The high carbohydrate content of both ACE domains has frustrated attempts to crystallize the enzyme. Finally, in 2003, the crystallization of the human testicular ACE, and thus, the C-domain of ACE without the hydrophobic transmembrane and intracellular domains, was reported. The enzyme was complexed with the inhibitor lisinopril. Although the first orally active ACE inhibitor, captopril, was synthesized on the basis of an assumed similarity to carboxypeptidase A, the structure of the crystallized enzyme resembled instead the other kininase II-type enzyme NEP, despite the lack of sequence homology. The active site is at the bottom of a groove in ACE; this may explain the rather limited size of the peptides that ACE can hydrolyze, consisting usually of less than a dozen amino acids.

Because both CPN and ACE are metallopeptidases, in initial experiments some inhibitors of BK breakdown by CPN, such as metal sequestering agents, inhibited both enzymes. Of other ACE inhibitors, the structures of two snake venom peptides that potentiated BK were reported at a meeting in 1969. The pentapeptide BPP_{5a} from *Bothrops jararaca* had a single C-terminal proline, whereas the undecapeptide from *Agkistrodon halys blomhoffii* had a C-terminal Pro-Pro sequence. A synthetic nonapeptide, teprotide – found in snake venom originally – also had C-terminal ProPro sequence and it became the first ACE inhibitor to be tested clinically. When this ACE inhibitor was given intravenously to patients, it not only lowered the elevated blood pressure, but was also beneficial in congestive heart failure.

The studies on kininase inhibition and BK potentiation led to the synthesis of ACE inhibitors that are given orally to millions of patients to treat hypertension and a variety of clinical conditions in which the effects are not related to lowering the blood pressure. These conditions range from congestive heart failure to diabetic nephropathy. ACE inhibitors lower the mortality and morbidity after heart failure and they even reduce its incidence. Many laboratory and clinical findings attributed at least part of the results with ACE inhibitors to enhancing the effects of BK. In addition to being involved in BK metabolism and potentiating the effects of B_2 agonists via ACE, some of the ACE inhibitors can directly activate the B_1 receptor of des-Arg-BK followed by the release of nitric oxide, in the absence of the peptide ligand in cultured endothelial cells.

The Angiotensin Metabolites

Some of the Ang metabolites, enzymatic breakdown products (see **Fig. 2**), are active on their own. Some of them mimic Ang II, whereas others antagonize the effects of Ang II. Two of them are mentioned here because they potentiate BK, probably by interacting with ACE, but not necessarily acting as inhibitors only.

Ang (1–7) (des-Phe^8-Ang II) is a substrate of the Ndomain, but an inhibitor of the C-domain of ACE. Another enzymatic product of Ang I hydrolysis, Ang (1–9) (des-Leu^{10}-Ang I), inhibits both domains of ACE; both Ang (1–7) and Ang (1–9) can enhance BK's effect on the B_2 receptor.

Serine Carboxypeptidases

A serine carboxypeptidase-type enzyme, called deamidase, cathepsin A, lysosomal protective protein, or lysosomal CPA, also cleaves BK at the Phe^8-Arg^9 bond as shown *in vitro*. This enzyme has an acid pH optimum for CP and esterase activities, but deamidates amidated C-terminal amino acids (e.g., substance P) at neutral pH.

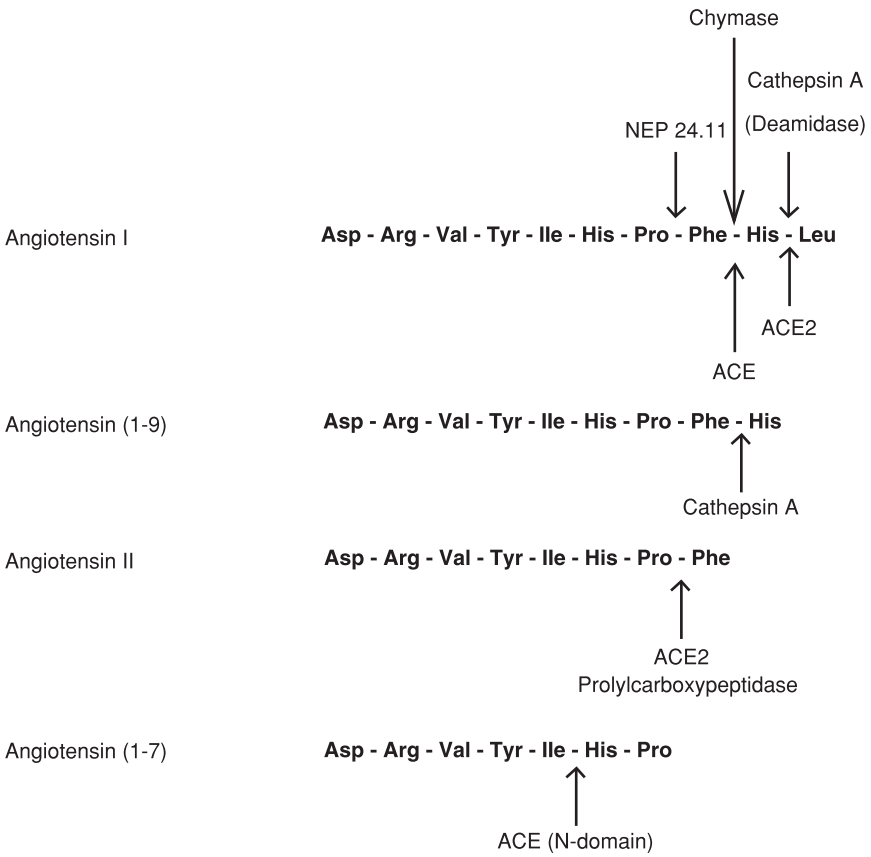

Fig. 2 Peptide bonds hydrolyzed in angiotensins by peptidases.

Another serine CP, the lysosomal Pro-X CP (prolylcarboxypeptidase or angiotensinase C), inactivates desArg^9-BK, the ligand of the B_1 BK receptor, at the Pro^7-Phe^8 bond (see **Fig. 1**). Prolylcarboxypeptidase occurs in abundance in neutrophils; this may have some bearing on B_1 receptor activity, as it is upregulated by agents promoting inflammation. Thus, this enzyme may be an inactivator of the B_1 receptor agonists. The same bond is also hydrolyzed in Ang II both by Pro-X-CP and by an enzyme called ACE2 with sequence similarities to ACE, but it is not inhibited by ACE inhibitors (**Fig. 2**).

Aminopeptidases

Aminopeptidases have two different functions in kinin metabolism. A blood-borne aminopeptidase, present also in tissues, converts Lys-BK to BK by cleaving the Lys^0-Arg^1 bond. A second aminopeptidase, called aminopeptidaseP,butoriginallyreferredtoas "prolidase", is presentinerythrocytes,kidney,lung,andothertissues.It inactivates BK by cleaving at Arg^1-Pro^2. Rat tissues have the-highestconcentrationsofthisenzyme;humantissues apparently express much less aminopeptidase P.

In contrast to ACE and NEP, which are bound by a transmembrane peptide as type I and type II transmembrane enzymes, aminopeptidase P is membranebound via a glycosylphosphatidylinositol anchor. Its molecular weight is approximately 90–95 kDa. As with some other peptidases, it forms dimers or even oligomers. Aminopeptidase P, a zinc metallopeptidase, can be activated by Mn^{2+} with some substrates and is inhibited by chelating agents. Other inhibitors include sulfhydryl compounds. Interestingly, many ACE inhibitors also inhibit aminopeptidase P, although with a higher K_i (in the micromolar range) and Mn^{2+} enhances this inhibition. This is likely to be due to the presence of Pro or Pro-like structures in the ACE inhibitors and to the effective zinc-binding moieties.

Neutral Endopeptidase 24.11

Neutral endopeptidase 24.11 (neprilysin, NEP) is a zinc metallopeptidase with a single active site containing the HEXXH sequence to bind Zn^{2+}. The enzyme is a single-chain protein of 742 amino acids and, as a type 2 membrane protein, is bound via an uncleaved N-terminal signal peptide.

NEP is distributed widely; its expression in vascular endothelial cells is low, but epithelial cells, especially in microvillar structures, are rich in NEP. Its presence in the CNS has been investigated in detail because neuropeptides are among its substrates.

The relevance of the high concentration of NEP in the male genital tract, especially in prostate gland, is not known. NEP under the name "common acute lymphoblastic leukemia antigen" (CALLA or CD10) is present in lymphoblasts and also in neutrophils. Of the solid tumors, NEP is highly expressed in malignant liver cells of rats and humans.

NEP cleaves peptides at the N-termini of hydrophobic amino acids and as such it is a second kininase II-type enzyme that releases the C-terminal Phe^8Arg^9 of BK. It was first discovered as an endopeptidase that cleaves the B-chain of insulin, but its substrates include enkephalins, endothelin, atrial natriuretic peptide, substance P, and a chemotactic peptide.

Purified human NEP was used to establish the kinetics of hydrolysis of BK. The k_{cat} for BK is higher with NEP than with ACE but because of the much higher K_m (120 mM versus 0.2 mM) the specificity constant, k_{cat}/K_m, of NEP is lower (40 μM^{-1} min^{-1} versus 3667 μM^{-1} min^{-1}).

The NEP level in circulating blood plasma is normally low, but increases 60- to 80-fold in adult respiratory distress syndrome with septic pneumonia. Inhibition of NEP in rat bronchial epithelium markedly enhances bronchoconstriction induced by substance P and BK. BK-induced bronchoconstriction in asthmatic patients is augmented by NEP inhibitors. Indirect actions of BK are also influenced by NEP inhibition, because when BK releases substance P from nerve endings, it is subsequently cleaved by NEP.

Microvascular leakage in guinea pig airways and enhanced myocardial blood flow after sensory nerve stimulation in the rat heart were potentiated by NEP inhibitors, possibly through blocking BK inactivation.

An NEP inhibitor has been used to successfully treat young boys suffering from acute watery diarrhea. The results were attributed to blocking the breakdown of endogenous enkephalins acting on δ-opiate receptors.

Because of the increased reactivity to the combined administration of inhibitors of two peptidases, several compounds that inhibit both NEP and ACE, or ACE and aminopeptidase, have become available. Extensive reports deal with the clinical and laboratory experimental results with the dual ACE and NEP inhibitors, for example, with omapatrilat (Vanlev).

Endothelin-converting enzyme, an NEP-related peptidase with some sequence similarity, also cleaved BK at the Pro^7-Phe^8 bond, albeit with a K_m approaching 1 mM.

Endopeptidases 24.15 and 24.16

Endopeptidase 24.15 (EP24.15; thimet oligopeptidase) and endopeptidase 24.16 (EP24.16; neurolysin) are closely related (80% similarity and 63% identity in amino acid sequences) zinc metalloenzymes that contain the HEXXH zinc-binding motif. They are active atneutral pH and cleave a number of biologically active peptides *in vitro*. Both enzymes are abundant in brain and have been purified from rat brain homogenates.

EP24.15 is a 78 kDa protein containing 687 amino acid residues and is expressed at highest levels in brain and testis. When EP24.15 was purified from rat brain, it was determined that the enzyme was identical to two other enzymes named earlier, endopeptidase A, originally described as a kininase, and Pz-peptidase, which cleaved a synthetic substrate of collagenase. EP24.15 is activated by low concentrations of thiols, which convert an inactive multimer, with a blocked catalytic site, to an active monomer by disruption of intermolecular disulfide bridges. EP24.16 does not have these –S–S– bridges.

Tissues such as spleen, liver, kidney, lung, adrenal, and thyroid also contain EP24.15 activity. Although the enzyme apparently lacks both a signal sequence and a membrane-binding motif, an estimated 10%–25% of activity is associated with the plasma membrane fraction of a number of tissues.

EP24.16 is a 704-amino-acid protein that, like EP24.15, is present in both plasma membraneassociated (10%–20% of activity) and soluble forms. In addition, EP24.16 is found in mitochondria. After EP24.16 was isolated from rat brain and sequenced, its identity to some other proteins, including a soluble Ang II-binding protein from porcine liver and a microsomal endopeptidase from rabbit liver, was revealed. The enzyme has also been purified from rat ileum and kidney and a variant, called EP24.16B, has been isolated from rat testis.

Both enzymes share most of their natural substrates and preferentially cleave them at the carboxyl side of hydrophobic amino acids. BK is hydrolyzed at the Phe^5-Ser^6 bond. Other peptides,such as AngI, opioids, gonadotropin-releasing hormone, substance P, and neurotensin, are also cleaved *in vitro* by both of the enzymes. These substances are hydrolyzed at the same bond by both enzymes, except for neurotensin, which is inactivated at Arg^8-Arg^9 by EP24.15 and at the Pro^{10}-Tyr^{11} bond by EP24.16.

Because of the predominantly cytosolic nature of these two enzymes, their roles as kininases are not clear. With the advent of specific, biologically stable enzyme inhibitors, investigators found that the enzymes can be kininases. An inhibitor of both EP24.15 and EP24.16 potentiated the increase in permeability of pial (brain surface) microvasculature induced by BK *in vivo*. This suggests that one or both enzymes can moderate BK's effect on the blood–brain barrier, possibly in cases of inflammation.

The formation of BK 1–5 in the medium of cultured bovine aortic endothelial cells after incubation with BK was inhibited 45% by an EP24.16 inhibitor and 18% by an EP24.15 inhibitor. Thus, even a transiently extracellular location of these enzymes on endothelial cells would allow them to function as kininases in the vasculature.

Epilogue

The very short half-life of kinins *in vivo* (seconds) pointed to the importance of their enzymatic metabolism but the acceptance of this conclusion took decades. It also follows that limited conclusions can be deduced from measuring circulating kinin levels, as

kinin's actions are more likely paracrine or autocrine in nature. Only a long time after the discovery of the "original" kininase, CPN, were some of its functions in the body, for example, on plasminogen activation, clarified.

The induction of so-called Chagas' heart disease by *Trypanosoma cruzi* has been found to be promoted by BK in mice. It was suggested that changes in kininase levels can affect parasite infectivity and thus the outcome of the disease.

ACE inhibitors, which have become widely used, originated from studies performed *in vitro*. The obvious consequence of the seemingly opposite, dual actions of kininase II or ACE on BK and Ang I was that its inhibitors block the release of Ang II while they can enhance the effect of BK. Because related peptidases cleave different active peptides, compounds that inhibit both ACE and NEP when tested clinically could block Ang I, BK, and atrial natriuretic peptide hydrolysis.

Tissue Ace–Angiotensin–AT_1 Receptor Axis and Repair in the Heart☆

Yao Sun and Karl T Weber, University of Tennessee Health Science Center, Memphis, TN, United States

Introduction

The circulating renin–angiotensin–aldosterone system (cRAAS) is integral to maintaining cardiovascular homeostasis (Chappell *et al.*, 2000; Erdös, 2001). Pharmacologic inhibition of angiotensin-converting enzyme (ACE) and antagonism of angiotensin (Ang) II and aldosterone (ALDO) cognate receptor binding have proven effective strategies in the management of resistant hypertension and heart failure. They further have provided important insights into the pivotal contribution of cRAAS activation to the pathophysiologic expression of these disorders (Francis *et al.*, 1990; Pitt *et al.*, 1999; Rouleau *et al.*, 1993; Swedberg *et al.*, 1990; Weber, 2001; Weber and Brilla, 1991). ACE inhibition leads to risk reduction for morbid and mortal events, including the progressive nature of heart failure (The SOLVD Investigators, 1991, 1992). More recently, a tissue fibrogenic ACE–angiotensin–AT_1 receptor axis has been recognized together with a counterregulatory fibrolytic ACE2/Ang1–7/MasR axis. The role of each in regulating repair in diverse tissues has received considerable interest (De Mello, 2017; Hammer *et al.*, in press; Kim *et al.*, 2016; Madro *et al.*, 2016; Morales *et al.*, 2016; Pawlik *et al.*, 2016; Rivoli *et al.*, 2016; Slamkova *et al.*, 2016; Wang *et al.*, 2012; Weber *et al.*, 2013). Herein, we focus on these fibrogenic and fibrolytic axes as they relate to the diseased heart.

Tissue Fibrogenic Ace/ANGII/AT_1R Axis

The number of ACE transcripts is increased in tissue homogenates prepared from the explanted failing human heart (Studer *et al.*, 1994). ACE and TGF–β_1 expression are each increased in myocardium obtained from patients undergoing aortic valve replacement for aortic stenosis, where they correlate with the extent of fibrosis (Hein *et al.*, 2003). In autopsied hearts, ACE and AngII are present in the fibrous tissue that contributes to human aortic sclerosis (O'Brien *et al.*, 2002). ACE-dependent AngII formation is increased in the infarcted myocardium (Ihara *et al.*, 2000), while the expression of angiotensinogen, renin, ACE, and AngII receptor genes is upregulated in cardiomyocytes in response to injury (Anversa *et al.*, 2000).

Temporal and spatial responses in autoradiographic ACE binding have been assessed in a rat model of MI, where other forms of injury are also present including the pericardium, kidneys, and incised skin. Each tissue serves as positive control in the analysis of ACE and tissue repair. Only low-density ACE binding is present in normal rat myocardium, where renin mRNA expression is not found (Sun *et al.*, 2001). High-density ACE binding and renin mRNA expression, on the other hand, appear at the site of MI and are coincident with the appearance of scar tissue. As scar tissue forms, the density of renin expression and ACE binding, AT_1R, TGF–β_1, and type I collagen (see panels A and F, **Fig. 1**) increase progressively. A large transmural MI is associated with high-density ACE binding and the appearance of fibrosis at sites remote to the infarct, including the noninfarcted left ventricle (LV), interventricular septum, and right ventricle (RV), where the appearance of fibrosis is directly related to the extent of infarction (Smits *et al.*, 1992; van Krimpen *et al.*, 1991; Volders *et al.*, 1993). With a large infarction, infarcted and noninfarcted LV are involved by fibrosis tissue.

Noninfarct-related sites of injury serve to further address the relationship between the appearance of ACE and repair. Sham operation includes manual handling of the heart leading to inflammation and subsequent pericardial fibrosis. Silk ligature placement around the left coronary artery or into skin for closure, a foreign-body fibrosis, appears at each site. At each site high-density autoradiographic ACE binding is temporally and spatially concordant with fibrous tissue formation. Angiotensinogen, renin, ACE, and TGF–β_1 mRNA levels are increased in the rat RV after monocrotaline-induced pulmonary injury (Park *et al.*, 2001).

Nonischemic models of cardiac myocyte necrosis also have been examined. They include endogenous release of catecholamines that accompanies AngII infusion from implanted minipump (Ratajska *et al.*, 1994) or exogenous administration of isoproterenol (Benjamin *et al.*, 1989) and chronic (4 weeks) administration of aldosterone by minipump in uninephrectomized rats on a 1% salt diet (Campbell *et al.*, 1993; Darrow and Miller, 1942). At each site of nonischemic myocyte loss, and irrespective of its etiologic basis, the temporal and spatial appearance of high-density ACE binding is coincident with the deposition of fibrous tissue (Sun and Weber, 1996a; Sun *et al.*, 1993).

Thus irrespective of the etiologic basis of injury, the tissue involved, or the presence of ischemic versus nonischemic repair, ACE binding is coincident with fibrous tissue formation. Furthermore, high-density ACE binding to be spatially concordant with marked autoradiographic AngII and TGF–β recepto-binding densities and type I collagen expression at these sites (**Fig. 1**) (Weber *et al.*, 2013). Collectively, these findings implicate the fibrogenic ACE/AngII/AT_1R axis as a common signaling pathway involved in repair (Weber, 1997a).

☆*Change History*: July 2017. Yao Sun and Karl T Weber updated the text of this article and references, and added new Figs. 1–3.

This chapter is an update of Yao Sun and Karl T. Weber, Tissue Renin–Angiotensin–Aldosterone System, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 586–593.

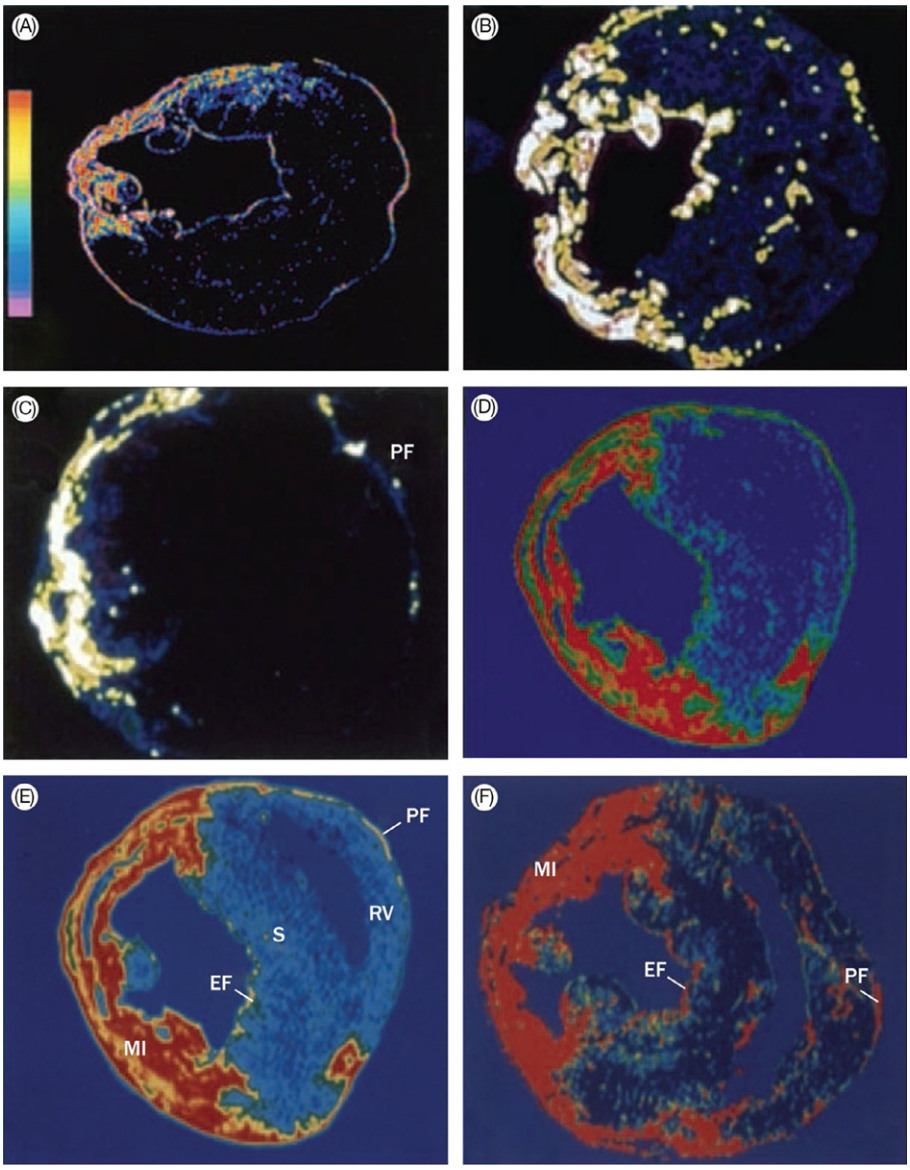

Fig. 1 Fibrous tissue is found at, and remote to, the site of injury 4 weeks after MI. Soluble signals generated by the "secretome" at the site of injury are capable of traversing the interstitial space to remote sites, including the interventricular septum and right ventricle, where they provoke interstitial and adventitial fibroblasts to produce collagen. Additionally, circulating signals might be transported to remote sites via the coronary circulation. mRNA expression of (A) renin, (B) angiotensin-converting enzyme, (C) the angiotensin II type 1 receptor, (D) transforming growth factor β1, and (E) type I collagen are shown. (F) Picrosirius red staining of fibrillar collagen. Notably, endocardial and pericardial fibrosis are also sites of high expression of angiotensin-converting enzyme and angiotensin II type 1 receptor. Abbreviations: *EF*, endocardial fibrosis; *MI*, myocardial infarction; *PF*, pericardial fibrosis; *RV*, right ventricle; *S*, interventricular septum. Cells Expressing Ace/Angii/AT_1R

Cells expressing ACE in normal rat heart include endothelial cells lining atrial and ventricular valve leaflet surfaces; and fibroblast-like cells residing within leaflet matrix also termed myoFb (Filip *et al.*, 1986; Katwa *et al.*, 1995; Messier *et al.*, 1994). The identity and temporal response in renin expression of ACE-positive cells seen at and remote to the infarct site include macrophages that invade the infarct site and myoFb (Falkenhahn *et al.*, 1995; Sun and Weber, 1996b; Sun *et al.*, 2001). Within 24 h of MI, macrophages appear at the interface between viable and necrotic myocardium; by day 3, stromal fibroblasts coaggregate with

macrophage clusters bordering on the infarct. Thereafter, fibroblast differentiation follows resulting in α-SMA positive myoFb phenotype that then proliferate and migrate into the site of necrosis during the remainder of week 1. A combination of cell growth with spatial control of growth and fibrillar collagen assembly governs rebuilding of infarcted tissue. Macrophages and myoFb found at the infarct site also express AngII receptors, TGF–β_1, and its receptors (Sun *et al.*, 2001).

Beyond day 14, only myoFb and endothelial cells are renin and ACE positive coincident with the gradual disappearance of macrophages via apoptosis. Persistent renin expression and high-density ACE and AngII receptor binding are present at the infarct site for 8 weeks of more postMI (Lefroy *et al.*, 1996; Sun *et al.*, 2001). This is primarily due to α-SMA positive myoFb, which remain in infarct scar tissue for prolonged periods of time. In the infarcted human heart these myoFb persist at the infarct site for years (Willems *et al.*, 1994).

MyoFb have considerable phenotypic and functional diversity (Sappino *et al.*, 1988; Skalli *et al.*, 1989). Immunolabeling with α-SMA, vimentin, and desmin defines their phenotype at the infarct site. Fibroblast-like cells express vimentin (V). ACE-labeled fibroblasts found in the infarct scar and involved in the expression of fibrillar collagen mRNA are positive for cytoskeletal proteins α-SMA and V. These VA-positive myoFb are instrumental to tissue repair including wound contraction. They likewise are found in the connective tissue that comprises endocardial fibrosis, pericardial fibrosis, renal infarction, and sites of foreign-body fibrosis. Unlike incised skin, where myoFb contribute to tissue repair and then progressively disappear through apoptosis at week 4 (Desmouliére *et al.*, 1995), the VA phenotype found at the infarct site remain for prolonged periods (Sun and Weber, 1996b).

In vitro emulsion autoradiography identifies α-SMA-positive myoFb as expressing AngII receptors (**Fig. 2**) (Sun and Weber, 1996c). Together with displacement studies, using an AT_1 receptor antagonist, losartan, or AT_2 receptor antagonist, PD123177, the great majority of receptors in the infarcted rat heart are of the AT_1 subtype (Lefroy *et al.*, 1996; Passier *et al.*, 1996; Sun and Weber, 1994, 1996c; Sun *et al.*, 1994). MyoFb found at sites of microscopic scarring involving both infarcted and noninfarcted tissue also express mRNA for the fibrogenic cytokine TGF–β_1 and TGF–β receptors (Sun *et al.*, 1998). This has implicated locally produced AngII in regulating collagen turnover, which has been further suggested by losartan in attenuating fibrous tissue formation at and remote to MI (Sun *et al.*, 1998).

ACE/ANGII/AT_1R and Cardiac Repair

High-density ACE binding in tissue repair implies marked ACE activity at these sites. ACE activity has been examined in the failing, infarcted, and noninfarcted human hearts (Hokimoto *et al.*, 1995). Infarct tissue ACE activity exceeds that of control tissue several fold, and the extent of activity is related to the severity of tissue damage. In rat heart tissue homogenates prepared from sites remote to a large transmural anterior MI, ACE activity is increased and the extent to which substrate conversion is increased correlates with infarct size (Hirsch *et al.*, 1991).

A paradigm of tissue repair has been proposed in which ACE and local AngII of the myoFb secretome are integral to the orderly and sequential nature of repair that eventuates in fibrosis (Weber, 1997b). ACE is involved in the de novo generation of AngII within granulation tissue that forms at sites of injury. The first component to local AngII generation is provided by macrophages. In an autocrine manner, it regulates expression of the fibrogenic cytokine TGF–β_1 that determines phenotype conversion of coaggregating stromal fibroblasts. VA positive myoFb generate AngII whose autocrine induction of TGF–β_1 regulates collagen

Fig. 2 Colocalization of α-SMA-positive myofibroblasts (left panel) expressing AT_1R receptors (middle panel) at a site of fibrosis and their overlay (right panel). Reproduced from Sun, Y., Weber, K.T. (1996). Cells expressing angiotensin II receptors in fibrous tissue of rat heart. *Cardiovascular Research* **31**, 518–525.

turnover at sites of fibrosis, including infarcted and noninfarcted myocardium. AngII generation at the infarct site by the myoFb secretome is related to the extent of the myoFb response and accordingly the degree of myocyte necrosis and subsequent healing. An extensive transmural MI and accompanying inflammatory cell response generates a large amount of AngII, which reaches remote sites via its diffusion through tissue fluid to promote fibrosis. Accordingly, activation of fibrogenesis is greatest at sites closest to the anterior MI (e.g., interventricular septum) and less so at more remote sites (e.g., RV). Expression of type I and III collagens is greater and persists longer in the septum compared to RV following left coronary artery ligation (Cleutjens *et al.*, 1995).

Fibrous tissue formation at sites remote to MI and the myoFb secretome is also influenced by pharmacologic interventions. Perindopril, given 1 wk. after MI, attenuates the endocardial fibrosis that appears in the nonnecrotic segment of the LV (Michel *et al.*, 1988). Captopril, commenced at the time of coronary artery ligation, attenuates the expected fibrosis of noninfarcted LV and RV (Bélichard *et al.*, 1994; van Krimpen *et al.*, 1991) and proliferation of fibroblasts and endothelial cells that appears at remote sites 1 and 2 weeks following MI (van Krimpen *et al.*, 1991).

Losartan, begun on day 1 after coronary artery ligation and in a dose that reduced AT_1 receptor binding by 50%, reduces infarct scar area (CdC *et al.*, 1997). Moreover, the expected rise in tissue AngII concentration found at the infarct site 3 weeks postcoronary artery ligation is markedly attenuated by an AT_1 receptor antagonist, introduced on postoperative day 1 (Yamagishi *et al.*, 1993). These findings raise the prospect that the number of myoFb or their AngII-generating activity per cell at sites of repair is influenced by AngII. Losartan also prevents fibrosis at remote sites (CdC *et al.*, 1997; Schieffer *et al.*, 1994; Smits *et al.*, 1992).

These cardioprotective effects of ACE inhibition or AT_1 receptor antagonism are not confined to the infarcted heart. The appearance of fibrosis in diverse organs with experimentally induced or naturally occurring tissue injury, without cRAAS activation. These include pericardial fibrosis postpericardiotomy (Sun and Weber, 1994), tubulointerstitial fibrosis associated with unilateral ureteral obstruction (Ishidoya *et al.*, 1995, 1996; Kaneto *et al.*, 1994; Morrissey *et al.*, 1996; Pimentel *et al.*, 1993, 1995; Yanagisawa *et al.*, 1990), toxic nephropathy (Cohen *et al.*, 1994; Diamond and Anderson, 1990; Lafayette *et al.*, 1993), remnant kidney (Anderson *et al.*, 1986; Ikoma *et al.*, 1991; Shibouta *et al.*, 1996; Tanaka *et al.*, 1995) or renal injury following irradiation (Juncos *et al.*, 1993), cardiovascular and glomerulosclerosis that appear in stroke-prone spontaneously hypertensive rats (Kim *et al.*, 1994, 1995; Nakamura *et al.*, 1994, 1996), interstitial pulmonary fibrosis that follows irradiation (Ward *et al.*, 1989, 1990, 1992) or monocrotaline administration (Molteni *et al.*, 1985), and subcutaneous pouch tissue in response to croton oil (Sun *et al.*, 1997). Attenuation of fibrous tissue formation by these interventions in diverse organs with various forms of injury supports the importance of AngII generated by the myoFb secretome in promoting fibrosis.

CounterRegulatory ACE2/Ang1–7/MasR in Repair

The myoFb RAS has expanded with the identification of a novel axis of ACE2, Ang1–7, and the G protein-coupled receptor, Mas (Ferrario *et al.*, 2016). This fibrolytic axis counterregulates the deleterious fibrogenic ACE/AngII/AT_1 axis and therefore could be invoked to regress cardiac fibrosis (**Fig. 3**). ACEI inhibitors and AT_1Ra upregulate the ACE2/Ang1–7/MasR axis in the hypertensive heart (Ferrario *et al.*, 2005,b), while inhibition of ACE2/Ang1–7/MasR axis exacerbates fibrosis (Liu *et al.*, 2012; Trask *et al.*, 2010; Zhong *et al.*, 2011); Ang1–7 overexpression prevents fibrosis (de Almeida *et al.*, 2015; Mercure *et al.*, 2008; Santiago *et al.*, 2010).

The regulation of tissue AngII involves ACE2, a homologue of ACE, which hydrolyzes AngII into Ang1–7, a pentopeptide, whose biologic activity is expressed via binding to its Mas receptor. The ACE2/Ang1–7/Mas axis is in equilibrium with the ACE/AngII/AT_1R axis, whereas Ang1–7 is counterregulatory to AngII, and therefore is cardioprotective. Ang1–7 formation is dependent

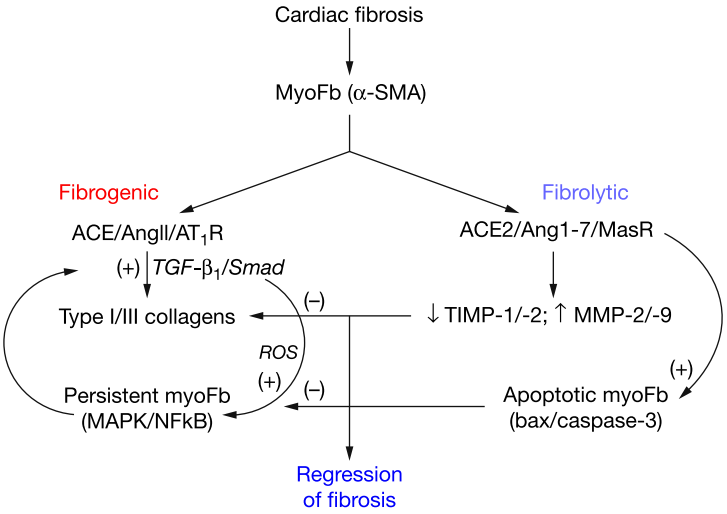

Fig. 3 Competing fibrogenic and fibrolytic axes represented by ACE/AngII/AT_1R and ACE2/Ang1–7/MasR, respectively.

on ACE2 and AngII as substrates (Keidar *et al.*, 2007). Increased levels of cardiac ACE2 and Ang1–7 forming activity are found in the failing heart, where this ectoenzyme is localized to macrophages, endothelial and vascular smooth muscle cells, fibroblasts, and myocytes (Burrell *et al.*, 2005; Zisman *et al.*, 2003). ACE2 activity is insensitive to ACE inhibitors; on the other hand, AT_1R antagonists increase cardiac ACE2 expression (Sukumaran *et al.*, 2011; Takeda *et al.*, 2007).

Targeted disruption or ACE2 overexpression has identified its significance in cardiac remodeling. Loss of ACE2 augments maladaptive AngII-based remodeling following either MI or LV pressure overloading, including ventricular dilation and infarct expansion, together with upregulation and activation of tissue matrix metalloproteinase, accompanied by disruption to fibrillar collagen which could be blocked by AT_1R antagonist (Kassiri *et al.*, 2009). Overexpression of ACE2 and upregulated Ang1–7 attenuate pathologic remodeling which follows MI and occurs in diabetic cardiomyopathy (Dong *et al.*, 2012; Zhao *et al.*, 2010), whereas chronic inhibition of ACE2 with tissue AngII accumulation is pathologic with fibrosis (Trask *et al.*, 2010).

Thus, increased ACE2 and Ang1–7 formation are counterregulatory to augmented tissue AngII formation found at sites of cardiac fibrosis and are cardioprotective by attenuating AngII-based maladaptive remodeling in diverse pathologic states. By raising cardiac ACE2 expression, AT_1R antagonists offer a unique salutary perspective in cardioprotection. Their use in combination with agents activating ACE2 may offer yet another dual strategy in preventing ongoing adverse remodeling in the failing heart.

