chondrocytes in the growth plates are surrounded by matrix consisting of proteoglycan aggregates and are divided into three zones, reserve/resting zone, proliferative zone and hypertrophic zone. The process starts with recruitment of chondrocytes in the stem cell zone, then actively proliferates by cell division and followed by differentiation, apoptosis and finally mineralization in the hypertrophic zone. Among other hormones, GH and IGF-1 regulates this process.

Clinical Aspects of GH Deficiency in Childhood

Faltering growth in children results from a number of potential causes, GH deficiency being one of them, along with other hormonal disturbances, genetic or congenital abnormalities, chronic medical conditions and malabsorptive states. Short stature in school children can have significant negative effects on psychology and physical development leading to

bullying, poor performances in sports, education and on the overall quality of life of the child itself (Tickner and Keady, 2011).

Growth failure can be detected early through regular growth monitoring. Isolated short stature in many instances is a normal variation resulting from familial/genetic short stature and having no underlying pathological cause and resulting in no psychological issues. If the normal variants of growth are ruled out, then investigation for underlying causes of growth failure is recommended.

Growth hormone deficiency may be an isolated deficiency or occur in combination with other pituitary hormone deficiencies. The frequency increases in the presence of any anatomical defects in the pituitary/hypothalamic region (e.g., septo optic dysplasia, absent corpus callosum, holoprosencephaly or tumors) and in those who have had cranial radiotherapy.

GH deficiency due to multiple anterior hormone deficiencies generally presents early in the newborn period or early infancy unless it is a result of acquired causes such as CNS tumors, cranial irradiation or histiocytosis. Symptoms and signs may include neonatal hypoglycaemia (combination of GH and ACTCH deficiency); cholestatic jaundice (in combination with low cortisol) and micropenis (prenatal testosterone deficiency secondary to luteinizing hormone, LH deficiency). Gene mutations affecting the pituitary transcription factors, Pit-1 and Prop-1 generally result in multiple anterior hormone deficiencies.

The pathogenesis of idiopathic isolated GH deficiency is unknown. However these patients respond to administration of exogenous GHRH by secreting GH, indicating that the somatotroph cells are functional and the primary defect is in the hypothalamus.

Investigations to establish deficiency of GH are widely used worldwide and GH treatment started before fusion of the epiphysis is expected to result in an increase in linear growth. It is recognized that growth hormone deficiency in adults results in poor muscle strength and fatigue and adult GH replacement is now common.

GH resistance and IGF-1 deficiency are now recognized as rare causes of poor growth and extreme short stature in childhood. IGF-1 replacement treatment is licensed for use in children but its use remains limited due to significant potential side effects (**Fig. 7**).

Summary

GH is a peptide hormone secreted in to the circulation from the somatotroph cells of the anterior pituitary gland. Its primary role is to promote linear growth in children. The action of GH is mediated directly through GH receptors, as well as indirectly via IGF-1. The secretion of GH is pulsatile and under a variety of hormonal influences such as stimulatory hypothalamic GHRH, ghrelin and sex steroids, and inhibitory somatostatin, IGF-1 and glucocorticoids. IGF-1, which is the principal mediator of peripheral actions of GH are primarily produced in liver and regulated by GH. Exogenous GH is widely used to treat both isolated and multiple anterior hormones deficiencies in children.

Infant, Childhood, and Adolescent Auxology

Gary Butler, University College London Hospital NHS Trust, London, United Kingdom; and UCL Great Ormond Street Institute of Child Health, London, United Kingdom

Principles of Auxology

Measuring Techniques

Much has been written about the physical assessment of growth (auxology) and how reliable measurements can be taken. In routine clinical practice this depends on appropriately accurate and well maintained and frequently calibrated equipment.

For height this would include a standard stadiometer whether mechanical or electronic or a supine length scale for children under 2 years.

For weight either class 3 electronic scales or a beam balance, both of which are reliable enough to require infrequent recalibration.

Measurements are taken to the nearest 0.1 cm for length/height and 0.1 kg for weight (www.rcpch.growthcharts).

Specialist Techniques for Specialist Pediatric Endocrine Clinics and for Research

A higher level of accuracy is required, so that for height measurements taken to a repeatability of 2 mm is needed. Traditional stadiometers such as the Harpenden as regarded as the gold standard but require careful maintenance and recalibration. Electronic ones such as the Seca generally do not require recalibration. Weight does require electronic equipment. Other detailed measurements such as sitting height for body proportion and arm span require specialist equipment and training in the technique.

Positioning of the child is even more important. For height the child should be measured in socks or bare feet with the heals placed against the measuring back plate and the child standing straight (https://www.rcpch.ac.uk/improving-child-health/public-health/uk-who-growth-charts/video-resources/). The head should be placed in the Frankfurt plane where the lower border of the orbit is in the same plain as the external auditory meatus to allow repeatability (**Fig. 1**). There is debate as to whether gentle pressure should be exerted upwards under the mastoid processes to reduce slumping and improve posture and there has been some debate as to whether this can compensate for the diurnal loss of height due to compression of the spinal discs but which every method is chosen consistence is the most important.

Infants

Weight in infants and supine length should always be measured with the infant completely naked so that no factors such as wet nappies can interfere with weight and when measuring in infant length it is necessary to be able to hold both legs jointly together and unimpeded by nappies to ensure accuracy of length measurement. Head circumference should be taken using a nonstretchable measuring tape no wider than 0.5 cm made of metal or plastic composite. This requires measures to be taken in the occipito-frontal circumference and repeated twice, and the largest measurement taken to 0.1 mm is recorded (**Fig. 2**).

Children and Young People With Disabilities

It may not be possible to obtain standing measurements in children with major disabilities. If possible supine measurements can be taken in older children using a supine length measuring table or device such as the Dunmow and if there is any deviation from standard measuring practice then this needs to be recorded. If weighing cannot be done independently it is possible to use the *buddy* method where a child is weighed with minimal clothing along with the parent and then the parent is then weighed separately and that value subtracted (https://www.rcpch.ac.uk/improving-child-health/public-health/uk-who-growth-charts/video-resources/).

Assessments of Body Composition

For research techniques, the most accurate method of assessing body composition is cross sectional computerized tomography imaging. This does require a significant dose of radiation and cannot be used in routine practice. Some methods of assessing bone density using DEXA techniques also include a measure of body composition but this depends on the software available. Routine and reasonably accurate measures of body composition can be made by bioelectric impedance techniques where a small electrical current is passed through the body. Equipment such as the Tanita has been shown to be reasonably reliable in clinical practice.

Body mass index (BMI) can be derived from a simple formula: weight in kilograms divided by height in meters squared. This can give an indication of body size but will not clearly differentiate between lean and non-lean body tissues. Higher BMIs are noted in short stocky individuals and conversely lower values in tall thin people, which may be misleading clinically. BMI charts are available to track the changes in BMI values over time (**Fig. 3**), but as it is the centile (or SDS score) for age which is important, separate BMI centile scales are available on the RCPCH school age charts (figure). A quick BMI centile lookup is available for quick reference, only requiring the height and weight centiles from routine plots (**Fig. 4**) allowing BMI changes to be tracked over time

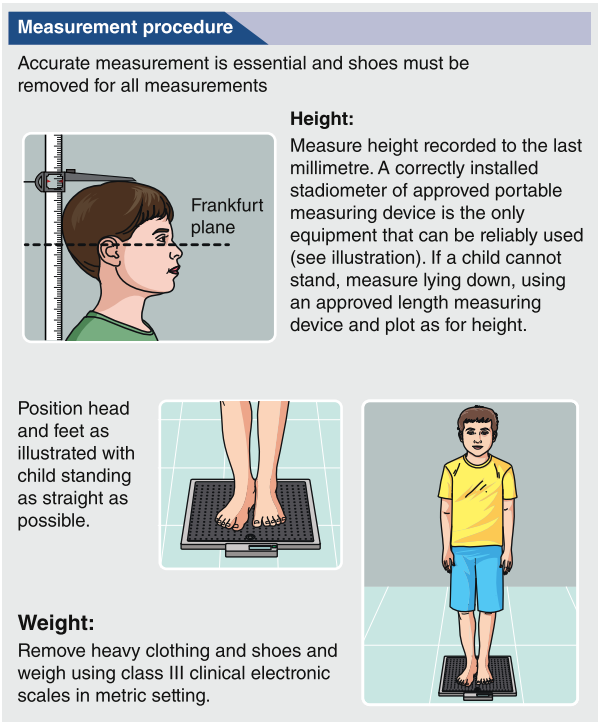

Fig. 1 Optimal height and weight measurement © RCPCH.

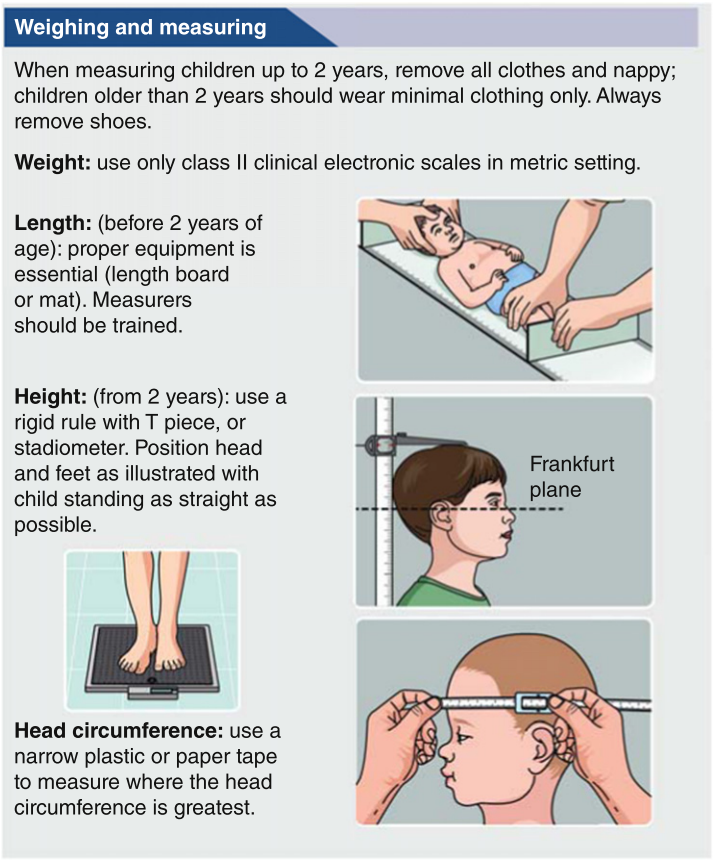

Fig. 2 Supine length and head circumference measurement © RCPCH.

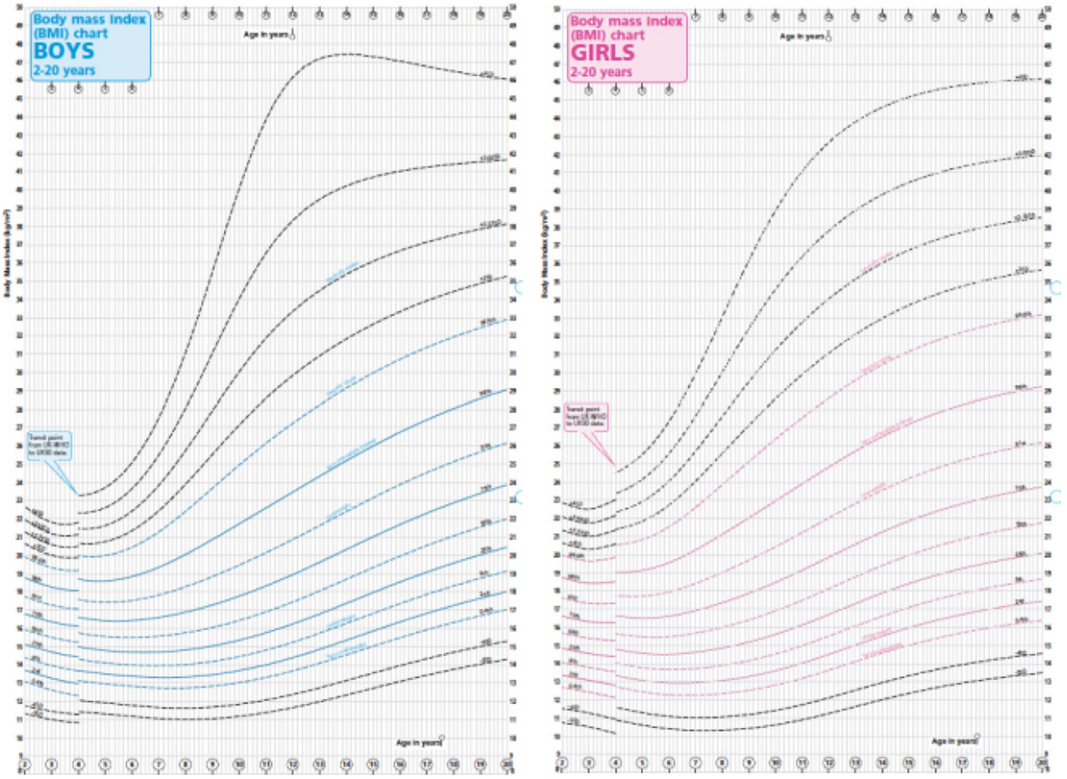

Fig. 3 BMI charts for boys and girls © RCPCH.

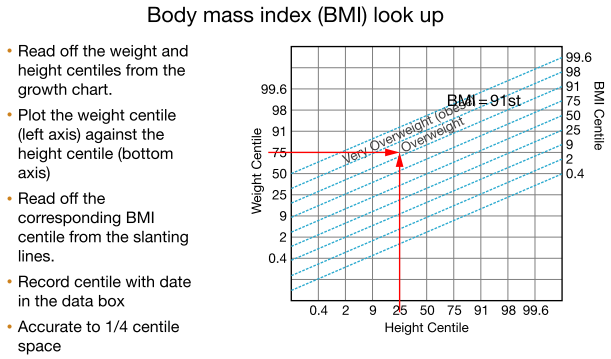

Fig. 4 BMI lookup © RCPCH.

(Fig. 5). Suggestions that the ponderal index (weight/height in meters cubed) is more accurate for clinical decision making has been proposed but no regular comparative standards are available.

Measuring in Low Income Countries

In low income countries, particularly in remote areas, there is often no access to accurate equipment and electricity for accurate measurement and there are fewer trained health care professionals to perform these measurements. It is in these parts of the world where under nutrition in children is a significant problem. The most accurate measurement of adequacy is nutrition is using the mid-upper arm circumference. Standards are available and can be measured with a simple tape measure, paper, plastic or metal but inexpensive color coded tape measures are available (http://www.who.int/nutrition/publications/severemalnutrition/9789241598163/en/).

Growth Concepts

Genetic Potential Mid-Parental Height

The accuracy of predicting a child's adult height and growth potential is relatively poor, but more accurate during mid-childhood during the steady growth period. Commonly used calculations include the mid-parental or target height where both parents' heights are fed

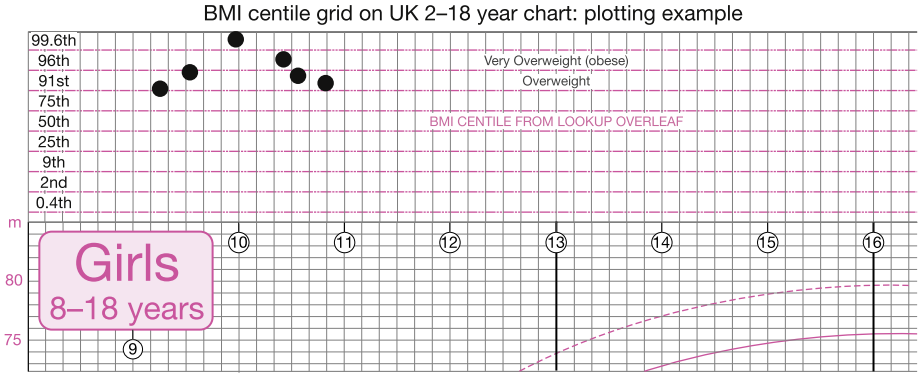

Fig. 5 Plotting BMI centile trends © RCPCH.

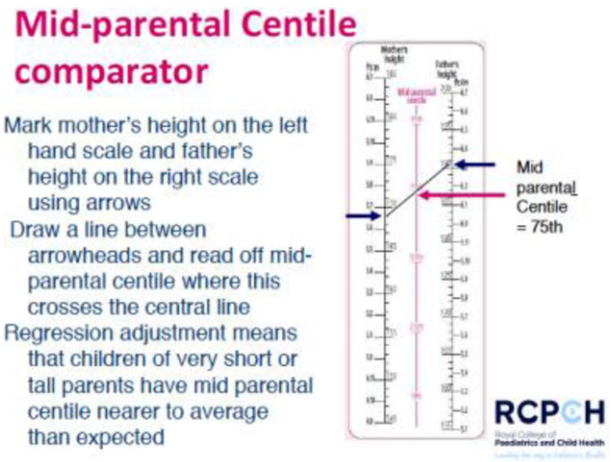

Fig. 6 Mid-parental height (target height) calculator © RCPCH.

into a calculation either of Tanner *et al.* (1970) or Hermanussen and Cole (2003) as below or using the graphical technique of Cole as on the United Kingdom growth charts (**Fig. 6**). All methods have a range of variability. Tanner method calculated in centiles is ± 6.5 cm, the Hermanussen method in standard deviations 1.3 standard deviations and the graphical method, most children fall between ± 2 centile bands, that is, 1.3 standard deviations and all children within ± 2 standard deviations.

Definitions of Tall and Short Stature

A child who is short and falls within the expected range for the parents can be described as having familial short stature. The term genetic short stature is best avoided here and reserved for situations where there is a known chromosome or genetic cause. A child who is at the lower range or below the expected centiles for their parents is described as having nonfamilial short stature and this maybe a clue to requiring further investigations. At the other extreme, a tall child whose height is within the predicted range for parents is described as having familial tall stature, whereas if they are above the range it would be nonfamilial tall stature which may require further investigations.

Predicting Adult Height Based on the Child's Height

In some situations, it is not possible to obtain parents' heights so the predicted adult height nomogram based on the child's current height centile on the UK RCPCH charts can be used. It is bases upon a predictive analysis between childhood/adolescent and adult heights and contains corrections for the phenomenon of regression to the mean. The child's current centile is plotted on the height prediction ladder and their adult height is read off with an error margin of ± 6 cm (**Fig. 7**). This actually produces a higher predictive accuracy than that when using the target height.

Speed of Growth/Growth Velocity

Challenges exist on assessing growth variations during infancy partly on account of the repetitive growth during the first year of life (see below), but also on accuracy of measurement which forms a greater part of the variability seen. During the first year of life, in a healthy infant there is a 300% increase in body weight, a 50% increase in length and a 33% increase in head circumference.

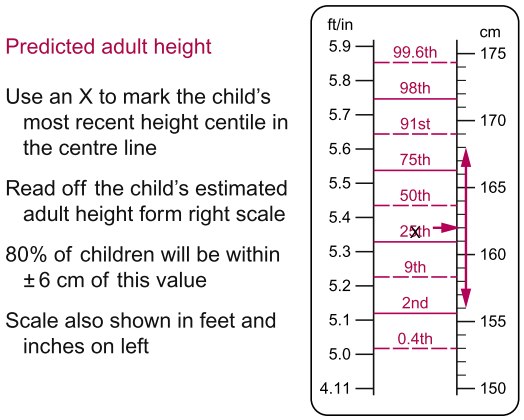

Fig. 7 Predicted adult height calculator © RCPCH.

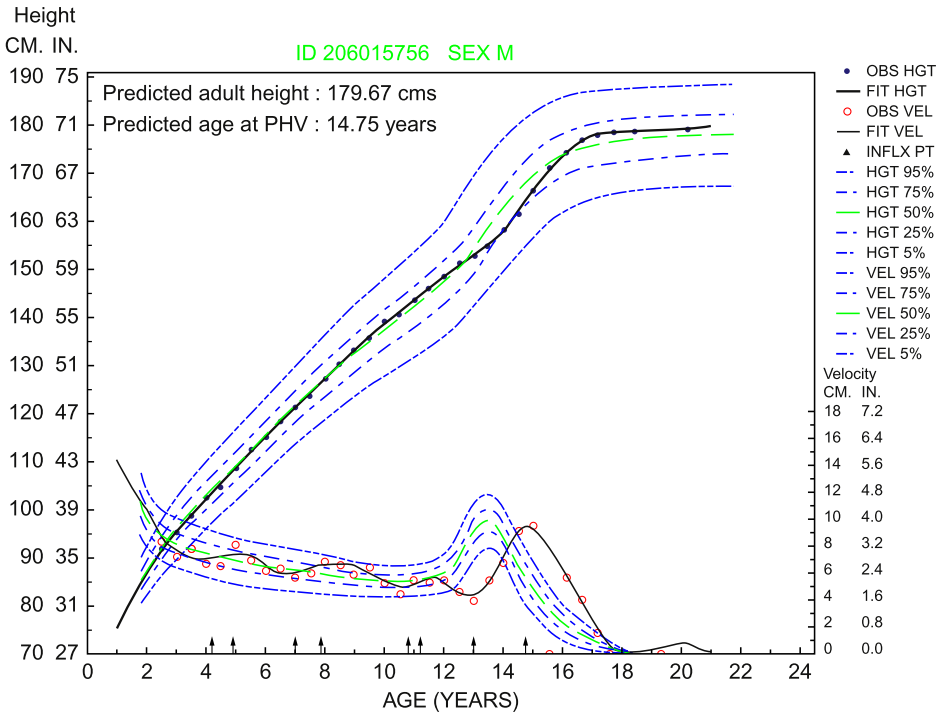

Fig. 8 Height velocity chart with the height velocity pattern of an individual child.

Childhood

The childhood phase of growth from the third year of life until the commencement of puberty is traditionally regarded as more steady. However, the smoothed height velocity curves of charts available do not display accurately the height variable in the individual patterns of growth in height and weight in children over this period (Butler *et al.*, 1990). They have been described as cycles of growth, approximately two yearly pattern of acceleration and deceleration, the cause of which is probably genetic but maybe hormonally driven (**Fig. 8**). This needs to be taken into consideration when investigating slow and rapid growth in mid-childhood.

Adolescence

The attainment of the rapid phase of growth during puberty is different between the sexes. It has been well described through many sources that the peak height velocity in girls will occur in mid-puberty, Tanner breast stage 3 at a mean age of around 12.0 years, whereas in boys this is 2 years later on at a mean age of 14.0 when further pubertal development has taken place (Cole *et al.*, 2014). Until the onset of puberty the growth between the sexes is almost identical but the later start of the growth spurt in boys by about 2 years contributes around 10–12 cm of additional height growth and the greater magnitude of the adolescent growth spurt will contribute around 2 cm of height gain consequently the height difference in adults between males and females is all accrued during puberty.

Detection of Abnormality

If the purpose of assessing growth is to define normality or detect abnormality what at the boundaries and what parameters should be used for considering additional referral.

Infancy

There is enormous variability in the first 6 months of life when an infant who become independent at birth will develop their own growth pathway. Thus, a genetically smaller infant from a large mother may show a period of decrease in growth called "catch down"; conversely a healthy genetically larger infant born from a smaller mother may show increase in growth in the first 6 months of life.

Definitions of what is the extreme of variation vary, with suggestions that >1 centile or SD division on the growth chart either up or down should be investigated but in general natural variations will balance by 6 months of age. However, if there are greater and continuous changes in either length or weight or head circumference, certainly more than two centile bandwidths in the first 6 months of life and certainly if the trend continues particularly in weight and length, then these require further investigation (**Fig. 9**). Children who have an advanced or delayed genetically preprogrammed growth pattern often called "constitutional advance" or "constitutional delay in growth" will show a period of acceleration or deceleration respectively usually in all parameters but in general, no further changes or centile shift will be seen after 6 months of age. However, clinical decision making needs to be exercised to ensure pathology is not missed.

Childhood

The assessment of growth in mid-childhood is more straightforward. Careful consideration has taken place as to the factors which allow the detection of growth pathology and interventions to restore normality whether this is due to chronic disease, lack of social deprivation, malnutrition or hormone deficiencies such as thyroxine and growth hormone. The most accurate ways of detecting abnormal growth either up or down include centile shift of more than two-thirds of a standard deviation (equivalent to one centile band width) over a year, together with height being outside the mid-parental target centile range (Stalman *et al.*, 2015).

Puberty

On account of the huge and unpredictable variability of pubertal growth which depends not only on the timing of the onset of puberty, height obtained at the onset of puberty and genetic growth potential, assessment of adequacy of growth needs to be made if concerns arise in parallel with the clinical assessment of puberty whether this is by Tanner staging in trained individuals or using the simpler *puberty phase* concept promoted by the Royal College of Pediatrics and Child Health (**Fig. 10**). As most published growth charts do not take into account normal pubertal variation and present the average growth centiles at the average age, then early maturers will show an acceleration up through the centile band and late maturers the opposite. It is the paradox of assessing pubertal growth that if an adolescent follows a centile band throughout puberty they may potentially be growing abnormally but that depends on how the growth charts are constructed, see below.

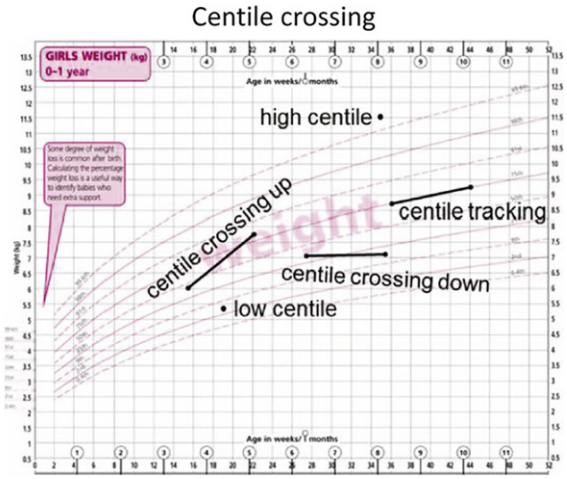

Fig. 9 Patterns of infant growth-normal and abnormal © RCPCH.

The 3 phases of puberty from history

	Pre-puberty (Tanner stage 1) *If all of the following*:	In puberty (Tanner stage 2–3) *If any of the following*:	Completing puberty (Tanner stage 4–5)
Girls	• No signs of nipple or breast development • No pubic hair	• Any breast enlargement so long as nipples also enlarged • Any pubic or axillary (armpit) hair growth	*If all of the following:* Started periods(menarche) with breast, pubic and axillary hair development
Boys	• High voice • No growth of testes or penis • No pubic hair	• Slight voice deepening • Reddening of scrotum with growth of the testes • Early testicular or penile enlargement • Early pubic or axillary hair growth	If any of the following: • Voice fully changed (broken) • Adult size of penis with pubic and axillary hair growth • Moustache and early facial hair growth

Fig. 10 RCPCH phases of puberty: a simpler assessment reference © RCPCH.

Growth Charts

Types of Growth Charts

Growth charts have been traditionally produced on paper for community use and hospital use, and in many countries parents are given a hand-held booklet (Personal Child Held Record) containing growth charts for ongoing surveillance of their child's wellbeing and care. In many parts of the world this is still regular practice but with community and hospital records becoming electronic, the recording and plotting of growth charts to evaluate a child's well being is also electronic. There are many systems available but the key factor is becoming familiar with what is available locally.

Derivation of Growth Charts

The way in which growth charts are constructed falls largely into two categories: that based on a large population selection of infant children and adolescents measured on one occasion. This allows the assessment of growth on a series of individual occasions, each measurement making a one-off comparison with the expected height range of children at that particular age. Although it is common to follow a child's growth serially on these charts, this is not for which they are principally designed. However as stated above the concept of centile shift can be used to detect growth excess or growth failure.

Longitudinal Growth Charts

For the correct assessment of serial growth measurements over time, then a growth chart or growth standard such as the WHO (see below) would need to be considered. These charts constructed are from measurements taken on individual children over a period of time. As this is quite a labor-intensive process, and may take 15–20 years to get a complete set of longitudinal data, very few data sets are available and often gathered from smaller numbers of children, but the pattern of growth is observed used to inform the construction of growth charts such as the RCPCH and WHO charts.

The WHO Infant Growth Concept

The World Health Organization Multi-Centre Growth Reference Study was established between 1997 and 2003 to examine the concept of universal infant growth (http://www.who.int/childgrowth/standards/en/). Height, weight and head circumference measures were taken in six places around the world identifying mothers living in socio-economically good environments who are nonsmokers, who are healthy and who breast fed their infant exclusively for 6 months. 8500 infants were measured longitudinally for up to 2 years and the data up to 5 years of age were supplemented with some cross-sectional measurements. Interestingly, there have been shown in this study very similar patterns in length up to age 2 years across all sites which confirms the universality of the pattern of infant growth irrespective of human racial origins. There are variations in weight which are due to the ethnic variations in build but similar enough for the concept of a universal growth chart to be established. Questions have arisen however about the value of the head circumference centiles which may under predict true size (Wright *et al.*, 2011). This may have been on account of different techniques used but until resolved the head circumference standard should be used with caution.

The Value of the WHO Charts

Not only do the WHO charts provide a universally acceptable set of measurements with which to compare child and infant growth but the concept allows additional use. As the 0–2 year charts are made principally from longitudinal data they can be considered as growth standards, in other words providing a pattern of infant growth that represents the optimal growth trajectory. Those charts constructed after the age of 2 years (and other national growth charts which are based principally on cross sectional data) are regarded as growth references, and allow the comparison of a child measure at a single point in time only. They are best for population growth evaluation, but are used in clinical practice to make assessment in individual children.

Comparison of National Charts With WHO?

The decision whether to use national references or WHO standard combined with WHO references after the age of two or national references requires a decision often dependent on how old the data are that constitute the local growth references and the how far these national references deviate from the WHO data set.

Percentiles or Standard Deviation Scores

WHO charts come in both percentiles using the American pattern that is, 5th, 25th, 50th, 75th, 90th, and 95th centile pattern or in standard deviation scores (https://www.cdc.gov/growthcharts/cdc_charts.htm). In most cases centiles are derived from SDS depending on how the growth chart measurement spread is constructed whereas SDS lines are equally spaced. Those following the United States pattern are not. Within the RCPCH UK standards the traditional choice of centiles is presented, but with a different spread 0.4th, 2nd, 9th, 25th, 50th, 75th, 91st, 98th, and 99.6th (www.rcpch.growthcharts). This apparently unusual pattern is more logical as each of the centile bands are two-thirds (0.67) of a standard deviation apart that is, equally spaced hence a growth deviation up or down by one centile space, where ever that happens on the growth chart is of equal significance. The addition of 0.4th centiles and 99.6th centiles representing ± 2.67 standard deviations is presented to allow a more accurate determination of pathology in extremely tall and extremely short children (**Fig. 11**).

Specialist Growth Chart

For a number of conditions specialist growth charts have been produced. Sometimes this will have in the background the growth pattern of typically growing children and sometimes the growth pattern of children with a diagnosis of any particular condition is presented. Commonly used ones include down syndrome (https://www.dsmig.org.uk/information-resources/growth-charts/) and Turner syndrome (http://www.healthforallchildren.com/shop-base/shop/growth-charts/turner-syndrome-growth-charts-100-pack/). They may have individual value but the variability of presentation of genetically determined syndromes does vary quite considerably and so comparison with the regular charts is recommended so that the growth of children with a defined condition or syndrome can be compared both with specialist charts and that of typically growing children.

Neonatal Growth Chart

Ideally the chart should be able to represent not only the expected growth of infants born at term but also those who are preterm that is, before 37 completed weeks of gestation. Preterm correction is variably applied depending on the etiology and does not exist for the WHO standards. Within the United Kingdom when infant WHO standards were adopted, two methods of adjustment for prematurity were

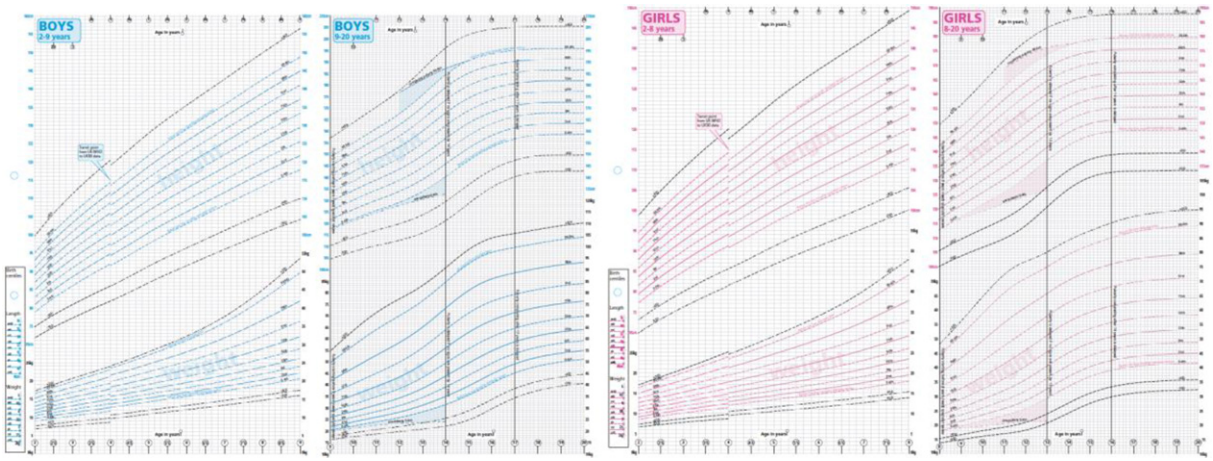

Fig. 11 UK 2–20 years childhood and puberty close monitoring charts; boys and girls © RCPCH.

applied. For infants of gestation 32 weeks and above, separate panels for head circumference and weight are included which can be used directly. For term and beyond it is recommended that double plotting of every measurement takes place. The exact measurement based on the age since birth is plotted using a dot and the same measurement is replotted at the gestationally corrected age with an arrowhead and a dotted line is drawn between the two (**Fig. 12**). This avoids the confusion of whether gestational age correction has been applied or not which can lead to either missed or false diagnoses of growth excess or failure to thrive.