Summary and Conclusion

The fibrogenic ACE/AngII/AT_1R axis represents a generalized response of multiple tissues evoked by injury and the need for repair. It serves to regulate local concentrations of AngII as a mediator of repair in diverse tissues, including the heart. MyoFb-bound ACE is integral to de novo generation of AngII that modulates expression of TGF–β_1 and whose auto-/paracrine properties regulate collagen turnover at sites of fibrous tissue formation that appear in response to various forms of cardiac injury, including infarction, pericarditis, and foreign-body implant. Persistent myoFb, resistant to apoptosis, and their expression of ACE at sites of injury contribute to a sustained metabolic activity, or secretome, that can account for a progressive fibrosis. Ongoing adverse structural remodeling by fibrous tissue eventuates in the progressive nature of chronic cardiac failure. The counterregulatory fibrolytic ACE2/Ang1–7/Mas axis of the myoFb secretome opposes this fibrogenic axis and may come to prove itself an effective cardioprotective strategy.

Glossary

Aldosterone A steroid hormone from the adrenal cortex that primarily functions to regulate sodium potassium, and chloride metabolism.

Peptide bond The bond formed between the carboxyl group of the amino acid and the amino group of another amino acid; an amide linkage joining amino acids to form peptides.

Proteolytic enzyme An enzyme that catalyzes the hydrolysis of peptide bonds in protein.

Introduction

In 1898, Tigerstedt and Bergmann discovered renin when they injected rabbit kidney extract into rabbits and observed an increase in blood pressure. In the following decades, the existence of the vasopressor substance was a subject of some controversy, and in 1934, Goldblatt rediscovered the importance of renin for blood pressure regulation and showed a relationship between renin secretion and renal ischemia. A few years later, in 1937, Blalock and Levy discussed a link between renin secretion and renal perfusion pressure, and renal baroreceptors were postulated. The enzymatic properties of renin were described by Page and Helmer and by Braun-Menendez et al. At the same time, Page et al. identified the renin substrate angiotensinogen as a plasma protein and interpreted the RAAS as a functional unit. In the mid-1950s, Skeggs et al. identified angiotensin-converting enzyme (ACE) in lungs and discovered that ACE catalyzes the conversion of angiotensin I (ANG I) to angiotensin II (ANG II), which mediates the actions of the RAAS. In 1958, Gross postulated a physiological link between the RAAS and aldosterone secretion in the zona glomeruloza of the adrenal gland, demonstrating that ANG II stimulates the secretion of aldosterone, which subsequently enhances sodium retention. Local RAASs—meaning that all components necessary for ANG II synthesis (angiotensinogen, renin, ACE) are expressed in one tissue—have been postulated in various organs such as the heart, vascular wall, kidney, adrenal gland, brain, and skin. Local actions of ANG II seem to comprise not just cardiovascular effects but also the control of cell proliferation and differentiation, thus taking part in mechanisms of tissue repair and remodeling.

The Renin Molecule

Renin is a proteolytic enzyme belonging to the aspartyl protease family. Differing from species to species, the molecular weight of renin varies between 37,000 and 42,000 Da. The active form of renin consists of two polypeptide chains linked by a disulfide bridge to form a bilobal structure with one active site. Renin shows an extremely high substrate specificity for angiotensinogen, the only known endogenous substrate for renin.

Renin Genes

Renin genes derived from various species, including humans, rats, and mice, have been cloned and sequenced. The human renin gene is located on the q42 band of chromosome 1 and spans 12,000 bp. The activity of the renin promoter is rather weak. It is regulated by multiple weak regulatory elements within the first 1301 bp of the 5′-flanking region, a classic silencer element within the first intron (Intron A) of the gene, and strong enhancer located far upstream (bp -5777 to -5552 in humans). There is accumulating evidence that renin expression is regulated according to the "variegation concept," meaning that transcription of a single gene is either switched on or switched off, but not gradually modified. A more or less pronounced expression of renin within a tissue would consequently be the result of more or less "switched-on" renin-transcribing cells.

Additional data show mechanisms for a posttranscriptional control of renin synthesis. These mechanisms seem to involve the stabilization of renin mRNA by the binding of specific proteins, whose expression is stimulated by cyclic AMP.

☆*Change History*: January, 2018. Elena Kaschina, U. Muscha Steckelings, and Thomas Unger updated the text and references.

This article is an update of Elena Kaschina, U. Muscha Steckelings, Thomas Unger, Hypertension, Renin and, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 609-614.

Molecular genetics studies did not find and evidence of an association between renin gene expression and hypertension.

Biosynthesis, Processing, and Expression of Renin

Translation of renin genes yields a precursor molecule, preprorenin, which consists of 340 amino acids. Preprorenin is processed to enzymatically inactive prorenin (MW 57,000). Prorenin can be activated in vitro by acidification or prolonged cooling, as well as by exposure to neutral serine proteases (e.g., trypsin, plasmin, kallikrein) or acid proteases (e.g., pepsin, cathepsin D). More than 80% of the total circulating renin is prorenin.

Renin is expressed in a complex tissue-specific and developmentally specific pattern. Early in development, renin is abundant in smooth muscle cells in the intrarenal arteries. During development, however, renin expression is progressively more reduced to the "classical" place of synthesis, the juxtaglomerular apparatus, where it is produced and stored in granules.

Very strong, chronic stimuli, however, are able to reestablish a cell's ability to synthetize renin. In the heart, for example, where renin mRNA is normally absent, conditions known to increase renin synthesis in the kidney (such as sodium depletion for at least a week or chronic ACE inhibition) lead to a massive rise in cardiac renin mRNA expression. The same phenomenon (called "recruitment") was observed in afferent arteriolar cells extending further upstream of the juxtaglomerular apparatus, which usually show no renin mRNA expression.

Mechanisms Controlling Renin Release

Renin is synthesized, stored, and secreted into the renal arterial circulation by the granular juxtaglomerular cells that lie in the walls of the afferent arterioles as they enter the glomeruli.

Effective stimuli for renin release and thereby for the induction of the renin–angiotensin–aldosterone cascade are sodium deficiency, hypovolemia, a significant decrease in arterial blood pressure, and increased sodium concentration in the distal tubule (tubuloglomerular feedback).

The secretion of renin from juxtaglomerular cells is controlled by three pathways, as follows:

The first intrarenal mechanism controlling renin release is called the macula densa pathway. A specialized segment of the early distal tubule, the macula densa segment, comes into direct contact with the afferent and efferent arterioles of its own nephron. A change in NaCl reabsorption by the macula densa results in the transmission of chemical signals to nearby juxtaglomerular cells, which modify the release of renin; the increase in NaCl flux across the macula densa inhibits the release of renin and the decrease stimulates the release of renin. The other chemical signals mediating the macula dense pathway involve adenosine, prostaglandins, and nitric oxide.

The second mechanism controlling renin release is called the intrarenal baroreceptor pathway. In 1934, Goldblatt showed that it was possible to produce persistent hypertension in dogs by constricting the renal arteries. Later, the concept of a "baroreceptor mechanism for renin secretion" was formulated by Skinner. Increases and decreases in blood pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The underlying mechanism is believed to be a reduction in the tension within the wall of the afferent arteriole.

The third mechanism is called the β-adrenergic receptor pathway. It has long been known that an increase in sympathetic activity influences renin release. The studies of Kirchheim and related investigations have clearly established that an increase in sympathetic tone to the kidney stimulates renin release via the activation of β_1-adrenergic receptors on juxtaglomerular cells.

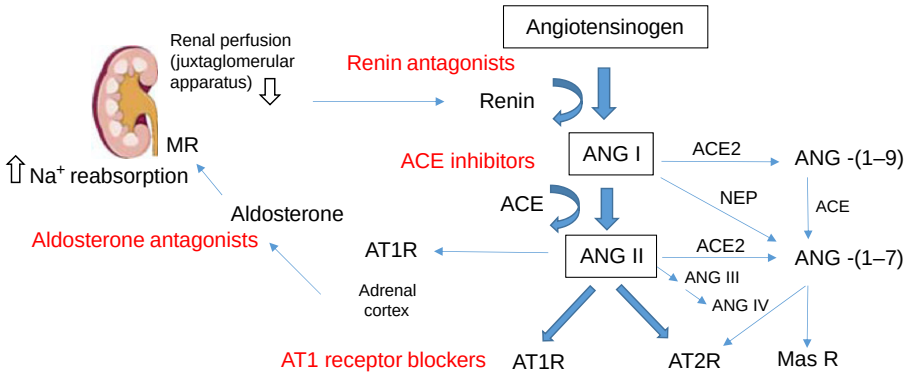

Fig. 1 Drugs affecting the renin–angiotensin–aldosterone system. *ANG*, angiotensin; *AT1R*, angiotensin AT1 receptor; *AT2*, angiotensin AT2 receptor; *ACE*, angiotensin converting enzyme; *MR*, mineralocorticoid receptor; *NEP*, neprilisin; *Mas R*, Mas receptor.

Renin Actions

Renin acts on angiotensinogen, splitting off a decapeptide, angiotensin I, from the N-terminal end of the protein (Fig. 1). ANG I is acted on by a second proteolytic enzyme, ACE, that removes two aminoacids to form the highly active octapeptide, ANG II. The removal of one more amino acids yields the heptapeptide, Angiotensin III (ANG III). ANG II and ANG III induce the release of the mineralocorticoid aldosterone, the most important hormone for sodium balance, from the adrenal cortex.

The Substrate for Renin: Angiotensinogen

Angiotensinogen, an α-globulin, is a precursor molecule for angiotensin II and the substrate for renin. Angiotensinogen is synthesized and secreted mainly by the liver and is found in the α-globulin fraction of plasma. Moreover, it is also found in diverse tissues expressing local RAASs. Its synthesis is stimulated by glucocorticoids, thyroid hormone, estrogens, and ANG II. Increases in angiotensinogen levels are associated with essential hypertension. Moreover, a linkage to essential hypertension was found in regions within or close to angiotensinogen gene. Transgenic mice expressing the rat angiotensinogen gene are hypertensive and mice lacking angiotensinogen gene are hypotensive.

Angiotensin-Converting Enzyme

ACE is the second enzyme (Fig. 1) in the cascade of ANG II synthesis, converting the inactive decapeptide, ANG I, to the potent octapeptide pressure hormone, ANG II. ACE is a nonspecific peptidase that can cleave C-terminal dipeptides from various peptides (dipeptidyl carboxypeptidase). The enzyme kininase II is identical to ACE and contributes to the activation of kinins, such as bradykinin, and other potent vasodilator peptides. ACE is primarily localized on the luminal side of the vascular endothelium. The lung, which has a vast surface area of vascular endothelium, is rich in ACE. Additionally, ACE is present in other organs including kidney, heart, brain, striated muscle, and skin, as it is a part of local RAASs.

Angiotensin converting enzyme 2 (ACE2) is a negative regulator of the RAAS, counterbalancing the multiple functions of ACE (Fig. 1). ACE2 converts the decapeptide, angiotensin I, to angiotensin ANG (1–9), which is converted by ACE to a shorter peptide, ANG (1–7). Alternatively, Ang (1–7) can also be formed directly from ANG I via neutral endopeptidase (NEP, neprilysin).

Ang (1–7) evokes a range of acute central and peripheral effects such as vasodilatation, inhibition of VSMC proliferation, and inhibition of vasopressin release. Furthermore, Ang (1–7) is an endogenous ligand for the Mas receptor, a seven transmembrane domain G-protein-coupled receptor sharing a 31% sequence identity with the AT2 receptor.

Angiotensin II and Its Receptors

ANG II, an octapeptide hormone, is the main active component of the RAAS. It contributes to the regulation of blood pressure, plasma volume (via aldosterone-regulated sodium excretion), and sympathetic nervous activity. Moreover, it is involved in such diverse effects as proliferation, differentiation, regeneration, and apoptosis. The multiple actions of ANG II are mediated via specific, highly complex intracellular signaling pathways that are stimulated following an initial binding of the peptide to its cell surface receptors. The major actions of ANG II are mediated by two subtypes of G protein-coupled angiotensin receptors, the angiotensin receptor type 1 (AT1) and the angiotensin type 2 (AT2) receptors (Fig. 1), which are seven-transmembrane glycoproteins with only 32%–34% sequence homology.

The AT1 Receptor

The AT1 receptor is involved in the classical physiological actions of ANG II: regulation of blood pressure, electrolyte and water balance, thirst, hormone secretion, and renal function. The AT1 receptor belongs to the G protein-coupled receptor superfamily and typically activates phospholipase C through the heterotrimeric Gq protein.

AT1 receptors are present in the human vasculature, lung, liver, brain, kidney, adrenal gland, skin, and endometrium.

The classical actions of AT1 receptors include the following: generalized vasoconstriction; increased release of noradrenaline from sympathetic nerve terminals, reinforcing vasoconstriction and increasing the rate and force of the heart; stimulation of the proximal tubular reabsorption of sodium ions; secretion of aldosterone from the adrenal cortex; and cell growth in the cardiac left ventricle and in the arterial wall.

ANG II via the AT1 receptor furthermore controls cellular growth, adhesion, migration, and intercellular matrix deposition, influencing chronic adaptive changes in vascular and cardiac growth, remodeling, repair, and atherosclerosis. In vascular smooth muscle cells and in endothelial cells, ANG II via its AT1 receptor stimulates phospholipase A_2 activity, leading to the release of arachidonic acid and eicosanoids, which influence vascular and renal mechanisms important in the regulation of blood pressure and cell growth.

ANG II via the AT1 receptor increases the activity of NAD(P)H oxidase thereby stimulating reactive oxygen species (ROS) and nitrogen formation in the vessel wall. ROS products such as superoxide and H_2O_2 may activate mitogen-activated protein kinases, tyrosine kinases, phosphatases, calcium channels, and redox-sensitive transcription factors. Activation of these signaling pathways results in cell growth and expression of proinflammatory genes. The ROS cause also lipid peroxidation and generation of various vasoconstricting molecules such as F2 isoprostans.

The expression of the AT1 receptors is altered by various pathophysiological conditions: renovascular hypertension, myocardial infarction, ventricular hypertrophy, and bilateral nephrectomy. Overexpression of the vascular AT1 receptor can be observed in hypercholesteremic men. These findings may help to explain why hypercholesterolemia is frequently associated with hypertension and why blockade of the RAAS attenuates the progression of atherosclerosis. The downregulation of AT1 receptors in sepsis is the main reason for the attenuated responsiveness of blood pressure and of aldosterone formation to ANG II and, therefore, may contribute to the characteristic septic shock.

The AT2 Receptor

The AT2 receptor is widely expressed in fetal tissues, whereas its expression is dramatically decreased after birth, being restricted to a few organs such as brain, adrenal, heart, kidney, myometrium, skin, and ovary. Although the AT1 receptor is dominant in the adult organism, an increase of AT2 receptor expression has been observed in pathological conditions, such as vascular injury, myocardial infarction, congestive heart failure, renal failure, brain ischemia, and sciatic or optic nerve transection.

The AT2 receptor exerts a protective effect against an overstimulation of AT1 receptors by counteracting AT1 receptor-mediated actions; for example, whereas the AT1 receptor stimulates cell proliferation, the AT2 receptor has an antiproliferative effect and promotes cell differentiation. Moreover, the AT2 receptor activation inhibits sympathetic activity and promotes antiinflammation. Inhibition of this receptor enhances the immediate left ventricular growth response to ANG II.

The AT2 receptor is a seven transmembrane domain G-coupled receptor that acts via several intracellular signaling pathways such as nitric oxide (NO)/cyclic GMP activation, inhibition of mitogen-activated protein kinases (MAPKs) by protein phosphatases, phospholipase A2 stimulation or disruption of AT1 receptor signaling by AT1–AT2 receptor heterodimerization.

The AT2 receptor stimulates the production of NO and, subsequently, the second messenger cGMP. cGMP, in turn, mediates vasodilation, natriuresis, and antigrowth by activating cGMP-dependent protein kinase. The AT2 receptor also inhibits renin biosynthesis and ANG II formation via nitric NO/cGMP dependent mechanism. Moreover, antigrowth, antifibrotic and antiinflammatory features of this receptor might contribute to blood pressure lowering and prevent remodeling in hypertension. Whereas acute vasodilator role of AT2 receptor is well described, chronic decrease of blood pressure seems to be minimal after AT2 receptor stimulation. Nevertheless, the AT2 receptor is known to be important in the prevention of vascular remodeling.

Recently, two selective AT2 receptor agonists (Compound 21 by Vicore Pharma, Sweden and MOR107 by Lanthio Pharma, Netherlands) have been developed and tested in Phase I trials demonstrating their safety in humans.

Further knowledge about the tissue-protective effects of the AT2 receptor might lead to new therapies in the future and should be confirmed by clinical studies.

Aldosterone

The mineralocorticoid aldosterone is produced in the zona glomerulosa of adrenal cortex. Its main action is the resorption of Na^+ (Cl^- and H_2O follow) in exchange for K^+ in the distal tubules of the kidney. Low plasma sodium or high plasma potassium concentrations affect the zona glomerulosa cells of the adrenal directly, stimulating aldosterone release. Aldosterone secretion is also controlled indirectly by the juxtaglomerular apparatus, which is sensitive to the composition of the fluid in distal tubule. A decrease in the sodium chloride concentrations of the filtrate is sensed by macula densa cells, which stimulate renin release. This leads—as illustrated above—to the formation of ANG II, which in turn, via AT1 receptors, stimulates the synthesis and release of aldosterone by the adrenal cortex. Moreover, in the process of aldosterone synthesis, angiotensins (ANG II and ANG III) regulate the corticosterone methyloxidase I and II enzymes, which catalyze the hydroxylation and aldehyde formation at C-18 of corticosterone.

In the kidneys, in the late distal tubule and collecting duct, aldosterone binds to cytoplasmatic mineralocorticoid receptors (MR), which migrate to the nucleus and initiate DNA transcription, translation, and production of proteins, which activate Na^+ and K^+ channels and increase the synthesis of Na^+/K^+ ATPase and production of ATP. As a result, the reabsorption of Na^+ (and the subsequent reabsorption of Cl^- and H_2O) and the secretion of K^+ and H^+ are increased. Na^+ reabsorption increases the osmolarity of extracellular fluids. This stimulates the hypothalamic osmoreceptor to release vasopressin from the posterior pituitary. Vasopressin leads to enhanced free-water reabsorption in the collecting duct, which expands extracellular volume and reduces plasma osmolarity. Vasopressin also acts on other tissues. In the vasculature, vasopressin increases intracellular Ca^{2+} and potentiates vasopressor responses.

The effects of aldosterone on blood pressure regulation extend beyond increased intravascular fluid retention and volume overload. Aldosterone modulates vascular tone by upregulation of the AT1 receptor, by limiting bioavailability of endothelial NO,

and by increasing pressor responses to catecholamines. Moreover, aldosterone excess activates inflammation and oxidative stress, decreases fibrinolytic activity, and promotes vascular hypertrophy.

All these cellular pathways regulated by aldosterone via the MR, and ANG II via its AT1 receptor can reinforce each other.

Drugs Affecting the RAAS

Renin Inhibitors

Since renin catalyzes the first and rate-limiting step of the RAAS cascade, interruption of the generation of ANG II by renin inhibitors at this highly specific initial step of the cascade has long been a therapeutic goal. The inhibition of renin would have the advantage of preventing RAAS synthesis without concomitant accumulation of other peptides, such as kinins or substance P, as in ACE inhibitor treatment, and it would have an advantage of the absence ANG II overexpression and stimulation of other ANG II receptor subtypes as in AT1 receptor antagonist treatment. Despite these theoretical advantages, the lack of oral availability, low efficacy, and high costs of development have thus far prevented renin inhibitors from becoming successful drugs. However, potent nonpeptidic inhibitor of renin, Aliskiren, with acceptable oral bioavailability, has been synthesized. Aliskiren has been shown to decrease in dose-dependent manner plasma renin activity, ANG I and ANG II levels in healthy volunteers, and blood pressure in hypertensive patients. Moreover, in comparison with antihypertensive treatments including AT1 receptor blockade, a β-blocker and calcium channel antagonist, Aliskiren was shown to have equally potent blood pressure lowering effects and antiatherosclerotic effects. On the other hand, large clinical trials, which investigated the combination of Aliskiren with other RAAS blockers, failed to show the expected outcomes or resulted with an increased incidence of adverse effects. In diabetic patients at high risk of developing cardiovascular and renal complications, dual RAAS blockade had no further benefit in preventing end-organ damage.

ACE Inhibitors

ACE inhibitors occupy the angiotensin-converting enzyme as false substrates, thus preventing the conversion of ANG I to ANG II and resulting in reduced levels of circulating and tissue ANG II. They also block the degradation of bradykinin and other vasodilatory peptides, which may have potential benefits in cardiovascular disease. ACE inhibitors affect capacitance and resistance vessels, reduce cardiac load as well as arterial pressure, improve endothelial function, and reduce left ventricular hypertrophy.

ACE inhibitors are well recognized as an important therapeutic step to control blood pressure in hypertensive patients and to reduce morbidity and mortality in patients with hypertension, congestive heart failure, or diabetes mellitus. They appear to possess unique cardioprotective benefits, even when used in patients without high blood pressure or left ventricular dysfunction. ACE inhibitors promote collateral vessel development and improve prognosis in patients who have had coronary revascularization procedure. ACE inhibitors are also effective in the management of chronic renal diseases to delay the progression of renal failure.

AT1 Receptor Antagonists

The "sartan" family comprises a rather new group of pharmaceuticals (losartan, valsartan, candesartan, irbesartan, telmisartan, eprosartan, azilsartan), which all act as antagonists on the AT1 receptor. AT1 receptor antagonists are specific for the RAAS, selective for the AT1 receptor, and act independently of the ANG II synthesis pathway, allowing a more selective blockade of the AT1-mediated effects of ANG II compared with ACE inhibitors. However, by inhibiting the AT1 receptor-mediated negative feedback of ANG II on renin release in the kidney, these drugs may evoke an overstimulation of the AT2 receptor by enhancing ANG II levels in the plasma. An AT2 receptor-mediated increase in the production of vasodilators (nitric oxide, cGMP, prostaglandins) as well as the antigrowth features of this receptor might contribute to a further decrease in blood pressure and prevent hypertrophy and remodeling. AT1 receptor antagonists do not inhibit the degradation of kinins and cough is not a frequent side effect.

The AT1 receptor antagonists are widely used as antihypertensive agents, especially in patients with type 2 diabetes or ACE inhibitor intolerance.

Aldosterone Antagonists

The mineralocorticoid hormone aldosterone is a product of the RAAS that contributes to the development of hypertension and myocardial hypertrophy and has a potential to cause edema through sodium and water retention. Spironolactone and its metabolite canrenone are antagonists of the aldosterone receptor and attenuate the effects of the hormone. Spironolactone is used for the treatment of hypertension, primary aldosteronism, and peripheral edema associated with heart failure.

Monotherapy with spironolactone was shown to be effective in patients with low-renin essential hypertension. Moreover, a recent clinical trial demonstrated that spironolactone was the most effective add-on drug for the treatment of resistant hypertension. However, spironolactone is associated with progestational and antiandrogenic side effects, such as gynecomastia and impotence, as a result of its binding to other steroid receptors.

Eplerenone is the first agent of a new class of drugs known as selective aldosterone receptor antagonists, which provide effective and well-tolerated blood pressure reduction. Because eplerenone has little affinity for androgen and progesterone receptors, it produces fewer steroid-like effects (such as gynecomastia in men) than spironolactone. Unfortunately, eplerenone features a reduced potency (40-fold lower affinity for MR in comparison with spironolactone). Therefore, despite of its better tolerability over spironolactone, the indication for hypertension is not recognized except in the presence of intolerance to spironolactone. Hyperkaliemia is a serious dose-related adverse effect of both spironolactone and eplerenone.

Other nonsteroidal aldosterone antagonists are being developed. Finerenone has greater affinity to the MR than eplerenone. Nevertheless, finerenone does not significantly influence systolic blood pressure.

An alternative approach is to inhibit aldosterone synthesis by selective inhibitors of aldosterone synthase. Such compound, LC1699, has been tested in patients with resistant hypertension and primary hyperaldosteronism. Due to lack of selectivity, LC1699 at higher doses also inhibits 11-beta-hydroxylase, which regulates cortisol synthesis. Thus, more selective substances will have to be developed.

Other Drugs Influencing Renin Release

Several drugs, which do not directly interfere with the cascade of ANG II synthesis, indirectly modify the rate of renin synthesis or release. Loop diuretics stimulate renin release by blocking the reabsorption of NaCl at the macula densa. Antihypertensive drugs in general increase renin release by decreasing arterial blood pressure, which in turn activates baroreceptors. Sympatholytic drugs and β-adrenoreceptor antagonists decrease renin release by blocking the β-adrenoreceptor pathway, leading to a diminished sympathetic tone in the kidney.

Hyperreninemia☆

Pierre-François Plouin, Laurence Amar, and Michel Azizi, Hôpital Européen Georges Pompidou, Paris, France and Paris Descartes University, Paris, France

Glossary

Primary reninism A rare, purely renin-dependent and surgically curable form of hypertension, usually caused by a juxtaglomerular cell tumor.

Renal artery stenosis A reduction of the diameter of a renal artery by 60% or more.

Renin An aspartyl protease produced by juxtaglomerular cells in the kidney. Renin is essential for the formation of angiotensin II, which is a key hormone in blood pressure regulation and in maintaining sodium, potassium and water homeostasis.

Definition

The renin-angiotensin system [RAS] is a cascade of proteins and peptides – angiotensinogen, renin, angiotensin converting enzyme [ACE], and angiotensins – that leads to the formation of angiotensin [Ang] II, the active hormone. Ang II is a vasoconstrictor and stimulates the adrenal release of aldosterone. Aldosterone in turn enhances sodium reabsorption and potassium secretion in the distal nephron. Vasoconstriction and sodium retention increase blood pressure [BP]. Hyperreninemia therefore includes a variety of conditions, mostly with hypertension, and frequently associated with potassium wasting and hypokalemia.

Assaying the Activity of the Renin-Angiotensin System

Biochemical tests aim to assess whether plasma levels of the RAS components are higher than expected for posture, sodium intake and age. Physiological tests measure the BP and hormonal responses to the acute administration of ACE inhibitors or Ang receptor antagonists.

Human active renin is an aspartyl protease of 340 amino acids and 40 000 Dalton molecular weight with two N-glycosylation sites. It is secreted by the renal juxtaglomerular granular epithelioid cells. It is synthesized in the cells as prorenin and activated by cleavage of an N-terminal prosegment of 43 amino acids. Prorenin or the inactive form of renin is also secreted into the blood. Total plasma renin therefore consists of prorenin and activated renin and the plasma prorenin/active renin ratio is around 9.

Biochemical Techniques

Angiotensinogen and ACE are not usually rate-limiting for Ang II formation, and plasma Ang II concentration is difficult to measure. The method for assaying renin can be indirect, involving the measurement of the enzymatic activity of the mature form of active renin through the *in vitro* production of Ang I. Ang I is produced by incubating plasma in standardized conditions of time, pH and temperature in presence of various inhibitors and is measured by a radioimmunoassay. The result, plasma renin activity [PRA], which describes the work of the enzyme, is generally expressed in ng $ml^{-1}h^{-1}$ Ang I. The plasma active renin concentration [PRC], which corresponds to the concentration of the renin molecules in plasma and is expressed in mU l^{-1}, can also be measured directly by use of an immunometric or a chemoluminescence assay. In physiological conditions, and in the presence of high angiotensinogen concentrations, PRC and PRA are well correlated.

Conditions for Valid Assessment of Renin Levels

Great care should be taken to draw blood and centrifuge the samples at room temperature to avoid cryoactivation of inactive prorenin into active renin by unfolding of the prosegment masking the active site, therefore artifactually increasing renin levels. The RAS is finely tuned by posture and sodium balance, and is affected by age, genetic factors and ethnicity. Walking for one hour increases the renin levels two-fold. Renin secretion is stimulated by sodium depletion and suppressed by sodium loading. In patients on a liberal sodium diet, the renin-sodium profile is based on a nomogram relating renin levels to urinary sodium excretion. Alternatively, patients are instructed to ingest 75 to 150 mmol sodium/day and sodium excretion is determined over a 24-h period to confirm that sodium output is within this range. Renin levels are not markedly affected by variations in sodium

☆*Change History:* January 2015. P-F Plouin, L Amar, and M Azizi updated the text and references.

This article is an update of Pierre-François Plouin, Laurence Amar, Sylvie Le Coz, Antoine Chedid, Hyperreninemia, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 572-576.

intake within these limits. Plasma concentrations of renin are markedly higher in children than in adults. In normal adults, they fall by half between the ages of 30 and 70 years. Patient values should therefore be compared with those of age-matched normal subjects studied in the same conditions. Most antihypertensive agents alter renin release either directly or through counter-regulations in response to BP decrease or suppression of renin-Ang II negative feed-back. Renin release is increased by diuretics, ACE inhibitors, Ang receptor antagonists, renin inhibitors, mineralocorticoid receptor antagonists and vasodilators, and decreased by ß-blockers and centrally-acting agents. Treatment with these drugs should be stopped 2–6 weeks before assessing renin levels, although this may be difficult in patients with severe hypertension. In such cases, alpha-blockers and non-dihydropyridine calcium channel blockers may be continued because they have little effect on renin release.

Acute Renin-Suppression Tests

Acute renin-suppression tests interrupt the RAS, showing that this system is involved in the control of hypertension. The ACE inhibitor captopril is generally administered orally due to its rapid onset of action (20 min) and maximum action (1–3 h). BP should consistently decrease in patients with renin-dependent hypertension. However, this test is no more used because it is not sensitive and specific enough and could mistakenly restrict the use of RAS blockers to patients with a high renin profile, even though the majority of patients with a high cardiovascular risk in whom it is justified to administer an ACE inhibitor have an average to low renin profile.

When is it Useful to Measure Renin? (Table 1)

In patients with essential hypertension, plasma renin determination may help physicians to select the most effective first-line treatment. Patients in the highest renin index quartile show the greatest response to RAS blockers and ß-blockers and those in the lowest quartile respond better to diuretics and CCBs. However, considering the fluctuations in renin levels in individual patients and the relatively high cost, the therapeutic value of measuring PRA or PRC during routine investigation of mild to moderate essential hypertension remains limited.

In contrast, renin should be measured in patients prone to secondary hypertension. Such patients can be identified by their medical history, signs and symptoms, by the presence of hypokalemia, chronic kidney disease, abdominal bruit, or asymmetrical kidneys. Renin should also be measured in the small proportion of patients with severe untreated hypertension or in whom hypertension is resistant to at least a triple therapy including a diuretic, all administered at an optimal and maximally tolerated dosage. In such cases, an unsuspected form of secondary hypertension or a pronounced drug-induced stimulation of the RAS may be found. Such findings may indicate that additional etiologic evaluation is required or that an ACE inhibitor, an Ang receptor antagonist or a ß-blocker should be added to the treatment regimen.

Renin-Dependent Forms of Hypertension (Table 2)

Primary Hypertension

About one in six patients with essential hypertension have high renin levels. The purpose and efficiency of screening for high renin hypertension in this setting is discussed above. Most patients with malignant hypertension have high renin levels. The renin concentration is very high in patients with hyponatremic hypertensive syndrome, leading to hyperangiotensinemia with thirst,

Table 1 When to measure renin?

Setting	*Aim*	*Comment*
Mild or moderate untreated hypertension	Determination of renin subgroup for prognostic or therapeutic purposes	Classification of individual patients into low or high renin subgroups probably not cost-effective in this setting
Severe untreated hypertension (diastolic BP consistently above 110 mm Hg) and/or hypokalemic hypertension	Guidance for subsequent etiologic investigations	High renin levels suggest that CT-angiography, magnetic resonance angiography, or Duplex Doppler sonography should be performed, whereas low renin levels suggest adrenal investigations
Drug-resistant hypertension	Guidance for antihypertensive treatment adaptation	Discontinue current treatment (calcium channel antagonists and α-blockers may be continued) and determine plasma renin levels. High renin levels suggest that a ß-blocker, an ACE inhibitor or an angiotensin II receptor antagonist should be added to the previous treatment regimen
Hypertension with renal failure	Guidance for antihypertensive treatment adaptation	Low or normal renin levels suggest that the daily dose of loop diuretic should be increased, high renin levels suggest that an ACE inhibitor should be added
Hypertension with renal artery stenosis or unilateral small kidney or kidney tumor	Evaluation of asymmetrical renin secretion before nephrectomy or renal artery angioplasty	A RVR ratio $\geq$ 1.5 is generally associated with a favorable BP outcome following nephrectomy or renal artery angioplasty

Table 2 Etiology, presentation and key findings in renin-dependent hypertension.

Underlying disease	*Usual presentation*	*Key tests and findings*
Primary hypertension		
Benign	Non specific. 10–15% of patients with primary hypertension belong to the high renin subgroup	Larger than average response to ß-blockers or ACE inhibitors
Accelerated or malignant	Headache, thirst, weight loss, diastolic BP usually $>$140 mm Hg with hypokalemia, chronic kidney disease, proteinuria	Funduscopy: hemorrhages, exudates, papilledema. An underlying renal disease is present in $\approx$50% of cases
Renal ischemia		
Renal artery stenosis	Recent, progressive and/or severe hypertension, hypertension in young females (fibromuscular dysplasia) or in patients with angina or arteritis (atherosclerosis), hypertension with ACE inhibitor-induced rise in plasma creatinine	Renal angiogram: renovascular (curable) hypertension is probably present if reduction in artery diameter (i) exceeds 75% or (ii) is between 50 and 75% with a positive captopril test, a lateralized captopril renography or a RVR ratio $\geq$1.5
Renal infarction	Hyponatremic hypertensive syndrome: lumbar pain and hematuria followed by acute hypertension, polyuria, hypokalemia, hyponatremia and very high renin concentrations	Segmental renal infarction is detected by CT scan and its cause is determined by renal angiogram (embolism, thrombosis, renal artery dissection or occlusion)
Polyarteritis nodosa	Systemic necrotizing vasculitis	Widespread microaneurysms on renal angiogram
Systemic scleroderma	Skin thickening, Raynaud's phenomenon, progressive hypertension and chronic kidney disease	Clinical presentation. ACE inhibitors greatly improve scleroderma crisis
Renal tumors and cysts		
Juxtaglomerular cell tumor	Severe hypokalemic hypertension with very high prorenin and active renin levels	Normal renal angiogram with a small cortical tumor on CT scan
Other renal renin-producing tumors	Hypertension with renal cell carcinoma	Primary reninism is present and BP returns to normal following nephrectomy in about 5% of cases
Compressive cysts and tumors	Hypertension with ultrasound scan evidence of a large cyst or tumor	Improvement in BP following cyst drainage or tumor resection may be expected if RVR ratio exceeds 1.5
Polycystic kidney	Family history of renal cysts, hypertension and chronic kidney disease	Ultrasound scan evidence of $>$3 bilateral cysts in a person with a positive family history
Unilateral non-vascular small kidneys	Hypertension with asymmetrical kidneys and frequently a history of recurrent urinary tract infection	Pyelographic or ultrasound scan evidence of pyelonephritic scarring, reflux nephropathy and/or segmental hypoplasia
Extrarenal tumors		
Pheochromocytoma	Paroxysmal hypertension with vasomotor symptoms	High urinary catecholamine metabolites, adrenal tumor
Ectopic primary reninism	Malignant tumor with hypertension and/or hypokalemia	Rare cases of lung, liver, pancreas or ovary cancers

polyuria and hyponatremia, and secondary aldosteronism with potassium wasting and hypokalemia. Malignant hypertension may be primary or, as in 45% of cases, the consequence of an underlying renal or adrenal disease.

Renal Artery Stenosis

Renal ischemia associated with renal artery stenosis [RAS] is the most frequent condition occurring with renin-dependent hypertension. About 80% of stenoses are due to atherosclerosis, usually in patients over the age of 50 years. Ten percent are due to fibromuscular dysplasia which is observed mostly in female patients. The gold-standard procedure for diagnosing RAS is catheter angiography. For screening purposes, this invasive procedure can be replaced by CT-angiography, magnetic resonance angiography, or renal Duplex ultrasound. These imaging procedures estimate the frequency of RAS at 1% in unselected patients with hypertension, and 10–30% in patients with drug-resistant hypertension or with atherosclerosis elsewhere.

The standard for defining renovascular hypertension is a favorable BP outcome following revascularization. This definition is retrospective and the actual frequency of the condition is low because hypertension reversal is dependent on several parameters such as stenosis etiology, patient's age, parenchymal consequences of hypertension, and the feasibility of revascularization. In patients with atherosclerotic RAS, randomized trials comparing percutaneous revascularization plus medication to medication alone reported no improvement in BP or renal function following angioplasty (generally with stenting). In patients with fibromuscular dysplasia, retrospective series reported a hypertension cure rate (normal BP without medication) of 30–50%.

Considering the risks associated with percutaneous angioplasty or renal artery surgery, several attempts have been made in the past to design tests to select RAS patients who have truly renin-dependent hypertension. In such patients, the captopril test is expected to induce a sharp decrease in BP. The captopril test, with concurrent determination of plasma renin levels, is predicted to induce a homeostatic increase in renin secretion from the stenotic kidney. Although the captopril test has been analyzed in

numerous patients at risk of having renovascular hypertension, a complete analysis is not possible because of multiple inconsistencies in patient selection, standards, test procedures, and cutoff points. This test has now been abandoned.