Extremely Preterm Infants Down to the Lower Limits of Viability of 23 Weeks' Gestation

More detailed assessment of growth, particular weight gain is required. Within the United Kingdom this has been tackled by the development of the neonatal and infant close monitoring chart which allows multiple plots on a frequent basis to be made up until the expected date of delivery and beyond (www.rcpch.growthcharts). The charts also allow ongoing monitoring under a more detailed schedule up until the age of 2 years, particularly for specialist new born follow up clinics which often need to look at the ongoing care of these infants from a close monitoring perspective. The method of gestational correction is different as the actual calendar date is back plotted from the estimated date of delivery and put on the chart at the time of first establishment and this prevents serial gestational age correction errors.

Growth Assessment During Puberty

The unpredictability of the onset of puberty and its subsequent pattern makes the development and presentation of a way of accurately assessing growth during puberty difficult. Current growth charts only represent the average amount of growth taking place for average children going through puberty at the average time.

Puberty Growth Chart

There have been several attempts to be able to design growth charts to allow for pubertal growth variations. There are four challenges needing to be met:

1. Age at the onset of puberty.
2. The proportion of growth completed at the onset of puberty.
3. The distance from target or genetic height.
4. The pace of puberty.

Additionally, the assessment of the degree of development during puberty either using Tanner stages or *puberty phases* has always been regarded as a separate assessment. The RCPCH UK charts for school age children and the specialist chart have attempted to address this by firstly depicting the normal ranges for beginning and completing puberty with vertical puberty lines creating zones on the growth chart to help interpret the appropriateness of growth (**Fig. 13**). As in most cases, normally developing and growing adolescence will not cause a concern. It is those that are at the extremes, the tall and advanced in maturing and the short and delayed who require some form of judgment as to whether their pattern of growth is acceptable. As a result of which additional lines at the extremes, 0.4th centile and 99.6th centile have been added which depict the upper ranges of normal growth that is, 99.6th centile for those adolescents who have completed puberty and a lower 0.4th centile for those adolescents who have not yet entered into puberty (**Fig. 14**). Thus, any young person whose height and weight plots within those ranges, a consideration needs to be made as to what has happened to puberty and whether that is indeed normal and this may help to differentiate

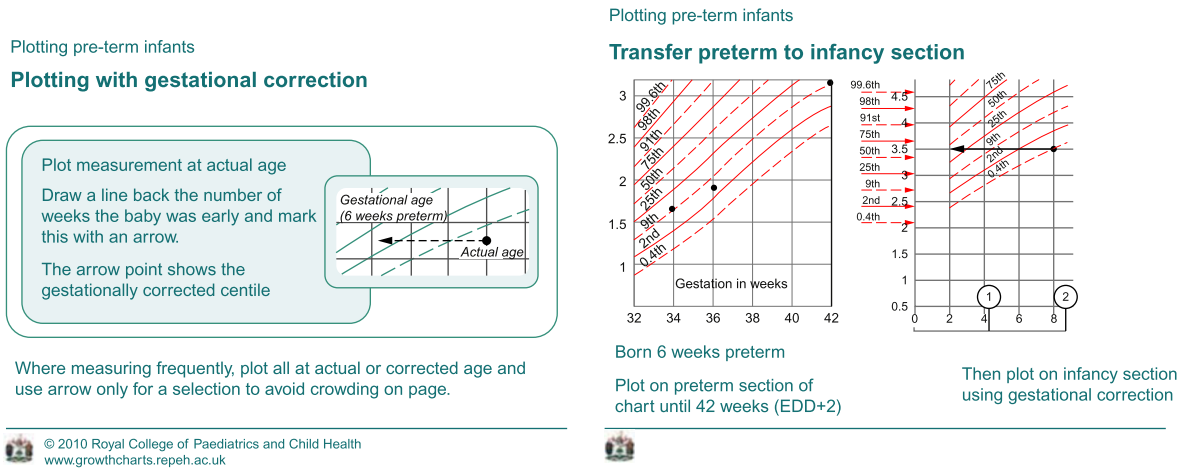

Fig. 12 Gestational age correction for preterm infants 32–37 weeks © RCPCH.

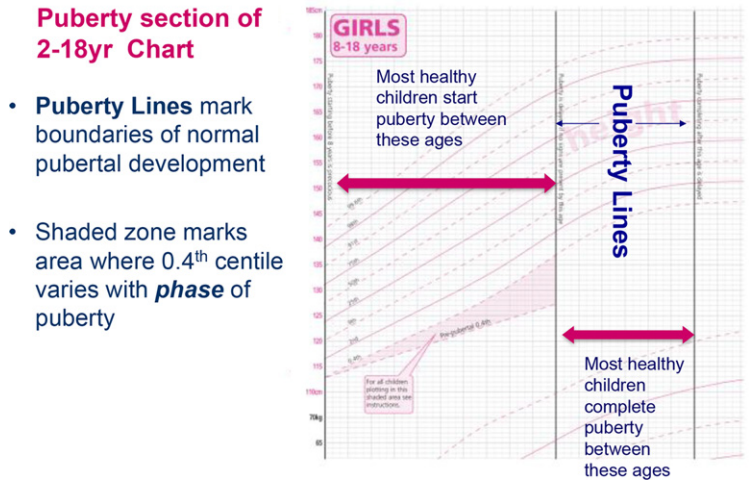

Fig. 13 Puberty zones on the RCPCH charts © RCPCH.

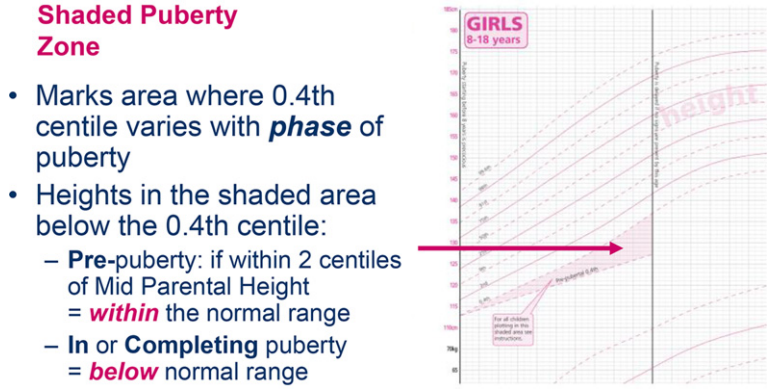

Fig. 14 Lower 0.4th centile for those children remaining prepubertal © RCPCH.

between pathology and normal variation. However, it is important to note that if a height plots within the shaded zone past the prepubertal 0.4th centile then growth could still be abnormal if the child is below their target centile range.

Changes in Population Growth

Obesity

By far the biggest influence on growth in height and particular in weight and BMI is the increasing obesity in high income countries. There is much evidence to suggest that excess of nutrition not only augments the general weight and BMI range but also promotes earlier maturation and tall stature during childhood, and it also has been linked with an earlier entry into puberty (Wagner *et al.*, 2012). Various estimates have been attempted to quantify this but are largely regional or national in nature and international comparison show quite marked ranges in development of obesity. These trends in obesity and height growth are more of public health and governmental interest with the intention of trying to buck these trends to restore better health and the prevention of other complications of obesity, such as hyperlipidaemia, type 2 diabetes and cancer risks. However, in the individual child, tallness, and advanced maturation with height within the target centile range maybe recognized if the child is overweight.

Effects on Puberty

Multiple studies have investigated trends of pubertal onset and completion (in females through age at menarche) to try and investigate trends. One of the challenges of obese children, particularly girls, is determining whether onset of puberty has clinically occurred on account of increased adipose tissue around the breast or whether there is true breast tissue present. In males, the clinical estimation of the onset of puberty by increase of testicular size is more straight forward, but again there have been suggestions of earlier trends and the possibility of different effect of increasing size on the age at the start and completion of puberty. This has been most well explored in the Copenhagen Study (Aksglaede *et al.*, 2008). Although there may have been some trends toward puberty starting a year earlier

approximately over the last two decades, the age of completion and the mean age of menarche does not appear to have shifted significantly and the process by which this trend has occurred has still not been clarified as hormonal determinates of the onset of puberty such as sex steroids and gonadotrophins do not appear to have shifted. Further investigation is required here.

Tempo of Growth Internationally

Multiple reports have suggested that as far back as records have been kept, that there has been an increase in average child growth by approximately 1 cm per decade. However reports are coming forward now about this trend is potentially ceasing and that humans have reached their maximal genetic potential as a result of nutritional adequacy. Whether there will be additional evolutionary benefits of being taller in size is not yet clear and there may be a reversal if this results in a disproportionate energy balance.

Growth in Immigrants

In the last 50 years with the breaking down of international borders and within the last 10 years of significant intercountry and intercontinent migration, there is the challenge of trying to explore what effect this has on child growth. For some time now it has been known that the heights of Japanese children whose parents migrated to Western United States had shown significant increase in growth which was due to longer legs, presumably secondary to improved nutrition and enhanced growth hormone secretion. Further investigation needs to be done on this to identify variations in health and whether moving from a situation from nutritional inadequacy to one of nutritional excess has a significant deleterious effect on individual health. For further reading see (Hemanussen, 2013).

Therapeutic Attempts to Modify Child Growth

Chronic Disease

It has been well established that the monitoring of a child's growth in height and weight is a good index of their general physical health. This is well understood in the investigation process where exclusion of cryptic chronic disease is part of the investigation pathway. Children in adolescence with known chronic disease may require growth assessment in case of the development of stunting that is, the inability be able to effect fully catch-up growth even with restoration of health. This is certainly true with gastrointestinal disease such as coeliac disease and inflammatory bowel disease where chronic nutritional inadequacy particularly if diagnosed late may not allow a full catch-up growth. Subtle slow patterns of growth such as in children with asthma and eczema who are often on intermittent or continuous low dose glucocorticoid may not result in a reduced ultimate adult height but the process of getting there may well be slowed down with full adult height not being achieved until the very late teens or early 20s.

Survivors of Childhood Cancers

Although the improvement in childhood regimens over the last 20 years has been impressive, unfortunately some of the treatment regimen significantly affect childhood growth. Whole body radiotherapy prebone marrow transplant will cause restriction of whole body growth and a degree of hormone resistance. Cranial irradiation particularly in the higher doses for childhood brain tumors will result in pituitary dysfunction, growth hormone deficiency, and disregulation of puberty causing both precocious and arrested puberty. Cranio-spinal irradiation used in common brain tumors such as medulloblastoma, particularly if given early on in life will result in disproportional growth overall on account of reduced spinal growth. Chemotherapeutic agents have less effect but this is very much dependent on the regimens used in the primary treatment program (Rose *et al.*, 2016).

Manipulating Childhood Growth

Growth failure due to hormonal deficiencies in particular growth hormone and thyroxine can be very successfully treated by restoration of the hormone concentrations within the body with exogenous treatment with growth hormone or thyroxine as needed. Attempts have also been made to boost the growth of normally growing children such as those with idiopathic short stature. At present the diagnostic process is not yet fully developed, so children who are short for their family may either have simple physiological growth delay or may have some subtle genetic variant which is going to reduce their overall growth. Many children worldwide with constitutional delay of growth are treated with growth hormone, which may in itself not be harmful but probably does not produce any overall long term benefit. With non-familial idiopathic short stature there are claims of small benefits in boosting adult height, but whereas this treatment is licensed within some countries including the United States, there is no current license within the countries under governance from the European Medicine Agency. Growth hormone treatment is also very costly.

Manipulating Puberty

More successful attempts occurred by using exogenous sex hormone treatments. Since physiological pubertal delay is more common in boys, multiple publications have shown that low dose testosterone treatment either for short course 3–6 months

or intermittently continuously up to 1–2 years may boost the growth spurt and does not compromise the predicted adult height but does not produce any overall gains than would be expected in adult height. Sex hormone treatment in tall children to restrict height (more often a concern in girls rather than boys) has had variable success. Higher dose estrogen treatment had previously been used but had shown no benefit over the age of 14 and there are reported risks of sensitization of breast tissue and the risk of breast cancer later on in life. Currently the only acceptable approach for girls would be to induce puberty and the growth spurt using a physiological dose of estrogen in increasing doses completing puberty in 2–3 years to try and accelerate epiphyseal fusion (Hannema and Sävendahl, 2016). The same is possible in boys with exogenous intramuscular testosterone.

Manipulation of the Pubertal Growth Spurt Using Gonadotrophin Releasing Hormone Analogues

Attempts at trying to prolong the adolescent growth spurt using GnRH analogues to slow down epiphyseal maturation have variable affect. In healthy individuals, treatment with GnRH analogues alone do not show any evidence of improvement in adult height. However, in pathological conditions such as those children who are born small for gestational age and are receiving growth hormone treatment, GnRH analogue for up to 2 years may enhance a total height gain if puberty starts early in that situation (van der Steen *et al.*, 2016). Furthermore, in girls with Turner syndrome who do not have spontaneous puberty, delaying the induction of puberty for up to 2 years may result in taller stature overall but may have lower acceptability with the adolescents themselves (Gault *et al.*, 2011).

Conclusion

The key to understanding, assessing, and managing childhood growth problems lies in the thorough understanding of the normal pattern of growth, how to make appropriate and accurate measurements and how to interpret those and compared with national or international growth standards of references. Identification of growth variations early is also key to successful treatment outcome whether that is restoration of normal health or starting an intervention to promote growth and/or puberty. Though much has been learned from simple observation on the auxology or measurement of growth, the individual variability remains a mystery, likely to be due to specific individual control variants and exploration of this will be important at the next stage in the understanding of the individual variation of childhood growth.

Body Proportions☆

Willem JM Gerver, Bas Penders, and Ralph Brecheisen, Maastricht University, Maastricht, The Netherlands

General Introduction

In 1943, Medawar gave a clear description of the transformation that occurs during growth, showing the head–trunk–legs gradient, which indicates that the development of the head is advanced over that of the trunk and the development of the trunk is advanced over that of the legs during the maturation process. This clearly shows that the growth of different parts of the body does not occur simultaneously or at the same speed. In a child, this transformation can be defined by the interrelationship of a number of linear measurements, such as sitting height to full height, or head circumference to crown rump length. The ease with which one can equate the human body's shape with an accurate estimate of human age—whether the compactness of a 5-year old, the coltishness of a young teenager, or the dimensions of a mature adult—tends to be taken for granted. Nevertheless, this feat is remarkable. Even more extraordinary is the precision with which the human eye registers any deviation from the norm. The mathematical expression of these perceptions for scientific purposes is a highly complex task with imperfect results. Vital information is lost. It is possible, however, to use a reference population to organize the complexity of what even the untrained eye perceives naturally. Knowledge of the body proportions gives insight into the natural process of maturation and any disturbance will be visible in abnormal body proportions. A principal distinction can be made between a child with stunted growth affecting the whole body or affecting just some body parts. Such an observation leads to different conclusions about the origin of some growth deviation.

There are different possibilities of taking measurements in children. The first method is the classical one by means of a stadiometer, measuring rod or tape. Another method is photometry or body scanning. An outline of the photometry is programmed at the Maastricht University and presented later.

In this article, an overview is given of different techniques for taking bodily measurements. The reference values are based on a Dutch study of 2001, presented in the Atlas of Pediatric Morphometrics by Gerver and de Bruin. Of the 20 measurements taken in the Dutch study, the most important are selected for discussion here.

Anthropometry

The Measurements

Length and height

In pediatrics, the curve representing a child's increase in height with age is used as one of the indicators of the child's health. The child's height is compared to that of a reference population in order to judge whether the child is atypical in terms of the height distribution of this population. Child and reference population must share the same geographical and socioeconomic background. Also, parental or familial height should be taken into consideration to assess the relative contribution of genetic and other factors to the child's height at any particular age.

Since growth is a dynamic process, one isolated measurement in time is meaningless for judging growth. Repeated measurements are needed to calculate the growth velocity. Knowledge of growth velocity is particularly relevant when dealing with a sick child. Depressed growth velocity may indicate the severity of an illness, whereas normalization of growth velocity or catch-up growth may signal recuperation.

Height is the distance between the top of the head and the sole of the foot. This distance is the sum of the height of the skull, the length of the spine, and the length of the lower extremities. Each of these different parts of the body has its own age-dependent growth velocity. Therefore, height is the result of the sum of different values, which are not linearly related in time.

Method of measurement

The distance between the top of the head and the sole of the foot is called length when an individual is measured lying down and height when the individual is measured standing upright.

Height is measured using a stadiometer. The stadiometer comprises a rigid vertical backboard and a horizontal headboard running free, perpendicular to the backboard and without cross-play. The top of the head must be in contact with the headboard. A 0.5 kg weight is placed on the headboard. This serves the purpose of flattening the child's hair and frees the physician's hands so as to enable him to keep the child in the correct upright position.

To measure standing height, the subject's shoes and socks are removed. The child is placed so that his heels, buttocks, and shoulders are in contact with the vertical plane of the stadiometer. The child's feet must be flat against the floor while either ankles or knees remain in contact. The child's head is held in the "Frankfurt plane": the lower borders of the orbits are in the same horizontal plane as the

☆*Change History*: February 2018. WJM Gerver, B Penders, and R Brecheisen updated the text and references.

This article is an update of William J. M. Gerver, Body Proportions, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 369-372.

external auditory meati. The measurement is taken while a gentle upward pressure is exerted on the mastoid processes so that the child is fully extended. In older children, stretching is achieved by telling them to breathe deeply.

To measure supine length, a measuring table resembling a stadiometer is used but on a horizontal plane. The headboard is fixed and the footboard is movable. Both the headboard and the footboard must be large enough to ensure that both the top of the head and the feet are in contact with them. To measure supine length, two people are necessary: one holds the infant's head in the vertical Frankfurt plane while at the same time another individual keeps the child's legs straight. The child's shoulders and buttocks must be in contact with the table. Supine length is measured in the first 2 years of age.

Crown Rump Length, Sitting Height, and Subischial Leg Length

As stated earlier, height defined as the distance between the top of the head and the sole of the foot is the result of the sum of different values, which are not linearly related in time. Therefore, the first step is to split height into its different components. Generally, sitting height is taken as one of the components and compared to height. The relationship between sitting height and height is often expressed as an age-dependent ratio.

Method of measurement

The distance between the top of the head and the buttocks is called sitting height when the measurement is taken of a child sitting upright and is called crown rump length when an infant is measured lying down.

Sitting height is measured using a sitting height table. The table comprises a rigid vertical backboard and a horizontal headboard running free perpendicular to the backboard and without cross-play. The surface of the headboard must be in contact with the top of the head. A 0.5 kg weight is placed on the headboard. This weight flattens the child's hair and also frees the physician's hands so as to be able to keep the child in the correct position. The child must be in the sitting position with his feet on a footrest so that his full weight is on his buttocks. Insofar as is possible, arching of the back is avoided by gently applying upward pressure to the mastoid processes. In older children, stretching of the back is achieved by asking them to breathe deeply. The child's head is held in the Frankfurt plane: the lower borders of the orbits are in the same horizontal plane with the external auditory meati.

The recommended instrument for measuring crown rump length is similar to the stadiometer used for supine length. The headboard is fixed and the footboard is movable. Headboard and footboard must be large enough to ensure that the most protruding points of both head and buttocks are in contact with the boards. In order to measure this length, an assistant holds the infant's head in the vertical Frankfurt plane while the physician holds the child's legs at a 90 degree angle with the table. When this is achieved, the footboard is pressed against the buttocks.

Subischial leg length is defined as the arithmetic difference between height and sitting height or between supine length and crown rump length.

Head Circumference

The head circumference is routinely measured in newborn infants since it correlates well with skull volume. Skull volume is highly correlated with gestational age, body weight, and body length. Since in intrauterine growth retardation, the brain is less affected than the weight and the length, the extent of the discrepancy between these measurements in the newborn will be an indicator of the severity of the retardation.

Because of the fast growth velocity of the head circumference, especially during the first year of life, its measurement provides important information about the general condition of the child. In full-term healthy newborns, the head circumference increases approximately 1 mm/day initially.

Method of measurement

To measure head circumference, a fiberglass-reinforced tape of nonstretchable material is used. The tape is placed around the head at the most protruding points of occiput and forehead. In younger children, the tape is placed just above the brow ridges. The tape is placed gently so as to leave no marks after removal.

Limb Length

Arm span, upper arm length, lower arm length, hand length, tibia length, and foot length

The measurement of the limbs so as to describe body proportions is an important tool when evaluating development. Arm span is the most common way to measure upper limb length. However, by measuring the span of the out-stretched arms from the tips of the longest fingers, the distorting information of the width of the trunk is added. What is required, however, is information on the growth of the long bones alone. Furthermore, the long bones of arms and legs can be accurately measured because of its bony marks. Hand and foot mature at an earlier age than other parts of the body. Therefore, the changing relationship of hand and foot to height is a useful criterium of the maturation of the child.

Method of measurement

To measure arm span, a measuring rod can be used. Standing with the arms fully extended, the distance between the tips of the stretched middle fingers is measured.

To measure the different parts of the arm, the arm should be relaxed and extended along the child's side. The bony prominences are used as anatomical landmarks. To measure the upper arm length, the lateral border of the acromion and the proximal head of the radius are palpated distal to the lateral epicondyle of the humerus. To measure the lower arm length, the proximal and distal heads of the radius are used. These landmarks are marked with a pen and the distance between them is measured. To measure the length of the hand, the distance between the tip of the longest finger and the distal head of the radius is measured with the hand and forearm flat on a table.

For tibia length, the distance between the proximal–medial border of the tibia and the distal border of the medial malleolus is measured with the Harpenden anthropometer.

The foot is measured while the child is standing. The distance between the most posterior part of the heel and the tip of the longest toe, normally the first toe, is measured on the left foot.

Biacromial Diameter and Biiliacal Diameter

Puberty is characterized auxologically by increasing diameter of shoulders and hips. The ratio of biacromial diameter to biiliacal diameter is a good index of sexual maturation. Biacromial and biiliacal diameter curves remain almost identical in both sexes until puberty. The increase of the biacromial diameter during puberty is more striking in boys than in girls. The change of the ratio between biacromial and biiliacal diameter signals the onset of puberty.

Method of measurement

With the Harpenden anthropometer, measurements of shoulder widths and pelvic widths are taken. When the child relaxes its shoulders, the distance between the most lateral borders of the acromial processes is measured to obtain the biacromial diameter. To measure the biiliacal diameter, the branches of the anthropometer are moved over the iliac crests at their widest point and the distance between the two blades of the anthropometer is measured. In children aged 0–1 year, it is not always possible to take these measurements because of unrest or obesity. Also in older children, the biiliacal diameter is hard to obtain in the case of obesity.

Photometry

Introduction

Manual measurement of body dimensions is common practice in pediatrics. However, it is a highly time-consuming procedure requiring a variety of measurement tools and the skills to use them. Even though it is likely to remain the golden standard for some time to come, alternative methods exist that allow for much faster measurement of body dimensions. One of the most promising of these methods is photometry that involves measurement of body dimensions on the basis of digital images. The overall procedure exists in taking a frontal and lateral picture of the subject, importing these pictures into photometry software, and measuring the body part dimensions by clicking anatomical points in the pictures using a mouse device.

The main advantages of the photometry method are (1) speed, (2) ease of use, and (3) flexibility. After taking the pictures, the whole procedure can be done in a few minutes by anyone with the required knowledge about the correct locations of each anatomical point. The flexibility of the method follows primarily from the separation of the procedure into multiple steps that can be performed at different points in time and place. The actual presence of the subject is only needed during the photography session. Transfer of the pictures and selection of anatomical points can all be done at a time most convenient for the measurer. Pictures are stored in digital format so they can be easily transferred across a computer network to a remote location for further processing. In most cases, a professional photographer will do photography. However, given some assistance this is also feasible for lay people, for example, parents taking pictures of their children.

Method of measurement

The first step of the photometry method involves photography of the subject together with a reference object of known length or size. Two pictures are taken, one from the front (frontal) and one from the side (lateral). The lateral picture is needed to measure foot length. The remaining lengths are measured in the frontal picture. It is important to take the picture of the subject standing or lying in the right position as described earlier. The reference object can be a vertical rod or a square mat lying on the floor, both of known size. It is needed in order to determine the correspondence between pixels in the image and length in centimeters. Once the reference object is indicated by two points in case of a line or by four points in case of a square mat, the correspondent distance manually measured in centimeters is imported in the computer program. Thereby the point selections on the computer screen are defined in pixel coordinates and a conversion from pixels to centimeters will be performed. The user can select the end-points of each body part after which the application automatically calculates the distance in centimeters (see

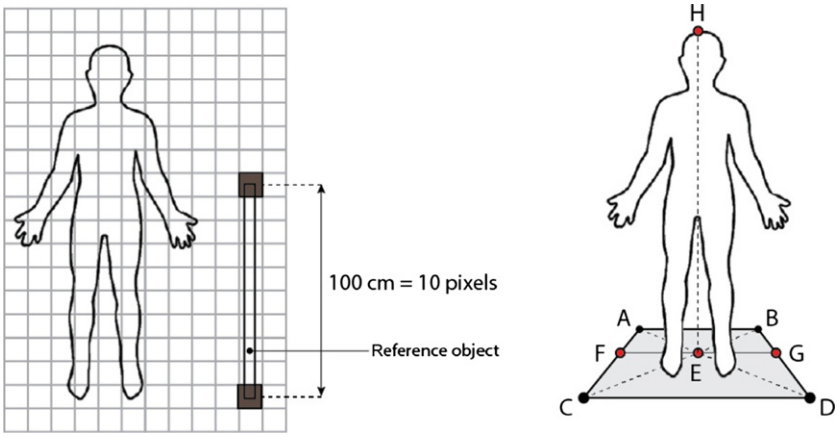

Fig. 1 Calculating centimeters per pixel using a vertical reference object (*left*) or a square mat (*right*). Using the corner points A–D, the intersection point E is calculated first, followed by the distance F–G in pixels. Since F–G is also known in centimeters, the centimeters per pixel ratio is obtained. To determine total body height, only point H has to be manually selected (point E is calculated automatically).

Fig. 1). When the user has finished measuring the body dimensions, the measurement can be saved. The user can easily perform and save additional measurements for the same subject in order to capture changes in body proportions over time. These measurements can be visualized inside the different growth curves of all body parts as used in the Pediatric Morphometrics atlas of Gerver and de Bruin.

Calculating the different body proportions

The measurements of height, biacromium width, biiliacum width, upper arm length, lower arm length, hand length, and foot length are performed by selecting the anatomical reference points in the photographs also used in the manual measurements. The *Paediatric Morphometrics* software automatically calculates the distances between the selected points.

Total sitting height cannot be allocated with the use of anatomical reference points in a frontal photograph. Therefore, this measurement was estimated by using just a part of the sitting height distance that can be selected accurately in the frontal plane, namely the distance between the nasal root and the umbilicus (*NaUm*), adapted by the linear regression formula:

$$SH_{ph} = 1.28^{*}NaUm + 13.7$$

where SH_{ph} is the calculated sitting height in the photograph in centimeters and *NaUm* is the distance between the nasal root and the umbilicus in centimeters ($r^2 = 0.94$).

Because arm span is measured in a different position manually than in the photograph, the arm span is estimated using the formula:

$$ArmSpan_{ph} = 0.886^{*}ArmSpan_{sum} + 4.4$$

where *Arm* $Span_{ph}$ is the calculated arm span in the photograph in centimeters and *Arm* $Span_{sum}$ is the sum of the biacromium width plus two times the length of the upper arm, lower arm, and hand in centimeters.

Calculating body composition

Body mass index (BMI) and waist circumference are used in daily pediatrics to classify children according to their weight. However, both give no insight in body composition such as the amount of body fat or fat free mass. This information is of importance because it has been proven to be more accurate in the assessment of metabolic risks such as the development of the metabolic syndrome. Unfortunately, established measurement methods of body composition such as the Deuterium dilution method or air displacement plethysmography (Bodpod) are cumbersome, costly, and not easily applicable outside research settings. Therefore, the use of photogrammetric anthropometry was investigated to estimate body composition in the two-dimensional picture. It was shown that the ratio between biacromial width and waist width (Biac/Ww), as shown in Fig. 2, correlated strong with fat mass as measured by the earlier-mentioned golden standard methods. Waist width is defined as the widest distance of the waist and not necessarily at the location of the biiliacal measurement.

Fat mass can be estimated as

$$\mathrm{Fm}(\%) = 105.83 - 67.61^{*}\left(\frac{\mathrm{Biac}}{\mathrm{Ww}}\right)$$

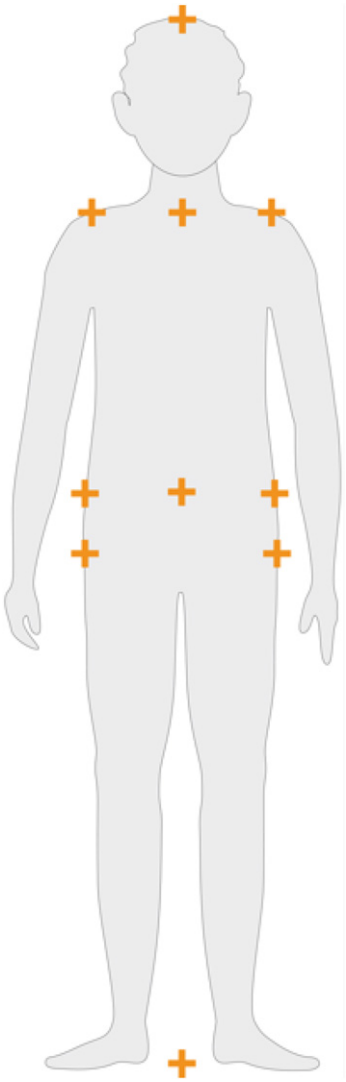

Fig. 2 To calculate body composition the biacromial diameter (Biac) and the widest distance of the waist width (Ww) are used. This distance is mostly below the biiliacal diameter as shown in the picture.

Calculating shape ages

The photometry software also allows automatic calculation of shape ages. This is the age the subject would have if his or her body measurement is considered to be average (i.e., at the p50 level). For example, take the particular height measurement of a subject of about 10.5 years old, plotted on the distance curve of the reference population. His particular shape age can be found by tracing a horizontal line from his measurement to the left or right until it intersects the p50 curve. At the intersection point the corresponding age is taken as the shape age, for example 8 years for this subject. Using the photometry software, the shape age is calculated automatically.

Interpretation of Body Proportions

The most commonly used ratios in anthropometry include: sitting height/height (SH/H), biacromium/biiliacum (Biac/Bill), and subischial leg length/sitting height (LL/SH).

To judge the body proportions of an individual, one can make use of the different expressions:

1. One can take the ratio of two measurements such as sitting height divided by height or even better the subischial leg length divided by sitting height. Ratios are age-dependent and the curve changes in time. However, the use of ratios can be misleading for two reasons: first, two ratios may be equal, while their nominators and denominators are not; and second, when a change in the nominator automatically leads to a change in the denominator, the change of the ratio will be even more misleading.

2. A more straightforward approach is to simply plot one measurement against another. In this way one can plot height against sitting height and an even clearer method is to use sitting height and subischial leg length as variables for comparison, since a change in sitting height will automatically induce a change in height but not a change in subischial leg length. It is better to use sitting height and subischial leg length as variables to compare than the use of height and sitting height because sitting height is part of height and a change in sitting height will automatically induce a change in height which is not the case when using two independent variables.

In the same way, a number of measurements can be compared to each other such as foot length to height, head circumference to supine length, arm span to height, biacromial to biiliacal diameter, and upper arm to lower arm.

First one calculates the standard deviation score, $z(t)$, of each measurement by

$$z(t) = \frac{x(t) - \mu(t)}{\sigma(t)}$$

where $x(t)$ denotes the individual's body measurement score at age t (e.g., height), $\mu(t)$ denotes the population mean at age t, and $\sigma(t)$ denotes the corresponding standard deviation.

Second, the squared distance D^2 is calculated as follows:

$$D^2 = \left[1 - r^2\left(h, h'\right)\right]^{-1}\left[z_h^2 + z_{h'}^2 - 2z_h z_{h'} r^2\left(h, h'\right)\right]$$

where r denotes the correlation coefficient of the two measurements h and h' according to **Table 1**.

$D^2 \leq 5.991$ indicates that the considered individual is typical or normal, whereas $D^2 \geq 5.991$ suggests that something is wrong with size and/or shape.

Graphically, one can display the atypicality of a particular individual by constructing an ellipse, which comprises 95% of the pairs of scores (**Fig. 3**).

Example

If a boy of 6.5 years has a height of 134.6 cm and a sitting height 63.5 cm, the corresponding z-scores for height and sitting height are $zh = 0.92$ and $zsh = -1.5$.

These scores considered separately do not indicate that something is wrong with this child. The difference in sign, however, is somewhat alarming because the correlation between the measurements is positive.

Table 1 Correlation coefficient of pairs of measurements of body proportions according to sex

	Boys	*Girls*	*Mean*
Height/arm span	0.87	0.85	0.86
Height/sitting height	0.82	0.82	0.82
Height/tibia length	0.80	0.80	0.80
Height/foot length	0.75	0.66	0.70
Height/hand length	0.76	0.64	0.70
Biacromial/biiliacal diameter	0.60	0.50	0.55

Note: These correlations are almost independent of age for children between the ages of 3 and 17 years.