Simultaneous determination of renin in both renal veins has also been largely used in the past to predict BP outcome following revascularization in patients with unilateral RAS. If the renal vein renin [RVR] ratio (i.e. the ratio between the RVR levels on the stenotic and non-stenotic sides) exceeded 1.5, the stenosis was assumed to cause renin-dependent hypertension amenable to angioplastic or surgical cure. The test could be performed after acute oral captopril administration. Post-captopril renal scintigraphy was a less invasive alternative to RVR determination and was more accurate than the captopril-renin test especially in unilateral RAS. Considering the poor outcome of revascularization in patients with atherosclerotic RAS, performing the captopril test, the determination of RVR ratio or captopril scintigraphy is no longer recommended. RVR determinations should only be performed in complex cases such as branch stenoses or renovascular disease associated with focal renal parenchymal infarction. In patients with fibromuscular dysplasia, defining the precise degree of stenosis may be challenging especially in patients with multifocal string-of-beads type of stenosis.

Other Conditions Associated With Renal Ischemia

A few conditions characterized by chronic or acute intra-renal ischemia may also induce renin-dependent hypertension. These include systemic diseases such as polyarteritis nodosa and scleroderma, in which BP and renal outcomes are greatly improved by ACE inhibitors, and segmental renal infarction. Segmental renal infarction may result from renal embolism, renal artery thrombosis or dissection, or *in situ* thrombosis in cases with coagulation disorders. It usually presents as an abrupt-onset malignant hypertension with hyponatremic hypertensive syndrome. The condition may revert spontaneously to normotension because the ischemic renal tissue, which releases large amounts of renin, may subsequently turn into a silent renal scar.

Renal Tumors and Cysts

Primary reninism is a very rare, purely renin-dependent form of hypertension. It may be caused by juxtaglomerular cell tumors, malignant kidney tumors (nephroblastoma, adenocarcinoma), epithelial or soft tissue tumors. Primary reninism is associated with very high PRC and by the absence of RAS and intra-renal ischemia as determined by renal angiography. A small, hypodense renal cortical tumor (juxtaglomerular cell tumor) or a larger renal or extrarenal tumor is then detected by CT scan. BP usually drops during ACE inhibition and hypertension can be cured by tumor resection, although it may recur if metastases develop in exceptional malignant cases. In the 43 reported cases of juxtaglomerular cell tumors, hypertension was severe and associated with hypokalemia. PRA or PRC was markedly elevated in all cases. CT scan revealed small renal tumors (diameter 25 [8–50] mm).

Some large non-renin-secreting cysts and tumors may be found in cases of renin-dependent hypertension as the mechanism of renin stimulation is renal artery compression. In selected cases, with a lateralized RVR ratio, cyst drainage or tumor resection may improve or cure hypertension.

Unilateral Non-Vascular Small Kidneys

Pyelonephritic scarring associated with urinary tract infection and vesicoureteric reflux can cause childhood hypertension and progressive degradation of renal function. Renin is often high and has been shown to be the cause of hypertension. High renin levels may also occur in cases of renal hypoplasia. In cases with a very small unilateral kidney and a lateralized RVR ratio, unilateral nephrectomy may improve hypertension.

Extrarenal Tumors

The high BP levels associated with pheochromocytoma are caused by high plasma catecholamine concentrations both directly, through stimulation of vascular alpha-adrenergic receptors, and indirectly, through renin activation mediated by the beta-adrenergic stimulation of juxtaglomerular cells and renal vasoconstriction. Consequently, ACE inhibition may be used to control BP before surgery.

As mentioned above, rare cases of primary reninism may be due to extrarenal tumors.

Hyperreninemia With Normal Blood Pressure Levels

In most conditions with normal BP levels, hyperreninemia is a homeostatic response to reduced renal perfusion pressure or plasma flow. These conditions include dehydration, hemorrhage, diuretic use or pharmacological vasodilatation, cardiac failure, and reduced plasma volume due to hypoproteinemia in patients with nephrotic syndrome or kidney failure. These conditions have numerous signs and symptoms that cannot be listed in this chapter, and the assessment of the RAS has no added diagnostic value. Renin levels are related to survival in patients with cardiac failure, high levels being associated with a poor prognosis. The

prognostic value of atrial and brain natriuretic peptides is higher than that of renin, however, meaning that the latter is rarely used to assess prognosis.

Bartter syndrome, or inherited hypokalemic metabolic alkalosis, is an autosomal recessive disorder due to inactivating mutations of NKCC2 gene which codes for the Na-2Cl-K channel at the level of the Henle's loop which is characterized by salt wasting, insensitivity to the vasoconstrictive effects of Ang II, and consequently high renin levels with normal BP, hyperaldosteronism and hypokalemia. Gitelman syndrome is another salt loosing tubulopathy due to inactivating mutations of the NCC gene which encodes for the NaCl cotransporter at the level of the distal tubule in which patients have hypomagnesemia and hypocalciuria. Recent advances in the field of molecular genetics have demonstrated that this disease is caused by four genetically distinct abnormalities that result from mutations in renal electrolyte transporters and channels.

Renal Vein Renin Measurement as a Diagnostic Tool☆

Gian Paolo Rossi, University of Padua, Padua, Italy

Abbreviations

Ang	Angiotensin
DRC	Direct (active) renin concentration
PRA	Plasma renin activity
RAO	Renal artery occlusion
RPT	Renin-producing tumors
RVH	Reno-vascular hypertension
RVR	Renal vein renin
RVR	Renal vein renin ratio

Definition

The measurement of renin in the renal vein (RVR) blood has been a powerful tool to understand the pathophysiology of renovascular hypertension (RVH). Experience has shown that it is clinically useful for diagnosing this condition as well as for identifying renin-producing tumors.

Introduction

The first to report an understanding of the phenomenon by which renal ischemia can raise blood pressure was Johan Loesch, a physician born in 1897 in a province of the Austro-Hungarian Empire, emigrated to the United States. In 1927 Loesch published in the *Archives of Pathology* a preliminary report of his studies on hypertension induced by renal ischemia, which he had performed in the Physiatric Institute in Morristown, New Jersey (Glodny and Glodny, 2006). Loesch's findings and conclusions were eventually published in an article titled "A contribution to Experimental Nephritis and to Arterial Hypertension" in a German-language journal, *Zentralblatt für Innere Medizin*, in February 1933, 1 year before Harry Goldblatt's most famous work (see later). After publishing few other papers out of the field of hypertension, Loesch moved to private practice and left research and there were no other scientific traces of his work. His seminal work was totally neglected by the scientific community and rapidly forgotten.

In 1932 at the Academy of Medicine in Cleveland, Oh, Harry Goldblatt presented the results of several experiments that he and his colleagues had been performing during the previous 4 years by inducing renal ischemia in dogs (Goldblatt *et al.*, 1934). Apparently Goldblatt and his coworkers had no knowledge of Loesch's prior work. Goldblatt and colleagues had invented a clip to constrict the renal artery and succeeded in inducing persistent elevation of blood pressure by clipping one renal artery. These results were eventually published in the Journal of Experimental Medicine in 1934. Peyton Rous, who was later awarded the Nobel Prize, on behalf of his co-Editor-in-Chief fully recognized the importance of the manuscript they had received and in the letter of acceptance wrote: *It is a pleasure for us as editors to receive a paper of such large significance, so admirably written*.

This article is one of the most highly cited in the medical literature and stimulated more medical research than any single experiment in medical history. The experiment described by Goldblatt and colleagues not only demonstrated that a factor released by the ischemic kidney entails one of the most likely mechanisms by which persistent arterial hypertension occurs, but also indicated that the ischemia of to one kidney is a sufficient condition for the production of persistently elevated BP.

An enormous number of studies have thereafter proved beyond doubts the concept that renin, which had been discovered in Scandinavia about 40 years before Goldblatt's studies, is a major mediator of hypertension induced by renal ischemia has been. This has resulted into a huge number of procedures worldwide aimed at correcting arterial hypertension through relief of renal ischemia and renin over secretion, including surgical revascularization, percutaneous transluminal renal angioplasty (PTRA) and stenting (Harden *et al.*, 1997; Radermacher *et al.*, 2001; Van Jaarsveld *et al.*, 2000). Nonetheless, strangely enough, Goldblatt did not receive the Nobel Prize in Medicine.

Pathophysiologic Principles

The induction of renal ischemia is followed within few minutes by renin release, both within the kidney and in the renal vein blood. In the kidney, locally generated Ang II serves mainly to constrict the postglomerular (efferent) arterioles to maintain glomerular pressure and thus glomerular filtration rate despite the fall in renal perfusion pressure.

Micro-perfusion preparations in vivo have in fact unequivocally confirmed that Ang II is a more potent vasoconstrictor of the efferent than of the afferent arteriole and that this difference is mediated by nitric oxide (NO)- and prostaglandins (PG)-induced modulation of Ang II-vasoconstriction in the afferent arteriole. The vasoconstrictor effect of Ang II on the efferent arteriole is

☆*Change History:* January 2018. Gian Paolo Rossi made some minor updates to the text.

This article is an update of Achille Cesare Pessina, Gian Paolo Rossi, Renal Vein Renin, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 198-203.

 doi:10.1016/B978-0-12-801238-3.03981-7

known to be modulated by PG produced upstream in the glomerulus and, therefore, the intrarenal generation of Ang II and its interactions with renal autacoids are key determinants of glomerular hemodynamics and glomerular filtration rate (Arima *et al.*, 2003).

The fall of renal perfusion pressure, either induced experimentally or caused by a renal artery stenosis, determines an initial release of renin, which is followed by activation of renin synthesis in cell phenotypes, such as the vascular smooth cells in the afferent (preglomerular) arterioles wall, which, under physiological conditions, do not synthesize renin. The recruitment of these cells explains why both renin synthesis and renal renin content are markedly increased after induction of renal ischemia. As time goes, the increase of systemic arterial pressure triggered by enhanced Ang II generation, along with the stimulation of sodium reabsorption resulting from a direct tubular effect of Ang II and from stimulation of aldosterone synthesis and secretion, brings renin secretion back toward values that can be seen as normal, but in reality are inappropriately high for the prevailing level of blood pressure and volume status (Vaughan *et al.*, 1973).

Ang II also exerts strong additional effects in that it induces an increase of wall-to-lumen ration and media cross-sectional area of small (100–300 μm lumen diameter) arterioles, for example, hypertrophic remodeling, which, enhances the pressor effect of Ang II at no energy cost, the so-called Folkow's structural amplifier.

Because of this time course the chances of detecting an activated renin angiotensin system and high plasma renin are, from the clinical standpoint, high when the patient is seen soon after a given renal artery obstructive lesion has become hemodynamically relevant, but wanes off afterwards.(Lüscher *et al.*, 1986).

Accordingly, it can be easily understood why at the time of diagnosis up to one third of the patients with renovascular hypertension (RVH) do not have high plasma renin, both in the peripheral blood and in vein blood from the affected side, unless there is marked persistent renal ischemia as it occurs in those with total occlusion of a renal artery (Rossi *et al.*, 1997; Pickering *et al.*, 1986; Marks and Maxwell, 1975). For these reasons, after the initial enthusiasms the measurement of plasma renin in peripheral plasma and in renal vein blood as a tool to diagnose renal ischemia and to predict the outcome of revascularization has lost ground, even though it still has an important place in the diagnostic work-up of at least two conditions, total renal artery occlusion and renin-producing tumors.

Methodology

Patients Selection

Renal vein renin measurement (RVR) is an invasive procedure, albeit minimally so, which means that patients should be selected for this test based on high degree of suspicion (pretest probability) of RVH, which can be established by using the criteria of Mann and Pickering or recommendations from updated guidelines such as those from American Heart Association (Whelton *et al.*, 2017).

Patients Preparations for RVR Measurements

Multiple conditions and drugs can affect RVR levels (**Table 1**); therefore, adequate preparation of the patient is mandatory in order to achieve the best diagnostic accuracy of this invasive test. The patient should be on a normal sodium intake, as verified by measuring 24-h urinary sodium excretion on the day of the test. Furthermore, since renin secretion is controlled by the sympathetic nervous system, which undergo a circadian pattern of activity, ideally RVR studies should be performed in the morning,

Table 1 Preparations of the patient for RVR studies

1. Put on a normal Na intake (about 6.3 g NaCl or 130 mmol/day) for 1 week.
2. Measure 24-h Na^+/K^+ excretion on the day of the RVR study.
3. Perform the test in the morning between 8 and 12 a.m.
4. Keep the patient supine for at least 1 h prior and during the test.
5. Avoid any stress by explaining the procedure and use benzodiazepines.
6. Control blood pressure with a long acting calcium entry blocker and/or doxazosin.
7. Withdraw mineralocorticoid receptor antagonists (spironolactone, canrenone and potassium canrenoate and eplerenone) at least 6 weeks before the RVR study.
8. Withdraw the following drugs for at least 3 weeks prior to RVR study:
   - diuretics*
   - β-blockers
   - direct vasodilators (minoxidil, hydralazine)
   - ACE—inhibitors
   - AT-1 receptor antagonists (ARBs, sartans)

between 8.00 and 12.00 a.m., after the patient has been fasting overnight and kept lying quietly in the supine position for at least 1 h before the test.

The drugs that alter renin-secretion and, therefore, must be withdrawn for at least 3 weeks prior to the RVR testing are listed in **Table 1**.

Use of a long-acting calcium entry blocker, such as verapamil or a long-acting dihydropyridine compound, alone or combined with doxazosin, if necessary to achieve a decent blood pressure control before and during the test, can be allowed as these agents under chronic conditions negligibly affect renin secretion.

Catheter Placement

A previous angio computed tomography with renal vein anatomy reconstruction should be performed before RVR studies, as it can guide the interventionist in accomplishing selective catheterization of the renal veins and their branches, besides allowing identification of the underlying renal or renovascular disease.

Several factors (listed in **Table 2**), can concur to determine inaccurate results of RVR studies, thus increasing the number of false negative and positive results. Utmost care should, therefore, be exercised in obtaining blood selectively from the renal vein, a task which can be a difficult undertaking, because on venography blood flow is toward the catheter lumen, often leaving uncertainties as to exact positioning of the catheter's tip. Accordingly, it is not uncommon to draw diluted renal blood, for example, blood not draining solely from the kidney. Additional problems relate to the fact that (a) multiple renal veins are present in a substantial proportion (20%–28%) of patients on the right side and in much lower (1%–3%) proportion on the left side, thus setting the stage for collection of less "pure" renal vein blood on the right than on the left side; (b) the right renal vein is shorter than the left renal vein thus exposing more commonly to admixture of vena cava blood on the right than on the left side; (c) plasma drawn from the lower pole vein might not identify an upper pole (segmental) ischemia and vice versa.

Nonsimultaneous Sampling

The use of a single catheter for the sampling of both renal veins can expose to the risk of detecting a factitious gradient between the kidneys or sites of sampling if the interventionist is not fast enough, particularly if an abrupt change in renin secretion occurs between the time of sampling on different sides/sites. Therefore, bilateral catheterization with simultaneous blood sampling is advisable unless the time elapsing between sampling from the two sides can be kept within 5 min. Furthermore, it is necessary to avoid any maneuver that can increase abruptly renin secretion, such as stressful stimuli, or administration of drugs (**Table 1**).

Assay Variability

The measurement of plasma renin, as plasma renin activity, shows some variability (ranging between 8% and 20%), even in the same laboratory and in experienced hands, which should be kept in mind in interpreting the results of RVR. However, it has been estimated that RVR ratio greater than 1.4 would almost never occur simply on the basis of within assay variability.

With the newer chemiluminescent automated assays of immunoreactive active renin there are several advantages and less variability (Rossi *et al.*, 2016) mainly because these methods do not depend on the assumption that the generation of Ang I occurs

Table 2 Factors responsible for failure of RVR determinations to predict response to revascularization accurately

Mix-up of Samples
Problems Related to renal lesions
– Bilateral disease
– Branch or segmental disease
Problems related to renal vein catheterization
– Renal vein not catheterized
– Multiple renal veins
– Dilution of renal vein blood
● Short renal vein on the right
● Gonadal vein enters renal vein on the left
Problems related to renin secretion
– Blunted secretion (usually due to beta-blockers or non-steroidal antiinflammatory drugs)
– Declining secretion (elderly patients, long standing renal artery stenosis)
Nonsimultaneous sampling
Assay variability

with a zero order kinetic as the renin substrate (angiotensinogen) is present in large excess. In fact, this assumption may not be verified if renin production is very high as in total renal artery occlusion or renin-producing tumours. Moreover, the direct assay of active immunoreactive renin assay provides a measurement of the concentration (not the activity) of active renin (DRC) and therefore is, because of this, to be preferred when measuring high or very high renin values as typically occurs in RVR studies in patients with total renal artery occlusion and renin-producing tumors.

Summary of Recommendations

In summary, to gain maximal diagnostic information from RVR studies protocols should take into consideration the principles listed in **Table 3**.Criteria for Interpretation of Results of RVR Measurements

The results of RVR studies can be interpreted by using the four different indexes reported in **Table 4**.

According to studies performed at Cornell in the last decades of the last centuries, (Vaughan *et al.*, 1973; Pickering *et al.*, 1986) if a patient with unilateral hemodynamically relevant renal artery stenosis is seen during the first stage of the disease, for example, when renin is high, the renal venous-arterial renin difference relative to arterial levels from the affected (Visch-Viivc)/Viivc kidney should range between 0.24 and 0.50 and values >0.50 would indicate reduced renal blood flow.

Conversely, values of the renal venous-arterial renin difference relative to arterial levels from the unaffected (Vctl-Viivc)/Viivc kidney close to zero would indicate absent renin secretion, for example, contralateral suppression. According to these premises, a value of [(Visch-Viivc)/Viivc] + [(Vctl-Viivc)/Viivc] <0.50 should suggest either incorrect sampling or a segmental disease, and therefore the RVR study should be repeated with segmental venous sampling.

Some Critical Considerations on Use of Indexes Derived From RVR Measurements

These important studies have provided the framework for the proper interpretation of RVR studies. However, there are several situations in which this simple scheme cannot be applied, such as those with bilateral hemodynamically relevant renal artery obstruction and those with segmental renal artery stenoses. Furthermore, as discussed below, the usefulness of the (Visch-Viivc)/Viivc] and the (Vctl-Viivc)/Viivc indexes did not seem to provide better diagnostic information over the simpler RVR ratio (RVRR).

To date only one study from our group has prospectively investigated by up-to-date statistical procedures, such as the receiver operator characteristics (ROC) curve analysis, in relatively large populations of patients, the usefulness of the indexes derived from the measurement of RVR (Rossi *et al.*, 1997). Until then, this lack of information had generated some confusion as regards the optimal cutoff values. As an example, even the empirically derived most popular cut-off value of 1.5 for the RVRR was never tested for its accuracy with the ROC curve analysis. Furthermore, only limited information existed on the usefulness of RVR measurements in patients with total renal artery occlusion and with bilateral renal artery stenoses. Thus, it remained unclear which of these

Table 3 Recommendations for RVR studies

1. Meticulous labeling of specimen
2. Placement of catheter's tip selectively (deeply) into the renal vein
3. Collection of segmental venous blood, when clinically indicated
4. Performance of the test during steady state renin secretion
5. Simultaneous renal vein sampling (use of separate catheters)
6. Proper consideration to renin assay variability in interpretation of results
7. Preference should be given to DRC assays
8. Frequent interaction between clinician and interventionist

Table 4 Indices derived from RVR studies

A. Indices of lateralization of renin secretion

- RVRR = the ratio of affected and unaffected side, for example, the DRC value in renal vein blood from the ischemic kidney over the DRC value in renal vein of blood from the contralateral kidney
- (Visch-Viivc)/Viivc = the renal venous-arterial DRC difference relative to arterial[a] levels from the affected kidney

B. Indices of contralateral suppression of renin secretion

- Vctl/Viivc = the ratio of unaffected side and infrarenal inferior vena cava blood, for example, the DRC value in renal vein of blood from the contralateral kidney over the DRC value in blood from the inferior vena cava
- (Vctl-Viivc)/Viivc = The simultaneous renal venous-arterial[a] DRC difference relative to arterial levels from the unaffected kidney

[a]The values measured in the infrarenal inferior vena cava blood (Viivc) are usually taken as surrogate of the level in arterial blood. DRC = direct renin (active) concentration.

indexes furnished the best diagnostic accuracy and at which cut-off values the optimal combination of sensitivity and false positive rate can be accomplished.

Clinical Relevance

The RVR measurement was introduced in the clinical arena three decades ago to demonstrate a unilateral overproduction of renin and thus to establish a pathophysiological link between ischemia-triggered activation of renin synthesis, and high BP. The usefulness of RVR for predicting the blood pressure response to angioplasty or stenting has been confirmed also recently. Nonetheless, most investigators would now support the concept that lateralization of renin secretion is not a prerequisite for cure of hypertension upon revascularization. There is, indeed, a general consensus among experts that RVH can only be diagnosed retrospectively, for example, upon demonstration of either normalization of a significant fall of BP values after correction of renal ischemia, due to the lack of accuracy of all tests that have been proposed over the years to predict the outcome of renal revascularization. As regards RVR, this might be due to the fact that at least one third of patients with proven RVH do not have evidence of an activated renin-angiotensin system at the time of diagnosis.

Although some large clinical trials, including the CORAL and the ASTRAL, (ASTRAL Investigators *et al.*, 2009; Cooper *et al.*, 2014) would support the contention that endovascular treatment by means of PTRA plus stenting does not offer substantial advantages in the patients with atherosclerotic renal artery stenoses who do not have compelling indications for revascularization, (Hirsch *et al.*, 2006) the results of a meta-analysis indicate that endovascular treatment is superior to medical treatment at least for control of diastolic blood pressure and lowering the need for antihypertensive drugs (Caielli *et al.*, 2015).

Thus, currently PTRA and stenting should still be used as effective alternative to surgery for the treatment of renovascular hypertension (RVH), because they imply substantially lower risks and minor costs, as compared to surgery, and can be performed on the same occasion of diagnostic angiography. Furthermore, they can be safe and effective even in patients for whom surgery is deemed to be contraindicated, such as those with atherosclerotic ostial renal artery stenosis who can be at high risk due to a widespread atherosclerotic involvement.

Avoidance of RVR measurements could result into saving of time and money due to cutting of catheters and assay costs and therefore, which explains why RVR measurement has largely been abandoned.

Yet there are patients in whom this issue is still relevant, such as those with unilateral small kidney due to total renal artery occlusion and those with renin-producing tumors.

In the former patients nephrectomy remains the best therapeutic option and RVR measurement might be useful to pose the indication to surgery, as discussed below. In the latter patients, a clear-cut gradient of renin secretion can be the only clue to the identification of a small tumor. These tumors can be quite small and therefore may escape detection with CT, MR and even with angiography. Thus, in patients with biochemical evidence of secondary (renin-dependent) aldosteronism and no renal artery stenoses RVR studies with segmental sampling is mandatory.

Use of RVR Data in Clinical Practice

We have investigated several relevant issues concerning RVR by applying systematically the test over the years in patients undergoing digital subtraction angiography, because of a high pretest probability of RVH, with the specific aims of establishing the diagnostic accuracy of the indexes listed in **Table 4**. We focused our attention on the subsets of RVH patients with and without total renal artery occlusion and with unilateral and bilateral renal artery disease (Rossi *et al.*, 1997). Based on this study, answers to the following questions can be put forward.

Which is the Best Index Derived From RVR Measurements?

The RVRR, for example, the ratio between PRA in the ischemic over the contralateral site appears to be the index that provides the best discrimination between patients with and without RVH. The ratio (Visch-Viivc)/Viivc, albeit on average significantly different between patients with and without RVH, shows a greater overlap of values (Rossi *et al.*, 1997). When we examined the usefulness of the RVRR index for diagnosing RVH by ROC curve analysis we found that the area under the ROC curve was significantly higher than for the identity line. Thus, the RVRR furnishes an incremental gain for the diagnosis of RVH. In contrast, the two indexes of contralateral suppression (Vctl-Viivc)/Viivc and Vctl/A) do not provide a satisfactory discrimination between patients with and without RVH.

Can RVRR Allow Identification of RVH Due to Total Renal Artery Occlusion?

A significant proportion of RVH patients that are referred today to hypertension clinics can have a totally occluded renal artery and practically all of them have markedly elevated renin levels both in the peripheral blood, but much more so in the renal vein plasma of the affected side. This translates into a significantly higher ratio of the affected over unaffected side (RVRR), compared to the patients with stenotic (nonoccluded) RVH and to the patients without RVH (Rossi *et al.*, 1997). Thus, unambiguous evidence

of renin lateralization is strongly suggestive of a totally occluded artery and, therefore, RVR could be useful not only for distinguishing vascular (occluded) from nonvascular unilateral small kidney, an information also attainable with echo-color Doppler assessment of intrarenal artery blood flow, but also to establish the indication to nephrectomy.

Can RVRR Allow Identification of RVH Without Total Renal Artery Occlusion

The RVRR offers an incremental diagnostic value to diagnose RVH, but this might be mostly due to the contribution of the RVH patients with total renal artery occlusion. By examining this hypothesis, we could show a clear-cut shift to the left of the ROC curve, which unequivocally confirmed the usefulness of RVRR for diagnosing RVH due total renal artery occlusion. Of note, when patients with angiographic evidence of renal artery occlusion were excluded, there was a shift to the right of the ROC curve, indicating a decrease of the AUC. Thus, RVR identify far more accurately RVH with than without renal artery occlusion (Rossi *et al.*, 1997).

Can RVRR Allow Identification of RVH in Patients With Bilateral Renal Artery Lesions?

We investigated this question with the ROC curve analysis in the subsets of patients with unilateral and bilateral renovascular disease. We found that RVRR, as well as the other indexes, were more accurate in the former than in the latter patients (Rossi *et al.*, 1997). As mentioned above, even for bilateral renal artery lesions, this was particularly true for the identification of RVH caused by total occlusion of the renal artery. When patients without total occlusion of the renal artery were excluded, the AUC of the ROC curve did not differ significantly from the identity line for all indexes. Thus, this finding indicates that in the presence of bilateral lesions lateralization of renin secretion is detectable by RVR measurements only in the presence of a total renal artery occlusion.

What Is the Best Cutoff Value of the RVRR?

At the ROC curve and Youden index analysis we could find that the optimal cutoff value, for example, the value providing the best tradeoff between sensitivity and specificity, for the identification of RVH was 1.55. However, even in a selected population with a high prevalence of RVH this cutoff value corresponded to a low sensitivity (54%) and a relatively high false positive rate (15%) (Rossi *et al.*, 1997).

This finding was at variance with what discovered for identification of RVH due total renal artery occlusion. In this case the RVRR cutoff value that warranted the best combination of sensitivity (87%) and false positive rate (22%) was 1.70, for example, higher than that for identification of RVH. It can, therefore, be concluded that in patients with RVH due to total renal artery occlusion: (a) the RVR measurements can provide a conclusive diagnosis in the vast majority of the cases; (b) a higher cut-off value is needed to optimize diagnostic accuracy of RVR measurements-derived indexes.

Even with such cutoff value, which is higher than the commonly used 1.5 value, the false positive rate is 22%. This high rate is certainly not reassuring from the clinical standpoint and mandates some caution, particularly in the presence of RVRR close to but just above this value.

Since the detection of a unilateral small kidney at an abdominal ultrasound in hypertensive patients is not uncommon, these results are of importance for the following reason. The patients with a unilateral small kidney due to renal artery occlusion pose a special challenge from the therapeutic standpoint because, surgical revascularization can be preferred to nephrectomy, in that it provides a preservation of renal function when undertaken in cases with angiographically demonstrated distal reconstitution of the vessels and an evident nephrogram. However, even in these cases revascularization is often unsuccessful, because of coexistence of marked obliterative changes of the intrarenal vascular bed, and leads to a high rate of secondary nephrectomy. On the other hand, primary nephrectomy normalizes blood pressure in the vast majority of the patients with a unilateral small kidney due to total renal artery occlusion. Thus, prior knowledge of the RVR measurements can help to establish the indication for nephrectomy.

RVR in the Diagnosis of Renin-Producing Tumors

Renin-producing tumors (RPTs) are held to be rare as less than 160 cases have been reported in the literature since the first reported by Richmond (1964). These patients usually present with stage III and/or malignant hypertension, (Rossi *et al.*, 1993) but cases with milder phenotypes have been reported recently (Maiolino *et al.*, 2018). RPTs typically have high renin and hypokalemia due to secondary aldosteronism, but renin can be underestimated because of angiotensinogen consumption when using the PRA method and therefore it is possible that RPTs are much more common than usually held.

In line with this contention, at our institution after the replacement of the PRA with the DRC assay for measuring plasma renin we have diagnosed two RPTs in 6 months, which compares with two cases in the previous 30 years.

In both cases a first imaging (with CT and MR) was held to be inconclusive, and the diagnosis was made only after subsegmental RVR studies demonstrated a clear-cut increase of renin secretion from a given portion of the kidney. *Re*-evaluation of the CT then permitted to locate a 10 and 8 mm size tumor in the first and the second case, respectively.

Thus, RVR studies are fundamental to diagnose and locate these usually small tumors.

Conclusions

RVR measurements are most useful for identifying patients with a small unilateral kidney due to total renal artery occlusion and with renin-producing tumors. At variance, RVR measurements are of limited value for deciding on whether to undertake revascularization of a kidney with renal artery stenosis. Since nephrectomy provides the best chances of cure of hypertension in patients with a totally occluded renal artery, RVR measurements are useful for deciding on the indication for nephrectomy. Therefore, they should be performed whenever the clinical picture is suggestive of a small unilateral kidney due to total renal artery occlusion and/or of a renin producing tumor.

Interference With the Renin–Angiotensin System (RAS): Classical Inhibitors and Novel Approaches

Katrina M Mirabito Colafella, Erasmus MC, Rotterdam, The Netherlands and Monash University, Melbourne, VIC, Australia
Estrellita Uijl and AH Jan Danser, Erasmus MC, Rotterdam, The Netherlands

Classical RAS Blockers: Single Versus Combined Blockade

The renin–angiotensin system (RAS) is a major player in cardiovascular homeostasis, with its end-product angiotensin II inducing vasoconstriction, water and salt retention, aldosterone synthesis, and growth and remodeling. Not surprisingly given these effects, blockers of the RAS are now widely used for the treatment of cardiovascular and renal diseases. Currently, three types of such blockers are available for clinical application: renin inhibitors, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II type 1 (AT_1) receptor antagonists (ARBs), blocking, respectively, angiotensin I generation from angiotensinogen by renin, angiotensin II generation from angiotensin I by ACE, and the above-mentioned effects of angiotensin II mediated via its major receptor, the AT_1 receptor (**Fig. 1**). Although originally it was thought that these drugs interfered with angiotensin II in the circulation, it is now well-established that the beneficial effects of these drugs are largely due to blockade of the generation or action of angiotensin II at tissue sites (Danser, 2003). According to this concept, angiotensin II is generated at tissue sites rather than in circulating blood. Multiple lines of evidence support this idea (Campbell *et al.*, 1993; Klotz *et al.*, 2005; van Kats *et al.*, 2005, 2001). Remarkably however, although several RAS components are locally expressed (e.g., ACE, AT_1 and angiotensin II type 2 (AT_2) receptors) (Batenburg *et al.*, 2004; Tom *et al.*, 2003; van Esch *et al.*, 2005), thereby allowing such local activity, renin and angiotensinogen are not (Danser *et al.*, 1994, 1997). Thus, the renin required for local angiotensin production is sequestered from the circulation, that is, is kidney-derived, and the angiotensinogen is derived from the major, if not the only, angiotensinogen-synthesizing organ in the body, that is, the liver. Indeed, current data do not support a contribution of nonhepatic angiotensinogen, for example, in the kidney or adipocytes (Koizumi *et al.*, 2016; Matsusaka *et al.*, 2012).

Renal renin release is inhibited by angiotensin II through activation of juxtaglomerular AT_1 receptors, and thus, when blocking angiotensin II production or AT_1 receptors (with ACE inhibitors and ARBs, respectively), the kidneys will release more renin, to counteract the effect of the RAS blocker. As a consequence of the rise in renin release, plasma renin activity (PRA) will increase, sometimes to levels that are several-fold above baseline. A rise in PRA will of course result in a parallel

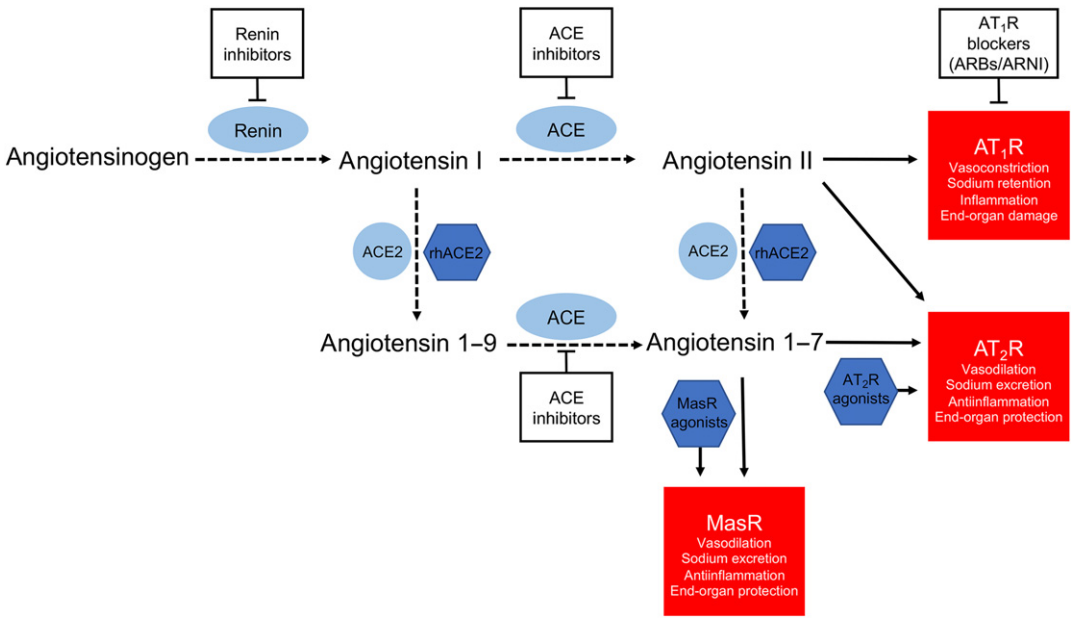

Fig. 1 Components of the renin–angiotensin system and main classes of pharmacological activators and inhibitors of the system. Angiotensin-converting enzyme (ACE); angiotensin-converting enzyme 2 (ACE2); angiotensin receptor blockers (ARBs); angiotensin receptor-neprilysin inhibitor, ARNI; angiotensin II type 1 receptor, AT_1R; angiotensin II type 2 receptor, AT_2R; recombinant human angiotensin-converting enzyme 2, rhACE2; Mas receptor, MasR.

rise in angiotensin I (Mooser *et al.*, 1990). During AT_1 receptor blockade, this rise in angiotensin I will lead to a similar rise in angiotensin II, whereas during ACE inhibition, the rise in angiotensin II will obviously be more modest. Depending on the degree of ACE inhibition however, angiotensin II levels may still return to or even rise above baseline (Campbell *et al.*, 1993; van Kats *et al.*, 2000). For instance, inhibiting ACE by 80% requires a fivefold rise in PRA to allow angiotensin II levels to return to normal.

Thus, plasma and tissue angiotensin II levels will not only rise during AT_1 receptor blockade, but often also following prolonged ACE inhibition ("angiotensin II escape"). During AT_1 receptor blockade, the rise in angiotensin II may result in AT_2 receptor stimulation. Since AT_2 receptors exert opposite effects as compared to AT_1 receptors (e.g., vasodilation) (Batenburg *et al.*, 2004), such AT_2 receptor stimulation has been proposed to contribute to the beneficial effects of AT_1 receptor blockers (Liu *et al.*, 1997). Nevertheless, under pathological conditions, AT_2 receptors may also induce constrictor responses (Verdonk *et al.*, 2015).