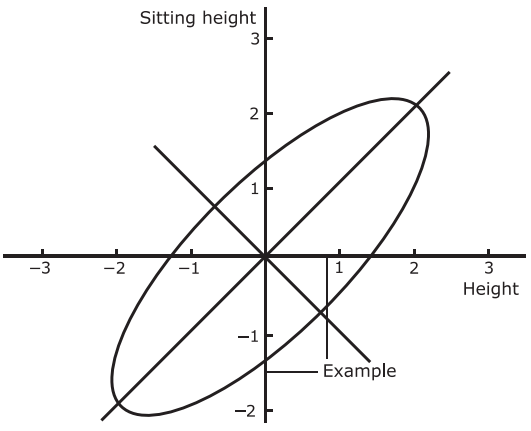

Fig. 3 The 95% confidence limits of the pair of z-scores of height and sitting height. The example is the patient mentioned in the text. With the consequence that the two scores considered together indicate atypicality. This is interesting because, as discussed earlier, separate considerations did not indicate sufficient evidence of abnormality.

Using the value 0.82 for the correlation coefficient between height and sitting height (Table 1), one obtains

$$|z_h - z_{h'}| / \left[2 + 2r\left(h, h'\right)\right]^{1/2} \geq 1.960 = 16.05$$
$$\geq \chi^2_{2.05} = 5.991$$

Conclusion

Pediatricians are often confronted with children of all ages who are referred for growth problems, such as growth retardation or dimorphism. One of the incentives of this article was to provide methods that will give the possibility of discerning growth variation according to typical or atypical patterns. Besides the techniques of measuring children manually also a new method is presented by means of photometry. It provides the possibility to be informed about the proportions of a child based on several measurements within a short time.

Genetic and Hormonal Control of Growth

George Paltoglou and Harshini Katugampola, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom
Mehul T Dattani, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom; and UCL Institute of Child Health, London, United Kingdom

Abbreviations

ACTH	Adrenocorticotropic hormone
AMP	Cyclic adenosine monophosphate
BDNF	Brain derived neurotrophic factors
BMPs	Bone morphogenetic proteins
CRH	Corticotropin-releasing hormone
EGFs	Epidermal growth factors
ER	Endoplasmic reticulum
ERK	Extracellular signal-regulated kinases
FGFs	Fibroblast growth factors
GABA	Gamma-aminobutyric acid
G-CSF, MCSF	Macrophage colony-stimulating factors
GDNF	Glial derived neurotrophic factors
GH	Growth hormone
GHBP	Growth hormone binding protein
GHRH	Growth hormone releasing hormone
GHRHR	Growth hormone releasing hormone receptor
HGF	Hepatocyte growth factor
HNFs	Hepatic nucleic factors
IGF	Insulin-like growth factor
IGFBP	Insulin-like growth factor binding protein
IHH	Indian hedgehog
IL	Interleukin
IRSs	Insulin receptor substrates
JAK	Janus kinase
KGF	Keratinocyte growth factor
LCR	Locus control region
Lhx4	LIM/homeobox protein 4
MAPKs	Mitogen-activated protein kinases
NGF	Nerve growth factor
PDGF	Platelet derived growth factor
PIAS	Protein inhibitors of activated Stats
PKC	Protein kinase C
Pou1f1	POU-domain transcription factor Pit1
Prop1	Prophet of Pit1
PTH	Parathyroid hormone
PTPs	Protein tyrosine phosphatases
RGD	Arginine-glycine-aspartic acid
SH	Src homology
SHH	Sonic hedgehog
SOCS	Suppressors of cytokine signaling
STAT	Signal transducer and activator of transcription
TGFβ	Transforming growth factor-beta
TNF	Tumour necrosis factor
TRH	Thyroid hormone-releasing hormone
VEGF	Vascular epithelial growth factor
VIP	Vasoactive intestinal polypeptide
WHO	World Health Organization
WNT4	Wingless-related integration site 4

Introduction

Growth is a complex, dynamic process in which an interplay of multiple factors determines not only the final height attained, but also the rate and timing of height increase in a remarkably predictable manner (Murray *et al.*, 2016; Brook *et al.*, 2009). A growing understanding of the spectrum of hormones and their mechanisms of action, as well as advances in molecular genetics, has helped to elucidate the physiology of growth and define the pathological basis of many endocrine growth disorders. This chapter provides an overview of the hormonal and genetic control accounting for variations in normal growth.

Physiology of Growth: The Infancy-Childhood-Pubertal Model of Growth

The rate of linear growth and its regulation varies with age. It is useful to recognize growth as occurring in four discrete but congruent phases (fetal, infancy, childhood, and adolescence), each with different predominating mechanisms (**Fig. 1**) (Tanner, 1962).

Fetal growth peaks at the end of the second trimester at approximately 10 cm/month. The placental supply of nutrients is the principal rate-limiting step in fetal growth. However, the placenta is a unique endocrine organ, actively producing a variant of growth hormone, human placental lactogen, CRH and epidermal growth factors. IGF-1 and -2, produced by the fetus in response to nutrition, are also crucial for growth. Infantile growth is initially an extension of fetal growth and then becomes hormone-dependent, as the hypothalamic-pituitary axis becomes increasingly dynamic. Early growth in height and weight requires adequate nutrition, and also normal thyroid function and bone metabolism. Growth hormone is critical for normal growth, even within the first six months of life. Childhood growth requires growth hormone, and this binds to its somatogenic receptors resulting in the production of IGF-1, the principal postnatal growth factor acting on bone epiphyses and stimulating growth. IGF-1

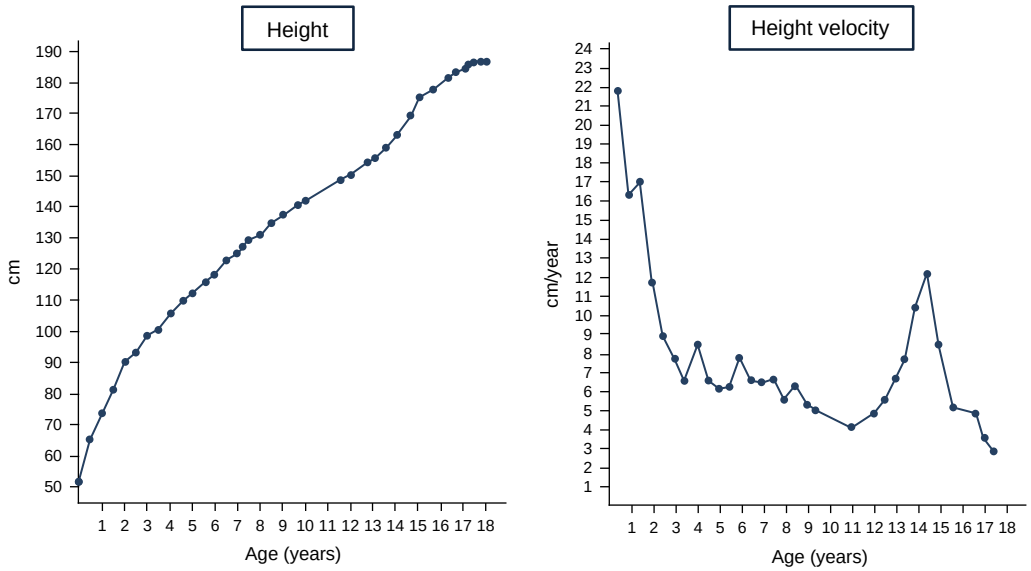

Fig. 1 Height and height velocity through childhood. The concept of plotting body measurements to illustrate growth pattern is attributable to Count Philbert de Montbeillard. The oldest known growth charts are from the 18th century of his son whose height was plotted every six months from birth to age 18 years (1759–1777). George Buffon published the chart in his *Histoire Naturelle*, producing the first growth curve for height (Tanner, 1962). Adapted from Growth and puberty, John W. Gregory. https://obgynkey.com/growth-and-puberty/.

feeds back at the level of both the pituitary and hypothalamus to negatively regulate GH secretion from the pituitary. This can be modulated by input from higher centers, for example severe psychosocial deprivation can result in reversible GHD. At the time of puberty, production of the sex steroids (estrogen and testosterone produced by the gonads) leads to a 2-3-fold increase in GH secretion; subsequently concentrations fall to pre-pubertal ranges and then decline further from middle age onwards ("the somatopause"). Whilst childhood growth occurs predominantly in the limbs, sex steroids augment growth of the spine in particular, and estrogen in both sexes causes fusion of epiphyses, marking the end of growth.

Clinical Evaluation of Growth

Growth should be frequently and accurately assessed as an integral component of health, as a variety of disease processes (endocrine and non-endocrine) can manifest as abnormal growth in children (Murray *et al.*, 2016; Brook *et al.*, 2009). Clinical assessment of growth is a standardized process and accurate, appropriate measurements should be taken by a trained observer, using well-calibrated and maintained equipment, and evaluated in the context of cross-sectional or longitudinal normal data (Tanner, 1986). Growth charts are constructed using growth references, which are usually compiled using data from normal healthy children. All growth references presently in use are descriptive of current growth patterns and are therefore "references" and not "standards" that define an optimum growth pattern (Wright *et al.*, 2002). The World Health Organization (WHO) growth charts are based on healthy breastfed children, and help define how all children from birth to 5 years should grow, irrespective of ethnicity (Wright *et al.*, 2013). It should be noted that growth charts are clinical tools that require careful design, instructions for use and evaluation before introduction to clinical practice (Wright *et al.*, 2013). In addition, disease-specific growth curves have been developed for use in clinical conditions associated with growth failure (Saari *et al.*, 2013). Unexplained acceleration or deceleration of height velocity, or abnormal growth states characterized by disproportionate growth, warrant further evaluation (Dattani and Preece, 2004).

In addition to linear growth, the progression of ossification within the epiphyses follows an expected sequence (normal skeletal maturation), indicative of the genetic potential of growth inherent in the tubular bones (Greulich and Pyle, 1959; Tanner, 1983). This "bone age" can clinically be usefully employed to predict final height potential (Tanner *et al.*, 1975; Roche *et al.*, 1975).

Lastly, since the genetic potential is of great importance as a determinant of final height, a child's stature should be evaluated relative to that of siblings and parents *via* a calculation of parental target height and the respective standard deviations (Tanner *et al.*, 1975). If a child's growth rate is noted to be tracking along a disparate percentile for their family, this should prompt investigation into the possibility of an underlying pathological process (Dattani and Preece, 2004).

Hypothalamo-Pituitary Development

The neuroendocrine network between the hypothalamus and pituitary gland is responsible for the regulation of growth by coordinating signals from the brain to key target organs (Bancalari *et al.*, 2012). The pituitary is located deep within the brain

parenchyma in the center of the cranial base, within a bony cavity known as the *sella turcica* (McCabe and Dattani, 2014). Two distinct components of the pituitary become evident during embryogenesis: the adenohypophysis (anterior and intermediate lobes) and neurohypophysis (posterior lobe) (McCabe and Dattani, 2014; Solov'ev *et al.*, 2008; Ooi *et al.*, 2004). The neurohypophysis arises from neural ectoderm, from the floor of the forebrain, and contains the terminal axonal projections of magnocellular neurons from the paraventricular and supraoptic nuclei of the hypothalamus (Ooi *et al.*, 2004). It produces oxytocin and vasopressin that do not play a role in human growth (Mastorakos and Ilias, 2003). The adenohypophysis (80% of pituitary weight) arises from stomodeal ectoderm, a diverticulum of the primitive oral cavity (Rathke's pouch) (McCabe and Dattani, 2014; Asa *et al.*, 1991). The adenohypophysis consists of five different endocrine cell types, each described by the hormone it produces and by the nature of their appearances on hematoxylin and eosin staining – the acidophils are somatotrophs that secrete growth hormone (GH). The adenohypophysis can be anatomically subdivided into the *pars distalis* (pars anterior or anterior lobe), the *pars intermedia* (intermediate lobe), and the *pars tuberalis* (pars infundibularis or pars proximalis) (Asa *et al.*, 1991; Ikeda *et al.*, 1988). *Pars distalis* in humans is the largest component of the adenohypophysis containing most hormone-producing cells (Asa *et al.*, 1991). *Pars intermedia* is typically poorly developed and consists of several cystic cavities lined by a single layer of cuboidal epithelium. *Pars distalis* and *intermedia* are separated by a cleft, a vestigial structure of Rathke's pouch from which it develops (Han *et al.*, 2014). This structure may often develop as a cyst (Rathke's cleft cyst) (Han *et al.*, 2014). In humans, *pars intermedia* is rudimentary as it largely disappears during embryogenesis (Solov'ev *et al.*, 2008). The *pars tuberalis* represents an upward extension of the *pars distalis* onto the pituitary stalk and may contain a limited number of gonadotrophin-producing cells (Solov'ev *et al.*, 2008). Although there is little direct evidence for the physiological processes underlying pituitary development in humans, development of the pituitary gland in the mouse is well-characterized, and the process appears to be highly conserved across all vertebrates (Rosenfeld *et al.*, 2000; Kelberman *et al.*, 2009). The pituitary placode appears at mouse embryonic day (E) 7.5 with a thickening of the ectoderm in the midline of the anterior neural ridge, forming the hypophyseal placode (Rosenfeld *et al.*, 2000; Dearden and Holmes, 1976). The onset of pituitary organogenesis corresponds to 4-6 weeks gestation in humans. At E9.0 in the mouse, the placode invaginates and forms the rudimentary Rathke's pouch from which the anterior and intermediate lobes of the adenohypophysis are derived. Between E10.5-12.0, the pouch epithelium continues to proliferate and is completely detached from the oral cavity at E12.5 to form the definitive Rathke's pouch (Dearden and Holmes, 1976). During the beginning of its development it is associated with developing hypothalamic territories, and later with the developing diencephalon (Solov'ev *et al.*, 2008; McCabe and Dattani, 2014; Treier and Rosenfeld, 1996). In humans, Rathke's pouch can be identified in the 3-mm embryo during the third gestational week (Han *et al.*, 2014). Subsequently during its development, a complete pouch is gradually formed and finally is disconnected from the oral ectoderm by the end of the sixth gestational week (Han *et al.*, 2014). In the murine embryo, the progenitors of the hormone-secreting cell types proliferate ventrally from the pouch between E12.5-17.5 and populate what will form the mature anterior lobe. The remnants of the dorsal portion of the pouch will form the intermediate lobe, whilst the lumen of the pouch remains as the pituitary cleft separating the two lobes of the adenohypophysis. Somatotrophs can be identified by 9 weeks gestation in human pituitary development, a time point that coincides with the development of vascular connections between the anterior pituitary and the hypothalamus (Asa *et al.*, 1988; Gorczyca and Hardy, 1987; Stanfield, 1960). The pituitary gland has a dual embryonic origin: the anterior and intermediate lobes are derived from oral ectoderm, and the posterior pituitary from neural ectoderm. The close apposition and interaction of these two ectodermal layers throughout neurodevelopment is crucial to the formation and function of a normal pituitary gland (Kelberman and Dattani, 2009; Davis *et al.*, 2010; Ericson *et al.*, 1998). This process is dependent upon the sequential temporal and spatial expression of a cascade of signaling molecules and transcription factors that play a crucial role in organ commitment, cell proliferation, patterning and terminal differentiation (**Fig. 2**) (Kelberman *et al.*, 2009).

Several studies have shown that normal pituitary development is mediated by the spatio-temporal expression of a complex cascade of transcription factors in response to signaling molecules from the surrounding tissues of the developing gland (Cohen, 2000; Parks and Brown, 1999; Davis *et al.*, 2010; Kerr *et al.*, 2008; Potok *et al.*, 2008). These signaling molecules are either intrinsic within the oral ectoderm, such as Sonic hedgehog (SHH), or extrinsic from the neuroectoderm (BMP4, FGF8, FGF4, NKX2-1, WNT5A), surrounding mesenchyme (BMP2, Indian hedgehog (IHH), chordin) and the pouch itself (BMP2, WNT4), and create a network of signaling gradients important for early pituitary morphogenesis (Gregory *et al.*, 2015; Zhao *et al.*, 2012; Guner *et al.*, 2008; Silberschmidt *et al.*, 2011; Labeur *et al.*, 2010; Shah and Kakar, 2011; Miyakoshi *et al.*, 2008; Aujla *et al.*, 2011).

These signaling molecules activate or repress transcription factors as part of a complex cascade that includes the POU-domain transcription factor *Pit1*, recently renamed *Pou1f1*, and its predecessor Prophet of Pit1 (*Prop1*), LIM homeodomain factors Islet1 (*Isl1*), *Lhx3*, and *Lhx4*, the pituitary homeobox genes *Pitx1* and *Pitx2*, and the Rathke's pouch homeobox gene *Hesx1* (also known as *Rpx*) (Kato *et al.*, 2010; Colvin *et al.*, 2009; Potok *et al.*, 2008). Birth-dating studies have revealed that the enrichment of cell types at specific positions along the caudal to rostral axis in newborn mice does not result from an ordered cell cycle exit for each cell type; cells exiting the cell cycle concurrently are dispersed throughout the anterior lobe of the pituitary (Davis *et al.*, 2011). Hence, the clustering of cell types in specific regions of the anterior lobe may be the result of an as yet undefined mechanism including network formation or lateral inhibition (Davis *et al.*, 2011).

Spontaneous and artificially induced mutations in the mouse have led to significant insights into human pituitary disease. Identification of mutations in genes implicated in normal hypothalamo-pituitary development that are associated with human pituitary disease has also been invaluable in defining the genetic cascade of pituitary development. The advent of new technologies such as whole genome sequencing has resulted in an expanding list of genetic factors involved in human hypothalamo-pituitary disease (Haston *et al.*, 2017; Fang *et al.*, 2016) (see **Tables 1** and **2**). Importantly, the Wnt signaling pathway has been implicated in pituitary organogenesis and

tumorigenesis (Cha *et al.*, 2004; Potok *et al.*, 2008). Evidence for Wnt signaling in pituitary development is derived from conditions associated with pituitary abnormalities that follow disruption of Wnt5a and Wnt4 (Cha *et al.*, 2004). Finally several microarray studies have identified altered expression of Wnt inhibitors in pituitary tumors and there is clear evidence that the Wnt/β catenin pathway is involved in the pathogenesis of craniopharyngioma, a rare tumor in the hypothalamo-pituitary region (Elston and Clifton-Bligh, 2010; Andoniadou *et al.*, 2012; Gaston-Massuet *et al.*, 2011).

Endocrine Regulation of Normal Growth

Growth Hormone Axis

Endocrine regulation of normal growth classically depends upon the growth hormone (GH) axis, where stimulatory growth hormone releasing hormone (GHRH) and inhibitory somatostatin from the hypothalamus modulate GH secretion (Brook *et al.*, 2009). GH, the main hormonal mediator of growth, stimulates the secretion of insulin-like growth factor (IGF)-1 from the liver, and this mediates most of the anabolic actions of GH (somatomedin hypothesis) (Kaplan and Cohen, 2007). GH also stimulates metabolic effects independently of IGF-1 activity (lipolysis, amino acid transport in diaphragm and heart, and production of specific hepatic proteins) (Green *et al.*, 1985; Kaplan and Cohen, 2007; Mauras and Haymond, 2005)

Table 2 Genetic disorders of hypothalamo-pituitary development resulting in syndromic hypopituitarism or combined pituitary hormone deficiencies.

Gene	*Endocrine phenotype*	*MRI phenotype*	*Other associations*	*Inheritance*
Syndromic hypopituitarism				
HESX1	Panhypopituitarism; GH deficiency; GH with evolving ACTH and TSH deficiencies	APH, EPP, ONH, ACC; normal AP with EPP and ONH	Septo-optic dysplasia and its variants	AD
	Panhypopituitarism; GH, LH, FSH, evolving ACTH and TSH deficiencies	APH, EPP, ONH, ACC; normal ON with EPP and APH; pituitary aplasia with normal PP and ON; pituitary aplasia with normal PP and ON coloboma		AR
TCF7L1	Isolated GH deficiency or low IGF-1, mildly elevated TSH with normal fT_4	APH, absent PP, ONH, thin optic tracts, partial agenesis of the corpus callosum, absent septum pellucidum, thin anterior commissure	Septo-optic dysplasia	AD with variable penetrance
LHX3	GH, TSH, PRL, LH, FSH deficiencies; ACTH deficiency may evolve	APH, enlarged/ cystic AP, normal PP and stalk	Limited neck rotation, short cervical spine, sensorineural deafness	AR
LHX4	Panhypopituitarism; GH with variable TSH, ACTH, LH and FSH deficiencies	APH, normal PP or EPP, Chiari malformation, cerebellar abnormalities	–	AD
	ACTH, TSH, PRL and probable GH deficiencies	Pituitary aplasia, EPP	Lethality in the first weeks of life with severe sepsis, poor tone, lung atelectasis, mid-facial hypoplasia, low-set ears	AR
SOX2	LH and FSH deficiencies, rarely GH deficiency	APH, thin CC; hippocampal abnormalities; hypothalamic hamartoma; slow-progressing hypothalamo-pituitary tumour	Bilateral/ unilateral anophthalmia, spastic diplegia, developmental delay, trachea-esophageal fistula, sensorineural deafness	AD
SOX3	Panhypopituitarism; GH, TSH, ACTH, LH and FSH deficiencies; isolated GH deficiency	APH, EPP; persistent craniopharyngeal canal	Variable mental retardation	XL
OTX2	Isolated or partial GH deficiency; GH, TSH, ACTH, LH and FSH deficiencies	Normal pituitary; APH, EPP, Chiari malformation	Anophthalmia, bilateral/ unilateral retinal dystrophy; normal eye phenotype	AD
ARNT2	Central diabetes insipidus, GH, ACTH, TSH deficiencies	APH, absent PP, thin CC; frontal & temporal lobe hypoplasia, large Sylvian fissure	Microcephaly, seizures, visual impairment, renal tract abnormalities	AR
Gene	*Endocrine phenotype*	*MRI*	*Other associations*	*Inheritance*
GLI2	Panhypopituitarism; GH, TSH, ACTH, LH and FSH deficiencies; isolated GH deficiency	APH, normal PP or EPP, hypoplastic PP, ONH, holoprosencephaly, cavum septum pellucidum	Mid-facial defects, cleft lip/palate, single central incisor, postaxial polydactyly	AD
PITX2	Reduced GH concentration	Sella turcica hypoplasia	Axenfeld-Rieger syndrome (malformation of the anterior segment of the eye, dental hypoplasia, protuberant umbilicus, brain abnormalities)	AD
*FGF8**	Borderline peak GH concentration	ACC, ONH	Moebius syndrome, spastic diplegia, developmental delay	AD
	Central diabetes insipidus, ACTH and TSH deficiencies	Semilobar holoprosencephaly, bulky AP, normal PP	Microcephaly, micrognathia, high arched palate	AR
*FGFR1**	GH, ACTH, TSH, LH and FSH deficiencies, central diabetes insipidus	APH, EPP, thin or normal pituitary stalk, ACC, ONH	Cleft lip/ palate, brachydactyly, single central incisor	AD
*PROKR2**	GH, ACTH, TSH, LH and FSH deficiencies; isolated GH deficiency	APH or normal AP, EPP, absent pituitary stalk, CC dysgenesis	Facial asymmetry, schizencephaly, cerebellar hypoplasia, hypoplastic optic discs	AD
PNPLA6	GH, TSH, LH and FSH deficiencies; isolated hypogonadotrophic hypogonadism	APH, cerebellar hypoplasia	Oliver-McFarlane and Gordon-Holmes syndromes; ataxia, chorioretinal atrophy, spasticity	AR

(*Continued*)

*KAL1**	GH, ACTH and TSH deficiencies	APH, ONH	Septo-optic dysplasia, females affected	XL
Combined pituitary hormone deficiencies				
POU1F1	GH, PRL and TSH deficiencies (TSH deficiency may present early or develop later)	APH or normal AP, normal PP and infundibulum, no extra-pituitary abnormalities	–	AD, AR
PROP1	GH, TSH, PRL, LH, FSH and evolving ACTH deficiencies with variable time of onset and severity	APH, normal or enlarged AP that may change over time, normal PP and stalk	–	AR
IGSF1	TSH $\pm$ PRL deficiencies, transient GH deficiency, macroorchidism (males), ovarian cysts (females)			XL
PC1	ACTH deficiency, hypoglycemia, hypogonadotrophic hypogonadism, obesity, GH deficiency, diabetes insipidus		Obesity, gastrointestinal disorder	AR

*These genes are also known to cause isolated hypogonadotrophic hypogonadism. ACC; absent corpus callosum, AD; autosomal dominant, AP; anterior pituitary, APH; anterior pituitary hypoplasia, AR; autosomal recessive, CC; corpus callosum, EPP; ectopic posterior pituitary, ON; optic nerves, ONH; optic nerve hypoplasia, PP; posterior pituitary, XL; X-linked.

The anabolic actions of GH either directly or via the IGF system include: (Nilsson *et al.*, 1994; Olney, 2003; Chikani and Ho, 2014; Moller and Jorgensen, 2009; Antonopoulou *et al.*, 2012; Gullett *et al.*, 2010):

a. *Bone:* stimulation of epiphyseal growth, osteoclast and osteoblast activity, stimulation of osteoclast differentiation and increase of bone mass by endochondral bone formation.
b. *Muscle:* increased amino acid transport, nitrogen retention, energy expenditure and lean tissue accrual.
c. *Adipose tissue:* increased lipolysis, stimulation of hormone sensitive lipase and inhibition of lipoprotein lipase, glucose transport, and lipogenesis (acute insulin-like effects).

Several studies have shown contradictory/opposing actions of GH and IGF-1 (Mauras and Haymond, 2005). A hypothesis for this contradiction has been proposed based on evidence that IGF peptides showcase endocrine, paracrine and autocrine effects (Green *et al.*, 1985). This hypothesis proposes a "dual-effector" model where GH stimulates differentiation of precursor cells (Green *et al.*, 1985). These differentiated or the neighboring cells secrete IGFs, which act as mitogens and stimulate clonal expansion (Green *et al.*, 1985). Their actions are achieved through the respective receptors, while crucial in the modulation of their effect are the respective binding proteins (Belfiore *et al.*, 2009; Forbes *et al.*, 2012). Additional contributors to their actions are sex steroids and thyroid hormone (Coutant *et al.*, 2004; Rhee *et al.*, 2015). In addition, many molecules have been identified and comprise the group of novel growth factors (Sederquist *et al.*, 2014). These include the fibroblast growth factor (FGF) family of peptides and their receptors and the epidermal growth factors (EGF) and their receptors (Kostopoulou *et al.*, 2017; McCabe *et al.*, 2011). Of special interest is a class of inflammatory cytokines (the most abundant being tumor necrosis factor alpha, interleukin 1beta (IL1beta), and IL6) that is known to directly act on growth plate cartilage to induce apoptosis and thereby suppress bone growth, and thus can negatively modulate cellular growth (Sederquist *et al.*, 2014).

Growth hormone

Human GH is produced from somatotrope cells within the anterior pituitary (Masuda *et al.*, 1988). *A* 217aa GH-precursor is transported in the lumen of the endoplasmic reticulum (ER) via a mechanism that involves the recognition of the signal peptide (first 26 aa) (Cogan *et al.*, 1993). The GH-precursor is cleaved, and a mature protein is transported to the Golgi apparatus and secretory vesicles. The GH molecule is a single-chain non-glycosylated 191-amino-acid 22-kDa protein (Lewis *et al.*, 1980). It has a core of four helices in a parallel /anti-parallel orientation with two disulfide bonds between cysteines 53-165 and 182-189 (de Vos *et al.*, 1992). It should be noted that the presence of zinc ions facilitates the formation of soluble GH dimer complexes within the secretory granules, as well as the storage and secretion of GH aggregates (Petkovic *et al.*, 2013).

Of note, several proteins demonstrate homology to GH. These include prolactin, chorionic somatomammotropin (CS, placental lactogen), and a 22-kDa GH variant (hGH-V) secreted only by the placenta (Frankenne *et al.*, 1988). Even though the genes for these homologous proteins are located on different chromosomes (chromosome 6 for prolactin and chromosome 17 for GH) a common ancestral chromosome might exist (Cooke *et al.*, 1988).

GH-1

GH-1 is located on the long arm of chromosome 17 (17q22-24) within a cluster of five homologous genes, encompassing a distance of about 65 kb, that include chorionic somatomammotropin pseudogene (*CSHP*), chorionic somatomammotropin gene (*CSH*)*-1*, *GH-2* and *CSH-2* (Procter *et al.*, 1998). Along with prolactin and placental lactogen, *GH* showcases a structural organization of four introns separated by five exons (Frankenne *et al.*, 1988), and its full length product is a 191 amino acid (22 kDa) peptide.

Expression of *GH-1* is regulated by the highly polymorphic proximal promoter and a locus control region (LCR) 15–32 kb upstream of the gene that confers the pituitary-specific and high-level expression of GH (Horan *et al.*, 2003). The pituitary normally produces mainly the mature 22-kDa form of GH (75% of pituitary GH), while alternative splicing of the second exon results in deletion of amino acids 32 through 46, yielding a 20-kDa form (less than 10% of pituitary GH) (Cooke *et al.*, 1988; Miller and Eberhardt, 1983; DeNoto *et al.*, 1981). Pituitary GH also includes desamidated and N-acetylated forms, as well as various GH oligomers (DeNoto *et al.*, 1981). A 17.5 kDa variant that results from complete skipping of exon 3 and lacks amino acids 32-71 forms 1-5% of pituitary GH (Miller and Eberhardt, 1983).

GH secretion is regulated by GHRH, somatostatin and other secretagogues

GH displays a characteristic pulsatile secretion pattern that is the result of a complex interplay of multiple regulators, including two hypothalamic regulatory peptides, GH-releasing hormone (GHRH) and somatostatin (Barinaga *et al.*, 1983; Holl *et al.*, 1988).

GHRH stimulates GH secretion through the 44-amino acid terminus (Mayo, 1992). Its activity in the somatotropes is species-specific mediated through a specialized G-protein–related receptor (G-protein–coupled receptor family B/secretin family; GHRHR) (Mayo, 1992). The gene encoding GHRHR maps to chromosome 7p15 and consists of 13 exons spanning approximately 15 kb. It encodes a 423-amino acid G-protein-coupled receptor comprising seven transmembrane domains. The expression of *GHRHR* is up-regulated by *POU1F1* and required for the proliferation of somatrotrophs. The GHRH receptor displays partial sequence identity with receptors for vasoactive intestinal polypeptide [VIP, secretin, calcitonin, and parathyroid hormone (PTH)] (Mayo, 1992). Binding of GHRH to the receptor results in stimulation of adenylate cyclase and transcriptionally mediated increases in intracellular cyclic adenosine monophosphate (AMP) concentrations, which result in increased GH synthesis (Mayo, 1992).

Somatostatin, a 14-amino acid protein, inhibits GH secretion through binding to its specific receptor, which then reduces adenylate cyclase activity and concomitantly intracellular calcium concentrations (Holl *et al.*, 1988).

The pulsatile pattern of GH secretion observed *in vivo* is due to the dual and opposing effects of GHRH and somatostatin secreted from the hypothalamus (Hartman *et al.*, 1991). A peak of GH results from a parallel reduction in somatostatin and an increase in GHRH secretion, while a trough of GH secretion results from a parallel increase in somatostatin and a decrease in GHRH secretion (Hartman *et al.*, 1991). The net effects of these two hypothalamic hormones is modulation of GH secretion, as well as the timing and amplitude of peaks, resulting in pulsatile GH secretion (Veldhuis, 1998).

The complex pattern of release of these hypothalamic hormones is understood to result from the interaction of multiple neurotransmitters and neuropeptides, including serotonin, histamine, norepinephrine, dopamine, acetylcholine, gamma-aminobutyric acid (GABA), thyroid hormone-releasing hormone (TRH), corticotrophin-releasing hormone (CRH), vasoactive intestinal peptide (VIP), gastrin, neurotensin, substance P, calcitonin, neuropeptide Y, vasopressin, and galanin (Blanchard *et al.*, 1988). The alterations of GH secretion observed in various physiological states (e.g. stress, sleep, hemorrhage, fasting, hypoglycemia, and exercise), are believed to be mediated through these factors (Giustina and Veldhuis, 1998).

Non-peptide hormones also modulate GH secretion, through potential complex interactions at the hypothalamic and pituitary level (Zeitler *et al.*, 1990). Spontaneous and provocative GH secretion is, on the one hand, attenuated by increased glucocorticoid and reduced thyroxine concentrations, while on the other is amplified by increased sex steroid concentrations (Martha Jr. *et al.*, 1989).

A receptor that is distinct from the GHRH receptor, termed the GH secretagogue receptor (GHS-R), has also been identified. This unique G-protein–coupled receptor has been characterized through special synthetic hexapeptides capable of stimulating GH secretion, termed GH-releasing peptides (GHRPs). These peptides, later recognized as analogues of the gastric hormone ghrelin, are capable of directly stimulating GH release and enhancing the GH response to GHRH (Bowers *et al.*, 1984; Smith *et al.*, 1999). The *GHS-R* gene is strongly expressed in the hypothalamus but specific binding sites for GH releasing peptides have also been identified in other regions of the CNS as well as peripheral tissues.