The rise in angiotensin II during ACE inhibition will result in activation of both AT_1 and AT_2 receptors. This activation probably occurs less efficiently than normal, since the majority of ACE is now inhibited (van Kats *et al.*, 2005). Normally, ACE generates angiotensin II in a highly efficient manner, in close proximity of AT_1 receptors (Saris *et al.*, 2002; Tom *et al.*, 2003). Consequently, little angiotensin II needs to be generated to obtain maximum (regional) AT_1 receptor stimulation. During chronic ACE inhibition, the increase in angiotensin I generation still allows angiotensin II generation by noninhibited ACE (possibly de novo synthesized ACE) or non-ACE converting enzymes like chymase (Tom *et al.*, 2003; Wei *et al.*, 1999). However, the latter type of angiotensin II generation is less likely to result in a high level of regional AT_1 receptor stimulation. In particular, angiotensin II generated by chymase (which is localized in the adventitia) will be subject to rapid metabolism in the interstitial space on its way to AT_1 receptors (de Lannoy *et al.*, 2001). Moreover, evidence for chymase-dependent angiotensin II generation in humans exclusively comes from studies in homogenized tissues, and whether chymase truly has any role in vivo remains to be proven.

Renin, unlike ACE, has only one substrate. As it is responsible for the first and rate-limiting step of the RAS cascade, without this enzyme (e.g., after a nephrectomy or in renin knockout animals) there are no angiotensins (Danser *et al.*, 1994). Thus, renin inhibitors, unlike ACE inhibitors and AT_1 receptor antagonists, will suppress both angiotensin I and II. As always during RAS blockade, this suppression of angiotensin II formation will result in a rise in renin. Due to the presence of the renin inhibitor however, such a rise in renin will not result in a rise in PRA, and this renin rise can therefore not be demonstrated by measuring the enzymatic (i.e., angiotensin I-generating) activity of renin. Therefore, to confirm this rise, renin must be measured directly, for example, with an immunoradiometric assay (Danser and Deinum, 2005). Importantly, renin rises during renin inhibition were found to be substantial, and increases of >300-fold have been noted (Balcarek *et al.*, 2014).

RAS inhibitors are potent antihypertensive drugs, with established cardiac and renal protective effects, related to and beyond their blood pressure lowering effect. These effects depend, at least in part, on their capacity to suppress aldosterone. Yet, following prolonged blockade, aldosterone levels often return to normal, due to the fact that angiotensin II is not the only aldosterone-regulating hormone, that is, other regulators (like K^+ and adrenocorticotropic hormone) now upregulate aldosterone synthesis. Based on their favorable renal outcomes, ACE inhibitors or ARBs are currently recommended as first-line treatment for patients with chronic kidney disease (CKD) (James *et al.*, 2014). However, effects on cardiovascular outcome and mortality are similar to that of other classes of antihypertensive drugs (Palmer *et al.*, 2015). Moreover, progression toward end stage renal disease is attenuated, but not prevented. Given the multiple feedback loops within the RAS, always allowing angiotensin II to restore its levels and/or effects, the idea has come up to use several RAS blockers in combination, for example in heart failure. There is a risk that such approaches may ultimately lead to RAS annihilation with adverse consequences such as hypotension, renal dysfunction and hyperkalemia (Danser and van den Meiracker, 2015; de Boer *et al.*, 2012). Important questions are therefore: what degree of RAS blockade should be achieved, and do we really need more than one agent for this? Theoretically, increasing the dose of a single RAS blocker should enable the desired degree of RAS blockade to be achieved, unless this dose increase results in adverse effects. For example, ACE inhibition can cause a rise in bradykinin levels, resulting in a dry cough. Continuous AT_2 receptor stimulation (as occurring during AT_1 receptor blockade) may not be beneficial in all patients. To what degree a several hundred-fold rise in renin is harmful is unknown. Increasing the dose of a single drug to an excessive level may therefore not be ideal; a better approach is to combine two or more RAS blockers at lower doses. Careful monitoring of blood pressure, renal function and hyperkalemia is required to determine the optimal number of RAS blockers for an individual patient (Nussberger and Bohlender, 2013). A worse outcome is to be expected in patients with low blood pressure and/or estimated glomerular filtration rate before the start of treatment, due to the fact the RAS is essential to preserve renal function and glomerular filtration. The kidneys will do everything possible to keep these in the normal range, including massive upregulation of renin during RAS blockade. This mechanism is referred to as the "nephrocentric" reaction to RAS blockade in patients with heart failure (Packer, 1987), and may ultimately even result in extrarenal angiotensin II upregulation.

In summary, the beneficial effects of RAS blockade are unequivocal, but the optimal degree of RAS blockade is not identical in each patient. Optimal RAS blockade may require more than one blocker, but simultaneously too intensive blockade of the RAS can be deleterious for the kidney, especially if renal function is already compromised when an additional RAS blocker is added. To solve this problem, either novel RAS-interfering agents might be considered (not blocking the classic renin/angiotensin II/AT_1 receptor axis), or the additional interference with hormonal systems beyond the RAS, like the atrial natriuretic system.

Novel RAS Interference: AT_2 Receptor and ACE2/Angiotensin-(1–7)/Mas Receptor Axis

AT_2 Receptor

The AT_2 receptor opposes all of the classical actions of the RAS mediated via the AT_1 receptor (**Fig. 1**). Preclinical studies have demonstrated that the AT_2 receptor exerts vasodilatory, natriuretic, antifibrotic, antiproliferative and antiinflammatory effects (Kaschina *et al.*, 2017; Mirabito Colafella *et al.*, 2016; Wang *et al.*, 2017). Expression of the AT_2 receptor is highest during fetal life and declines shortly after birth (Kaschina *et al.*, 2017). In general, females have greater expression of the AT_2 receptor as the gene encoding the AT_2 receptor is located on the X chromosome and the female sex hormones, estrogen and relaxin increase expression of the AT_2 receptor (Mirabito Colafella *et al.*, 2016). A polymorphism in the gene encoding the AT_2 receptor is associated with hypertension. During pathological situations including cardiac failure, cardiac fibrosis, renal failure, diabetes and atherosclerosis, expression of the AT_2 receptor may be upregulated (Kaschina *et al.*, 2017), suggesting that the AT_2 receptor plays a protective role in cardiovascular and renal diseases.

Compound 21 (C21)

Originally described in 2004, Compound 21 (C21) is the first selective nonpeptide AT_2 receptor agonist (Wan *et al.*, 2004). C21 is orally and systemically active and is ~4000-fold more selective for the AT_2 receptor than the AT_1 receptor (Bosnyak *et al.*, 2011). Cardiovascular, renal and neurological protective effects of C21 have been reported in various disease models, including stroke, obesity, ischemia–reperfusion injury, pulmonary hypertension, diabetic nephropathy and renal toxicity (Matavelli and Siragy, 2015). Similarly, C21 exerts protective cardiovascular and renal effects in genetic models of cardiovascular disease including the spontaneously hypertensive rat (SHR) and the stroke-prone-SHR (Kaschina *et al.*, 2017). C21 produces dose-dependent relaxation in isolated vessels from mice, rats and humans which is blocked by AT_2 receptor antagonism, although at high doses C21 can have off-target effects (Verdonk *et al.*, 2012). In vivo, C21-mediated vasodilation is usually only apparent in the presence of an ARB (Matavelli and Siragy, 2015). However, it was recently reported that chronic C21 treatment abolishes angiotensin II-induced hypertension in female rats without concomitant AT_1 receptor blockade (Kemp *et al.*, 2016). Within the kidney, C21 has potent diuretic and natriuretic effects which have been observed in normotensive, hypertensive and diabetic rodents (Kaschina *et al.*, 2017). AT_2 receptor stimulation with C21 reduces renal vascular resistance and enhances renal blood flow, urinary sodium and fractional sodium excretions without altering glomerular filtration rate. Moreover, the natriuretic effect of C21 involves changes in sodium'hydrogen exchanger 3 (NHE3) and Na^+/K^+-ATPase within the proximal tubule (Kemp *et al.*, 2016). C21 does not cross the blood–brain barrier. However, central AT_2 receptor stimulation with C21 inhibits sympathetic outflow, with decreases reported in renal sympathetic nerve activity and urinary norepinephrine levels in normotensive and hypertensive rats (Brouwers *et al.*, 2015; Gao *et al.*, 2014). Centrally administered C21 also reduced baroreflex sensitivity in rats with heart failure (Gao *et al.*, 2014). C21 has potent antifibrotic effects. Depending on the tissue, C21 elicits its antifibrotic effects via changes in transforming growth factor β1 (TGFβ1), matrix metalloproteinases, the NO/cGMP pathway and immune mediated mechanisms (Wang *et al.*, 2017). The antiinflammatory effects of C21 are mediated by changes in macrophage differentiation and infiltration, inhibition of the nuclear factor-κBα (NFκB) pathway, which modulates transcription of many cytokines, chemokines and vascular adhesion molecules including tumor necrosis factor-α, interleukin-1β and interleukin-6 and alterations in T-cell populations which are implicated in the pathogenesis of hypertension and cardiovascular and renal diseases (Kaschina *et al.*, 2017).

Interestingly, the majority of the protective effects of AT_2 receptor stimulation with C21 are blood pressure-independent, suggesting that C21 may not be suitable as an antihypertensive medication. However, C21 may be beneficial for end-organ protection in combination with established antihypertensive therapies due to its strong antifibrotic and antiinflammatory effects. Moreover, C21 may be a novel therapy for diseases where fibrosis and/or inflammation are significant aspects of the pathology. C21 has been granted orphan drug status for idiopathic pulmonary fibrosis and has completed stage 1 clinical trials to assess safety, tolerability, pharmacokinetics and pharmacodynamics in healthy men (Steckelings *et al.*, 2017) and in group of men with a compromised metabolic situation (body mass index of 30–35 and waist-to-hip ratio above 0.9; results are yet to be released).

Other AT_2 receptor agonists in development

Two novel AT_2 receptor agonists are currently undergoing phase 1 clinical trials. MP-157 (Mitsubishi Tanabe Pharma Corporation, Japan) is being developed as an antihypertensive therapy. MOR107 (formerly LP2; Lanthio Pharma, The Netherlands) has been reported to reduce alveolar septum and arterial wall thickness, and pulmonary inflammation in neonatal rats (Wagenaar *et al.*, 2013), and is being developed as an antifibrotic agent.

ACE2/Angiotensin-(1–7)/Mas Receptor Axis

The angiotensin-converting enzyme 2 (ACE2)/angiotensin-(1–7)/Mas receptor axis is an endogenous counter-current pathway to the classical RAS pathway (**Fig. 1**). ACE2 controls the pressor/depressor balance of the RAS by (i) converting angiotensin I to angiotensin-(1–9), limiting the amount of substrate available to generate angiotensin II, (ii) converting angiotensin II to angiotensin-(1–7), limiting angiotensin II stimulation of the AT_1 receptor and (iii) generation of angiotensin-(1–7), which is able to bind to its own receptor, Mas receptor or the AT_2 receptor, to oppose the pressor actions of the AT_1 receptor (**Fig. 1**) (Patel *et al.*, 2016). It should be noted that other enzymes can produce angiotensin-(1–7) from angiotensin I and II including neutral

endopeptidase and prolyl-endopeptidase (Santos, 2014). Once synthesized, angiotensin-(1–7) is rapidly broken down into inactive fragments via aminopeptidases and ACE (Santos, 2014).

The ACE2/angiotensin-(1–7)/Mas receptor axis has been shown to play protective roles in numerous disease models including heart failure, diabetic nephropathy, hypertension, liver disease and metabolic syndrome (Bernardi *et al.*, 2016; Moreira de Macedo *et al.*, 2014; Patel *et al.*, 2016; Rentzsch *et al.*, 2008; Ye *et al.*, 2006). In humans, ACE2 mRNA is upregulated in patients with heart failure. The protective effects of the ACE2/angiotensin-(1–7)/Mas receptor axis are primarily mediated by reductions in angiotensin II and proinflammatory cytokine release and inhibition of signaling pathways involved in tissue fibrosis (Rodrigues Prestes *et al.*, 2017). Similar to the AT_2 receptor, expression of the ACE2/angiotensin-(1–7)/Mas receptor axis is greater in females than in males (Mirabito Colafella *et al.*, 2016). The gene encoding ACE2 is located on the X chromosome and ACE2 polymorphism is associated with hypertension (Patel *et al.*, 2014). Furthermore, in women, the response to ACEi is influenced by ACE2 polymorphisms (Chen *et al.*, 2016). While there are numerous pharmacological strategies to enhance the ACE2/angiotensin-(1–7)/Mas receptor axis, including ACE2 supplementation/activators, angiotensin-(1–7) analogs and protection of angiotensin-(1–7) (encapsulated proteins) (Tamargo and Tamargo, 2017), the majority of these are limited to preclinical applications or have been withdrawn from clinical development.

Human recombinant ACE2 (rhACE2)

Preclinical studies have demonstrated that recombinant human ACE2 (rhACE2) has a half-life of ~8.5 h in mice (Wysocki *et al.*, 2010) and that rhACE2 exerts beneficial effects in murine models of cardiac hypertrophy, myocardial fibrosis and cardiac dysfunction (Zhong *et al.*, 2010). Furthermore, in male mice, rhACE2 was able to prevent angiotensin II-induced hypertension (Wysocki *et al.*, 2010). This effect was primarily attributed to circulating ACE2 activity and the lowering of plasma angiotensin II rather than the associated increase in plasma angiotensin-(1–7) (Wysocki *et al.*, 2010). Furthermore, in a model of diabetic nephropathy, rhACE2 reduced tubulointerstitial fibrosis and albuminuria and normalized blood pressure (Oudit *et al.*, 2010). Aside from its effects in cardiovascular and renal diseases, rhACE2 may be a novel therapy for acute lung injury. ACE2 deficient mice develop severe lung injury, which is ameliorated by treatment with rhACE2 (Gu *et al.*, 2016). Similarly, systemic administration of rhACE2 improved pulmonary hemodynamics and oxygenation in a lipopolysaccharide-induced model of acute respiratory distress syndrome in piglets (Treml *et al.*, 2010).

In 2013, the pharmacokinetic and pharmacodynamics characteristics of rhACE2 were first described in healthy men and women (Haschke *et al.*, 2013). The half-life of rhACE2 was ~10 h and in both men and women, rhACE2 reduced plasma angiotensin II and increased plasma angiotensin-(1–7) (Haschke *et al.*, 2013). This effect was apparent within 30 min of administration of rhACE2 and persisted for 24 h. Moreover, these effects were mediated without alterations in blood pressure or heart rate (Haschke *et al.*, 2013). However, it is important to note that this study was not powered to detect acute differences in physiology, rather, it was a proof of principle study. In 2017, a second clinical study with rhACE2 was reported in patients with acute pulmonary injury (Khan *et al.*, 2017). In this study, rhACE2 favorably altered the circulating RAS profile, reducing plasma angiotensin II and increasing angiotensin-(1–7) levels. However, rhACE2 did not improve physiological or clinical measures of acute respiratory distress syndrome. Consistent with the in vivo data, ex vivo treatment with rhACE2 effectively reduced angiotensin II levels and increased angiotensin-(1–9) and angiotensin-(1–7) levels in plasma and cardiac tissue samples collected from heart failure patients (Basu *et al.*, 2017). Collectively, these findings suggest that rhACE2 may be a promising drug for treatment of patients with intolerance to classical RAS inhibitors or in diseases where circulating angiotensin II is elevated.

Mas receptor agonists

Angiotensin-(1–7) has a short plasma half-life and is rapidly degraded in the gastrointestinal tract when given orally. The combination of hydroxylpropyl-β-cyclodextrin (HPβCD) with angiotensin-(1–7) (HPβCD/angiotensin-(1–7)) protects angiotensin-(1–7) from enzymatic degradation allowing angiotensin-(1–7) to be administered orally. Chronic oral administration of HPβCD/angiotensin-(1–7) lowered blood pressure and reduced markers of fibrosis (TGFβ1 and collagen type I) in rats following ischemia–reperfusion injury (Marques *et al.*, 2012). Moreover, HPβCD/angiotensin-(1–7) has been shown to have antiinflammatory effects in a model of atherosclerosis (Fraga-Silva *et al.*, 2014), and improved insulin sensitivity in a model of type 2 diabetes (Santos *et al.*, 2014). In humans, the HPβCD/angiotensin-(1–7) formulation allows the absorption of angiotensin-(1–7), and is safe and well-tolerated. Future clinical trials are now needed with HPβCD/angiotensin-(1–7) to determine its efficacy as a novel treatment for cardiovascular and renal diseases.

Interference With Systems Beyond the RAS: The Natriuretic Peptide System

Like the RAS, the natriuretic peptide system primarily regulates salt, fluid and pressure homeostasis (Zois *et al.*, 2014). In this respect, it can be perceived as an endogenous counterbalance of the RAS. Main effector molecules include A-type (atrial), B-type (brain) and C-type natriuretic peptide, as well as urodilatin. Via their second messenger cyclic guanosine 3′5′monophosphate (cGMP), natriuretic peptides not only counter the RAS by stimulating natriuresis, diuresis and vasodilation (Wong *et al.*, 2017), but also by directly inhibiting renin secretion (Kurtz *et al.*, 1986). Furthermore, cGMP improves myocardial relaxation and reduces cardiac hypertrophy (Tsai and Kass, 2009). Reinforcement of the natriuretic peptide system is therefore a rational and promising strategy to lower blood pressure and prevent complications in patients with essential hypertension.

Natriuretic peptides are degraded by neprilysin (neutral endopeptidase; NEP). Therefore, in the past, NEP inhibitors have been pursued as a potential new class of antihypertensive drugs. However, NEP degrades many enzymes, among which not only vasodilators (e.g., natriuretic peptides, bradykinin and adrenomedullin), but also potent vasoconstrictors (e.g., angiotensin II and endothelin-1) (**Fig. 2**). Hence, monotherapy with NEP inhibition can even raise blood pressure, as was shown in healthy individuals (Ando *et al.*, 1995). Consequently, subsequent strategies involved prolonging activation of the natriuretic peptide system by NEP inhibition on top of RAS blockade. This combination would hold the beneficial effects of increasing natriuretic peptides, while preemptively countering the harmful effects of a NEP inhibitor-induced rise in angiotensin II. The combination of ACE/NEP inhibition was attempted first, and successfully lowered blood pressure. However, both ACE and NEP inactivate bradykinin. As a consequence, dual inhibition often caused angioedema due to increases in bradykinin, prompting discontinuation of drug development (Kostis *et al.*, 2004; Packer *et al.*, 2002). Hence, a better approach is to combine an ARB with a NEP Inhibitor (ARNI). Still, the dose of the NEP inhibitor in this combination remains critical: when dosed too high, endothelin-1 levels start to increase, resulting in a rise in blood pressure (Roksnoer *et al.*, 2015).

Randomized controlled clinical trials demonstrated that ARNI is superior to the ARB valsartan in the treatment of patients with essential hypertension (Ruilope *et al.*, 2010), and also to the ACEi enalapril in patients with heart failure with reduced ejection fraction, in whom this treatment reduced hospitalization and mortality related to progression of disease (McMurray *et al.*, 2014). This led to the current registration of ARNI for this patient population (Ponikowski *et al.*, 2016). While simple RAS blockade is known to improve survival in patients with heart failure with reduced ejection fraction, it has little or no effect in patients with heart failure with preserved ejection fraction (Zheng *et al.*, 2018). However, a phase II trial in this patient population demonstrated a greater, albeit transient, reduction in N-terminal-proBNP at 12 weeks of treatment with ARNI, when compared to valsartan (Solomon *et al.*, 2012). Although this difference was no longer significant at 36 weeks of treatment, at this time point, ARNI superiorly reduced left atrial width and volume, echocardiographic indicators of diastolic dysfunction. Hence, the effect of ARNI on mortality in patients with heart failure with preserved ejection fraction is of great interest and currently under evaluation in a phase III clinical trial (Solomon *et al.*, 2017).

Interestingly, a post-hoc analysis revealed that estimated glomerular filtration rate was better preserved in patients with heart failure after ARNI, when compared to ARB (Voors *et al.*, 2015). In contrast, evaluation of urinary albumin-to-creatinine ratio

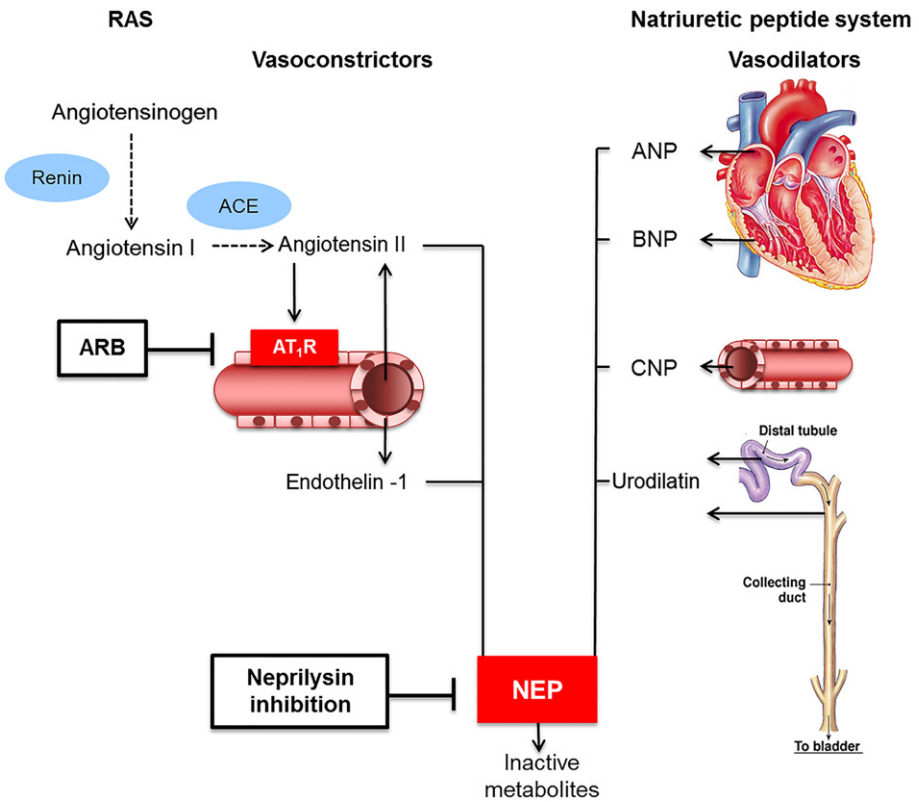

Fig. 2 The angiotensin II type 1 (AT_1) receptor-neprilysin (NEP) inhibition ("ARNI") concept. NEP degrades vasodilators (e.g., A-type (atrial) natriuretic peptide (ANP) produced by atrial myocytes, B-type (brain) natriuretic peptide (BNP) produced by ventricular myocytes, C-type natriuretic peptide (CNP) produced by endothelial cells, and urodilatin produced by the distal convoluted tubule and the collecting duct) as well as vasoconstrictors (e.g., angiotensin II and endothelin-1 produced by endothelial cells) into inactive metabolites. Dual NEP inhibition and AT_1 receptor blockade (ARB) would result in sustaining the beneficial effects of upregulated natriuretic peptides, while not suffering from the harmful consequences of the upregulation of angiotensin II that will simultaneously occur. RAS, renin–angiotensin system.

demonstrated a small but significant increase after ARNI. However, baseline albuminuria was very low in these patients. Furthermore, ARNI treatment did reduce proteinuria in patients with CKD, particularly in those with macroalbuminuria (Ito *et al.*, 2015). Indeed, in rats with severe diabetic, hypertensive kidney damage, greater beneficial effects on proteinuria and glomerular sclerosis were observed after ARNI, when compared to ARB, despite a similar effect of these treatments on blood pressure (Roksnoer *et al.*, 2016). This suggests that ARNI exerts a renoprotective effect, independent of its antihypertensive properties. Possibly, this relates to improvements in glycemic regulation, since ARNI lowered hemoglobin A1c values in patients with heart failure and diabetes (Seferovic *et al.*, 2017), and increased insulin sensitivity in patients with hypertension (Jordan *et al.*, 2017). Most of the pathways proposed to mediate kidney damage due to increased blood glucose levels hold activation of the profibrotic agent TGFβ1 in common as an intermediary step (Ziyadeh, 2004). In addition to a reduction in TGFβ1 upregulation directly related to lower blood glucose levels, ARNI treatment could prevent nuclear localization of TGFβ1 due to augmented half-life of atrial natriuretic peptide (Li *et al.*, 2008), and thereby counteract the effects of TGFβ1 activation at the postreceptor level. The safety and efficacy of ARNI in patients with CKD are currently being studied in a phase III clinical trial (HARP, 2017).

Conclusion

Classical RAS blockers are well-established drugs for the treatment of cardiovascular and renal diseases. Contrary to what was originally thought, more blockade (e.g., by using multiple blockers at the same time) is not necessarily better, and rather results in more side effects. Thus, we either need novel approaches to interfere with the RAS (e.g., stimulate the protective receptors AT_2 and Mas), or combine RAS blockade with drugs that additionally stimulate other, protective hormonal system, like NEP inhibitors. An example of the latter is the ARNI approach, which is now successfully applied in heart failure.

Aldosterone; Synthesis and Metabolism

John W Honour, University College London, London, United Kingdom

Glossary

Aldosterone A steroid hormone synthesized in the zona glomerulosa of the adrenal cortex; the major mineralocorticoid in humans.

Mineralocorticoid Corticosteroid hormone secreted by the adrenal gland and exerting its function through the mineralocorticoid receptor; also referred to as a hormone that affects water and electrolyte homeostasis.

Renin It is a key enzyme of the renin–angiotensin–aldosterone system (RAAS), cleaving angiotensinogen to angiotensin I and thereby having an impact on the synthesis rate of the effector hormone of the RAAS, angiotensin II. The RAAS is a hormone system that plays a central role in the control of sodium excretion, fluid volume, and vascular tone, thus controlling blood pressure.

StAR steroidogenic acute regulatory protein Is a transport protein for cholesterol into the mitochondria, a rate-limiting step in the synthesis of steroids.

HSD3B2-3β-hydroxysteroid dehydrogenase δ5-δ4 isomerase (HSD3B2) belongs to the family of oxidoreductases and is an enzyme that catalyzes the formation of progesterone from pregnenolone.

Cytochromes P450 Are proteins of the superfamily containing heme as a cofactor. In the adrenals they are terminal oxidase enzymes in electron transfer chains with NADPH. Hydroxylation reactions use CYP450 enzymes.

Aldosterone synthase CYP11B2 is a member of the cytochrome P450 family of enzymes. The protein only expresses in the zona glomerulosa cells of the adrenal cortex. It catalyzes 11-hydroxylation of deoxycorticosterone (DOC) to corticosterone then 18-hydroxylation and oxidation of that group to the C-18 aldehyde.

Calcium signaling Is required to maintain intracellular concentrations of calcium. Transfer of calcium ions from the extracellular to the intracellular compartment in both directions alters membrane potential of the cell. Calcium ions can be released from intracellular stores, imported, and exited through membrane ion channels. The activities and expression of StAR and CYP11B2 are stimulated at higher calcium concentrations in the mitochondria.

Introduction

The outer layer of the adrenal cortex, the zona glomerulosa, is responsible for the synthesis of aldosterone, although new sites are now recognized, notably adipose, cardiac, and vascular tissues. The glomerulosa cells, when highlighted through specific protein expression, are now seen as small clusters under the capsule rather than what used to be described as a discrete layer. This zona glomerulosa lacks expression of the cytochrome 17α-hydroxylase which is important for cortisol synthesis in the zona fasciculata. The protein also expresses 17,20-lyase activity leading from steroids with 21 carbon atoms to male sex hormones with 19 carbon atoms. Cytochrome P450 enzymes are important in steroidogenesis; these are proteins of about 500 amino acids with a heme group that absorb light at 450 nm (as their name implies) in their reduced states complexed with carbon monoxide. The proteins are denoted with the prefix CYP and the genes are in italics, hence *CYP*. The mechanisms covered in this article have been examined at the molecular genetic level in the search for the basis of primary aldosteronism (see Bandulik, 2017).

Cholesterol

Aldosterone, like other steroid hormones, is synthesized from cholesterol. Most of the cholesterol derives through a receptor-mediated endocytosis uptake of low-density lipoprotein (LDL) into vesicles that fuse with lysosomes. Cholesterol can be esterified by acyl-CoA cholesterol acyl transferase (ACAT) and stored in lipid droplets. Hormone sensitive lipase (HPL) will liberate free cholesterol. There is intracellular trafficking of cholesterol between touching membranes and by cholesterol binding proteins. Steroidogenic acute regulatory protein (StAR) facilitates the transfer of cholesterol from the outer to the inner mitochondrial membrane. Several related proteins called StAR-related lipid transfer proteins (START) are likely involved in intracellular cholesterol transfer. Within the START family, there are a number of START domain proteins (StARD) of which StARD4 and 5 are likely involved in cholesterol transfer. The mechanisms of cholesterol transfer in adrenal cells are not well understood and further debate is not needed in this review. Further discussion can be found in a comprehensive review on the initial steps of steroid synthesis (Miller, 2017). Some clinical disorders (Smith–Lemli–Opitz syndrome, Wolman disease, Nieman–Pick C syndrome (NPC)) have given clues for the involvement of other cholesterol transfer steps like NPC1 and NPC2, SNARE (soluble NSF attachment protein receptor) and oxysterol binding protein. Other proteins may be involved in cholesterol movement into the mitochondria. The benzodiazepine receptor

(translocator protein TSPO) and its ligand, the AT-binding cassette subfamily D (ABCD1) and sterol carrier protein 2 (SCP2), may act as a docking site for StAR but more research is required to delineate all the players in cholesterol transport.

The side chain of the 27-carbon cholesterol is reduced in length to the 21-carbon pregnenolone in mitochondria, which is converted to progesterone and deoxycorticosterone (DOC) in the endoplasmic reticulum. The final steps from DOC to aldosterone are achieved with one mitochondrial enzyme, aldosterone synthase (Fig. 1). Three of these reactions are performed by cytochromes with different cofactor needs.

Pregnenolone

Steroidogenic acute regulatory protein increases the transfer of cholesterol into the mitochondrial inner membrane where a cytochrome P450 for side chain cleavage (scc) enzyme is located. The conversion of cholesterol to pregnenolone involves 22-hydroxylation of cholesterol, 20-hydroxylation of 22R–hydroxycholesterol, and cleavage of the C20 to C22 bond with release of isocaproaldehyde and pregnenolone. Cytochrome P40 scc (desmolase) requires electrons from a flavoprotein called adrenodoxin reductase, an iron sulfur protein called ferredoxin and NADPH. The expression of scc requires the action of the zinc-finger transcription factor, steroidogenic factor 1 (SF1).

Progesterone and Deoxycorticosterone

In the endoplasmic reticulum of the zona glomerulosa cells, pregnenolone is converted to progesterone with oxidation of the 3β-hydroxyl to a ketone and switch in the double bond in the B-ring to the A-ring by 3β-hydroxysteroid dehydrogenase and Δ5–Δ4 isomerase (shift in the double bond from C5 to C4). NAD is the cofactor for this enzyme. A microsomal P450 enzyme (CYP21A2 or CYP21B) catalyzes the C-21 hydroxylation of progesterone to DOC. This enzyme receives electrons from NADPH via a flavoprotein called cytochrome P450 (POR). In evolution, the gene has become duplicated (CYP21A1P or CYP21A), although mutations in the second gene prevent transcription of active protein. Exchange between the two genes is common which is the basis for some cases of 21-hydroxylase deficiency.

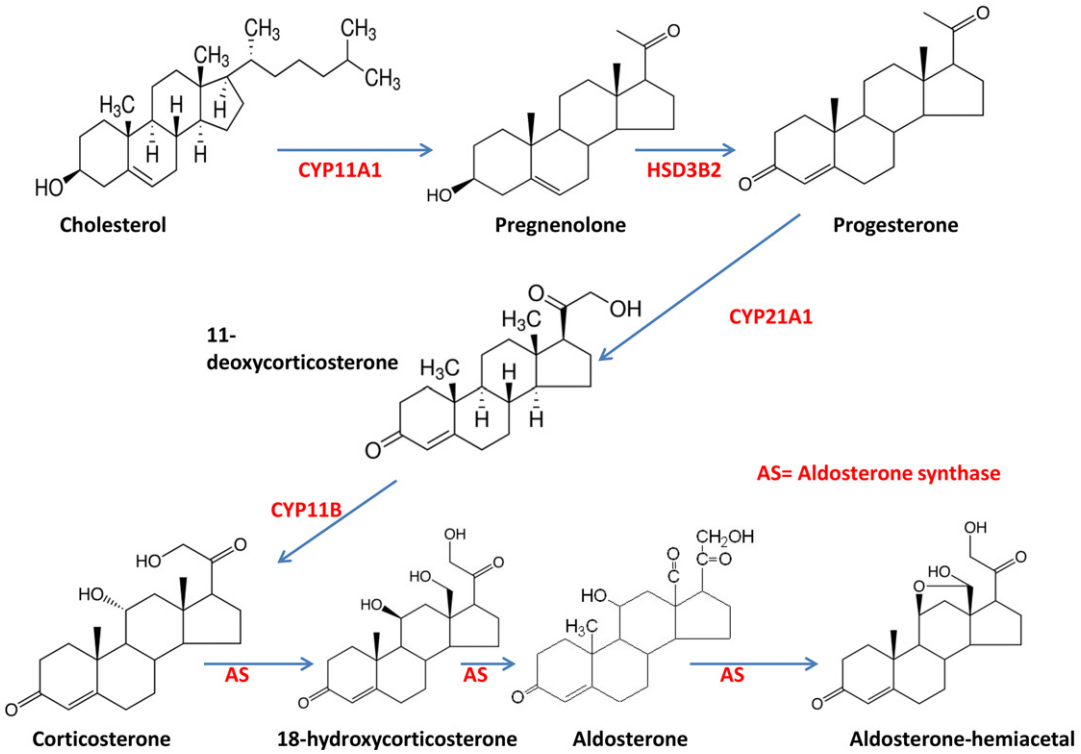

Fig. 1 Aldosterone biosynthesis.

Aldosterone via Corticosterone

The actions of a mitochondrial enzyme are required to complete the synthesis of aldosterone. CYP11B1 is active in the zona glomerulosa and the fasciculata to introduce a 11β-hydroxyl group to DOC or 11-deoxycortisol, respectively, yielding corticosterone or cortisol. In the zona glomerulosa, CYP11B2 (aldosterone synthase) catalyzes 11 hydroxylation, 18-hydroxylation, and oxidation to a C-18 aldehyde (corticosterone methyl oxidase). Both enzymes use ferredoxin, ferredoxin reductase to transfer electrons from NADPH. SF1 and other transcription factors such as NURR1 and NGF1B are needed. This is the late rate-limiting step of aldosterone synthesis.

Regulation of Aldosterone Production

Many factors are involved in the regulation of aldosterone production (summarized in Fig. 2). Aldosterone synthesis is mainly controlled by changes of the membrane potential and calcium homeostasis. The activities and expression of StAR and CYP11B2 are stimulated at higher calcium concentrations in the mitochondria. The cytosolic concentrations of glomerulosa cells are about 100–200 nmol, whereas the extracellular calcium concentration is 1–2 mmol. The sodium/calcium exchanger (NCX) and plasma calcium ATPases (PMCA) export calcium to maintain the resting low calcium concentration. Calcium influx is controlled by store-operated channel (SOC) and two voltage-activated calcium channels (CaV) which are activated by depolarization of the cell membrane. T type CaV is partially open at resting potential, but the L-type CaV is closed at resting potential and opened at higher levels of membrane depolarization. The membrane potential and cytosolic calcium concentrations depend on the actions of

potassium channels (TASK or KCN), calcium channels (CaV), sodium/potassium exchangers (ATP1A1), sodium/calcium exchanger (NCX), sodium/hydrogen exchanger (NHE), and plasma membrane calcium ATPases (PMCA). The specific contributions of these pathways to calcium signaling in glomerulosa cells are largely unknown. More detail can be found in a 2014 review by Bollag.

Angiotensin II

Angiotensin II (AII) in the human binds to a membrane AII receptor type 1 (AT1R). The activated receptor in turn couples to G-protein $G_{q/11}$ and this activates phospholipase C (PLCβ) to stimulate inositol triphosphate (IP3) production and diacylglycerol which through specific receptors in the ER generates a calcium release signal from the ER storage site. An α-subunit of the G-protein, with intrinsic GTPase activity, dissociates from the β-subunit. A diacylglycerol lipase releases arachidonic acid and this is converted to further prostaglandin metabolites (HETE) that increase cytosolic calcium concentration, mitogen-activated protein kinase (MAPK), phospholipase C, and cAMP response element binding (CREB). AII depolarizes the cell membrane and inhibits the TASK potassium channels that maintain resting potassium concentrations. AII also inhibits the NA/K ATPase (ATP1A1). Depolarization of the membrane also activates voltage-dependent calcium channels (CaV). The increase in the cytosolic Ca^{2+} concentrations promotes binding of calcium to activate calmodulin which then stimulates calmodulin-dependent kinases (CAM) which in turn triggers cellular responses such as stimulation of protein kinase C, mitochondrial production of NADPH, activated transcription factors CREB, NURR1, and NGF1B, activation of StAR by phosphorylation, and expression of CYP11B2 through cAMP-dependent response elements in the 5′ region of the *CYP11B2* gene. A low sodium diet leads to upregulation of AT1R levels which affects a physiological response to increase aldosterone production.