The endogenous ligand for GHS-R is a 28-amino-acid peptide, the gastric hormone ghrelin (Smith *et al.*, 2001). Smaller amounts are also produced within the intestine, pancreas, kidney, immune system, placenta, pituitary, testis, ovary and hypothalamus (Smith *et al.*, 2001). Ghrelin is a unique gene product that requires octanoylation for normal function, and its main function is to stimulate appetite and is therefore considered obesogenic (Kojima *et al.*, 1999). It raises plasma GH synergistically with GHRH, and to a lesser extent prolactin and adrenocorticotropic hormone (ACTH) concentrations (Hosoda *et al.*, 2000). Ghrelin also influences endocrine pancreatic function and glucose metabolism, and controls gastric motility and acid secretion (Hosoda *et al.*, 2000). Further effects on gonadal, cardiovascular function and behavior are postulated (De Vriese and Delporte, 2008). These functions suggest that ghrelin is a component of the GH regulatory system of growth, by providing a stimulus for nutrient intake and allocation as well as regulating metabolism (De Vriese and Delporte, 2008). A second peptide product of the ghrelin gene, obestatin, has been identified but it regulates weight, not GH secretion (Zhang *et al.*, 2005).

In addition to the complex regulatory processes described previously, the synthesis and secretion of GH are also regulated by negative feedback (inhibition) by insulin-like growth factors (IGF) (Berelowitz *et al.*, 1981; Abe *et al.*, 1983). This inhibition has been demonstrated in the pituitary and in the hypothalamus, as well as in humans treated with recombinant IGF-1 (Ceda *et al.*, 1985; Guler *et al.*, 1987).

GH receptor

The effects of GH are mediated through interaction of the molecule with the GH receptor (GHR), a member of class 1 hematopoietic cytokine family (Leung *et al.*, 1987). The gene for human GHR has been localized to chromosome 5p13.1-p12, where it spans more than 87 kb (Leung *et al.*, 1987; Trivedi and Daughaday, 1988). The coding and 3-prime untranslated regions of the human GHR are encoded by nine exons, numbered 2 to 10 (Kelly *et al.*, 1991). Specifically, exon 2 encodes the secretion signal peptide, exons 3 to 7 encode the extracellular domain, exon 8 encodes the transmembrane domain, exon 9 encodes the intracellular domain and exon 10 encodes the 3-prime untranslated region (Trivedi and Daughaday, 1988).

The first transcript of *GHR* is a 638-amino-acid peptide, which through processing matures to a 620 amino acid receptor with a predicted molecular mass of 70 kDa before glycosylation (Leung *et al.*, 1987). The complete GHR comprises an extracellular hormone-binding domain (246 amino acids), a single membrane-spanning domain and a cytoplasmic domain (350 amino acids) (Leung *et al.*, 1987). In humans, proteolytic cleavage of the extracellular domain of the receptor forms the circulating GH-binding protein (GHBP) (Leung *et al.*, 1987). There are two genomic GHR isoforms in humans resulting from ancestral homologous recombination with subsequent retention or deletion of exon 3 (Jensen *et al.*, 2007). While the deletion of exon 3 of the GHR has been documented in a substantial number of normal individuals, this polymorphic variant has been associated with receptor responsiveness to GH and with birth size and postnatal growth (Jensen *et al.*, 2007; Mullis *et al.*, 2002).

GHR is highly homologous with the prolactin receptor and shares sequence homology with erythropoietin, leptin, granulocyte-macrophage colony-stimulating factor, interferon and several interleukin receptors (Brooks and Waters, 2010).

JAK-STAT signaling

As revealed by crystal structure examination, the GH-GHR complex consists of one molecule of GH bound to two GHR molecules, indicative that receptor dimerization is necessary for GH action (Brooks and Waters, 2010; de Vos *et al.*, 1992). It has been shown that the GHR is pre-formed as a dimer and is transported in a non-ligand bound state to the cell surface (Brooks and Waters, 2010;

Wilkinson *et al.*, 2007). GH displays two binding sites (1 and 2) with the first GHR monomer binding to the stronger site 1, followed by the second GHR monomer binding to the weaker site 2 (Argetsinger *et al.*, 1993). Binding results in conformational changes of the GHR dimers that result in repositioning of the intracellular domains and of Box1-associated Janus Kinase (JAK)2, a major GHR-associated tyrosine kinase (Waters and Brooks, 2015). This dimerization supposedly induces proximity of the associated JAK2s, resulting in their trans-activation and signal initiation (Waters and Brooks, 2015). More recent models have shown that dimerization of the receptor extracellular domains alone is insufficient to trigger activation, and that a specific receptor alignment or conformational change is needed (Waters and Brooks, 2015). This activation leads to cross phosphorylation of distal tyrosine residues of GHR that then enables Src homology (SH)2 domain molecules to dock to these sites (Argetsinger and Carter-Su, 1996). Two such molecules Stat5a and Stat5b contain SH2 domains and after binding to these phosphorylated tyrosine sites they in turn become phosphorylated (Brown *et al.*, 2005). Phosphorylated Stat5 molecules (homo- and hetero-) dimerize and translocate to the nucleus where they bind DNA, as dimers or as tetramers, and activate target genes (Brown *et al.*, 2005). Both Stat5a and Stat5b, as well as Stat1 and Stat3, are activated by GH, and they have both overlapping and distinct functions (Yoo *et al.*, 2011). Gene inactivation mouse models have shown that Stat5b is of greater importance for stimulation of growth than Stat5a, while both Stat 5a and Stat 5b seem to play critical roles in cell proliferation, particularly in immune cells (Yoo *et al.*, 2011; Gebert *et al.*, 1997; Imada *et al.*, 1998; Yao *et al.*, 2006; Cohen *et al.*, 2006). A pulse of GH stimulates Stat5b phosphorylation and after this rapid activation, Stat5b becomes temporarily refractive to further or continuous stimulation (Gebert *et al.*, 1997). There appear to be gender-specific differences in GH secretion and Stat5b signaling (Davey *et al.*, 1999). Hepatic nucleic factors (HNF)s, especially HNF3, 4α and 6, interact with Stat5b to induce these Stat5b-dependent gender-specific gene expression patterns (Choi and Waxman, 2000).

The phosphorylated Stat5a and Stat5b bind as dimers or tetramers to the Stat5 Response Element (RE), which is enhanced by the interaction of co-activators binding to adjacent DNA binding sites. Known co-activators are the γ-interferon activated sequence (GAS) motif, the glucocorticoid receptor (GR) response element, C/EBP and HNFs (Soldaini *et al.*, 2000). The gene of human IGF1 contains Stat5 RE in the second and third intron and with lesser effectiveness a distant Stat5 RE 73 kb upstream of the initiation site (Rotwein, 2017). Several other genes contain Stat5 RE including *Spi2.1*, *CIS*, *SOCS2*, *HNF6* and several genes for CYP450 enzymes (Soldaini *et al.*, 2000).

Following GH stimulation, the activation of JAK-STAT signaling occurs rapidly (within minutes) and is followed by negative regulation of signaling, indicative of the tight control of termination signaling (Gebert *et al.*, 1999). This occurs through GHR internalization and through the action of Suppressors of Cytokine Signaling (SOCS), Protein Tyrosine Phosphatases (PTP)s, and Protein Inhibitors of Activated Stats (PIAS) (Hansen *et al.*, 1999; Flores-Morales *et al.*, 2006; Gu *et al.*, 2003; Frank and Fuchs, 2008). The inhibition of GH signaling by several members of the GH-inducible SOCS family occurs through inhibition of JAK proteins and inhibition of JAK-STAT signaling, through competitive binding of positive regulators of signaling or docking sites, and through promoting GHR ubiquitination and inhibition of the GHR-dependent tyrosine phosphorylation of JAK2 (Hansen *et al.*, 1999; Waters *et al.*, 2014). Interestingly, endotoxin and proinflammatory cytokines such as interleukin-1b (IL-1b) and tumor necrosis factor-a (TNFa) induce a state of GH resistance, through induction of SOCS proteins (Colson *et al.*, 2000). The inhibition of GH signaling by several PTPs, (PTP-1, PTP-H1 and PTP-B1 and TC-PTP), occurs through dephosphorylation of activated phosphorylated proteins. It usually involves cytokine signaling pathways but also insulin signaling pathways (Frank and Fuchs, 2008). PTP-1B is involved in fasting-induced GH insensitivity, while PTPN11 mainly functions in RAS-MAPK signaling (Gu *et al.*, 2003).

Alternative signaling through the GHR

The activated GHR alternatively activated pathways include mitogen-activated protein kinases (MAPK)s, extracellular signal-regulated kinase (ERK)-1 and ERK2, the insulin-signaling pathway [through the insulin receptor substrate (IRS)-1 and IRS-2], and protein kinase C (PKC) (Brooks and Waters, 2010).

GH binding proteins

The soluble extracellular domain of GHR (molecular mass 55 kDa) is the main GH binding protein (GHBP) that is present in many tissues (Baumann *et al.*, 1986; Sotiropoulos *et al.*, 1993). It has identical affinity for the GH molecule as the GHR, binding with high specificity and affinity, but relatively low capacity (Baumann *et al.*, 1986). GHBP in the circulation is mostly derived from the liver, functioning as a transporter of GH to target tissues and aiding the subsequent binding to GHR (Baumann *et al.*, 1986). It is derived through proteolytic cleavage of the cell membrane anchored GHR, by enzymes such us TNFα-converting enzyme (TACE) (Zhang *et al.*, 2000).

Generation of insulin-like growth factors

The two insulin like growth factor (IGF)s, IGF-1 and IGF-2 (Daughaday and Kapadia, 1989; Rinderknecht and Humbel, 1978a; Rinderknecht and Humbel, 1978b), are basic peptides of 70 and 67 amino acids respectively. IGF-1 and IGF-2 are structurally related and have 50% amino acid homology to insulin (Rinderknecht and Humbel, 1978a, Rinderknecht and Humbel, 1978b). All three molecules have A and B chains connected by disulfide bonds and a connecting (C-peptide) region that bears no homology with the C-peptide region of proinsulin (Daughaday and Kapadia, 1989). This structural homology and the disparities explain the ability of both IGFs to bind to the insulin receptor and for insulin to bind to type 1 IGF receptor, but not to the IGFBPs.

IGF-1 *and* IGF-2 *genes*

The human *IGF-1* gene spans 95 kb and is located on the long arm of chromosome 12 and contains at least six exons (Brissenden *et al.*, 1984; Tricoli *et al.*, 1984). Specifically, exons 1, 2, 3 and 4 encode alternative signal peptides, probably for several transcription start sites (Brissenden *et al.*, 1984). In addition, exons 3 and 4 encode the remainder of the mature IGF-1 molecule, and part of the trailer peptide (Brissenden *et al.*, 1984). Exons 5 and 6 encode alternatively used segments of the trailer peptide (resulting in the IGF-1A and IGF-1B forms), as well as 39 untranslated sequences, with multiple different polyadenylation sites (Brissenden *et al.*, 1984). The human *IGF-2* gene spans 35 kb and is located on the short arm of chromosome 11, adjacent to the insulin gene, and contains nine exons (Bell *et al.*, 1985). Exons 1 through 6 encode 59 untranslated RNAs (multiple promoter sites) (Brissenden *et al.*, 1984). Exon 7 encodes the signal peptide, while exons 7 and 8 encode most of the mature protein and the carboxyl-terminal portion of the protein, respectively, and exons 8 and 9 encode the trailer peptide (Brissenden *et al.*, 1984). Control of *IGF-1* and *IGF-2* expression is complex, with multiple mRNAs that result in great variability in tissue expression in the embryo, fetus, child, and adult (Agrogiannis *et al.*, 2014).

IGF receptors

Both IGF-1 and IGF-2 are known to bind (generally with low affinity) to insulin receptors (IR), although at least two classes of specific IGF receptor forms exist (Massague and Czech, 1982; Belfiore *et al.*, 2009). Type 1 IGF receptor (IGF1R) (chromosome 15q26.3) and IR (chromosome 19) are closely related, both being heterotetramers, composed of two alpha and two beta subunits (Massague and Czech, 1982). The alpha membrane-spanning subunits (molecular mass 130 kDa), contain the binding sites for IGF-1 and are linked by disulfide bonds (Massague and Czech, 1982). The beta intracellular subunits (molecular mass 90 kDa) contain a transmembrane domain, an adenosine triphosphate (ATP)-binding site, and a tyrosine kinase domain, which constitutes the presumed signal transduction mechanism for the receptor (Laviola *et al.*, 2007). The IGF1R has high affinity for both IGF-1 and IGF-2 and 100-fold less for insulin (Laviola *et al.*, 2007). IGF1 acts primarily through IGF1R, but can bind with lower affinity to the highly homologous IR, and to IGF1R/IR heterodimers and vice versa for insulin, as evident in pathological IGF1 or insulin signaling (Rosenzweig and Atreya, 2010; Laviola *et al.*, 2007).

IGF1R and IGF2R signaling

The IGFR1 mediates IGF actions on all cell types through tyrosine kinase activation and phosphorylation of substrates (Laviola *et al.*, 2007). These include the members of the insulin receptor substrate (IRS) family (particularly IRS-1 and IRS-2) (Valverde *et al.*, 1998). Several signaling molecules respond to IGF receptor activation, propagating signal transduction or regulating IGF action through negative feedback (Tsuruzoe *et al.*, 2001). Several studies have shown seemingly anomalous competitive binding results, indicative that variant or atypical insulin and IGF receptors might exist (Oh *et al.*, 1993). In accordance with this, the existence of hybrid receptors composed of 1 alpha-beta dimer of the IR and 1 alpha-beta dimer of the IGF1R has been postulated, although the physiologic significance is unknown (Slaaby, 2015).

The type 2 IGF receptor (IGFR2) is a monomeric protein (molecular mass 271 kDa), that bears no structural homology with either IR or IGFR1 (Braulke, 1999). The IGFR2 is composed of a lengthy extracellular domain (15 repeat sequences of 147 residues), followed by a transmembrane domain (23 residues) and a small cytoplasmic domain (164 residues) (Braulke, 1999). It does not contain an intrinsic tyrosine kinase domain or any other recognizable signal transduction mechanism (Braulke, 1999). Interestingly IGFR2 is identical to the cation-independent mannose-6-phosphate (CIM6P) receptor (such as cathepsin and urokinase), although binding sites for IGF-2 and CIM6P appear to reside in different areas of the receptor (MacDonald *et al.*, 1988). Still, the two ligands (IGF-2 and CIM6P) show some reciprocal inhibitory effects on receptor binding, indicating an association between IGF-2 and the sorting of lysosomal enzymes (MacDonald *et al.*, 1988). The majority of CIM6P receptors are located on intracellular membranes in equilibrium with receptors on the plasma membrane, and are associated with the intracellular lysosomal targeting of various acid hydrolases and other mannose-6-phosphate containing proteins and enzymes (such as cathepsin and urokinase) (MacDonald *et al.*, 1988; Braulke, 1999). This might be indicative of an important function in removing these enzymes from the cellular environment (Braulke, 1999).

It should be noted that most studies indicate that the classic mitogenic and metabolic actions of IGF-1 and IGF-2 are mediated through IGFR1 and the corresponding tyrosine kinase signal transduction mechanism (Conover *et al.*, 1986; Furlanetto *et al.*, 1987). Nevertheless, many observations are consistent with the possibility of IGF-2 actions mediated via IGFR2, not duplicated by either IGF-1 or insulin (Rogers and Hammerman, 1988; Minniti *et al.*, 1992). In addition, it has been suggested that IGFR2 acts as a growth inhibitory component of the IGF system responding to and mediating multiple antimitogenic systems, including retinoids (Tian *et al.*, 2016; Kang *et al.*, 1999).

IGF-binding protein superfamily

IGFs circulate in plasma as complexes with IGF binding protein (IGFBP)s (Rajaram *et al.*, 1997). The function of these carrier proteins is to extend the serum half-life of the IGF peptides, transport the IGFs to target cells, and modulate the interaction of the IGFs with their surface membrane receptors (Rajaram *et al.*, 1997). The family of IGFBPs includes six distinct proteins with important structural relationships among them (Forbes *et al.*, 2012). The most important similarity is the conservation of the number and placement of the cysteine residues and the corresponding disulfide bonds, which confers maintenance of the secondary structure of the IGFBPs and the IGF-binding sites of each IGFBP (Forbes *et al.*, 2012). In addition, an arginine-glycine-aspartic acid (RGD) positioned near the carboxyl terminus of IGFBP-1 and IGFBP-2 is present, possibly facilitating the association

of IGFBPs with the cell surface (Shen *et al.*, 2012; Reyer *et al.*, 2015). However, IGFBP-3 nevertheless lacks an RGD sequence, but is capable of specific binding to cell membrane receptors, possibly through specific membrane binding proteins (Firth and Baxter, 2002).

Recently several families of IGFBP-related proteins (IGFBP-rPs) have been described, indicating that an IGFBP superfamily might exist (Rosenfeld *et al.*, 2001; Rodgers *et al.*, 2008). The physiological role of IGFBP-rPs in cell growth has not yet been elucidated, though it is likely that they can act through IGF-independent and/or IGF-dependent mechanisms (Hwa *et al.*, 1999). Three IGFBP-rPs (Mac25/IGFBP-rP1, CTGF/IGFBP-rP2 and NovH/IGFBP-rP3) have been shown to bind IGFs with considerably lower affinity than IGFBPs (Hwa *et al.*, 1999).