Angiotensin II can also bind to angiotensin II receptor type 2 (AT2R). This protein has 34% sequence homology to AT1R and expression widely in fetal tissues then restricted to brain, adrenal, heart, kidney, myometrium, skin, and ovary. Expression has been increased in pathological conditions such as vascular injury, myocardial infarction, renal failure, and brain ischemia. The mechanisms of action are not clear but Gi protein coupling, activation of serine/threonine phosphatase PP2A, phosphotyrosine phosphatase, phospholipase, release of bradykinin, and nitric oxide have been reported. Cyclic GMP mediates actions of nitric oxide leading to vasodilatation and natriuresis.

Potassium and ACTH

In addition to the renin–angiotensin system which is the major regulatory mechanism, adrenocorticotrophic hormone (ACTH) provides a transient control mechanism. The plasma potassium concentration also influences aldosterone synthesis. A small increase in extracellular K^+, when potassium efflux is prevented from efflux through the G-protein-activated inward rectifier potassium channel 4 (GIRK4), causes membrane depolarization increasing intracellular calcium concentrations which increases expression of genes for aldosterone synthesis. Conversely hypokalemia inhibits aldosterone synthesis. Potassium acts through several signaling steps (TASK, ATP1A1).

Adrenocorticotrophic hormone binds to the melanocortin receptor MC2R to stimulate cyclic AMP production via the heterotrimeric G-protein G_s which activates protein kinase A and cAMP-dependent protein kinase which increases hormone sensitive lipase as well as increasing StAR and aldosterone synthase gene expression via NURR1 and NGF1B.

Calcium Homeostasis

From the preceding discussion, aldosterone secretion will be clearly influenced by calcium homeostasis. The plasma-ionized calcium concentration is regulated to within very narrow limits (1.3–1.5 mmol/L). This is achieved by both the parafollicular cells of the thyroid gland, and the parathyroid glands sensing the concentration of calcium ions in the blood flowing through them. When the concentration rises the thyroid gland increases the secretion of calcitonin into the blood. At the same time the parathyroid glands reduce their rate of parathyroid hormone (PTH) secretion into the blood. The resulting high levels of calcitonin in the blood stimulate the skeleton to remove calcium from the blood plasma, and deposit it as bone. The reduced levels of PTH inhibit removal of calcium from the skeleton. The low levels of PTH have several other effects: loss of calcium in the urine increases, and loss of phosphate ions via that route is inhibited. Phosphate ions will therefore be retained in the plasma where they form insoluble salts with calcium ions, thereby removing them from the ionized calcium pool in the blood. The low levels of PTH also inhibit the formation of calcitriol (1,25 dihydroxyvitamin D_3) from cholecalciferol (vitamin D_3) by the kidneys. The reduction in the blood calcitriol concentration acts (comparatively slowly) on the epithelial enterocytes of the duodenum inhibiting their ability to absorb calcium from the intestinal contents. The low calcitriol levels also act on bone causing the osteoclasts to release fewer calcium ions into the blood plasma.

When the plasma-ionized calcium level is low the opposite happens. Calcitonin secretion is inhibited and PTH secretion is stimulated, resulting in calcium being removed from bone to correct the plasma calcium level. The high plasma PTH levels inhibit calcium loss in the urine and stimulate the excretion of phosphate ions by that route. The kidneys secrete calcitriol, which

enhances calcium absorption from the intestinal contents into the blood, by stimulating the production of calbindin. The PTH-stimulated production of calcitriol also causes calcium to be released from bone into the blood, by the release of RANK1 (a cytokine) from the osteoblasts which increases the bone resorptive activity by the osteoclasts, although these are relatively slow processes. Hence, regulation of the plasma-ionized calcium level primarily involves rapid movements of calcium into or out of the skeleton in the short term. Longer term regulation is achieved by regulating the amount of calcium absorbed from the gut or lost via the feces. Studies in animals and humans have shown that vitamin D decreases activity of the R–A system by suppressing expression of the renin gene via a cis-DNA element in renin production. This is independent of calcium metabolism.

Actions of Aldosterone

Aldosterone controls blood pressure through blood volume and sodium homeostasis. Aldosterone acts at the distal nephron, salivary glands, and colon. A target cell is entered by passive diffusion of aldosterone, and then reacts with the mineralocorticoid receptor (MR) which is complexed with a dimer of heat shock protein and other proteins such as cyclophilin and FKBP52. This complex dissociates on aldosterone binding and as a homodimer translocates to the nucleus, where they bind to response elements of aldosterone sensitive genes. The transcribed proteins then stimulate the synthesis and activity of sodium channels and pumps to influence sodium transport inward. This is covered elsewhere.

An essential aspect of the MR is the colocalization of an enzyme 11β-hydroxysteroid dehydrogenase type 2 (HSD3B2) that inactivates cortisol to cortisone preventing any effect of cortisol on the MR. This is covered in detail elsewhere.

The Renin–Angiotensin–Aldosterone System

In the juxtaglomerular apparatus of the kidney, low plasma sodium concentrations or low renal blood flow stimulates release into the circulation of renin from prorenin. Renin, a proteolytic enzyme, then acts on angiotensinogen to free a 10-amino acid angiotensin I (once considered inert). Angiotensinogen is synthesized in the liver. A further two amino acids are cleaved, at several sites including the lung, from AI to produce AII by angiotensin converting enzyme (ACE). AII has two actions, firstly as the most potent vasoconstrictor but secondly at the adrenal cortex it binds to the angiotensin receptor to stimulate aldosterone secretion as described in detail earlier.

The Renin–Angiotensin–and Other Angiotensins–Aldosterone System

In recent years, our understanding of the RAAS has been extended with the knowledge of the generation of angiotensin peptides downstream of AII. [A(1–8)] is a product of ACE action and is then converted to A(1–7) by the angiotensin converting enzyme ACE2 through the identification of A(1–7) and the enzyme for this conversion, ACE2. This enzyme can also convert AI [A(1 − 10)] to A(1–9)]. The A(1–7) binds to a mas receptor (MrgD-R) that leads to inhibition of MAPK, stimulation of cellular phosphatase, inhibition of cyclooxygenase 2 (COX2), and facilitation of nitric oxide release. A(1 − 7) is implicated in the pathogenesis of cardiovascular diseases. A(1 − 8) acts at the AT2R. A peptide A(1 − 12) has also been discovered as a carboxyl-terminally extended AI with valine and isoleucine. A(1 − 12) is present in plasma and tissues including aorta and kidney. A(1 − 12) is converted to AII by chymase in the heart. The conversion of A1 to A(1–12) has been proven in rat aorta experiments. AII can also be converted to AIII [(A(2–8)] and AIV [A(3–8)] by aminopeptidases A (APA) and N (APN), respectively. AIV can be further cleaved to A(5–8) by endopeptidase and A(5–7) by carboxypeptidase (CPP). AIV inhibits the insulin receptor aminopeptidase (IRAP). The AIV/IRAP axis induces the release of nitric oxide and promotes antiinflammatory and antifibrotic effects. Dipeptidyl peptidase III (DPP III) cleaves two amino acids from the N-terminus of AIV and A(3 − 7) to give A(5 − 8) and A(5 − 7) oligopeptides. Angiotensin A is a newly characterized peptide related to AII with Ala instead of Asp in the first position of the sequence generated by aspartate decarboxylase. Alamandine is A(1–7) with alanine instead of aspartate in the first amino acid position that binds to a novel G-protein-coupled receptor Mas (MrgD). Angioprotectin is like AII with Pro and Glu instead of Asp and Arg. Angioprotectin has high affinity for the mas receptor and has vasorelaxing properties. There is evidence for an intrarenal renin angiotensin system (RAS) as a local feed-forward system for augmentation of intrarenal generation or action of RAS that plays a role in pathogenesis of hypertension and renal disease. There are several components such as PRR, Wnt/β-catenin signaling, and PEG2/EP4 as positive elements and Klotho, VDR, and LXR in the negative arm. These discoveries open potential for the development of new drugs.

The RAAS is continually being revised and at August 2017 there are now five axes identified:

- the classical angiotensin-renin–ACE–AII–AT1R-aldosterone axis
- the prorenin receptor (PRR)–mitogen activated protein (MAP)–kinase pathway
- the AIII-APN-AIV-IRAP-AT4 receptor axis
- the AII-APA-AIII -AT2R-NO-cGMP axis where ATR2 is the angiotensin II receptor type 2, NO is nitric oxide, and cGMP is cyclic GMP
- the AI-AII-ACE2/ang(1–7)-mas receptor axis

The first three axes are powerful vasopressor systems, whereas the others are vasodepressor and cardiorenal protective axes. The effects have been described as Devil/Angel or Yang/Yin of vasoactive systems. The action of angiotensin II through ATR2 is independent of aldosterone.

The idea that AII is the only active peptide of the RAAS is outdated because angiotensinogen is the source of several peptides with new biological actions in adrenal, cardiac, renal, and brain tissues and our understanding of their roles in pathophysiological states is incomplete.

Catabolism and Excretion of Mineralocorticosteroids

Hormones circulating in plasma are inactivated by metabolism primarily in the liver. Conjugation with glucuronic or sulfuric acid also in the liver is important to increase the solubility of steroids prior to renal extraction and excretion in urine.

There are two major pathways of steroid catabolism in the liver:

(1) Reduction of the double bond at C-4 with accompanying reduction of the 3-keto group to a secondary alcohol group—add four hydrogens (tetrahydro products). 5α and 5β-reductases are involved—androst-4-enes to 5-androstanes (dihydro-) followed by 3α-hydroxysteroid dehydrogenase.
(2) Reduction of the 20-keto group to a secondary alcohol group (if after tetrahydro steroid formation gives hexahydro product). 20α and 20β reductases.

Oxidative cleavage of the side chain is confined to 17-hydroxy C21 steroids. Hydroxylation of the aldosterone nucleus has been demonstrated as for other steroids at C2α, 6β, 19 but not 1,7,15,16. 21-Deoxy and 19-nor aldosterone have been identified.

Aldosterone metabolites are conjugated and excreted mainly as glucuronides but also as sulfates at the C3 and C21 positions.

Hepatic Catabolism of Mineralocorticosteroids

Reduction of the "A"-ring to form a 3α-hydroxy-5β-tetrahydro metabolite is the major fate of aldosterone (Fig. 3), DOC, and 18-hydroxy DOC.

In man, the principal metabolites of corticosterone belong to the 3α,5α pregnane series which contrasts with the predominance of 3α,5β pregnane metabolites of aldosterone and DOC as well as progesterone and cortisol. Normally, corticosterone metabolites retain the hydroxyl at C-11, but 18-hydroxy 11-dehydro tetrahydrocorticosterone (tetrahydroCompound A) is the principal metabolite of 18-hydroxy corticosterone. Dihydro reduced metabolites of both corticosterone (20α- and β) and, 21-hydroxy-4-pregnene-3,11, 20-trione (20β only) were identified after ingestion of a large dose of the hormone. Pregnane-3α,11β,20,21-tetrols (hexahydrocorticosterone, 5β- and 5α-) were identified in the urine of a healthy man also following a pharmacological dose of the hormone. The 5α/5β ratio was about 2 and the conversion rate was at least 10% in the first 24 h urine collection, making these metabolites as significant as tetrahydro corticosterone. In the absence of suitable reference compounds, the stereochemistry at C-20 was not established.

Aldosterone in blood and urine exists primarily as 11–18 hemiacetal, so the C-11 hydroxyl is not normally available for oxidation. Although 11-dehydroaldosterone (21-hydroxy-4-pregnene 3,11,20-trione-18-al) has been shown to be an effective

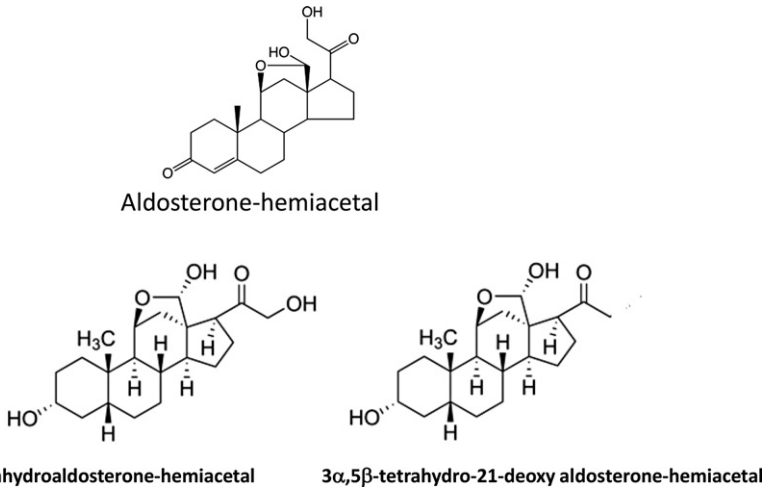

Fig. 3 Metabolites of aldosterone.

precursor in vitro for aldosterone biosynthesis by rabbit adrenal tissue, no aldosterone metabolites with a carbonyl function at C-11 have been positively characterized. Primarily on the basis of its infrared spectrum, 21-hydroxy-4-pregnene-3,11,20-trion-18-al was identified in urine, but this has never been confirmed. 5-Dihydroaldosterone and the 3α, 5α, and 3β epimers of tetrahydroaldosterone were also characterized by synthesis, degradation, and infrared spectroscopy, but the urinary excretion of each represented less than 1% of the original dose. Improved syntheses and identification using nuclear magnetic resonance spectroscopy enabled the characterization of 3α,5β-tetrahydroaldosterone-3-β-glucosiduronic acid after isolation from a 12 h urine collection using ion-exchange chromatography. The recovery was 34% of oral dose which is in good agreement with other reported figures. 3α,5β-tetrahydroaldosterone is inactive but 3α,5α,-tetrahydroaldosterone possesses GLAF activity, potently inhibiting HSD11B2 but not HSD11B1. The excretion of 3α,5α-tetrahydroaldosterone has not been measured and this would be an interesting experiment in sodium deprivation and certain categories of hypertension.

Conjugation and Urinary Excretion

The above reactions serve to inactivate the steroid hormones but before excretion, the polarity of these metabolites is increased by conjugation. Glucuronide conjugates at C-3 and C21 are more readily excreted in the urine than sulfate esters which are also formed. A unique conjugate of aldosterone occurs in human urine as a highly polar metabolite from which free aldosterone can be liberated by hydrolysis at pH1. The structure was confirmed, by degradation and synthesis, as the C-18-β-D-glucosiduronate of aldosterone hemiacetal. This metabolite is produced primarily in the kidney although an increased excretion of aldosterone-18-glucosiduronate in the third trimester of pregnancy has been attributed to metabolism in other organs. The synthesis of aldosterone-21-sulfate preceded the detection and measurement of this compound in urine. Approximately 0.7% of injected aldosterone was recovered in the sulfate fraction of a 48 h urine collection. 6β-hydroxycorticosterone was found to be excreted in urine as the free steroid and equally as its C-21 sulfate ester. This was a minor product but may become important if 6β-hydroxylase enzyme in human liver is induced by certain drugs.

In addition to these conjugates produced during hepatic catabolism of free steroid hormones, the adrenal gland itself secrets steroid C-21 sulfates, particularly in the newborn period. A comparison of the fate of ^{3}H–corticosterone sulfate with ^{14}C–corticosterone injected simultaneously indicated that the conjugate was rapidly metabolized by adults to polar urinary metabolites without hydrolysis, whereas most of the free corticosterone was converted to glucuronide-conjugated tetrahydro-derivatives. This metabolism may be important in pregnancy and the newborn period because the fetal adrenal secretes large amounts of corticosterone sulfate.

Biliary Excretion and Metabolism in the Intestine

After intravenous injection of radiolabeled aldosterone, 90% of the activity can be recovered from the urine. The recovery of activity after injection of other mineralocorticosteroids is much lower, typical values being 79% for corticosterone, about 45% for DOC and about 50% for 18-hydroxy DOC. A comparison of the fate of radiolabeled corticosterone with a separate study of cortisol injected intravenously into the same patients and volunteer indicated major difference in the metabolism of these hormones. The rate of disappearance from plasma of free corticosterone was faster than for cortisol, yet in a 2-day collection of urine less corticosterone metabolites were excreted than cortisol metabolites.

In two patients undergoing cholecystectomy, bile was collected from a T-tube previously inserted at surgery for cholecystitis. The cumulative excretion of activity after corticosterone administration in the first 12 h bile collection reached 20% and 31% of the labeled dose, although no further change was noted. A similar proportion of radioactivity was found in bile after intravenous administration of DOC. From a 16% recovery of a dose of 18-hydroxy-DOC in bile from a patient with incomplete biliary fistula as a guide it was estimated that for a normal bile flow the true excretion could account for 24%–39% of the total dose.

A comparison of steroid metabolism in vitro and in vivo using germ-free and conventional rats demonstrated extensive metabolism of steroid hormones and their metabolites by intestinal bacteria. Subsequently bacteria isolated from the human intestine have been shown in culture to reduce hydroxyl groups in steroids at the 16α- and 21-positions. Since no 21-dehydroxylating enzymes have been reported in human tissues, it must be concluded that the earlier isolation of pregnanediol and 11-oxo-pregnanediol from urine after the administration of DOC and 21-hydroxy-4-pregnene-3,11,20-trione, respectively, was due to bacterial metabolism of biliary steroids which had been readsorbed from the intestine. 11-oxo-pregnanolone and allo-pregnanolone (Fig. 4) may inhibit 11β-hydroxysteroid dehydrogenase type 2 and thus act as glycerrhitinic acid like compounds (GALF's) as proposed recently by Morris. Thirty-three percent of an intravenous radioactive dose of DOC has been recovered from feces, but this is not a significant excretory route for other mineralocorticosteroids since they are effectively reabsorbed from the intestine. The predominant isomers of the steroids both remaining in the free steroid fractions of feces and reabsorbed from the intestine have a 3α,5β, or 3β,5α configuration which indicates that the bacteria also possess reductase and isomerase activities.

Among the steroid conjugates excreted in bile tetrahydro DOC was identified as a mono-and-di-sulfate whilst 5α (and β) tetrahydrocorticosterone and 3α, 21-dihydroxy-5β (and α) -pregnane-11,20-dione were excreted only as monosulfates. Bacteria in the intestine have been shown to possess sulfohydrolase activity so the freed metabolites may be reabsorbed into the pool of neutral metabolites.

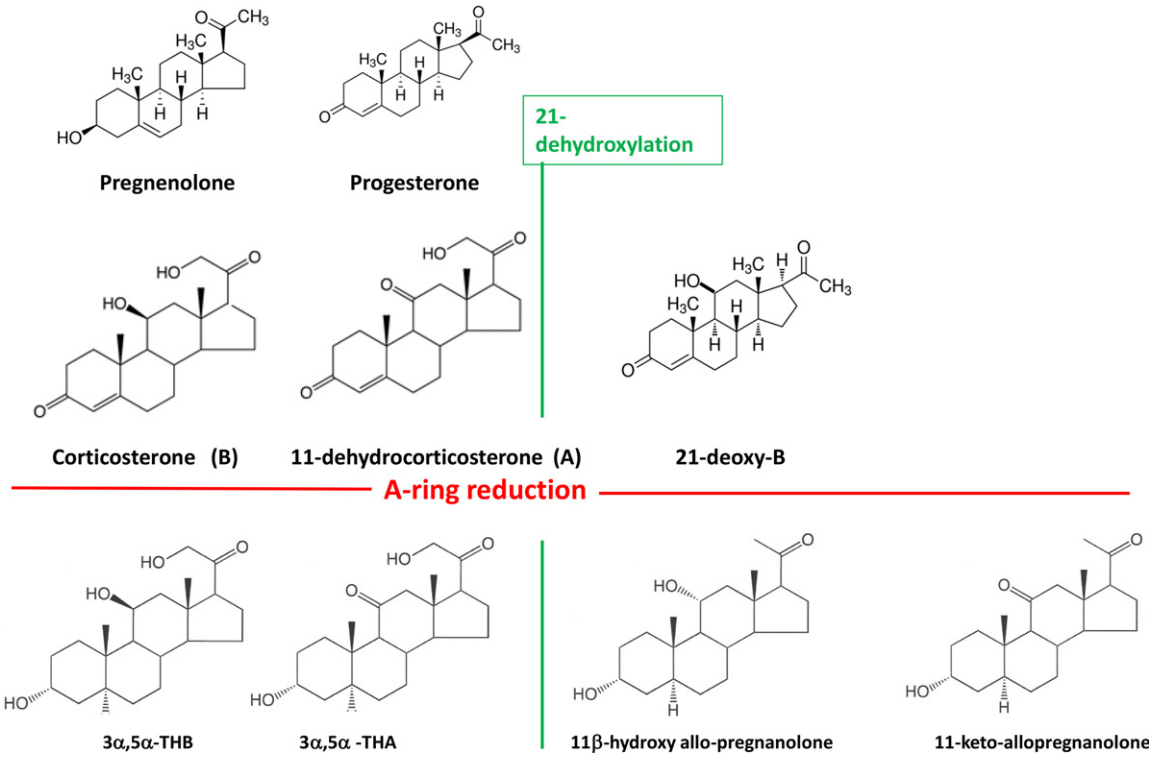

Fig. 4 21-Deoxysteroids that are GALF's.

Two bicyclic acetal metabolites of tetrahydroaldosterone were characterized and formed in each case by reduction of the C-20 carbonyl to a secondary hydroxyl group which then reacts with the 11–18 hemiacetal with the elimination of water. The minor acetal metabolite, representing 1.4% of the oral dose of aldosterone-21-acetate, can be regarded as a product of hexahydroaldosterone which itself was not identified. A 21-deoxy metabolite of tetrahydroaldosterone was characterized as the hemiacetal of 3α, 11β-dihydroxy-5β-pregnane-20-one-18-al, and the second acetal (8% of the dose) was a ketal of this metabolite justified by the general observation that 21-deoxy compounds formed by the bacterial metabolism of 21-hydroxy 20-keto precursors had always been recovered in urine as the 20-alcohols. The structures were confirmed by synthesis of the two compounds. This suggests that tetrahydroaldosterone may also be excreted in bile and reabsorbed from the intestine after bacterial 21-dehydroxylation. No 21-deoxy metabolites of 18 hydroxy DOC or its tetrahydro metabolites have yet been identified in urine or feces.

The neutral corticosteroid metabolites described so far may still represent 70% or less of the total radio activity recovered in urine. However, with improved methods for steroid extraction (e.g., Amberlite XAD-2 and solid phase extraction), it has become possible to recover from aqueous solution some further activity not extracted with organic solvents and, for example, an additional 5%–30% of the total metabolites of cortisol can now be accounted in polar fractions of steroids acids with a 20-oic acid group. An enzyme that oxidizes corticosteroids at position 21 has been purified from human liver obtained at post-mortem but the activity with 17-deoxy C21 steroid substrates is considerably lower than for cortisol and evidence in vivo suggests that acidic metabolite formation from DOC may account for only 0.5%–2% of the hormone, although by measuring the transfer of radiolabel from [21-^{3}H]– DOC into body water. The oxidation of DOC to an acid may be from 2.3% to 8.2%. Some of this activity can probably be attributed to bacterial metabolism of DOC in the intestine since loss of tritium has been demonstrated when [21-^{3}H]-DOC was incubated with human fecal flora. The investigations of steroid acids are in their infancy and the biological activity and influence of disease on these metabolic changes has still to be evaluated. The possibility must also be considered that nonsteroidal acidic or neutral metabolites might be excreted after degradation of the steroid nucleus.

Aldosterone; Action and Function

Peter J Fuller and Morag J Young, Hudson Institute of Medical Research, Clayton, VIC, Australia

Glossary

Aldosterone A steroid hormone secreted from the adrenal cortex that primarily controls sodium and potassium transport in the kidney and colon.

Epithelial sodium channel (ENaC) A protein complex that spans the cell membrane to create a pore through which sodium can selectively pass into the cell down an electrochemical gradient.

Mineralocorticoid The name given to corticosteroid hormones that control electrolyte (sodium and potassium) transport. The principal mineralocorticoid is aldosterone.

Renin–angiotensin–aldosterone system (RAAS) A signaling cascade that is involved in the maintenance of blood pressure through control of vascular tone and salt balance.

Introduction

The adrenal steroid, aldosterone is the primary "mineralocorticoid" in many species; it was first isolated by Simpson *et al.* (1953). Aldosterone, or more specifically aldosterone synthase, appeared in evolution with the emergence of terrestrial life and the consequent need to conserve sodium. The primary function of aldosterone, as implied by the term "mineralocorticoid," is to conserve sodium and with that water (Fuller and Young, 2014). This role in sodium homeostasis is tightly coupled to roles in potassium and hydrogen ion homeostasis.

The receptor for aldosterone, the mineralocorticoid receptor (MR), first appeared in cartilaginous fish preceding the appearance of aldosterone synthase by ~80 million years ago (Baker and Katsu, 2017). The MR also binds other steroids, most notably cortisol. Given that cortisol circulates at much higher levels than aldosterone, the MR is arguably functionally only a receptor for aldosterone in those tissues that preclude cortisol binding to the MR through the action of 11β hydroxysteroid dehydrogenase type 2 (HSD2). HSD2 converts cortisol (or corticosterone in rodents) to its receptor inactive metabolite cortisone (11 deoxycorticosterone in rodents). The MR is therefore effectively a "glucocorticoid receptor" in tissues that do not contain HSD2. In this article we therefore focus on those tissues in which aldosterone is acting via "its" receptor by virtue of coexpression of HSD2. It should be noted that in states of aldosterone excess, such as seen in aldosterone-producing adenoma, MR that are unprotected by HSD2 will also be activated by aldosterone with a series of adverse consequences.

Control of Aldosterone Secretion

Aldosterone maintains sodium and potassium homeostasis through a series of endocrine feedback loops. The renin–angiotensin—aldosterone system (RAAS) responds to decreases in volume status to increase sodium retention and vascular tone, thereby increasing available volume (sodium) and decreasing the "space" to be filled (vascular contraction). Volume status is sensed by the renal juxtaglomerular (JG) cells; they release renin, an aspartyl protease, in response to a decrease in tubular flow, to process angiotensinogen to angiotensin I decapeptide, which in turn is subject to further proteolysis by angiotensin-converting enzyme to yield angiotensin II. Angiotensin II mediates both arms of the response being a potent vasoconstrictor and the primary stimulus of aldosterone synthesis in the glomerulosa cells of the adrenal cortex. Aldosterone then acts on the distal nephron to promote sodium reabsorption. This signaling pathway from the JG cells to the sodium transporting epithelia is the RAAS.

The feedback loop involved with potassium homeostasis operates in parallel with, and overlaps, those for sodium. Aldosterone increases potassium secretion in the distal nephron to lower serum potassium levels; these in turn feedback on the glomerulosa cells to decrease aldosterone synthesis. The reverse is true in that increased serum potassium levels stimulate aldosterone synthesis. Aldosterone also modulates acid–base balance by increasing the exchange of hydrogen ions for sodium. Therefore, the net effect of an increase in aldosterone levels, as may result from an aldosterone-producing tumor (Conn syndrome) or exogenous mineralocorticoid administration (e.g., 9α-fludrocortisone), is sodium resorption with consequent volume expansion, hypertension, suppression of plasma renin activity, hypokalemia, and metabolic alkalosis.

Aldosterone synthesis is also positively regulated by adrenocorticotropic hormone (ACTH), and subject to negative regulation by atrial natriuretic peptide, consistent with its role in promoting natriuresis; and dopamine.

 doi:10.1016/B978-0-12-801238-3.66134-2

Mineralocorticoid Receptors

The actions of aldosterone are mediated, arguably exclusively, by the MR, a ligand-dependent transcription factor and member of the nuclear receptor superfamily. A putative G-protein-coupled membrane receptor GRP30 has been reported to respond to aldosterone, but its physiological relevance remains to be determined. Haploinsufficiency of the classic MR is associated with salt-wasting in the condition of pseudohypoaldosteronism type 1 and in transgenic mice rendered null for the MR profound neonatal salt-wasting is observed. The MR is described in detail in a separate chapter. Although the MR is widely expressed across a range of tissues, the most abundant expression is observed in traditional mineralocorticoid responsive tissues, the distal nephron, distal colon, and the salivary glands, where abundant HSD2 coexpression is also observed. In the central nervous system MR expression is largely independent of HSD2 expression with very high levels in subregions such as the hippocampus. In most of these CNS regions, the MR is thought to be acting as a cortisol/corticosterone receptor rather than an aldosterone receptor, however, in discrete nuclei associated with salt-appetite MR and HSD2 coexpression are observed (de Kloet and Joëls, 2017).

Mechanisms of the Regulation of Sodium Transport

Aldosterone-mediated transepithelial sodium flux primarily occurs in the cortical collecting ducts and to a lesser extent, in distal convoluted tubules of the nephron and in the distal sigmoid of the colon. In each case, there is a decreasing, distal to proximal, gradient of MR expression. As expected with a nuclear receptor, the temporal pattern of the aldosterone response has a lag period of 30–60 min, followed by an early phase in which preexisting pumps and channels are utilized with a late-phase at 3–6 h. In the late-phase, the number of pumps and channels increases and, with longer exposure, morphological changes are also observed. This time course is consistent with a primarily genomic response, which is to say that ligand-mediated activation of the MR results in the transcriptional regulation of the genes whose encoded proteins either mediate sodium transport per se or modulate components of the transport pathway. Although aldosterone accounts for only a small percentage ($\sim$2%) of the sodium reabsorbed in the nephron, the aldosterone-responsive regions in the nephron and indeed bowel are effectively the final arbiter of urinary sodium excretion; this critical role is reflected in the number of monogenetic syndromes of hyper- and hypotension in which the etiologic mutation involves a component of the aldosterone-responsive sodium transport pathway.

In the classic model of aldosterone-induced vectorial sodium transport across a polarized epithelium, sodium entry at the apical membrane is through an amiloride-sensitive electrogenic sodium channel with efflux mediated by an energy-dependent sodium pump at the basolateral membrane. These mechanisms are best reflected in the predominant cell type of the collecting duct, the principal cells (Shibata, 2017).

Epithelial Sodium Channel

The epithelial sodium channel (ENaC) is central to the aldosterone response (Soundararajan *et al.*, 2012). It consists of three homologous subunits (α, β, and γ) each characterized by two transmembrane domains with intracellular N- and C-termini. All three subunits are required for maximal amiloride-sensitive sodium transport. They form a heterotetromeric complex composed of 2α subunits and one each of the β and γ subunits. The ENaC subunits are members of the DEG/ENaC superfamily of sodium channel genes which are relatively conserved across evolution. The central role of ENaC is reflected both in Liddle syndrome, where activation, secondary to a mutation in the ENaC β or γ subunits results in increased sodium retention and hypertension, or in a subtype of PHA1 where an inactivating mutation in the subunits results in a salt-losing syndrome. Characterization of the mutations in Liddle syndrome identified a motif, proline–proline–proline–X-tyrosine (PY) in the C-terminus of the subunits which is disrupted in all cases. ENaC is a relatively short-lived protein that is ubiquitinated on residues in the N terminus of the α and γ but not β subunits; the PY motif interacts with Nedd4-2, a ubiquitin protein-ligase, whose role is to target the channels for proteosomal degradation. Although there is evidence that ENaC subunit gene expression is regulated by aldosterone this is tissue specific with both β- and γENaC subunit mRNA levels being increased in the colon by aldosterone but not in the renal cortex, whereas an increase in αENaC mRNA levels is seen in the inner medulla. Overall, it would seem that aldosterone can increase ENaC synthesis (at least in the late-phase), an effect in the early phase (i.e., a primary effect) is not a feature at least in the distal nephron. Aldosterone does however increase the expression of the serine, threonine kinase, serum and glucocorticoid-regulated kinase-1 (sgk-1), with a time course consistent with an effect on transcription. Sgk-1 directly interacts with Nedd4-2 to block its binding of the ENaC and, as a consequence, slows ENaC degradation. The primary acute effect of aldosterone is thus to increase the number of channels in the apical membrane by reducing their efflux from the plasma membrane. The glucocorticoid-induced leucine zipper protein, which is also aldosterone-induced, acts to repress ERK-signaling, a negative regulator of ENaC, as well as directly interacting with Nedd 4-2. A further aldosterone-induced protein, connector enhancer of kinase repressor of Ras3 (CNK3), serves as a scaffold protein in the assembly of the ENaC-regulatory complex.

Sgk-1 is also involved in the regulation of ENaCα-subunit gene expression through relief of Dotla-Af9-mediated transcriptional repression. Nedd4-2 is regulated by Usp2-45, a deubiquitinylation enzyme which is itself regulated by aldosterone. Sgk-1 requires phosphorylation by the phosphatidylinositol 3-kinase (PI 3-kinase) pathway which may integrate signaling from membrane-

associated receptors such as the insulin receptor. PI 3-kinase may be activated by small monomeric G proteins including K-ras 2A which has been identified as an aldosterone-induced gene.

Aldosterone also increases the open probability of the ENaC complexes in the plasma membrane through the action of serine protease such as prostasin and kallikrein which cleave the extracellular loop between the two transmembrane domains of the subunits.

NA^+/K^+-ATPase

Active extrusion of sodium from the cell to maintain intracellular sodium homeostasis reflects sodium pump activity in the basolateral cell membrane. Na^+/K^+-ATPase activity is increased in a number of epithelia by aldosterone. Na^+/K^+-ATPase α and β subunit gene expression is significantly increased in the late-phase in response to aldosterone. Na^+/K^+-ATPase activity is exquisitely sensitive to intracellular sodium concentrations; in cortical tubules, the early Na^+/K^+-ATPase response to aldosterone is blocked by amiloride, suggesting that the increased activity is secondary to the sodium influx at the apical membrane. In the late-phase of the aldosterone response, levels of Na^+/K^+-ATPase mRNA, protein, and activity are all increased. Channel-inducing factor (CHIF) is a member of the FXYD family of small transmembrane proteins that includes the γ subunit of Na^+/K^+-ATPase. CHIF gene expression is upregulated in the distal colon in response to aldosterone. CHIF increases the affinity of Na^+/K^+-ATPase for sodium which suggests that the early aldosterone-induced increase in Na^+/K^+-ATPase activity is, at least in part, mediated by CHIF.

Potassium and Hydrogen Ion Transport

Potassium flux occurs in transporting epithelia in response to aldosterone as a result of Na^+/K^+-ATPase-mediated exchange at the basolateral membrane, with the resulting electrochemical gradient favoring potassium excretion. Sgk-1 has been reported to increase the apical membrane channel density of ROMK, a potassium channel, through direct phosphorylation, through Nedd4-2 in the principal cells and also via the WNK (with-no-lysine-kinases) kinases in the distal DCT which also expresses the MR. Also present in the collecting duct are intercalated cells with subtypes α, β, and non-α/non-β. Intercalated cells have a well-recognized role in acid–base homeostasis, and also in potassium homeostasis. Regulation of potassium homeostasis by aldosterone, independent of its effects on sodium transport, and Na^+K^+-ATPase-mediated basolateral membrane exchange of sodium and potassium occurs in the β-intercalated cells. They express the Cl/HCO_3 exchanger, pendrin on the apical plasma membrane, and H^+-ATPase at the basolateral plasma membrane such that increased activity will promote potassium retention. A recent study has suggested that the response of the β-intercalated cell to aldosterone is modulated by phosphorylation of a specific serine in the ligand-binding domain of the MR (serine 843 in the human MR) which then precludes aldosterone binding. Diminished plasma potassium levels promote dephosphorylation of this serine allowing aldosterone-induced increases in both pendrin and H^+-ATPase. Dephosphorylation was also described in response to angiotensin II; this has been suggested to provide a mechanism by which the angiotensin-stimulated, aldosterone-mediated response to volume depletion can result in sodium reabsorption with limited potassium depletion.

As for potassium, aldosterone also has effects on proton excretion in addition to the cation exchange for sodium across the epithelium to maintain electroneutrality in the principal cells. The targets for this effect are carbonic anhydrase-rich cells, particularly the α-intercalated cells within the outer medullary collecting ducts. Aldosterone-induced transport across the apical membrane is through an H^+-ATPase activity, coupled with increased activity of the basolateral Cl/HCO_3 exchanger.

Aldosterone and Nonepithelial Tissues

The last decade has seen significant insights into the nature of the response in other nonepithelial tissues. In some tissues such as the vasculature and specific regions of the central nervous system where HSD2 is coexpressed with the MR, the response is indeed to aldosterone. In other tissues where the MR is expressed absent of HSD2, the biology is that of cortisol activation rather than of aldosterone action, except perhaps in states of aldosterone excess. Several studies have identified aldosterone-induced genes in the heart and the central nervous system, although their full physiological significance remains to be determined. Studies in transgenic mice using tissue-specific deletion of the MR are starting to clarify the specific roles and mechanisms of signaling through the MR in these tissues.

Vascular integrity and homeostasis

As noted earlier, a primary role for MR action is to regulate sodium excretion and resorption in the kidney and thus extracellular volume and cardiovascular homeostasis. Outside of the renal epithelia, the MR has a number other of physiological actions in response to aldosterone that also contribute to cardiovascular homeostasis. This is best defined for the cardiovascular response to hypovolemic shock. In this setting, poor renal perfusion increases renin release and activation of the RAAS. The elevated serum levels of aldosterone act to preserve (defend) circulating plasma volume via the aforementioned renal mechanisms of sodium and

water resorption in the distal nephron but also via two other key mechanisms. Aldosterone acting via the MR in vascular smooth muscle cells and endothelial cells enhances vascular reactivity and constriction in response to vasoactive peptides, thereby increasing total peripheral resistance. Aldosterone also acts on MR in cardiomyocytes to regulate increase chronotropic and ionotropic actions of the myocardium and hence cardiac output. These, largely transient, physiological responses to aldosterone action serve to also reduce aldosterone levels to baseline once homeostasis is restored.

In addition to the peripheral actions of aldosterone, it is well known that aldosterone can also regulate blood pressure when acting at MR located in the CNS. The continuous intracerebroventricular infusion of aldosterone at levels that are without effect when administered subcutaneously produces significant increases in resting blood pressure. Although the MR is expressed numerous locations including in the hippocampus, amygdala, lateral septum, and hypothalamus where the maintenance of normal blood pressure as well as ACTH release, arousal and fluid osmolality equilibrium are regulated largely by glucocorticoids, aldosterone signaling via the MR can also interact with specific signaling systems in the CNS to fine tune sympathetic outflow and salt sensitivity/appetite, and thus have a profound effect on blood pressure control in physiology and disease.

As discussed earlier, the MR has a number of ways to regulate cell function from canonical transcription of target genes to rapid actions on noncanonical pathways such as second messenger systems. Similarly, nonrenal actions of aldosterone in the heart, vasculature, and brain are driven by both transcriptional regulation of genes encoding ion channels (e.g., L-type, T-type calcium channels), sodium and calcium exchangers (e.g., sodium hydrogen exchanger 1; sodium calcium exchanger), vasoactive peptides (e.g., endothelin, nitric oxide), and their receptors (e.g., endothelin 1 receptor; angiotensin receptor 1). The MR can also regulate cellular function in these tissues via numerous noncanonical pathways including rapid phosphorylation events and interaction with cell signaling intermediates (Feldman and Gros, 2013; Ong and Young, 2017). This will be discussed in further detail in the pathophysiological section later.

Aldosterone Action and Function: Other Tissues

Although the MR is expressed in many cell types that regulate homeostasis in the cardiovascular/renovascular system it is also found in an increasing number of tissues unrelated to renal/cardiac function. In these tissues, a new biology is being described that involves many aldosterone-independent effects that presumably indicate that cortisol is the primary ligand in these tissues, for example, adipose tissue both white and brown, and immune cells. However, this does not preclude a role for aldosterone when serum levels are elevated as in primary aldosteronism.

Tissues where ion transport is tightly regulated to control fluid volume and ion concentrations can be regulated by aldosterone. The salivary glands express MR and HSD2 and control ion transport in a manner not dissimilar to the distal nephron. Similarly, HSD2 and MR also colocalize in many cell types of the respiratory tract; in the tracheal and bronchial glands, ciliated bronchial epithelial cells and in type II alveolar epithelial cells, indicating important roles for mineralocorticoid action in the lung.

The ear is another less-appreciated site for aldosterone action that also expresses HSD2, indicating aldosterone-dependent MR signaling in the endolymphatic sac and cochlear in particular. Clinical and experimental studies suggest that aldosterone can restore cochlear auditory function as well as prednisolone, in a manner not related to immune function but via aldosterone-dependent control of ENaC and osmotic pressure of the endolymph in the luminal fluid of the inner ear. Indeed, a low-salt diet has been the main treatment modality for Ménière's disease since the 1930s and is proposed to serve to increase aldosterone levels to increase endolymph absorption in the inner ear.

The MR is also found in several ocular cell types where it is also coexpressed with HSD2. Retinal cone cells, pigment epithelium, epithelium of ciliary body, iris, cornea, and lens all express the MR. In the eye, the neuroretina in particular is mineralocorticoid-sensitive and aldosterone control of hydration of the healthy retina through regulation of ion/water channels expression is a physiological response. Acute aldosterone administration upregulates expression of the ENaC α-subunit, the potassium channel Kir4.1 and aquaporin 4 (AQP4) a water channel to induce retinal swelling and activation of glial cells located in the retina. The importance of this MR signaling in the eye is also demonstrated by the condition of central serous chorioretinopathy (CSCR), a vision-threatening eye disease. CSCR is characterized by dilation and leakage of choroid vessels beneath the retina to cause fluid accumulation and retinal detachment, which is exacerbated by glucocorticoids and involves MR-dependent activation of the endothelial vasodilatory potassium channel, KCa2.3. MR antagonist (MRA) are very effective at reversing this disorder. Whether they are effective in retinopathy associated with diabetic vascular changes is less clear.

The skin is also a tissue in which the function of the MR is incompletely understood. Aldosterone and MRA can modulate elastin and collagen deposition in human skin fibroblasts via regulation of IGF-I signaling and may have therapeutic value for the treatment of damaged skin with reduced volume and elasticity particularly as a therapy for disfiguring dermal lesions to prevent their relapse. Aldosterone is also important in the conservation of sodium in the sweat gland. The MR is also located in the eccrine ducts of sweat glands where the activity of HSD2 has been demonstrated and indicates aldosterone-dependent regulation. Other types of sweat glands (sebaceous and apocrine) do not appear to expression MR and HSD2.

In contrast, epidermal barrier formation in mice in which the MR is overexpressed occurs early and is associated with reduced epidermal atrophy, increased keratinocyte apoptosis, and premature eye opening. Whereas overexpression in the adult leads to alopecia and hair follicle dysfunction and cysts while other areas of skin remained normal. Consistent with these data, MR epidermal knockout mice exhibited increased keratinocyte proliferation and differentiation and showed resistance to glucocorticoid-induced epidermal thinning. However, loss of epidermal MR causes mice to be more sensitive to skin damage and

inflammation. Thus epidermal MR in adult skin regulates homeostasis with a nonredundant role in mediating glucocorticoid actions. Aging-like skin changes in the metabolic syndrome may also be mediated by MR signaling. MR expression is higher in aged skin and in skin from animals subjected to the metabolic syndrome. Given that aging is associated with increased oxidative stress and inflammatory pathway activation, common mediators of aging and metabolic syndrome, it may be that topical MR blockade with spironolactone could be a useful therapy to reverse the progressive tissue damage in this and other pathologies that involve similar etiologies.

In the last decade, a role for aldosterone signaling in the function of adipose tissue has been proposed and supported by a series of experimental and clinical studies. The original observations of a MR-dependent mechanism in adipose depots arose from MR over expressing mice who showed increased brown fat depots that resulted in a "buffalo-like" hump in the mid-scapula space. Cell culture studies subsequently identified aldosterone-mediated regulation of both white and brown adipocytes. MR activation by aldosterone or glucocorticoids is required for expansion and differentiation and, in the mature cell, aldosterone promotes proinflammatory capacity within the cells as well as dysfunction of lipolytic and glucose handling pathways. Given the absence of HSD2 in these white adipose cells, it is likely that under normal conditions, the MR responses to glucocorticoids in most part. However, in the setting primary aldosteronism, MR activation is increasingly recognized as a contributing factor to the onset of metabolic disease in these patients (Manrique *et al.*, 2014). MR signaling in brown adipose cells also regulates proliferation, as evidenced by the expanded brown adipose intrascapular depot in MR plus mice, but more importantly, it also plays a role in regulating brown adipocyte metabolism and nonshivering thermogenesis. Specifically, the use of MRA in experimental animals fed a high fat diet upregulates brown adipocyte-specific transcripts and markedly increased protein levels of uncoupling protein 1. Moreover, these features were also detected in visceral and inguinal fat depots in response to MRA, indicating a transition of white adipose tissue to brown. Underlying mechanisms involved MR-dependent control of autophagic rate. In brown adipose tissue, the MR is similarly unprotected by HSD2, suggesting that glucocorticoids may have a role in regulation of brown adipose tissue, similar to white, via a second receptor signaling mechanism. In the setting of elevated aldosterone it is likely that the adipose receptor is another mediator of tissue and/or systemic pathological changes.

CNS and Salt Appetite

As noted earlier, increasing renal sodium retention is required to restore salt balance and fluid volume homeostasis. Integral to this response is the control of salt appetite in specific regions of the brain that in turn regulates sympathetic outflow to the kidney and vasopressin release, responses that are also tightly controlled by aldosterone. The MR is widely expressed in the brain in regions that include the choroid plexus, hippocampus, specific hypothalamic nuclei, the amygdala, circumventricular organs, brain stem, cerebellum, and cortex. Notably, HSD2 expression has been detected in the nucleus tractus solitarius (NTS) and hindbrain where it is proposed to control aldosterone actions on sodium appetite. Sodium deprivation and salt intake activate separate neuronal subpopulations in the NTS which relays efferent signals via the parabrachial complex in an aldosterone-dependent manner. It is proposed that in some brain regions aldosterone activates signaling mechanisms that are analogous to those in the kidney and colon (e.g., SGK1, NEDD4-2, ENaC) to mediate these responses (Geerling and Loewy, 2009). The MR may also influence "gustatory salt sensing" in the tongue, which is a key requirement for increasing salt intake. Thus, mineralocorticoids appear to induce and regulate similar molecular pathways in multiple tissues in the behavioral/cardiorenal/sensory processes involved in sodium appetite. Given that renal salt retention and increased sodium appetite can, for example, be maladaptive, aldosterone acting at one or more functional sites can sustain the pathophysiology of salt-sensitive hypertension and chronic heart failure. Of note, reduced HSD2 activity in the brain does not inherently cause hypertension, but instead promotes salt appetite and the transition from salt resistance to sensitivity. Data suggest that HSD2-positive neurons (i.e., NTS) integrate salt appetite and the blood pressure response to dietary sodium through a MR-dependent pathway.

The MR has a range of other, nonsodium-related effects in brain regions where cortisol/corticosterone plays a more prominent role given the absence of HSD2. Receptors located in limbic brain regions including hippocampal neurons respond to very low levels of cortisol/corticosterone and aldosterone. Here, the function of the MR is to stabilize neuronal transmission and integrity of the dentate gyrus. In the presence of stress or at the circadian rise in hormone levels, high concentrations of corticosterone also activate GR, which play a role in the maintenance of homeostasis. Coordinated responses for the two corticosteroid receptors is thus essential for regulation of the stress response and behavioral adaptation (Gomez-Sanchez, 2014).

Aldosterone and the MR in Pathophysiological Signaling

The sodium-retaining, potassium-wasting actions of aldosterone were known before aldosterone was isolated in 1953. The first MRA was developed in the few years following aldosterone's discovery and was proposed for clinical use as a potassium sparing diuretic for the control of hypertension. The pressor effect of elevated or continuous aldosterone was thus well recognized as a pathophysiological action of the hormone. In 1956, Jerome W. Conn was the first to describe a patient with uncontrolled hypertension, muscle weakness, and electrolyte imbalance that was due to autonomous aldosterone production by an adrenal cortical tumor. Conn syndrome, together with other mechanisms of autonomous aldosterone production termed "primary aldosteroneism," is now recognized as a potentially curable primary cause of hypertension that may affect up to ~10% of resistant

hypertensive patients. Primary aldosteronism now encompasses many subtypes and is discussed in full detail in the accompanying chapters.

Despite primary aldosteronism being a well-recognized risk factor for cardiovascular and renal disease, it was not until 1992 that experimental studies investigating the pathophysiology of elevated aldosterone renewed research efforts into understanding the action of aldosterone on the cardiovascular system. Experimental animals given exogenous aldosterone and 1% saline solution to drink develop hypertension, cardiac hypertrophy, and fibrosis that recapitulate the tissue inflammation and remodeling observed clinically in patients with heart failure (Lother and Hein, 2016). Many of the pathological processes involved were first described decades earlier by Hans Selye who described the histological changes of the "general adaptation syndrome" in response to high levels of exogenous deoxycorticosterone administration. However, the "granuloma tissue formation, fibrosis and dysfunction of peripheral organs" were ascribed to glucocorticoid actions of deoxycorticosterone (a naturally occurring mineralocorticoid) given that aldosterone was yet to be discovered. These early studies raise an important point that the inflammatory and fibrotic processes and gene expression changes that follow increased MR signaling are to some extent similar between tissues. For example, cardiomyocytes respond to increased aldosterone by regulating a program of gene expression and protein regulation that promotes cardiac hypertrophy, electrical signaling disturbances, and expression of inflammation and chemotactic proteins (Kritis *et al.*, 2016). In the kidney, markers of podocyte injury and glomerular dysfunction and hypertrophy follow aldosterone signaling and regulation of profibrotic markers, chemoattractant factors, and a coordinated program of inflammation by stromal and infiltrating immune cell populations. MR blockade is thus protective against the progression of tissue fibrosis in a range of tissues including heart, kidney, liver, vessel wall, and lung.

There are many pathological actions of the MR that have been described for an increasing number of tissues where the action of aldosterone-mediated MR signaling is on the stromal cells of the organ—podocytes, cardiomyocytes, lung epithelial, adipocytes, etc. Many of these pathological actions are covered in the accompanying sections in the current issue of this Encyclopedia.

Summary

Therefore aldosterone action in epithelial cells results in MR-mediated increased apical sodium influx through the ENaC with a coupled export of sodium at the basolateral membrane by sodium–potassium ATPase, an energy-dependent process. Given that the MR is expressed in a range of other tissues some of which are also involved in electrolyte transport and many other that are not, that is, cardiovascular homeostasis, aldosterone action clearly encompasses a broad range of physiological and pathophysiological roles. It is of course important to keep in mind that in tissues where HSD2 is not coexpressed, the physiological role of the MR may primarily be to mediate glucocorticoid signaling, but in situations of aldosterone excess their inappropriate activation may mediate adverse consequences, which contribute to the pathophysiology of conditions including primary aldosteronism (Conn syndrome) and cardiovascular disease.

Glossary

Aldosterone A steroid hormone synthesized in the zona glomerulosa of the adrenal cortex; the major mineralocorticoid hormone in mammals.
Mineralocorticoid Corticosteroid hormone secreted by the adrenal gland or synthetic compound exerting its function through binding to and activation of the mineralocorticoid receptor (MR), also referred to as ligand that regulates water and electrolyte balance.

Introduction

The aldosterone receptor, also referred to as the mineralocorticoid receptor (MR), is a member of the nuclear receptor superfamily (*NR3C2*) that acts as a ligand-dependent transcription factor mediating mineralocorticoid effects on a large variety of target cells. These include epithelial cells of the kidney and colon but also nonepithelial cells in the cardiovascular and central nervous systems, adipose tissues, immune cells, for instance. Alterations of the mineralocorticoid signaling are involved in several pathophysiological conditions in humans. Aldosterone exerts multiple actions through genomic and nongenomic mechanisms. This article will mainly focus on genomic actions which are the best characterized and probably the most prominent in terms of general physiology.

Mechanism of Aldosterone Action

Aldosterone and glucocorticoids (cortisol in humans and corticosterone in rodents) bind to MR with the same affinity (K_d in the nanomolar range). However, the mineralocorticoid selectivity is partly ensured by the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) in epithelial tissues, which metabolizes 11β-hydroxysteroids into 11 keto-derivatives such as cortisone, which exhibits no affinity for MR, thus preventing permanent occupancy of the MR by the more prevalent glucocorticoid hormones (Funder *et al.*, 1988; Edwards *et al.*, 1988). **Fig. 1** illustrates the mechanism of aldosterone action in a typical, polarized epithelial principal cell of the distal nephron. Aldosterone penetrates cells by passive diffusion and binds to the MR. In the absence of its ligand, the receptor is mainly located in the cytoplasm and is complexed with various chaperon proteins such as the heat shock protein 90 (hsp90), the heat shock protein 70 (hsp70), but also with other proteins including immunophilins such as cyclophilin (Cyp40), and FKBP52 in a hetero-oligomeric complex. These receptor-associated proteins dissociate from the MR upon aldosterone binding, thus inducing conformational changes of the MR. In the nucleus, the hormone-receptor complexes bind mostly as homodimers to specific DNA sequences, which have been identified as mineralocorticoid response elements (MREs), and have been located in the regulatory regions of aldosterone-sensitive genes. The consensus sequence of these MREs has recently been characterized as a 15-nucleotide-sequence AGtACAgxatGTtCt consisting of partial inverted direct repeat as identified by chromatin immunoprecipitation assays followed by DNA sequencing (ChIP-Seq) (Le Billan *et al.*, 2015). Thereafter, MR interacts, in a cyclic, sequential and/or combinatorial manner, with several transcriptional coregulators and some basal transcription factors or components of the machinery to enhance transcriptional activation (initiation and elongation) and to facilitate chromatin remodeling involving histone acetylation/methylation. In epithelial tissues such as kidney and colon, MR stimulates expression of ion transporters: the amiloride-sensitive epithelial Na^+ channel (ENaC), located at the apical membrane, and the basolateral Na^+, K^+-ATPase pump. These channels or transporters are involved in the unidirectional transepithelial sodium transport from the lumen to the interstitium. The best studied aldosterone-regulated gene in epithelial tissues is the serum- and glucocorticoid-regulated kinase (sgk1), which phosphorylates the ubiquitin ligase Nedd4-2, which in turn controls the retrieval of the subunits of ENaC from the apical membrane of the cell. Several other aldosterone-target genes have been identified by high throughput techniques (SAGE or ChIP-sequencing) such as the small monomeric GTP-binding protein Kirsten Ras (Ki-Ras), the glucocorticoid-induced leucine zipper protein (GILZ), the serine/threonine kinase KS-WNK1 (with no lysine K kinase), the N-myc down-regulated gene 2 (NDRG2), which also seem to

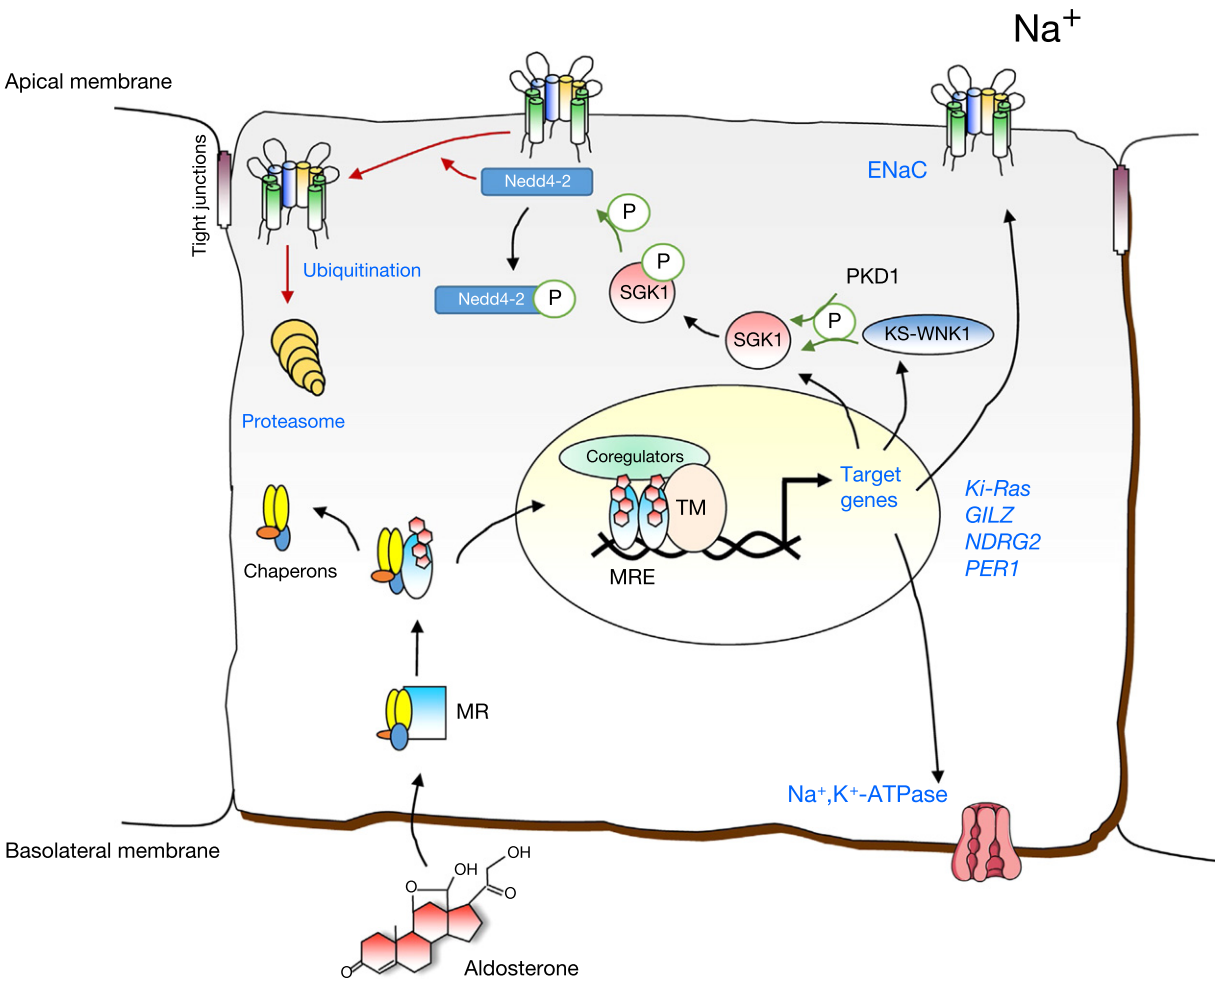

Fig. 1 Schematic representation of aldosterone action in a renal polarized epithelial cell. Aldosterone enters the cell and binds the cytoplasmic MR, which is translocated into the nucleus. MR interacts with mineralocorticoid response elements (MRE), recruits various transcriptional coregulators and some basal transcription factors or components of the machinery to enhance transcriptional activation, and thus modulates expression of aldosterone target genes. At the apical membrane, ENaC (epithelial sodium channel) constitutes the rate-limiting step of apical Na^+ entry. Na^+ is then extruded into the basolateral space by the Na^+/K^+-ATPase pump, the activity of which is enhanced by aldosterone. In the absence of aldosterone, ENaC proteins interact with Nedd4-2, an ubiquitin-ligase, responsible for ENaC degradation by the proteasome. *Sgk1* (serum and glucocorticoid-regulated kinase) is a key aldosterone-regulated target gene that plays a central role in Na^+ reabsorption. Upon aldosterone exposure, activated-PDK1 phosphorylates Nedd4-2, which in turn dissociates from ENaC, increasing its apical membrane abundance. Other aldosterone-induced genes included *Ki-Ras*, kidney specific *KS-WNK1* (serine/threonine kinase With No K), *GILZ* (glucocorticoid-induced leucine zipper), *NDRG2* (N-myc down-stream regulated gene 2) and *PER1* (period circadian regulator 1).

play important roles during the early phase of aldosterone responses in the nephron (Viengchareun *et al.*, 2007). Of particular interest, the *PER1* gene has recently been identified as another aldosterone-target gene in the kidney, suggesting that aldosterone may also regulate the rhythmicity of renal sodium reabsorption since *PER1* belongs to the circadian clock gene family. Beyond this classical model of aldosterone action, recent data obtained from ChIP experiments revealed that MR can also indirectly bind to recognition motifs for other transcription factors (FOX, EGR1, AP1, PAX5), suggesting functional interactions of MR with other transcription factors through tethering mechanisms, thus enabling to modulate target gene expression (Le Billan *et al.*, 2015).

Structure of the MR

The year 2017 marks the 30th anniversary of the cloning of the human MR cDNA by Ron Evans's group (Arriza *et al.*, 1987). This achievement enabled the definition and the characterization of distinct functional domains, which are common to other members of the nuclear receptor superfamily: first, the transactivation domain or amino terminal region (N-Terminal Domain, NTD) is the longest domain (602 amino acids) among nuclear receptor family members and shares less than 15% homology with its closely related receptor, the glucocorticoid receptor encoded by the *NR3C1* gene. However, more than 85% of this MR NTD domain is

highly conserved among all known mammalian species, suggesting that it contains specific and important functional motifs. Indeed, this NTD harbors two ligand-independent activation functions: AF1a located in amino acid (aa) 1–167 and AF1b spanning aa 445–602 and presumably an inhibitory transactivation region between aa 167 and 437 (Tallec *et al.*, 2003). This NTD was also shown to interact specifically with coregulators capable of modulating aldosterone-activated MR transcription. Next, the highly conserved DNA-binding domain (DBD) is responsible for the specific interaction with MREs located in the regulatory regions of aldosterone target genes. This short (<70 aa) hydrophilic domain, rich in cysteine residues, has a rigid structure composed of two zinc finger structures. The P box offers the interacting contact with the half-site of the response element and the D box is responsible for weak dimerization interface with another MR monomer. A nuclear export signal has also been identified between the two zinc fingers, and a weak ligand-independent nuclear localization signal, NSL1, has been shown to be located next to the C-terminal site of the DBD. Finally, the ligand-binding domain (LBD), which is 250 aa long and is separated from the DBD by a hydrophilic proline-rich hinge region, is responsible for ligand binding and contains a ligand-dependent nuclear localization signal (NLS2), multiple contact sites for hsp90 interaction, and a ligand-dependent activating function AF2 domain. This highly structured domain is composed of 11 α-helices (H1–H12, H2 is somehow absent) and two antiparallel β strands on which the steroid hormone lies. It is interesting to note that the mineralocorticoid selectivity of aldosterone action within target cells, beyond the 11β-HSD2 enzyme, is also ensured by an intrinsic property of MR, which is able to discriminate between aldosterone and glucocorticoids since dissociation rates (k_{-1}) are much faster for glucocorticoids than for aldosterone. Moreover, it has been shown that the aldosterone–MR complex presumably adopts structural conformation somehow different from that of the glucocorticoid–MR complex, thereby allowing distinct interaction between the N-terminal domain and the LBD to occur. This leads to the recruitment of specific coactivators resulting in a highly specific transcriptional response (Farman and Rafestin-Oblin, 2001). It has also recently been proposed that specific cyclical and dynamic interaction of MR with DNA, as a function of the nature of the MR-bound ligand, is responsible for distinct transcriptional signature.

Site of MR Expression

Cell-specific MR expression was initially mostly characterized in polarized cells of sodium-transporting epithelia: distal parts of the nephron (distal convoluted tubule, connecting tubule and cortical collecting tubule), small intestine and colon, pneumocytes, salivary and sweat glands, keratinocytes and hair follicles, eye and inner ear (Viengchareun *et al.*, 2007). However, it is now well established that MR expression is also detected in nonepithelial cells or tissues such as neurons of the hippocampus and hypothalamus, cardiomyocytes, endothelial cells, adipocytes, vascular smooth muscle cells, liver, leukocytes, macrophages, uterus and gonads where it is principally activated by cortisol, owing to the absence of 11β-HSD2 expression. In parallel, MR also demonstrates a tissue-specific developmental expression pattern. Indeed, it has been shown that, while MR (kidney, heart, brain and lung), is expressed in the fetus starting from mid gestation (E18 in mice, 20–25 gestational weeks in humans), its expression is

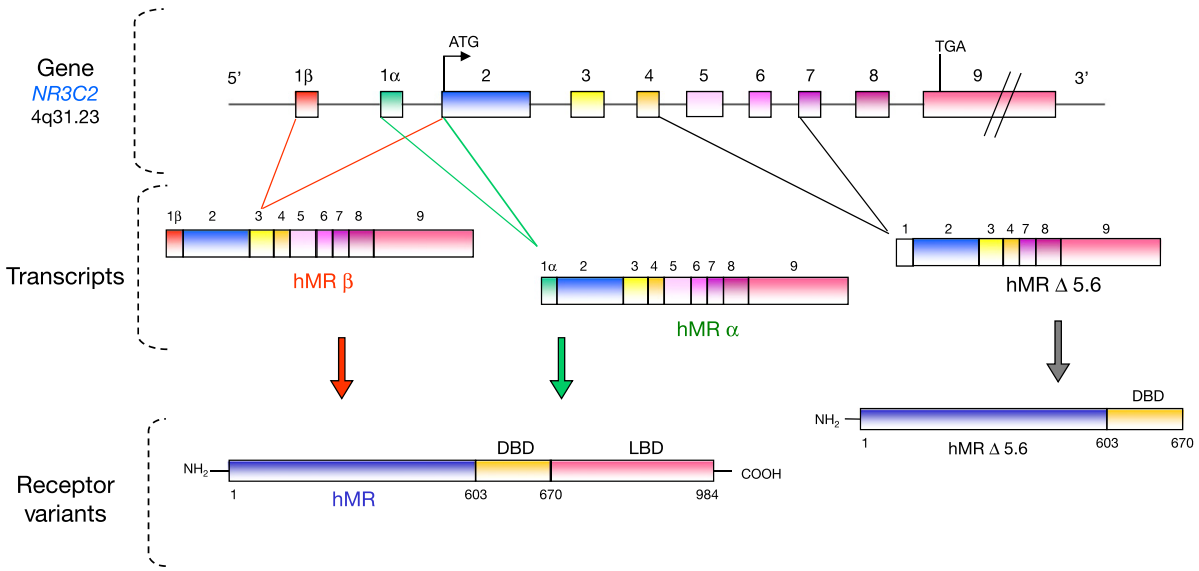

Fig. 2 Schematic illustration of the human *NR3C2* structure. *NR3C2* gene, transcripts, receptor variants, and functional domains are depicted. The human *NR3C2* gene is composed of 10 exons, including two untranslated first exons (1α and 1β).The AUG translational initiation start codon is located 2 bp after the beginning of exon 2, while the stop codon is located in exon 9. Multiple mRNA isoforms generated by alternative transcription or splicing events are translated into various protein variants (i.e., the human MR α, β and Δ 5.6 variants). The receptor is comprised of distinct functional domains: the N-terminal domain (NTD), the DNA binding domain (DBD) and the C-terminal domain (LBD).

temporarily downregulated during the perinatal period in a tissue-specific manner, with no renal, cardiac or neuronal MR expression, at variance with a maintained pulmonary MR expression (Martinerie *et al.*, 2009, 2013).

Regulation of MR Expression

The *NR3C2* gene, which encodes for the human MR, is localized to the q31.2 region of chromosome 4 and spans approximately 450 kb. This gene is composed of 10 exons: exon 2 encodes for the NTD of the receptor and the two small exons 3 and 4 encode for the two zinc fingers of the DBD, whereas the last 5 exons encode for the LBD of the receptor. However, the two first exons, referred to as exon 1α and exon 1β, are not translated (**Fig. 2**). Alternative transcription of these two 5′-untranslated exons generates two mRNA isoforms, referred to as hMRα and hMRβ, which give rise to the same translation product (Zennaro *et al.*, 1995). Interestingly, several other MR splice variants, lacking one (Δ6 MR) or two exons (Δ5,6 MR), have been identified so far and such splice variants seem to play major roles in modulating receptor function (Zennaro *et al.*, 2001; Lema *et al.*, 2017a).

At the Transcriptional Level

The *NR3C2* gene expression is controlled by two alternative promoters which differ in terms of their basal activity as well as their hormonal regulation. Experiments in transgenic mice have shown distinct tissue-specific usage and activity of these two hMR regulatory regions in vivo. The proximal P1 promoter corresponding to the 5′-flanking region of exon 1α is a relatively strong promoter that is transcriptionally active in all aldosterone target tissues, whereas the distal P2 promoter flanking exon 1β is weaker and has a more restricted pattern of expression, notably in the central nervous system; thus, it is presumably activated during specific developmental stages or physiological situations (Le Menuet *et al.*, 2000).

At the Posttranscriptional Level

The stability of MR transcripts is also regulated at the posttranscriptional level. This is particularly true in the kidney where renal MR expression was recently shown to be modulated by large variations of extracellular tonicity, prevailing in the nephron (Viengchareun *et al.*, 2009). Indeed, hypertonicity (500 mOsm/L) was shown to greatly decrease renal MR levels by recruiting the RNA binding protein (RBP) Tis11b (tetradecanoyl phorbol acetate inducible sequence 11b), which physically interacts with MR transcript 3′-untranslated region (3′-UTR), thus modulating its mRNA turnover in response to osmotic stress (Viengchareun *et al.*, 2014). Conversely, renal MR transcript and protein levels were shown to increase under hypotonicity (150 mOsm/L) by recruiting HuR (human antigen R), another RBP member of the Hu family. Under hypotonic stress, HuR behaves as a novel posttranscriptional regulator of MR expression. HuR is specifically and rapidly exported to the cytoplasm of renal cells upon hypotonic stress, where it interacts with MR 3′-UTR to stabilize and increase MR levels, thereby modulating MR signaling (Lema *et al.*, 2017b). During this past decade, microRNA (miRNA) have also emerged as new class of posttranscriptional regulators. Indeed, binding of these miRNA in the 3′-UTR of a target transcript may affect its stability or translation (Bartel, 2004). Interestingly, we and other groups have recently identified several putative miRNA binding sites in MR 3′-UTR, suggesting that miRNA may also modulate MR expression at the posttranscriptional level. Taken together, RNA Binding Protein and miRNA seem to be of particular importance in the control of MR expression, presumably during the prenatal period and notably at birth, where renal MR expression is downregulated, accounting for the transient physiological renal resistance to aldosterone observed in the early neonatal period (Martinerie *et al.*, 2009). Of note, several studies reported that MR protein may also be submitted to posttranslational modifications (PTM) such as phosphorylation, sumoylation or ubiquitinylation (Viengchareun *et al.*, 2007). These PTM did not seem to modulate per se MR expression but rather might alter MR transcriptional activity or bioavailability in cells.

Biological Functions

Mineralocorticoid signaling is primarily implicated in the maintenance of water and salt homeostasis by regulating sodium reabsorption and potassium excretion across tight epithelia. As such, it plays a key role in the control of blood pressure, and in turn, the dysregulated aldosterone secretion and/or mineralocorticoid action are involved in many human diseases such as hypertension, heart failure and chronic kidney diseases associated with increased activation or upregulated mineralocorticoid signaling, while dehydration and sodium loss are related to downregulated or defective mineralocorticoid signaling. In none-pithelial target cells, mineralocorticoid signaling has been linked to various physiological processes, such as memorization and learning, stress response, neuroprotection and regulation of sodium appetite (hippocampus), thermogenesis and differentiation of preadipocytes into mature adipocytes (adipose tissue) and cardiac remodeling.