Function of IGFBPs

Studies suggest that IGFBPs appear to inhibit IGF action, possibly through competitive binding with IGFR1, or through a direct inhibitory effect (Ritvos *et al.*, 1988; Cohen *et al.*, 1993; Hochscheid *et al.*, 2000). Interestingly, under specific conditions, several of the IGFBPs can enhance IGF action, possibly through facilitated IGF delivery to target receptors (Elgin *et al.*, 1987). Additionally, a number of IGF-independent functions have been suggested, that include growth inhibition or stimulation of cell growth, direct induction of apoptosis and modulation of action of other non-IGF growth factors (Oh *et al.*, 1995; Conover *et al.*, 1996; Conover *et al.*, 2000; Rajah *et al.*, 1997). The IGF-independent effects are mediated through separate specialized receptors and IGFBP-signaling pathways (Liu *et al.*, 2000).

It should be noted that concentrations vary in biological fluids, with IGFBP-1 being the major IGFBP in human amniotic fluid, and IGFBP-2 being the major IGFBP in cerebrospinal fluid and seminal plasma (Rosenfeld *et al.*, 1989; Rosenfeld *et al.*, 1990). In normal human serum, IGFBP-3 is the major IGFBP, being also highly GH-dependent (Martin and Baxter, 1986). Furthermore IGFBP-3 and IGFBP-5 circulate in serum as part of a ternary complex along with an IGF peptide, and an acid-labile subunit (Twigg and Baxter, 1998). IGFBP analysis is further complicated by the presence of IGFBP proteases, capable of various levels of IGFBP degradation (Giudice *et al.*, 1990; Muller *et al.*, 1993). The limited proteolysis of IGFBPs might result in decreased affinity of the IGFBP for IGF peptides, although the exact physiological significance remains undetermined (Binoux *et al.*, 1993).

Other Novel Growth Factors

The FGF family of peptides and receptors

Fibroblast growth factors (FGFs) constitute a family of peptide cytokines with many defined and yet undefined functions (Balasubramanian and Zhang, 2016). It has initially been suggested that these factors are specific for stromal cells, although other cells respond to FGFs as well (Su *et al.*, 2014). This family of proteins includes at least seven different FGFs (FGF-1 through FGF-7) (Balasubramanian and Zhang, 2016). The best characterized are acidic FGF (aFGF or FGF-1), basic FGF (bFGF or FGF-2), and keratinocyte growth factor (KGF or FGF-7) (Balasubramanian and Zhang, 2016). The actions of FGFs are mediated by binding to three characterized receptors (FGFR1, FGFR2, and FGFR3), with distinct tissue distributions (Ornitz and Itoh, 2015). In terms of their function, FGFs appear to be autocrine-paracrine growth factors that participate in specific organ growth and differentiation and in carcinogenesis (Ornitz and Itoh, 2015). While FGFs do not participate in somatic growth *per se*, a genetic form of dwarfism (achondroplasia) exists, caused by an activating mutation in *FGFR3* (Rousseau *et al.*, 1994; Wilkin *et al.*, 1998). This suggests that normal FGFR3 signaling is essential for the normal growth of long bones (Rousseau *et al.*, 1994).

The EGF family

The epidermal growth factor (EGF) family appears to be important in mammalian development and function, although their precise roles are yet undefined, and they do not appear to be directly involved in somatic growth (Fisher and Lakshmanan, 1990; Kostopoulou *et al.*, 2017). Nonetheless, EGF receptors have been identified in fetal tissues, suggesting a role in embryogenesis and fetal growth, while abnormal EGF-EGF receptor interactions appear instrumental in the development of cancers (Oliver, 1988; Seshacharyulu *et al.*, 2012). The EGFs have been extensively studied *in vitro* for their mitogenic actions, while the receptor for EGF is the prototype model for tyrosine kinase mediated signal transduction (Lemmon *et al.*, 2014). However, no major deleterious effects after EGF pathway disruption, either via antibody administration or gene targeting, have been demonstrated (Fisher and Lakshmanan, 1990).

Other growth-promoting peptides

A number of growth-promoting peptides have been described including platelet derived growth factor (PDGF), vascular epithelial growth factor (VEGF), granulocyte and macrophage colony-stimulating factors (G-CSF, MCSF), erythropoietin, and thrombopoietin (Passaretti *et al.*, 2014; Shibuya, 2011; Athanasopoulos *et al.*, 2007; Calhoun *et al.*, 1999; Nijaguna *et al.*, 2015; Heikal *et al.*, 2016; Kuter, 2009). Cytokines, interleukins and interferons have been shown to modulate growth of various cells of the immune system (Turner *et al.*, 2014; Street *et al.*, 2003; Sederquist *et al.*, 2014). Other tissue-specific growth factors include nerve growth factor (NGF), brain- and glial-derived neurotrophic factors (BDNF, GDNF), and hepatocyte growth factor (HGF) (Loeb *et al.*, 1991; Bathina and Das, 2015; Orth *et al.*, 2000; Nakamura and Mizuno, 2010).

Growth inhibitory peptides

Peptides including transforming growth factor-beta (TGFβ), tumor necrosis factors (TNFs) and other compounds have been shown to inhibit cellular growth and malignant transformation or regulate the entry of cells into apoptosis (Huang and Huang, 2005; Rusten *et al.*, 1994; Penn *et al.*, 2012). These peptides may be involved in fetal growth (Toder *et al.*, 2003; Lyall *et al.*, 2001). A family of genes of which the most important is p53 is also critical to growth and tumor suppression (Rodier *et al.*, 2007).

Other Hormones Contributing to Growth

Sex steroids

Conditions characterized by androgen or estrogen excess (e.g. precocious puberty or virilizing congenital adrenal hyperplasia), occurring before epiphyseal fusion, are invariably characterized by increased linear growth and advanced skeletal maturation (Ghizzoni *et al.*, 1999; Carel *et al.*, 2004). Androgens and estrogens, which increase in concentration during puberty, are important physiological components of the pubertal growth spurt (Bourguignon, 1991). This normal linear growth response to endogenous or exogenous sex steroids requires adequate GH secretion and action (Meinhardt and Ho, 2006). It should also be noted that androgens function through enhancement of GH and IGF-1 secretion (Coutant *et al.*, 2004). The increased skeletal maturation and epiphyseal fusion, however, appears to be estrogen-mediated (Borjesson *et al.*, 2013; Smith *et al.*, 1994)

Thyroid hormone

Hypothyroidism occurring postnatally results in growth failure and arrest of epiphyseal cartilage fusion (Siebler *et al.*, 2001). Thyroid hormone also appears to have a permissive effect on GH secretion, as indicated by decreased spontaneous GH secretion and the blunted response to GH provocative tests of patients with hypothyroidism (Katakami *et al.*, 1986; Rhee *et al.*, 2015). Patients replaced appropriately with thyroxine demonstrate rapid "catch-up" growth and skeletal maturation, and this can potentially compromise adult height (Bassett and Williams, 2016; de Wit *et al.*, 2013), especially if puberty then occurs early with the risk of earlier epiphyseal fusion.

Conclusion

The genetic and hormonal regulation of growth is complex. The hypothalamo-pituitary neuroendocrine network can be disrupted by causes that may be congenital or acquired later in life leading to various syndromes of endocrine deficits or hormonal excess, including GH. Animal models have advanced our understanding of the pituitary as central to the control of growth, and studies in the mouse have led to significant insights into human pituitary development and disease. The endocrine regulation of normal growth classically depends upon a hormonal axis involving hypothalamic stimulatory GHRH and inhibitory somatostatin, pituitary secretion of GH, and liver-derived IGF-1. The functionality of this axis depends upon several molecules that include the respective families of receptors, carrier proteins and contributing molecules such as hormones, binding proteins and anti-inflammatory cytokines. Finally, several local cell-specific growth factors display important autocrine/paracrine and endocrine functions, even though they lack direct effects on somatic growth.

Contemporary research into the array of putative contributing novel growth factors, and the potential associations between these molecules, is likely to uncover an increasing intricacy in the regulation of growth.

Abnormal Growth: Small for Gestational Age

Kathryn Beardsall, University of Cambridge, Cambridge, United Kingdom
Meera Mallya and Ajay Thankamony, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom

Glossary

Adrenarche A period during normal development when the adrenal glands begin to produce increased androgens. This normally occurs prior to puberty, between the ages of 6–8 years.

Appropriate for gestational age When a baby is born at a birth weight that is appropriate for the gestation of pregnancy, usually between the 10th and 90th centile for age.

Catch down growth When a baby's weight does not increase as expected along its growth centile, and it decreases more than 1 centile (0.67 SD) below where it plotted at birth.

Catch up growth When a baby's weight increases more than expected, so that it increases more than 1 centile (0.67 SD) above where it plotted at birth.

Epigenetics The study of inheritable changes in gene expression that do not change the underlying DNA sequence.

Growth restricted Where growth of the baby/child has been limited.

Insulin resistance Where the body needs to produce more insulin to induce a set reduction in glucose levels.

Insulin sensitivity The ability of insulin to decrease blood glucose levels.

Intrauterine growth restricted Where there has been restriction in the growth of the fetus; this requires at least two growth measurements to show there has been abnormal growth over a period of time.

Metabolic syndrome Also known as syndrome X; a combination of risk factors including impaired glucose metabolism, hypertension, increased abdominal circumference, raised triglycerides and low HDL cholesterol. There is an increased risk of cardiovascular disease, stroke and myocardial infarction.

Noncommunicable diseases Diseases, such as heart disease or certain types of cancer, that are not caused by infectious organisms.

Puberty A normal stage in development where there is the development and maturation of male and female sexual organs, such that at the end they are capable of sexual reproduction.

Small for gestational age When a baby is born smaller than expected for their gestation; different definitions have been used, but a consensus statement from 2007 uses babies born below the third centile for age.

Introduction

Being born small for gestational age (SGA) is one of the most common causes of childhood short stature. Size at birth, particularly being born relatively small is important not just in relation to early life morbidity and mortality but is associated with increased prevalence of noncommunicable diseases during later life. Therefore, understanding the etiology of small for gestational age and mechanisms that lead to these lifelong consequences is important if we are to optimize individual's growth and health outcomes. The growth pattern of these infants in the early years of life is an important determinant of later health risks. In particular, infants who show catch up growth have increased risks for coronary artery disease, stroke and the metabolic syndrome. The impact of this has been most prevalent in countries where fast economic changes have led to changes in infant and adult dietary habits, with rapid childhood growth, resulting in a marked increase in prevalence of metabolic syndrome and type 2 diabetes in adulthood. For SGA children who remain short, interventions, such as growth hormone therapy have been approved, but responses to treatment are varied, and there remains significant controversy regarding the benefits of such treatment and long-term outcomes. Better understanding of the nutritional and hormonal mechanisms that drive early growth and the relationship to longer-term health risks will be important in the future if we are to provide a more personalized approach to health. It may also provide insights into public health management approaches to reduce the increasing prevalence of the metabolic syndrome and type 2 diabetes.

Etiology

The most widely accepted definition for small for gestational age (SGA) is that of the World Health Organization (WHO); a baby with a birth weight less than the 10th centile for sex and gestational age. In 2007 a consensus statement by the International Societies of Pediatric Endocrinology and the Growth Hormone Research Society defined SGA as a birth weight and/or length at least two standard deviations (SD) below the mean for gestational age (GA). The use of this 3rd percentile instead of the 10th percentile does increase the specificity but decreases the sensitivity. Infants who are SGA may have experienced growth restriction

but intrauterine growth restriction (IUGR) is a distinct definition and varies in that there must be evidence of impaired in utero growth (with at least two in utero growth measurements), and the terms should not be used interchangeably. The proportion of infants defined as SGA will inevitably vary depending on the definition used and the population from which the normative data were derived. Differences in prevalence of SGA also exist between countries, with the incidence estimated at 5%–7% in developed countries compared to up to 30% in developing countries such as India (Lee *et al.*, 2013; Yadav and Rustogi, 2015).

The etiology of being born SGA is multifactorial. Clinicians historically have tried to attribute causality based on relative growth parameters such as symmetrical or asymmetrical body proportions, that is, whether infants are small for weight, length and head circumference or whether they have head sparing compared to proportionately lower weight. Clinically this can help in determining the timing and etiology as maternal, placental or fetal in origin. Maternal factors such as chronic disease, maternal smoking, or pregnancy complications such as preeclampsia and congenital infections can affect growth. Nutrition and oxygen delivery from a well vascularized placenta and endocrine regulation of cellular expansion and cell turnover is also imperative and multiple pregnancies or pathologies that impact on nutritional delivery or cause fetal hypoxia can impair fetal growth (**Table 1**).

Pregnancy complications such as gestational diabetes mellitus (GDM) and preeclampsia, directly affect placental and therefore fetal growth, but have also been shown to be associated with changes in methylation of placental genes. Differential methylation and expression patterns of genes involved in the regulation of glucose homeostasis and lipid metabolism have been demonstrated in SGA compared to appropriate for gestational age (AGA) pregnancies. These epigenetic variations may influence fetal growth, early body composition, and lifelong diabetes risk (Díaz *et al.*, 2017). The *ATG2B*, *NKX6.1*, and *SLC13A5* genes (respectively related to autophagy, β-cell development and function, and lipid metabolism) have been found to be hypermethylated in placenta and cord blood from SGA newborns, whereas *GPR120* (related to free fatty acid regulation) were hypomethylated in placenta and hypermethylated in cord blood. Gene expression levels were opposite to methylation status, and both correlated with birth weight, circulating insulin like growth factor 1 (IGF-I), and total and abdominal fat at age 2 weeks (Díaz *et al.*, 2017). The growth hormone IGF-I axis plays a key role in in utero growth and mutations and altered gene expression can therefore lead to infants who are SGA. Counterintuitively mRNA and protein expression levels of IGF-I and its receptor are increased in the placenta of mothers who delivered SGA offspring, and key signaling pathways downstream such as IGF-I receptor AKT and mTOR have been reported to be upregulated in preterm infants born SGA (Iñiguez *et al.*, 2014). This may be due to compensatory mechanisms to increase nutritional delivery in the setting of growth restriction.

Knockout animal studies as well as case reports (Woods *et al.*, 1996) have shown mutations in the fetal IGF-I gene itself as well as the IGF-I receptor to impact on fetal growth. Deletions of chromosome 15 in the region of the IGF-IR have also been associated with SGA. SGA associated with such defects are commonly associated with learning and hearing difficulties demonstrating the key role of IGF-I in central nervous system development. As IGF-I bioavailability is critically dependent on its association in a ternary complex with an 8 KDa glycoprotein acid labile subunit (ALS) which prolongs its half-life, mutations in the *IGFALS* gene will decrease IGF-I bioavailability and reduce growth (Storr *et al.*, 2015). The d3-GHR polymorphism is a 2.7 kB deletion in exon 3 of the GHR gene and is associated with SGA (Jensen *et al.*, 2007). This mutation is of particular interest as an individual's allelic combination can impact their response to GH treatment (see below).

Genetic mechanisms related to differences in maternal and paternally inherited gene expression and imprinting also play a role in fetal growth. This is of particular relevance in the setting of uniparental disomy. Uniparental disomy (UPD) describes the condition where an individual inherits both copies of a gene from one parent and no copy from the other parent. This becomes significant if the UPD gene is also an imprinted gene, where genes are only active from one parent. Paternally expressed genes tend to promote placental and fetal growth (Wang *et al.*, 2013; Coan *et al.*, 2005), and maternal genes suppress growth (Netchine *et al.*, 2007). Examples of these include mutations in chromosome 7 and 11 both of which contain groups of genes that undergo imprinting and cause 75% of the cases of Silver Russell Syndrome (Netchine *et al.*, 2007). The imprinting center region 1 (ICR1) which is affected in these cases regulates the expression of IGF2 and H19. UPD of the long arm of chromosome 14 (UPD14) has also been associated with SGA and poor postnatal growth, and is thought to be related to an absence of paternal information, which leads to growth restriction through impact in the placenta and skeletal maturation (Hoffmann and Heller, 2011).

Table 1 Associations and etiologies found in infants born small for gestational age

Maternal	*Fetal*	*Placental*
Age (<16 years or >35 years)	Chromosomal abnormalities (e.g., trisomy 13/18/21 or uniparental disomy)	Placental dysfunction (e.g., preeclampsia)
Weight (<45 kg or >75 kg)	Congenital abnormalities (e.g., congenital heart disease, congenital diaphragmatic hernia, abdominal wall defects)	Multiple gestation
Chronic disease (e.g., hypertension, diabetes, renal disease)	Congenital infection (e.g., TORCH, malaria, HIV)	Abnormal utero-placental vasculature
Substance abuse (e.g., alcohol, cocaine, tobacco smoking)	Genetic syndromes (e.g., Russell-Silver, Cornelia de Lange)	
Maternal infection (e.g., TORCH, TB, malaria)	Metabolic disorders (e.g., galactosemia, congenital lipodystrophy, fetal phenylketonuria)