MR in (Patho)Physiology

Numerous studies have demonstrated a direct relationship between mineralocorticoid signaling dysregulation and human pathologies, mostly in cardio-vascular and kidney diseases. This has led to the emergence of several classes of

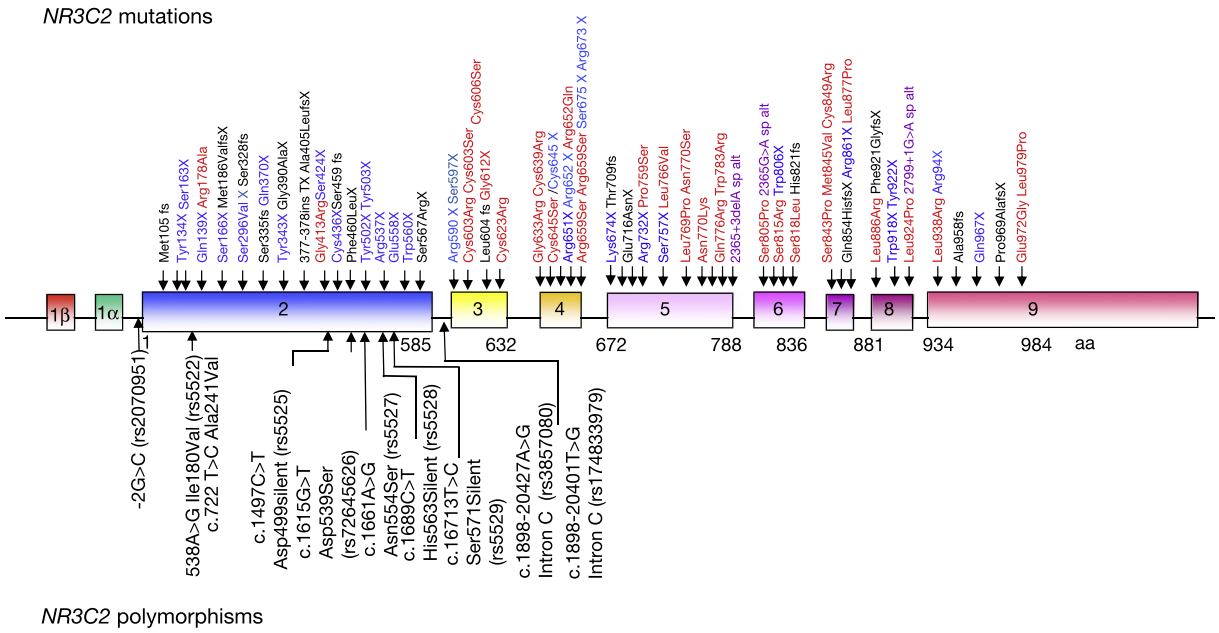

Fig. 3 Reported MR mutations and their localization on the human *NR3C2* gene (as to Jan. 2018). Schematic representation of *NR3C2* gene and its genomic structure (10 exons, from 1β to 9) encoding for various functional domains of the MR protein. Color code of the reported *NR3C2* mutations: *Black* frame shift (fs) mutations associated with premature codon stop. *Red* missense mutations corresponding to a specific aa substitution at a particular position onto a functional domain of the MR protein; NTD, N-terminal domain (1–585 aa encoded by exon 2); DBD: DNA binding domain (586–671 aa encoded by exons 3 and 4); LBD: ligand-binding domain (672–984 aa, encoded by exons 5 to 9), *Violet*, splice variation mutants, *Blue* nonsense mutations with introduction of a stop codon. Localization of some *NR3C2* polymorphisms: most of them are located in exon 2, while others are located in intron B or C. Rs indicates the # single nucleotide polymorphism.

antimineralocorticoid compounds in order to prevent or cure deleterious effects of MR activation. In humans, major clinical trials (RALES study, EPHESUS study, EMPHASIS-HF study, REMINDER study) demonstrated a beneficial effect of antimineralocorticoid drugs (spironolactone, eplerenone) in reducing morbidity and mortality of patients with severe cardiac failure (Pitt *et al.*, 1999; Zannad *et al.*, 2011) or after acute myocardial infarction (Pitt *et al.*, 2003; Montalescot *et al.*, 2014). However, these antagonists induce a nonnegligible risk of hyperkalemia, which has led to the generation of new nonsteroidal antimineralocorticoids (finerenone, esaxerenone) (Arai *et al.*, 2015) that are presently being evaluated in phase-III clinical trials (Kolkhof and Bärfacker, 2017). There is now also clear evidence that genetic alterations of the *NR3C2* gene are associated with human diseases. The first MR mutations were found in patients with autosomal dominant or sporadic pseudohypoaldosteronism type I, an inherited disorder characterized by renal salt wasting during infancy and associated with failure to thrive, hyponatremia, hyperkalemia, and high plasma aldosterone levels, clinical and biological features that are consistent with aldosterone resistance (Geller *et al.*, 1998). These heterozygous frameshift, nonsense, or missense mutations are located within different functional domains of the MR and in turn, differentially impair its function, generally resulting in receptor inactivity (**Fig. 3**). Aside from these mutations, to date 380 polymorphisms have been identified in the *NR3C2* gene (Lek *et al.*, 2016) that may be implicated in variation in sensitivity to salt, blood pressure, stress response or depression. Indeed, these polymorphisms have been linked to differential levels of MR expression and transactivation capacity (Zennaro and Fernandes-Rosa, 2017). Conversely, only one gain of function mutation in the MR has been reported to date, in a family with severe early-onset hypertension that was exacerbated by pregnancy (Geller *et al.*, 2000). The mutation, a substitution of leucine for serine at codon 810, lies within the LBD and has been shown to drastically modify the steroid specificity of the receptor. Indeed, further experiments demonstrated a constitutive MR activation in the absence of ligand. In addition, progesterone, spironolactone, and even cortisone were able to fully activate the mutant receptor, consistent with the clinical presentation of gestational hypertension. Interestingly, various genetically engineered animals mimicking human diseases have proven to be useful in terms of analyzing the in vivo function of the MR. *Nr3c2* gene inactivation achieved by homologous recombination in mice or by the use of a RNA interference strategy in rat led to knockout animals developing symptoms of pseudohypoaldosteronism (Berger *et al.*, 1998; Lim *et al.*, 2008), that can be rescued by intra-peritoneal injections of NaCl (Bleich *et al.*, 1999). In contrast, hMR overexpressing transgenic mice exhibited specific alterations in renal and cardiac function (Le Menuet *et al.*, 2001; Ouvrard-Pascaud *et al.*, 2005). Several cell-specific MR knockdown or overexpressing animals, notably in adipose tissue (Adipo-MORE) presenting with metabolic syndrome (Nguyen Dinh Cat *et al.*, 2016) have been generated. These animal models constitute attractive new experimental systems to further explore the widespread and pleiotropic function of aldosterone receptors in vivo and to decipher the molecular and cellular events underlying the aldosterone signaling pathway.

Regulation of Potassium Homeostasis☆

Paola Russo, Fabio Lauria, and Alfonso Siani, National Research Council of Italy, Avellino, Italy

Glossary

Extracellular fluid The fluid found between the cells in a tissue.

Homeostasis Maintenance of a stable and balanced environment in the body.

Intracellular fluid The fluid within the tissue cells, constituting approximately 30%–40% of the body weight.

Potassium The major intracellular cation (symbol K (kalium), atomic weight 39.0).

Potassium, deficiency A condition due to decreased dietary intake of potassium, as in starvation, or due to gastrointestinal loss in diarrhea, chronic laxative abuse, vomiting, gastric suction, or bowel diversion.

Potassium, dietary Potassium or potassium compounds used in foods or as foods.

Introduction

Chemistry

Potassium is the eighth most abundant element in the Earth's crust. Its abundance is estimated to be about 2.0%–2.5%. It is a soft, silvery-white with an atomic mass of 39.1 Da. Potassium is present in only one oxidation state ($+1$). It is a powerful reducing agent that is easily oxidized. Potassium is an extremely active metal that reacts violently with oxygen in water and air. Because of its high reactivity, potassium is not found free in nature but only as salts. Potassium compounds have good water solubility.

Biochemical Aspects

Potassium is the most abundant exchangeable cation in the body. As the major intracellular solute, potassium plays a relevant role in modulating cell volume and osmolality. Moreover, it has an important role in several metabolic processes. The total body content of potassium is about 40–55 mmol/kg body weight (Preuss and Clouatre, 2012), corresponding to 3–4 mol (110–150 g) for a 70-kg adult. In infants and children, the potassium body content (expressed per kg/body weight) is similar to that reported for adults (Fomon *et al.*, 1982; Butte *et al.*, 2000). Approximately 98% of the total body potassium content is found within cells (particularly muscle cells) at a concentration of 140–150 mmol/L; the concentration of the remaining 2% contained in the extracellular fluid is 3.5–5.5 mmol/L. Therefore, a gradient exists for the diffusion of potassium from the intracellular to the extracellular fluid, whereas a reverse gradient exists for sodium, which is present at a high concentration extracellularly and at a low concentration intracellularly (Bailey *et al.*, 2014; Gumz *et al.*, 2015). The maintenance of the large concentration gradient between intracellular and extracellular potassium is of paramount importance for electrolyte and fluid homeostasis, regulating neural transmission, muscle contraction, and vascular tone (Bailey *et al.*, 2014; Gumz *et al.*, 2015).

Passive transport of potassium occurs via intracellular and paracellular pathways. The intracellular transport mechanism involves potassium channels. The term potassium channels covers different families of membrane proteins found in both excitable and nonexcitable cells. More than 90 genes coding for principal subunit of potassium channels were identified in the human genome. The common characteristic of the channels is that they have "gates" which open or close in response to specific stimuli, such as voltage, ATP, ionic calcium concentration, hormones, and neurotransmitters. Various stimuli sometimes act together on a channel. Potassium channels exhibit great diversity and may be divided into four main groups: voltage-gated potassium channels (Kv channels); calcium-activated (KCa) channels, including big conductance (BK), intermediate conductance (IK), and small conductance (SK) channels; eukaryotic inward-rectifying potassium channels (Kir channels), and two-pore potassium channels (K2p channels) (Tian *et al.*, 2014). Different types of potassium channels have been implicated in functions such as salivary secretion, bile and gastric acid secretion, protein digestion and absorption, insulin secretion, carbohydrate digestion and absorption, and taste transduction.

Since diffusion occurs along concentration gradients, potassium is actively pumped into the cell from the extracellular fluid by Na^+/K^+-ATPase, also called sodium–potassium pump, which reestablishes the gradients, by moving sodium out and potassium in. Na^+/K^+-ATPase, present on the membrane of almost all cell types, is critical to maintain potassium homeostasis close to its setpoint (Palmer, 2015).

☆*Change History*: December 2017. P. Russo, F. Lauria, and A. Siani updated abstract, keywords, main text, references, further reading and deleted Table 3.

This chapter is an update of Paola Russo, Gianvincenzo Barba, Antonella Venezia and Alfonso Siani, Potassium Homeostasis, Regulation of, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 29–33.

 doi:10.1016/B978-0-12-801238-3.65419-3

In the mammalian system, the defense against sustained potassium derangements results from a complex balance among intake, excretion, and the distribution between the intracellular and extracellular spaces. Whereas extrarenal mechanisms that modulate potassium concentration inside and outside the cells are the first line of defense, the kidney is the final effector of long-term defense.

Distribution of Potassium Between the Body Compartments

Potassium homeostasis is finely regulated, so that wide variations in dietary potassium intake produce, in healthy individuals, only small changes in the total body potassium content and in the plasma potassium concentration. After being almost completely absorbed in the gut, potassium is distributed widely throughout the body; of a total potassium intake of 50–100 mmol/day, all but a few millimoles are excreted in the urine (only 5% is excreted in stool and sweat) (Agarwal *et al.*, 1994; Bailey *et al.*, 2014). Therefore, loss of potassium through urine, stool, and sweat generally matches potassium intake, and potassium balance is maintained. Two major physiological mechanisms cooperate to achieve this end, namely, extrarenal mechanisms that control the tissue uptake and distribution of the electrolyte, and a renal tubular system that regulates potassium excretion as a function of acute and chronic changes in potassium intake (Gumz *et al.*, 2015).

Although only a small fraction of total body potassium in humans is in the extracellular space, minor changes in extracellular potassium concentration can be life-threatening (Pepin and Shields, 2012). Therefore, plasma potassium concentration must be maintained close to its setpoint. Cells act as an important storage pool for potassium, alternatively taking up excess potassium or releasing potassium, and operate to maintain its plasma concentration within the narrow limits allowed for physiologic function.

Extrarenal Regulation of Potassium Balance

Potassium can be actively transported into and can diffuse out of all cells. Extracellular potassium concentration is therefore regulated by cell membranes that act as effector organs, by buffering rapid changes in plasma potassium concentration, such as those occurring during the absorptive period. This system is highly effective, particularly in protecting against sudden changes in potassium concentration. As an example, within 60 min of an intravenous load of 0.5 mmol/kg of KCl, only 41% appears in the urine, but plasma potassium rises by no more than 0.6 mmol/L, showing the crucial role of intracellular potassium pool in buffering the extracellular load (Williams *et al.*, 1984).

The maintenance of the distribution of potassium across cells is largely dependent on the activity of the Na^+/K^+-ATPase, which expends energy to pump sodium out of the cell and potassium into the cell. Virtually every cell in the body uses this mechanism to maintain a high intracellular potassium concentration and a low extracellular potassium concentration (Palmer, 2015).

There are several regulatory factors that control the distribution of potassium within body fluid compartments (**Table 1**). Among them, hormones play a prominent role. Insulin drives potassium into cells independent of its hypoglycemic effect, possibly increasing Na^+/K^+-ATPase activity (DeFronzo *et al.*, 1980; Cohen *et al.*, 1991). Also, β-agonists, such as epinephrine, promote rapid and profuse potassium movement from the extracellular to the intracellular fluid by cyclic AMP-dependent activation of the Na^+/K^+-ATPase (DeFronzo *et al.*, 1983; Katz *et al.*, 1984). Both insulin release and epinephrine release increase

Table 1 Determinants of transcellular potassium distribution

Lower plasma potassium concentration
Hormones
Insulin
β-Adrenergic agonists
Aldosterone
Metabolic alkalosis/respiratory alkalosis
Increase plasma potassium concentration
Cell destruction (hemolysis, crushing)
Hormones
α-Adrenergic agonists
Glucagon
Hyperchloremic acidosis
Plasma hyperosmolality
Drugs
β2-Antagonists
Angiotensin-converting enzyme inhibitors
Digitalis
Prostaglandin synthesis inhibitors
Succinylcholine

after meals, thus facilitating the movement of the ingested potassium to the intracellular space and preventing meal-related hyperkalemia.

Hyperkalemia stimulates adrenal aldosterone secretion, which not only affects the renal excretion but also favors a shift of potassium to the intracellular space (Rabinowitz, 1996). Apart from hormonal factors, there are other extrarenal mechanisms that control the distribution of potassium within the body compartments. Changes in the acid–base status can lead to changes in plasma potassium concentration. In particular, a decrease in blood pH causes hydrogen ions to enter cells. Consequently, potassium exits cells in exchange for hydrogen entering. Alkalemia generally induces the opposite response (Lee Hamm *et al.*, 2013). An acute rise in plasma osmolality causes an abrupt increase in plasma potassium, most likely due to the rapid exit of water from the cells, accompanied by an increased amount of potassium leaving the cell (Rastegar, 1990). Finally, several drugs (**Table 1**) could significantly affect extrarenal potassium homeostasis.

Renal Regulation of Potassium Balance

About 90% of dietary potassium is readily absorbed, mainly in the small intestine, mostly through passive mechanisms in response to electrochemical gradients and in proportion to the actual load (Agarwal *et al.*, 1994; Bailey *et al.*, 2014). Circulating potassium concentrations remains relatively stable, even in the presence of wide variations in daily potassium intake, due the rapid cellular uptake of potassium entering the body after meals. This process, defined as extrarenal or internal potassium balance, has been discussed in the previous section and is under the control of the factors reported in **Table 1**.

The long-term potassium homeostasis is regulated mainly by the kidney, which ultimately controls plasma potassium concentration as well as total body potassium. Approximately 90% of the daily K intake (40–100 mEq) is excreted in the urine, the balance between dietary intake and renal excretion being the main regulator of body potassium content. During conditions of neutral potassium balance, the daily intake of potassium is equal to the daily excretion rate, primarily in the urine. The remaining part of dietary potassium is eliminated in the feces and, to a lesser extent, in the sweat (Bailey *et al.*, 2014).

Potassium is freely filtered by the glomerulus. In healthy adults, the rate of potassium filtration by the glomerular capillaries is 756 mmol/day, considering a glomerular filtration rate of 180 L/day multiplied by a plasma potassium concentration of 4.2 mmol/L (Guyton and Hall, 2006). Although there is a complex process of potassium reabsorption and secretion by the nephron from the proximal tubule through the loop of Henle, the bulk of filtered potassium load is reabsorbed in the proximal tubule and loop of Henle, so that $<10\%$ of the filtered load reaches the distal nephron. Beyond the early distal tubule, the tubule may modulate potassium delivery by either reabsorbing or secreting it, through both transcellular and paracellular pathways. Hence, urinary potassium excretion is ultimately regulated by changes in potassium secretion at the distal tubule and the collecting duct under the influence of a number of modulators (Giebisch and Wang, 2010; **Table 2**).

Table 2 Determinants of renal potassium excretion

Lower potassium excretion
Decreased intracellular potassium concentration
Decreased dietary intake
Acidosis
Unfavorable electrical or chemical profile
Reduction of lumenal electronegativity
Reduction of distal urine flow
Reduction of distal sodium delivery or reabsorption
Kidney function
Decreased tubular filtration rate
Tubular damage
Diuretics
Inhibitors of the apical sodium channel (amiloride, triamterene)
Inhibitors of aldosterone
Increase potassium excretion
Increased intracellular potassium concentration
Increased dietary intake
Alkalosis
Aldosterone
Favorable electrical or chemical profile
Increase in lumenal electronegativity
Increase in distal urine flow
Increase in distal sodium delivery
Low lumenal chloride concentration
Loop diuretics (furosemide)

It should be considered that under most circumstances, the kidney primarily works to excrete (rather than to reabsorb) potassium to maintain potassium balance against variation in potassium intake from dietary or other sources. Under normal conditions, when ample potassium is consumed in the diet, there is an addition of potassium along the distal nephron; in the presence of a very high potassium intake, the distal nephron effects net secretion, whereas it effects net potassium reabsorption only in the presence of potassium restriction (Unwin *et al.*, 1994). Cells in the connecting and collecting tubules respond to a number of signals by modulating their rate of potassium secretion over a wide range of values. The Na^+/K^+-ATPase located in the basolateral membranes of the tubules provides the driving force for potassium secretion by pumping potassium into the cells. This enzyme system responds to changes in extracellular potassium concentration, changes in extracellular pH, and changes in mineralocorticoid hormone secretion (O'Neil, 1990).

First, the potassium load absorbed with a meal is the most important determinant of potassium secretion, because it is perceived as a stress upon the organism, which requires immediate response, through the involvement of multiple organs, including the gut, kidney, and the muscle and liver (Boyd-Shiwarski and Subramanya, 2017). Second, the feedback control of aldosterone secretion by the zona glomerulosa of the adrenal cortex is needed for regulation of potassium excretion. Aldosterone secretion is under the strict control of two stimuli, that is, the plasma concentration of angiotensin II and the plasma concentration of potassium itself. Aldosterone, which stimulates Na^+/K^+-ATPase, promotes potassium secretion by increasing basolateral potassium entry into the cells and intracellular potassium concentration (O'Neil, 1990). This in turn will favor the delivery of potassium into the renal tubule lumen down its concentration gradient, thereby stimulating potassium secretion. Glucocorticoids also affect potassium secretion primarily by increasing tubule fluid flow rate (Adam *et al.*, 1984). Acid–base changes acutely affect secretion. Alkalosis induces greater potassium secretion at the distal tubule by moving potassium into the cells and acidosis moves potassium out of cells as hydrogen ions move in. The urine flow rate itself affects potassium secretion; with diuresis, increased amounts of fluid and salts move to the distal tubule, enhancing potassium excretion (Giebisch, 1998). Finally, a number of drugs can affect renal potassium handling by a variety of different mechanisms (Howes, 1995). For instance, loop diuretics, such as furosemide, in addition to increasing flow rate to the distal nephron, inhibit potassium reabsorption by the thick ascending limb of the loop of Henle. In contrast, the so-called potassium-sparing diuretics amiloride and triamterene block the apical sodium channel in the late distal tubule and collecting duct. The blockade of the apical sodium channel increases sodium excretion without affecting potassium secretion. Finally, aldosterone antagonists (e.g., spironolactone) also increase sodium excretion without an increase in potassium excretion.

More recently, it has been reported that renal potassium excretion has also a circadian rhythm independent of food. The circadian rhythm, which is regulated by a central clock in the brain, is transmitted to circadian clocks in the tubule cells responsible for variations in potassium excretion. As a result, potassium excretion is enhanced during the daylight phase and reduced during the night time phase (Gumz and Rabinowitz, 2013).

Nutritional and Metabolic Aspects

Potassium is largely present in many foods, particularly fruits, vegetables, whole grains, legumes, and nuts, typically in the form of organic (gluconate and citrate) salts, or, to a lower extent, of inorganic (bicarbonate and phosphate) salts. Potassium is also found in milk and dairy products and in some types of meat. Substantial potassium losses may occur during food processing and cooking. Estimates of the potassium content in different foods can be found in publicly available repositories (e.g., https://ndb.nal.usda.gov/ndb/nutrients/).

The total, nondiscretionary intake of potassium varies among different populations. In the International Collaborative Survey of Electrolyte Excretion and Blood Pressure, which analyzed 24 h sodium and potassium urinary excretion in over 10,000 individuals from 32 countries, the average potassium intake ranged from 25 mmol/day (American blacks in Goodman, Wisconsin, United States) to 87 mmol/day (Xingu Indians, Brazil) (Intersalt Cooperative Research Group, 1988). A few isolated populations participating in this worldwide survey were found to consume much greater amounts of potassium and smaller amounts of sodium than people living in industrialized countries, their sodium/potassium ratio being similar to that estimated by anthropologists for our hunter–gatherer ancestors (Western diet >3, primitive diets 0.5 or below) (Intersalt Cooperative Research Group, 1988; Frassetto *et al.*, 2009). Potassium intake has been reported to be associated with several health outcomes, particularly cardiovascular endpoints. High dietary potassium intake may protect against developing hypertension and improve blood pressure control in patients with hypertension, while inadequate potassium intake may increase blood pressure (Aburto *et al.*, 2013). Furthermore, there is consistent evidence from observational cohort studies that potassium intakes below 3500 mg (90 mmol)/day are associated with a higher risk of stroke (Vinceti *et al.*, 2016). Thus, to prevent the possible consequences of insufficient potassium intake, international bodies such as WHO (WHO, 2012) and EFSA (EFSA, 2016) considered a potassium intake of at least 90 mmol/day (3500 mg/day) adequate for healthy adults.

As discussed earlier, major sustained increases in plasma potassium concentration are almost never caused by dietary changes, because the homeostatic mechanisms are highly efficient in healthy individuals. In response to a large oral potassium load, the excess potassium is partly stored in the large cellular compartment and partly excreted in the urine in a matter of a few hours. Thus, hyperkalemia may develop only in the presence of severe pathological conditions that impair the activity of these defense mechanisms (e.g., renal failure, adrenal insufficiency) (Lehnhardt and Kemper, 2011). On the other hand, the control of potassium homeostasis is less effective in preventing the hypokalemia caused by a subnormal potassium intake, particularly in the

presence of a concomitant high'sodium diet, which induces an obligatory potassium loss. In fact, severe potassium depletion may occur when habitual potassium intake is <25 mmol/day (Young *et al.*, 1995). In particular, two conditions may often lead to potassium depletion. One is the "protein-modified fast," which may be adopted by severely obese patients in the early phase of a weight-reducing program (Lin *et al.*, 1997), and the other is chronic alcoholism, due to the large amount of "empty calories" ingested from alcohol (Elisaf *et al.*, 2002).

For the reasons just discussed, the collection of accurate information about dietary potassium intake is of primary importance. As powerful homeostatic mechanisms act to minimize changes in plasma potassium, the measurement of plasma potassium concentration is of limited value in estimating the adequacy of potassium intake. Several approaches based on dietary assessment methods have been proposed. The personal recall of food consumption is the least reliable method; history records are slightly better, although their accuracy may be hampered by incomplete record-keeping, variability in the potassium content of foods, and errors in estimation of quantity (Freedman *et al.*, 2015). The most accurate single technique for estimation of dietary intake of nutrients, including potassium, is the collection and analysis of duplicate food samples; unfortunately, this method is expensive and not applicable to population studies. For everyday purposes, the measurement of urinary potassium excretion provides a reasonably good estimate of dietary intake (Tasevska *et al.*, 2006). Its use is based on the assumption that at least 90% of the potassium ingested is eliminated through the renal route. Well-recognized limitations of this method include the relatively high day-to-day intraindividual variability in potassium intake (and thus potassium excretion), and also the concomitant variability in sodium intake, which in turn influences potassium excretion (Siani *et al.*, 1989). To overcome this problem, a certain number of 24 h urine collections are requested if a reasonably good estimate of an individual's habitual potassium intake is to be obtained. Despite these limitations, the measurement of urinary excretion is as yet the simplest and least expensive way to assess dietary sodium and potassium intakes in population studies as well as in clinical studies.

Salt-Sensitivity of Blood Pressure

Pasquale Strazzullo, Ferruccio Galletti, and Lanfranco D'Elia, Federico II University of Naples, Naples, Italy

Abbreviations

20-HETE	20-hydroxyeicosatetraenoic acid
ABPM	Ambulatory blood pressure monitoring
ANPs	Atrial natriuretic peptides
BP	Blood pressure
EETs	Epoxyeicosatrienoic acids
NO	Nitric oxide
OW	Overweight
RAAS	Renin–angiotensin–aldosterone system
SNS	Sympathetic nervous system
WHO	World Health Organization

Glossary

Salt-sensitivity of blood pressure The interindividual difference in the blood pressure response to changes in salt intake.

Introduction

Dietary salt intake plays a key role for cardiovascular health (Aburto *et al.*, 2013). A huge amount of animal experimental investigation, epidemiological studies and controlled clinical trials support the strong relationship existing between salt intake and blood pressure (BP) (He and MacGregor, 2009; He *et al.*, 2013). In most countries worldwide the habitual average sodium intake largely exceeds the physiological needs and the recommended adequate intake determined on the basis of scientific evidence (He and MacGregor, 2009; World Health Organization, 2012). In fact, the majority of individuals experience a decrease in BP when reducing salt intake for a sufficiently prolonged period of time (Sacks *et al.*, 2001). The so-called salt-sensitivity of BP actually refers to the interindividual difference in the BP response to a given change in salt intake. Based on these responses, it has become popular to identify, within a given population sample, individuals (or patients) who are defined either salt-sensitive or salt-resistant using "arbitrary" cut-offs (Weinberger *et al.*, 1993; Galletti *et al.*, 1997a, b). Actually, the BP response to changes in salt intake exquisitely behaves as a continuous variable with a simil-Gaussian distribution (Weinberger *et al.*, 1986; He *et al.*, 2001; Sullivan, 1991), not allowing to detect any distinct subpopulation (He *et al.*, 2009). This notwithstanding, salt-sensitivity of BP is of interest and of potential clinical importance as it is associated with several cardio-metabolic risk factors (Galletti *et al.*, 1997b; Strazzullo *et al.*, 2006) and even with a higher risk of premature death (Weinberger *et al.*, 2001). Therefore, scope of this short review will be (1) to focus on the main factors that determine the individual BP salt-sensitivity, including inherited and acquired factors or medical conditions which are at least partly modifiable; (2) to briefly discuss the methods commonly adopted to assess BP salt-sensitivity either as research tools or in clinical settings.

Determinants of Blood Pressure Salt-Sensitivity

Genetic Factors

Rare monogenic forms of hypertension are paradigmatic expressions of the influence of genetic factors on BP salt-sensitivity, in which mutations in a single gene, encoding a molecule involved in sodium transport through the tubular epithelium, lead to an excess in renal tubular sodium reabsorption (Luft, 2002). Typical examples are the mutations in the aldosterone synthase/11β-hydroxylase genes (glucocorticoid-remediable aldosteronism), in the renal-specific isoform of the 11β-hydroxysteroid dehydrogenase gene (apparent mineralocorticoid excess syndrome), and in the (β or γ subunits) amiloride sensitive epithelial sodium channel, as reported in the Liddle syndrome. All these alterations affect the renal-pressure natriuresis curve and cause salt-sensitive hypertension (Luft 2002; Luft *et al.*, 1988).

In addition to these monogenic forms of hypertension, a large number of genetic polymorphisms have been associated with a high rate of hypertension (Strazzullo and Galletti, 2007), among which those affecting the α-adducin molecule (Bianchi *et al.*, 2005; Manunta *et al.*, 1999), the glucagon receptor (Strazzullo *et al.*, 2001a), the G-protein beta-3 subunit (Pamies-Andreu *et al.*, 2003), the adrenergic receptors (Svetkey *et al.*, 2011; Pojoga *et al.*, 2006), the renal–angiotensin–aldosterone system (Siani *et al.*, 2004), the renal isoenzyme of 11beta-hydroxysteroid dehydrogenase (Agarwal *et al.*, 2000; Lovati *et al.*, 1999), the nitric oxide (NO) production (Hoffmann *et al.*, 2005; Dengel *et al.*, 2007), the natriuretic peptides (Arora *et al.*, 2013), and the arachidonic acid metabolites (Laffer *et al.*, 2008; Williams *et al.*, 2011).

Physiological Aspects Affecting Blood Pressure Salt-Sensitivity

There is ample evidence that aging is associated with increasing BP response to high salt intake (Weinberger and Fineberg, 1991; He *et al.*, 2009). One of the reasons for this could be the progressive loss of functional nephrons and in turn the decline in renal function occurring at a rate of approximately 10% per decade of life after age 40 (Dunnill and Halley, 1973; Hall *et al.*, 1989). This condition is further amplified by hypertension, diabetes or coexisting renal disease (Johnson *et al.*, 2005; Weinberger 1996). Ethnic group comparisons showed that black individuals have a higher BP response to changes in salt intake than whites (Weinberger *et al.*, 1982), independently of baseline BP (Vollmer *et al.*, 2001; Aburto *et al.*, 2013). Few data are available about comparisons between other ethnic groups (He *et al.*, 2009).

Also, little evidence is available about intergender comparisons. The results of the Dash-trial indeed suggested that women may have greater BP salt-sensitivity than men (Vollmer *et al.*, 2001). Notably, salt-sensitivity of BP is highly variable in women due to changes in circulating levels of sex hormones. Data on young women showed that estrogens may protect them toward the unfavorable effect of salt on BP by affecting the pressure–natriuresis relationship (Pechere-Bertschi and Burnier, 2004). In fact, the pressure–natriuresis curve was shown to move to the right in postmenopausal women (Pechere-Bertschi and Burnier, 2004) and other studies pointed to an association between the age-related loss of estrogens and the development of salt-sensitive hypertension (Weinberger and Fineberg, 1991).

A number of physiological mechanisms that regulate the cardiovascular adaptation to salt intake may affect the BP salt-sensitivity. A major role in this regard is played by the renin–angiotensin–aldosterone system (RAAS) (Hall, 1986). During high salt intake, suppression of the RAAS should allow quantitative excretion of sodium and water with maintenance of a neutral balance and without elevation in BP. RAAS suppression however may be blunted in obese individuals and in type 2 diabetic patients, thus increasing BP salt-sensitivity. On the other hand, the fall in BP following reduction of salt intake may depend on the compensatory increase in RAAS activation which may markedly differ among individuals (He *et al.*, 2001; Yatabe *et al.*, 2010).

Aldosterone affects the pressure–natriuresis relationship to an extent similar to that observed for Angiotensin II. Excess aldosterone secretion leads to higher BP salt-sensitivity: indeed, a moderate rise in plasma aldosterone provokes marked hypertension when salt intake is normal or high, while during low salt intake the effect on BP is modest (Guyton, 1980; Hall *et al.*, 1984; de Paula *et al.*, 2004).

A number of studies suggest that impaired NO production may contribute to sodium balance regulation and may play a role in the pathogenesis of salt-sensitive hypertension (Granger and Alexander, 2000; Sanders, 2004). NO reduction may be a consequence of endothelial dysfunction and contribute to BP salt-sensitivity by inhibition of the vasodilatory response to salt loading (Campese *et al.*, 1997). Several lines of evidence indicate that also the endothelin system could play a role in salt-sensitivity of BP: for instance, urinary endothelin-1 is negatively associated with BP while it is positively associated with sodium excretion during a salt load. One study showed that salt-sensitive hypertensive patients had lower levels of the peptide than salt-resistant patients (Hoffman *et al.*, 1994), supporting its possible pathogenetic role, in keeping with the results from experimental studies in animal models (Kassab *et al.*, 1997, 1998).

Also cytochrome P450-derived metabolites of arachidonic acid, in particular 20-hydroxyeicosatetraenoic acid (20-HETE) and epoxyeicosatrienoic acids (EETs), may have a role in BP salt-sensitivity through their effects on renal pressure natriuresis (Roman, 2002). 20-HETE inhibits sodium reabsorption at the proximal tubule (Quigley *et al.*, 2000; Schwartzman *et al.*, 1985) and at the thick ascending loop of Henle (Wang *et al.*, 1996). On a study in hypertensive individuals receiving a salt load, a correlation between urinary excretion of 20-HETE and sodium excretion in salt-resistant hypertensives was showed, while no association with BP was found. Conversely, no correlation between urinary 20-HETE and sodium excretion was detected in salt-sensitive individuals, while positive correlation with BP was found (Laffer *et al.*, 2003). These findings indicate a possible defect in the ability of 20-HETE to inhibit sodium reabsorption in salt-sensitive patients during salt-loading, leading to a shift in the pressure natriuresis curve and to an increase in BP.

In addition to the vasodilator effect, EETs may affect BP salt-sensitivity by inhibition of sodium transport at the proximal tubule (Harris *et al.*, 1990) and collecting duct (Sakairi *et al.*, 1995). This activity could contribute to the adaptation to a salt diet. Indeed, during salt restriction, EETs were found to be lower in plasma and urine of salt-sensitive compared with salt-resistant subjects (Gilbert *et al.*, 2013).

Contrasting results were reported concerning the relationship between atrial natriuretic peptides (ANPs) and salt-sensitive hypertension (Jin *et al.*, 1992; Campese *et al.*, 1996). Some studies reported a decrease in plasma ANP levels during high salt intake (Campese *et al.*, 1996; Lieb *et al.*, 2011), whereas they showed no difference in the ANP response to high salt intake between salt-sensitive and salt-resistant individuals (de la Sierra *et al.*, 1996).

Last but not least, the sympathetic nervous system (SNS) is involved in BP salt-sensitivity. Salt-sensitive subjects were reported to have a greater plasma catecholamine responses to salt depletion than salt-resistant hypertensive individuals due to sympathetic stimulation by the decrease in BP (Laffer *et al.*, 2006; Elijovich *et al.*, 2001). Moreover, salt-sensitive hypertensive patients provided a higher BP response to exogenous norepinephrine than salt-resistant patients, suggesting substantial differences in norepinephrine metabolism between salt-sensitive and salt-resistant hypertensive patients (Campese *et al.*, 1993). This response was also detected in salt-sensitive normotensive individuals during high salt intake (Sharma *et al.*, 1992).

Salt-Sensitivity of Blood Pressure in Relation to Specific Clinical Conditions

A few clinical conditions are associated with higher BP salt-sensitivity. Among these, overweight (OW) and obesity are definitely the most common ones (Galletti *et al.*, 1997b; Strazzullo *et al.*, 2003). An elegant demonstration of the impact of OW on BP salt-sensitivity was provided by an intervention study in obese and nonobese adolescents by Rocchini *et al.* (1989): on a low-salt diet,

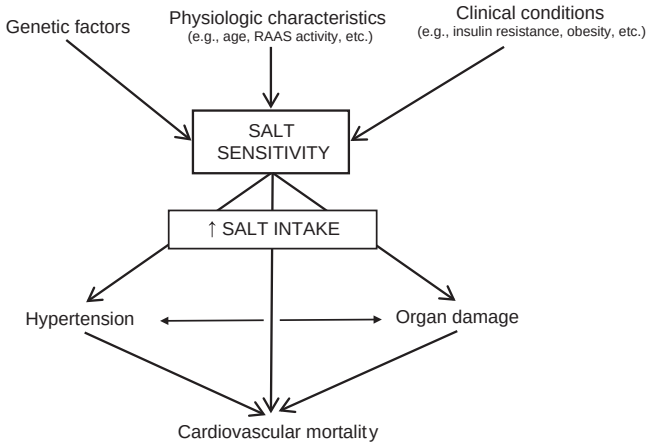

Fig. 1 Mechanisms associated with the heterogeneity in salt-sensitivity of blood pressure. *RAAS*, renin–angiotensin–aldosterone system.

obese and lean adolescents had similar BP, but upon switching to a high-salt consumption, the obese participants developed a much greater increase in BP, arguing for an altered pressure-natriuresis relationship. Moreover, after partial correction of OW through caloric restriction and increased physical exercise, BP salt-sensitivity was reduced and the BP-natriuresis relationship turned out similar to that of normal weight adolescents. Similar alterations of BP salt-sensitivity were described by Strazzullo *et al.* in patients with metabolic syndrome (Strazzullo *et al.*, 2006), confirmed later by the results of the GENSALT study that showed a greater BP response to dietary salt restriction in subjects with metabolic syndrome (Chen *et al.*, 2009). Indeed, both abdominal adiposity (Strazzullo *et al.*, 2001b) and metabolic syndrome (Strazzullo *et al.*, 2006) are associated with an altered rate of proximal tubular sodium reabsorption, which is at least partially explained by the effects of hyperinsulinaemia (Barbato *et al.*, 2004) and hyperleptinaemia (Barba *et al.*, 2003), both common conditions in these subjects.

There is also experimental and clinical evidence of a direct relationship between BP salt-sensitivity and insulin resistance. Thus, in essential hypertensive patients with normal glucose tolerance, insulin-stimulated whole-body glucose uptake was negatively associated with BP salt-sensitivity, independently of age and body mass index (Galletti *et al.*, 1997b). Moreover, BP salt-sensitivity may also be affected by insulin effects through modulation of endothelial relaxation (Bragulat *et al.*, 2001) (**Fig. 1**).

The Assessment of Blood Pressure Salt-Sensitivity

Several ways to measure BP salt-sensitivity have been explored and more or less extensively investigated, however no reliable marker of BP salt-sensitivity has been detected. The gold standard for the evaluation of BP salt-sensitivity should be represented by the BP response to moderate reduction of salt intake maintained over a period of several weeks. However, poor patients' compliance is a serious limitation. To overcome this problem, the assessment of BP salt-sensitivity has most often been made using short-term tests applying huge differences in salt intake for only a few days. Unfortunately, most of the tests have proved inaccurate, poorly reproducible, often costly and not applicable in real life conditions. A widely used protocol for the assessment of BP salt-sensitivity in clinical investigation is the Grim-Weinberger test, which evaluates the BP response to a rapid volume expansion and contraction protocol applied in sequence (Weinberger *et al.*, 1993). BP salt-sensitivity is defined as a 10-mmHg or higher change in mean BP from the level assessed after a 4-h infusion of 2 L of saline solution compared to the level measured the morning after 1 day of a low (10 mmol) sodium diet and administration of three doses of diuretic (Furosemide). This protocol has undergone several reproducibility and comparability tests versus the BP response to dietary salt restriction (Galletti *et al.*, 1997a; Strazzullo *et al.*, 2000) with unsatisfactory results.

More recently, ambulatory blood pressure monitoring (ABPM) has been proposed as another possible way to clinically assess BP salt-sensitivity (Castiglioni *et al.*, 2011). The main study result was that the subjects with greater salt-sensitivity based on the BP response to one-week sodium chloride restriction exhibited an altered circadian BP pattern, with higher night-time BP and heart rate levels, possibly explained as a neurohormonal response to sodium and water retention occurring during daytime. Although of interest, the size of the correlation coefficients was definitely too small to support the possibility of a practical application and, once again, the index of salt-sensitivity used as a reference standard was based on the response to short-term severe reduction in salt intake rather than to moderate long-term salt intake reduction.

Further studies should be carried out for the accurate assessment of the BP salt-sensitivity phenotype in clinical practice, and to overcome the arbitrary stratification of BP salt-sensitivity.

Salt- Sensitivity of Blood Pressure and Cardiovascular Risk

Several studies suggest that BP salt-sensitivity is associated with higher rates of organ injury and cardiovascular events (Bihorac *et al.*, 2000, Morimoto *et al.*, 1997, Weinberger *et al.*, 2001). A longitudinal study showed that BP salt-sensitivity was associated

with higher cardiovascular risk, independently of BP and smoking habits (Morimoto *et al.*, 1997). Another prospective study with 27 year follow-up indicated a higher mortality rate from all causes, both in hypertensive and normotensive subjects, with higher BP salt-sensitivity (Weinberger *et al.*, 2001).

An observational study on normotensive and apparently healthy men with different BP salt-sensitivity showed that the incidence of hypertension, over 15 years, was significantly higher among subjects with a greater degree of BP salt-sensitivity at baseline compared with subjects with lower BP salt-sensitivity (Barba *et al.*, 2007). BP salt-sensitivity was also associated with a higher prevalence of organ damage (e.g. left ventricular hypertrophy, renal dysfunction, etc.) clustered with hyperinsulinaemia, hyperlipidaemia, and evidence of endothelial dysfunction, in untreated hypertensive patients (Bihorac *et al.*, 2000). Likewise, patients with higher BP salt-sensitivity had reduced flow-mediated vasodilation and endothelial dysfunction (Liu *et al.*, 2012).

Conclusions and Perspectives

In summary, a large body of evidence from experimental, clinical and epidemiological studies supports a role for BP salt-sensitivity as predictor of cardiovascular morbidity and mortality. In addition to the genetic and demographic factors, several metabolic and neurohormonal conditions affect BP salt-sensitivity, including excess body weight and its related alterations (i.e. hyperinsulinemia and insulin resistance, hyperleptinemia, over-activity of the RAAS and of the SNS, etc.): most of these conditions are in turn associated with altered renal sodium handling.

In consideration that the majority of subjects in any given population experience a decrease in BP in response to gradual, long-term and moderate dietary salt intake reduction, a population strategy aiming at gradual salt intake reduction as indicated by WHO and the United Nations (World Health Organization, 2013) should be pursued.

Endogenous Ouabain☆

Paolo Manunta and Marco Simonini, University Vita-Salute San Raffaele, Milan, Italy

Glossary

Allele Any of two or more alternative forms of a gene occupying the same chromosomal locus.

Hypertension A condition of persistently high arterial blood pressure; in adults, this is usually identified as a blood pressure reading that exceeds 140/90 mmHg. The condition may be associated with other disorders (secondary hypertension) or may not have a single identifiable cause (essential or primary hypertension). Individuals affected by hypertension are at risk for heart disease, kidney failure, and stroke.

Ouabain Hygroscopic white plates that are soluble in water and alcohol and used in medicine.

Introduction

Cardiac glycosides have been among the most frequently used classes of drugs for the treatment of heart failure and arrhythmias. It is generally accepted that cardiac glycosides exert their cardiotonic action by binding to the extracellularly exposed recognition sites on the Na^+,K^+-ATPase, an integral membrane protein that establishes the electrochemical gradient of Na^+ and K^+ across the plasma membrane. The phylogenic conservation of isoform-specific regions involved in digitalis binding within the Na^+,K^+-ATPase in distantly related species has led to the proposal that an endogenous counterpart to the plant cardiac glycoside might exist in mammals as well and that the Na^+,K^+-ATPase might represent its functional receptor. The cardiotonic steroid–binding site of the Na,K-ATPase is often called the ouabain-binding site, as this is the cardiotonic steroid most often used in the laboratory. This binding site is highly conserved in diverse organisms (from *Drosophila* to rodent and sheep and to human). The ouabain sensitivity of the Na,K-ATPase is determined by the α subunit.

The Endogenous Na^+,K^+-ATPase Inhibitor: Background Research

Experimental evidence substantiated the presence of several candidates for the mammalian Na^+,K^+-ATPase inhibitor. In particular, the development of volume-expanded conditions in animals was demonstrated to be associated with the appearance in the circulation of an endogenous substance able to inhibit cell membrane sodium transport. These studies documented the existence of a "natriuretic hormone" involved in the control of sodium homeostasis. It has been proposed that an increase in the extracellular fluid volume might be a stimulus for the release of a humoral substance able to counterbalance the increased renal sodium and water reabsorption through its ability to inhibit renal Na^+,K^+-ATPase, the key enzyme involved in renal tubular sodium reabsorptive processes. Moreover, by acting as a physiological regulator of the Na^+–K^+ pump in regions other than the kidney (such as the neurovascular system), the endogenous inhibitor might cause peripheral vasoconstriction, mediated by the increase in intracellular sodium and calcium, leading to a sustained rise in blood pressure (Blaustein, 2014; Hamlyn and Blaustein, 2016).

Many research groups have pursued extensive studies aimed at characterizing the putative humoral substance(s) by isolating the compound(s) under physiological and pathological conditions (hypertension, pregnancy, neonate). Consistent findings over the years indicate that mammalian plasma, urine, and tissues indeed contain distinguishable biologically active candidate inhibitors of the Na^+,K^+-ATPase.

Among the putative endogenous inhibitors, a compound that resembles most of the functional properties of the plant-derived cardiac glycoside has been identified and chemically and functionally characterized. In the human circulation and bovine hypothalamus, Hamlyn's and Haupert's groups recognized this novel steroidal isomer of the plant glycoside ouabain in which the location of two or more steroidal hydroxyl groups may differ. An endogenous compound, showing similarities to ouabain in terms of high-performance liquid chromatography retention time and cross-reactivity with a specific anti-ouabain antibody, was purified from hypertensive rats of the Milan hypertensive strain (MHS) and human plasma (Zhao *et al.*, 1995).

Several other research groups were able to recognize in mammalian plasma and tissues an inhibitor that was indistinguishable from plant ouabain by multiple biochemical and physiological criteria, although the chemical characterization was not completed. Experimental evidence has documented the presence in mammals of several endogenous steroids structurally related to the bufodienolides (as marinobufagenin).

☆*Change History*: February, 2018. P Manunta and M Simonini have updated text and references.

This chapter is an update of Paolo Manunta, Marco Ferrandi, and G Bianchi, Ouabain, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 447–450.

 doi:10.1016/B978-0-12-801238-3.95902-6

The existence of distinct endogenous inhibitors of the Na^+,K^+-ATPase is in accordance with the hypothesis that they may be functionally involved as tissue-specific regulators of the different Na^+,K^+-ATPase isoforms and thus they may be independently regulated following particular stimuli. This evidence indicates that such endogenous regulators of the Na^+,K^+-ATPase may play distinct pathophysiological roles.

The Pressor Mechanism of the Endogenous Ouabain

For many years, the authors have been involved in the attempt to elucidate the molecular mechanisms leading to hypertension. The strategy has included studies of renal function and cellular, biochemical, and molecular characterization of the MHS rats, considered a suitable model for at least a subgroup of hypertensive patients. Common genetic–molecular mechanisms underlying the disease have been identified in both species. Increased circulating levels of endogenous ouabain (EO), considered the mammalian counterpart of plant ouabain, and mutations of the gene coding for the cytoskeletal protein adducin have been demonstrated to correlate with increased renal tubular sodium reabsorption and hypertension in both MHS rats and humans. Experimental evidence has suggested that Hexogen (plant) ouabain itself may act as a pressor agent in vivo, since the prolonged infusion of low doses of ouabain into normotensive rats (OS), induces a sustained and reversible form of hypertension. An increased expression and increased activity of renal Na^+,K^+-ATPase have been documented both in vivo, in OS and in MHS rats, and in rat renal cultured cells chronically exposed to nanomolar concentrations of ouabain or in cells transfected with the MHS adducin genetic variant (Manunta *et al.*, 1994). Interestingly, additional data have further investigated the mechanism underlying the increased surface expression of the Na^+,K^+-ATPase induced by both ouabain and adducin. Indeed, it was identify a slower recycling of the protein from the plasma membrane (due to a reduced rate of internalization through the clathrin-coated vesicles during endocytosis) in presence of both conditions (increase of ouabain level and mutated adducin variant). Furthermore, in vitro studies have confirmed that adducin directly interacts with Na^+,K^+-ATPase and that the mutated adducin variant interacts with the enzyme at significantly lower concentrations than the wild-type adducin. Therefore, the overexpression of the renal Na^+–K^+ pump, most probably resulting from a tighter anchoring of the enzyme to the cytoskeletal proteins, appears to be a common biochemical alteration present in both the ouabain- and adducin-dependent forms of hypertension (Lanzani *et al.*, 2010).

At first glance, these findings seem to be inconsistent with the traditional view postulated for the "endogenous Na^+,K^+-ATPase inhibitor," the so-called natriuretic hypothesis, supporting the proposal that the expansion of extracellular volume might induce the release of an endogenous hormone able to promote natriuresis and diuresis. According to this "*old*" hypothesis, a reduction, rather than an increase, in renal Na^+,K^+-ATPase activity would be expected in association with high levels of EO. In order to better clarify this issue, the relationship between EO and changes in sodium balance in both rats and essential hypertensive patients has been investigated and it was demonstrated that an acute and chronic restriction of salt intake, but not acute salt loading, is responsible for a significant rise in plasma EO in both MHS rats and humans (Tripodi *et al.*, 2009).

Collectively, findings in rat and human indicate that EO does not behave like a natriuretic hormone in vivo, but rather EO may be activated under conditions of salt and water reduction. These findings raise the possibility that EO participates in the conservation of body sodium and thus it may be involved in the reestablishment of the hydro-saline homeostatic equilibrium, mediated through its ability to enhance renal Na^+,K^+-ATPase activity. Studies support a unique role played by renal Na^+,K^+-ATPase in the pathophysiological action of EO (Hamlyn and Manunta, 2015).

Since it has been demonstrated that adducin is directly involved in renal Na^+,K^+-ATPase modulation also, the question of whether adducin polymorphism might affect EO response in the adaptation to a low-salt diet has been raised. Indeed, a chronic low-salt diet significantly increased plasma EO levels in hypertensive patients carrying the mutated Trp-460 allele in the ADD1 gene locus, but not in Gly-460 subjects, thus counteracting the hypotensive effect of the low-salt diet. Similarly, an increased EO was shown in MHS rats and in the congenic rat strain NA (obtained by introgressing the MHS ADD1 locus into the normotensive genetic background) but not in normotensive rats. No modifications of plasma EO following consumption of a high-salt diet have been observed in either rats or humans. Data support the hypothesis that the adducin genotype might predict changes in plasma EO levels under salt restriction conditions (Hamlyn and Blaustein, 2013).

Another study has further explored the relationship between EO and blood pressure in the general population and several new findings were reported: (1) the carriers of the mutated α-adducin Trp allele show higher plasma levels than the homozygotic Gly/Gly individuals; (2) EO plasma levels positively correlate with urinary potassium excretion; and (3) there is a significant interaction between EO and urinary sodium excretion in relation to blood pressure (Manunta *et al.*, 2008).

EO appears to behave like a positive regulator of blood pressure when a low-salt diet is followed, whereas EO may act as a compensatory hormone preventing salt-induced high blood pressure when salt intake is elevated. Data indicate that a complex, although not fully elucidated, interrelationship does exist between EO and genetics in the homeostatic regulation of blood pressure in response to changes in salt intake.

Endogenous Ouabain as a Risk Factor for Cardiac and Renal Complications

EO and CV Disease

Data have indicated that EO, in addition to directly influencing blood pressure, is involved in the development of cardiac complications (hypertrophy, heart failure, myocardial infarction) associated with hypertension, as shown in rat models (OS and

MHS rats) and in hypertensive subjects, studied at different stages of the disease (Manunta *et al.*, 1999; Pavlovic, 2014; Pierdomenico *et al.*, 2001). In approximately 50% of patients with uncomplicated essential hypertension, plasma EO levels are increased and positively correlate with left ventricular mass index and stroke volume and negatively correlate with heart rate (Manunta *et al.*, 2011). Moreover, may authors identified a relationship between increased circulating EO and cardiomyopathy; in particular, in the advanced phases of cardiac pathology, plasma EO levels are inversely correlated with stroke volume and are inversely correlated with the ejection fraction. Finally, endogenous cardiotonic steroids (CTS), and in particular endogenous ouabain, have been shown to contribute to pro-hypertrophic and pro-fibrotic cell signaling (Bagrov and Shapiro, 2008).

These findings suggest that EO may play a novel and direct role in vivo as a pro-hypertrophic hormone and thus may affect cardiovascular function and structure, by functioning in cardiac remodeling, which contributes to an increased risk of morbid events. Studies carried out in cultured cells have indeed provided the sequence of the ouabain-induced intracellular events leading to hypertrophic stimuli. The findings described in these reports support the notion that ouabain behaves like a growth-promoting hormone by acting as a signal transducer. By binding to the Na^+,K^+-ATPase, considered the only known functional receptor for digitalis, ouabain activates a complex intracellular signaling cascade, triggered by a tyrosine kinase-activated pathway, via epidermal growth factor receptor transactivation, that finally leads to the transcription of growth-related genes. The molecular mechanism leading to organ hypertrophy in vivo in OS rats has been hypothesized to occur through the activation of an intracellular signaling pathway similar to that described in cultured cells. Preliminary data are in line with the hypothesis that in vivo ouabain activates an intracellular signaling cascade within highly specialized membrane subdomain (Hamlyn and Blaustein, 2016).

EO and Renal Disease

The clearance of cardiac glycosides is one significant determinant of their circulating levels. Although digoxin and digitoxin are cleared primarily by the liver, clearance of EO is mediated to a large extent by the kidneys. Plasma EO rises with the progression of chronic kidney failure (CKF) (Hamlyn and Manunta, 2015). Moreover, with the advent of end-stage failure and near-zero urinary excretion, plasma EO rises substantially into the low nano-molar range. This scenario, analogous to unwanted and uncontrollable digitalization, is worrisome in terms of the potential for undesirable cardiac and vasopressor effects. Indeed, among patients with ESRD in dialysis, plasma EO was strongly associated with left ventricular mass and geometry (Stella *et al.*, 2008). This association was independent of arterial pressure and other well-established determinants of left ventricular mass. Thus, in ESRD, left ventricular hypertrophy and high cardiovascular risk, including that from hypertension, represent additional multifactorial problems potentially related to EO.

In addition to raising BP, the elevated EO in kidney failure may directly damage podocytes. In rats, the chronic elevation of circulating ouabain reduced creatinine clearance, increased urinary protein excretion, and reduced the expression of podocyte nephrin, a selective podocyte marker protein. This last finding was replicated ex vivo by incubating podocyte primary cell cultures with low-dose ouabain.

The observation that ouabain foments kidney damage in the rat suggested a possible role of EO in acute kidney injury (AKI). Indeed, circulating EO rises with an interesting time course during the induction of anesthesia in patients about to undergo elective cardiac surgery. Recently, a significant association has been reported of preoperative EO levels with adverse renal outcomes in cardiac surgery patients and with mortality in critically-ill patients.

In a observational study, the preoperative plasma levels of EO were measured in more than 800 patients admitted for elective cardiac. An increase in incidence of AKI (2.8% vs. 8.3% vs. 20.3%) and ICU stay with each incremental preoperative EO tertile was observed (Bignami *et al.*, 2013). Moreover, the preoperative EO value was added to a different clinical AKI predictive model and resulted in a significant improvement of risk prediction power (AUC of AKI from 0.79 to 0.84) (Simonini *et al.*, 2014). Finally, post-operative EO levels were also associated with a higher mortality rate after cardiac surgery (Simonini *et al.*, 2015).

In this way, EO was identify as a potentially valuable biomarker of individual susceptibility to the development of mild to severe AKI after cardiac surgery. Indeed, EO from one side it is responsible of the initial nephrinuria and of glomerular damage, and, on the other side, it modulates the basolateral Na–K-ATPase, that is known to be involved in tubular ischemic damage.

Endogenous Ouabain as a Target for a Novel Therapeutic Approach

As already mentioned, more than one-third of patients with EH, mostly all patients with CKF, and a large portion of patients with heart failure have increased circulating levels of EO. In this way the pathophysiological implication of EO in hypertension and its associated cardiac and renal complications has led to an interest in developing a novel class of antihypertensive agents for use as antagonistic drugs that can correct selectively the genetic–molecular mechanisms involved in EO and adducin in both rat and human hypertension. Following this original physio-pathological idea, the authors' research group developed a new digitoxigenin derivative compound: *rostafuroxin*. It was selected for its ability to lower blood pressure in the experimental and genetic strains of OS and MHS rats, at oral doses of micrograms/kg/day, and to normalize the biochemical alteration, namely, the up-regulation of renal Na^+,K^+-ATPase activity, in both rat models (Ferrari *et al.*, 1998).

Interestingly, rostafuroxin displays an antihypertensive activity in other rat models, such as the deoxycorticosterone acetate salt rat and the reduced-renal-mass hypertensive rat, both characterized by volume expansion, low renin levels, and increased EO levels. The selectivity of the antihypertensive effect of rostafuroxin is sustained by the absence of activity in normotensive control rats and in spontaneous hypertensive rats (SHR) rats, a model in which EO, adducin polymorphism, and renal Na^+,K^+-ATPase seem not to be involved in the etiology of the disease. Finally, preliminary data suggest that the compound, at oral doses of 7–10 μg/kg/day, is able to revert in vivo in OS rats the ouabain-induced hypertrophic activity (Ferrandi *et al.*, 2010).

However, in a trial of unselected patients with EH (i.e., in which 50%–70% of the patients would not have elevated EO), rostafuroxin had no overall impact on BP. Instead, the BP-lowering activity of rostafuroxin depended on genomic variation in factors related to the synthesis and clearance of EO and to cytoskeletal polymorphisms. In rostafuroxin-sensitive patients, the systolic BP declined 14 mmHg after 4 weeks of treatment relative to controls the gene variants encode enzymes in steroid biosynthesis, transmembrane EO (ouabain) transport, and the cell cytoskeleton. This combination of gene variants occurred in 23% of the 196 (never treated) hypertensives in the study (Lanzani *et al.*, 2010).

Data regarding the impact of rostafuroxin in treating heart failure and the hypertension in patients with end-stage kidney failure are not available. In the latter settings, circulating EO levels are considerably higher than in EH, and dramatically larger doses of rostafuroxin than those used in prior trials may be needed to demonstrate efficacy.

The pharmacological profile of rostafuroxin suggests that it may represent the prototype of a novel class of antihypertensive drugs that is devoid of undesired cardiac and hormonal effects, which are typical of digitalis and diuretics. The compound does not interfere either in vivo or in vitro with a panel of receptors involved in blood pressure regulation or hormonal homeostasis and it has no intrinsic cardiac inotropic or arrhythmogenic activity.

Conclusion

This evidence reinforces the concept that high EO levels and adducin polymorphism are associated with an increased risk of developing hypertension and organ complications. Therefore, particularly in the case of complex multifactorial diseases, such as essential hypertension, a tailored approach should be pursued in order to treat individual patients carrying specific pathogenetic mechanisms.

Rostafuroxin may be considered a safe drug of great relevance for the therapy of those hypertensive patients in whom increased EO levels and adducin polymorphism exert a causal role.

Atrial Natriuretic Factor and the Family of Natriuretic Peptides☆

Tsuneo Ogawa and Adolfo J de Bold, University of Ottawa, Ottawa, ON, Canada

Introduction

The atrial natriuretic factor family of natriuretic peptides (NPs) consists of three members: atrial natriuretic factor (ANF or ANP), brain natriuretic peptide or B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP) (de Bold and Flynn, 1983; Flynn *et al.*, 1983; Kojima *et al.*, 1990; Sudoh *et al.*, 1988). These polypeptide hormones play central roles in maintaining fluid and electrolyte balance and circulatory homeostasis. In mammals, the bulk of ANF and BNP is produced and secreted by the cardiac muscle cell (cardiomyocyte). CNP is produced mainly by the vascular endothelium and the brain (Morel and Heisler, 1988; Mukoyama *et al.*, 1991; Suga *et al.*, 1992).

Physiology, Structure, Biosynthesis, and Regulation of ANF

Physiological Actions of ANF

In 1981 it was demonstrated that injections of heart atrial extracts into rats gave rise to pronounced diuresis, natriuresis, and lowered blood pressure (de Bold *et al.*, 1981). Within a short time, a peptide with the same biological properties as the crude atrial extracts was isolated and its amino acid sequence was identified (Flynn *et al.*, 1983). This peptide, known as atrial natriuretic factor (ANF) or atrial natriuretic peptide (ANP), firmly established the heart as an endocrine organ and heralded a new era of research on the control and maintenance of blood pressure, blood volume, and vascular tone. ANF is a potent natriuretic and diuretic agent, owing these properties to both its renal hemodynamic actions and its direct tubular actions (McGrath *et al.*, 2005). By simultaneous dilation of afferent arterioles and constriction of efferent arterioles, ANF increases the glomerular filtration rate and filtration fraction. ANF will directly inhibit water reabsorption by the renal cortical collecting duct and contributes to inhibition of $Na+$ reabsorption by the renal inner medullary collecting duct (Melo *et al.*, 2000). ANF also has profound effects on the cardiovascular system. Acute administration of ANF causes a fall in arterial pressure due to a reduction in cardiac output mediated by a decreased preload and vascular resistance (Lang *et al.*, 1987; Loutzenhiser *et al.*, 1988). The decreased preload is believed to be a consequence of venodilation and reduction of the intravascular volume. Furthermore, ANF also reduces sympathetic tone by inhibiting arterial baroreceptor response and suppression of catecholamine release from autonomic nerve endings (Atchison and Ackermann, 1990; Butler *et al.*, 1994).

The renin–angiotensin–aldosterone system (RAAS) is also a target for ANF. ANF will directly reduce renin secretion, which has the cascade effect of lowering circulating levels of angiotensin II (Ang II), a potent vasoconstrictor and stimulator of aldosterone (Struthers *et al.*, 1986). ANF can also directly inhibit aldosterone synthesis and secretion from the glomerulosa cells of the adrenal cortex (Brenner *et al.*, 1990; Burger, 2005; Franco-Saenz *et al.*, 1989). The central actions of ANF include inhibition of secretion of vasopressin and of salt and water intake (Inoue *et al.*, 2001). ANF also possesses important antimitotic actions on vascular endothelial cells, smooth muscle cells, and cardiac fibroblasts (Calderone *et al.*, 1998; Kapoun *et al.*, 2004; Tamura *et al.*, 2000).

Structure and Biosynthesis of ANF

The mRNA is approximately 1 kb long and encodes a preproANF that contains between 149 and 153 amino acids depending on the species (Flynn *et al.*, 1985; Lewicki *et al.*, 1986; Nakao *et al.*, 1992) (**Fig. 1**). The human amino acid sequence shares strong homology with peptides from other species including rat, mouse, and pig (Potter *et al.*, 2009). In the human atria, ANF is stored mainly within organelles referred to as specific atrial granules as a prohormone called proANF1–126 (Thibault *et al.*, 1987). Subsequent processing releases into the bloodstream the biologically active hormone, ANF99–126. Normal human plasma concentrations of ANF are approximately 6 fmol mL^{-1}. The biological half-life of ANF99–126 is very short (less than 5 min) (Biollaz *et al.*, 1987; Yandle *et al.*, 1986).

All members of the ANF family of natriuretic peptides share a common central ring structure formed by a disulfide bridge (positions 105 and 121 for ANF). Disruption of this 17-member ring leads to a loss of biological activity (Hirata *et al.*, 1988) (**Fig. 2**).

This article is an update of Kenneth K.-Y. Ma and Adolfo J de Bold, Atrial Natriuretic Factor and Family of Natriuretic Peptides, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 295–300.

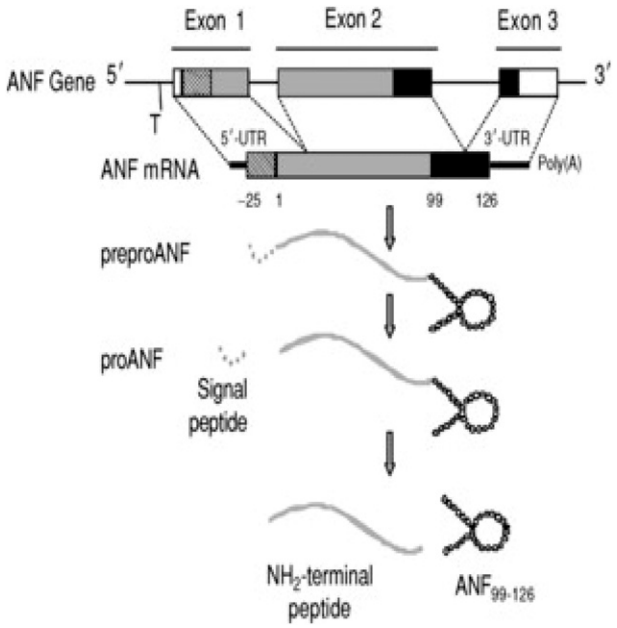

Fig. 1 Structure of the gene and biosynthetic pathway of human ANF. *Solid black* sections are those that code for the mature ANF99–126. *Gray* sections code for NH2-terminal fragments and the striped section codes for the signal peptide. Numbers indicate the amino acid position relative to the sequence encoded in proANF. T indicates the location of the TATAAA-box. *UTR*, untranslated region.

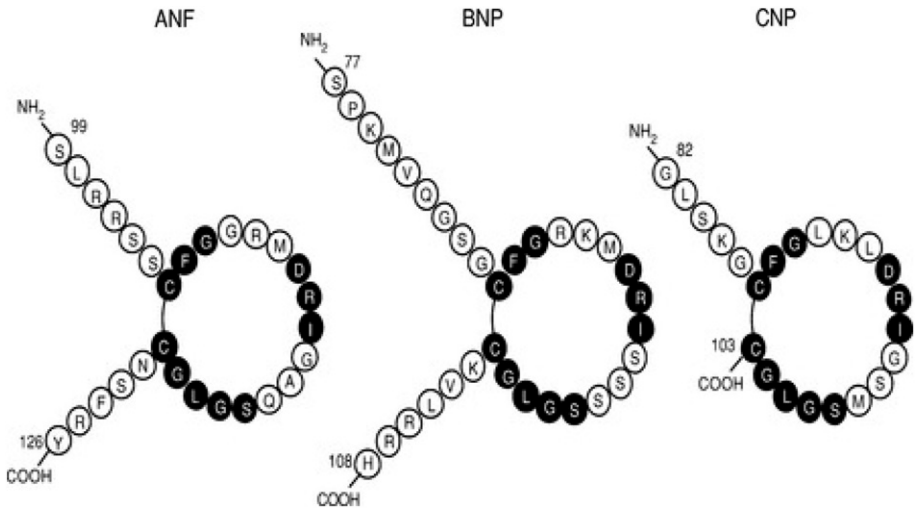

Fig. 2 The biologically active forms of the natriuretic peptides. Amino acids that are shared by all members of the natriuretic peptide family are identified by filled circles. A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

ANF Gene Regulation

The ANF gene is mapped to chromosome 1 in humans, chromosome 4 in mouse, and chromosome 5 in rats (Argentin *et al.*, 1985; Nemer *et al.*, 1984). Structurally, the ANF gene is similar in all mammals and consists of three exons and two introns (**Fig. 1**).

Tissue-specific and developmental regulation of ANF gene expression

Atrial expression of ANF rises continuously during fetal and postnatal development to comparatively high levels (1%–3% of total atrial mRNA), whereas ventricular expression of ANF, although quite high during fetal development, falls quickly after birth (1% of atrial levels) (de Bold and Bruneau, 2000). Extracardiac (aortic arch, hypothalamus, pituitary, and kidney) sites of synthesis have also been documented, but the major site of ANF production remains the atria (Lim *et al.*, 1990; Morel and Heisler, 1988). In adulthood, ANF expression by the heart can be markedly increased by mechanical stretch of the cardiomyocyte and/or by neuroendocrine hormones (Ogawa *et al.*, 1999).

The 5′ flanking region of the ANF gene contain cis-acting elements to which various transcription factors are known to bind and thus regulate the level of genetic expression. There are two GATA-4 binding sites in the ANF gene promoter (Charron *et al.*, 1999), and patients with heterozygous GATA-4 mutations shows various congenital heart diseases (Clark *et al.*, 2006), suggesting that GATA-4 is essential for normal heart development. GATA-4 is also involved in the regulation of cardiac hypertrophy and ANF gene expression (Kessler-Icekson *et al.*, 2002; Liang *et al.*, 2001a). The AP-1 transcription factor and the products of two proto-oncogenes, c-fos, and c-jun, bind to AP-1/CRE-like binding sites in ANF gene (Rosenzweig and Seidman, 1991). C-fos and c-jun have been shown to regulate ANF gene expression associated with cardiac hypertrophy (Kovacic-Milivojevic *et al.*, 1996). Two CArG boxes are other binding sites in the ANF gene that bind serum response factor and play important roles in cardiovascular development and diseases (Miano, 2010). Nkx2.5 is an essential transcription factor for cardiac development as mutation of Nkx2.5 accounts for 4% of congenital heart diseases (Clark *et al.*, 2006). Two Nkx2.5 response elements, which are the binding site of Nkx2.5, can be seen in the ANF promoter (Small and Krieg, 2004). Tbx5, another important transcription factor, binds to the T-box binding elements found in the ANF promoter (Bruneau *et al.*, 2001; Hiroi *et al.*, 2001). Tbx5 and Nkx2.5 synergistically activate ANF gene transcription and mutation of Tbx5 results in various cardiac defect and conduction abnormalities (Basson *et al.*, 1997).

Acute mechanical stretch for the regulation of ANF gene expression

ANF is continuously released from the atria of the heart, but appropriate mechanical stretch can increase the rate of ANF secretion (de Bold *et al.*, 1996;Ogawa *et al.*, 1999). In acute experiments with isolated atrial preparations, increases in atrial wall stretch are met with corresponding increases in ANF secretion with no change in ANF gene expression (Bruneau *et al.*, 1997). Despite continued mechanical stimulation, the acute increase in ANF release eventually decays to baseline values within minutes. The precise mechanism underlying mechanotransduction of stretch-induced ANF release remains to be elucidated. However, there is clear evidence that it is mediated by Gi protein signaling (Bensimon *et al.*, 2004).

Neuroendocrine hormones or agents for the regulation of ANF gene expression

Numerous neuroendocrine agents can also increase ANF gene expression and release. α1-Adrenergic agonists (e.g., phenylephrine) and vasoactive peptides, such as endothelin-1 (ET-1) and Ang II, are potent stimulators of ANF gene expression and release (Bruneau *et al.*, 1996, 1997; Bruneau and de Bold, 1994). The vasoconstrictor ET-1 is synthesized and released by the endothelial and mesothelial cells. It is believed that ET-1 can act in a paracrine fashion in vivo to modulate ANF gene expression and release (Bianciotti and de Bold, 2000; Kassab *et al.*, 1998). Ang II, an effector molecule of RAAS, is a potent vasoconstrictor as well as a growth factor for cardiomyocytes (Bianciotti and de Bold, 2002; van Wamel *et al.*, 2001).

Ang II, ET-1, and catecholamines bind to the heterotrimeric G protein heptahelical transmembrane family of receptors. In general, activation of the receptor leads to the recruitment of secondary effector molecules that activate cytosolic and/or nuclear substrates. In particular, Ang II, ET-1, and phenylephrine will rapidly stimulate protein kinase C and the mitogen-activated protein kinase, p44/42 (ERK), which in turn will activate trans-acting factors responsible for the increase in ANF expression (Takahashi *et al.*, 2003; Ueyama *et al.*, 2000). These include the immediate-early genes (IEGs), such as the c-fos and c-jun heterodimer, that can bind to activator protein-1 (AP-1) consensus elements on the 5′-flanking region of the ANF promoter (Kovacic-Milivojevic and Gardner, 1993). Hormonal ligands for nuclear receptors, such as glucocorticoids, have also been shown to upregulate ANF gene expression and release (Kanda *et al.*, 1989). IL-1beta and TNF alpha are powerful stimulants of ANF gene expression and secretion (Ma *et al.*, 2004, 2005). Cardiotrophin I, a member of the interleukin-6 superfamily of cytokines, has been shown to upregulate ANF gene expression (Hamanaka *et al.*, 2000).

Chronic hemodynamic overload and changes in ANF expression

Under chronic hemodynamic overload, mature terminally differentiated cardiomyocytes will respond with cellular hypertrophy to normalize wall stress (Ogawa *et al.*, 1996). Importantly, ANF gene expression and release are markedly increased not only from the atrial cardiomyocytes, but also from the ventricular cardiomyocytes by the hypertrophic stimuli (Yokota *et al.*, 1995). This can translate into a 100-fold increase in ANF plasma concentrations in certain pathophysiological conditions such as chronic congestive heart failure (Cohn, 1990). Hypertrophic stimuli, such as prolonged myocardial stretch or humoral growth factors, will activate the IEGs, such as c-myc, c-fos, and/or c-jun (Bruneau and de Bold, 1994). This is followed by activation of the characteristic embryonic gene program seen during cardiac development. Molecularly, this gene program accounts for the re-expression of ANF, BNP, β-myosin heavy chain, and skeletal α-actin in the hypertrophic adult ventricle (Ogawa *et al.*, 1996). The precise mechanisms responsible for the chronically increased ventricular ANF gene expression and secretion have not been fully elucidated. In vivo experiments have demonstrated that there may be two components responsible for these changes in natriuretic peptide expression: one that is dependent on hemodynamic load (i.e., mechanical stretch) and one that is load independent (i.e., direct effects of humoral growth factors, such as ET-1 and Ang II, on cardiomyocytes) (Ogawa *et al.*, 1996).

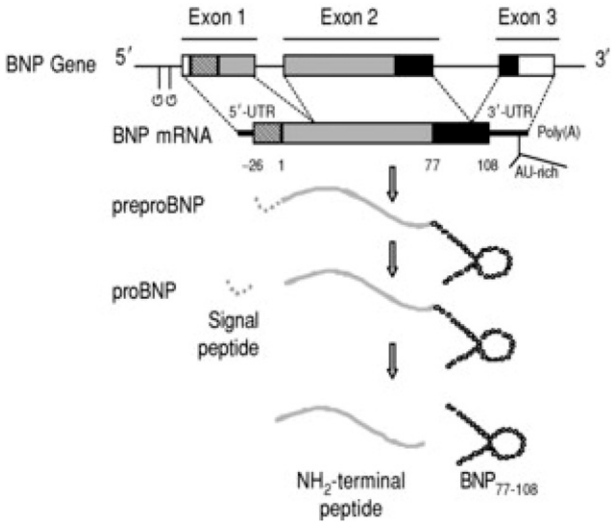

Fig. 3 Structure of the gene and biosynthetic pathway of human BNP. *Solid black* sections are those that code for the mature BNP77–108. *Gray* section codes for the NH2-terminal fragment and the striped section codes for the signal peptide. Numbers describe the amino acid position relative to the sequence encoded in proBNP. G's indicate the location of the GATAAA sequences (TATAAA-box). *UTR*, untranslated region.

Physiology, Structure, Biosynthesis, and Regulation of BNP

Physiological Actions of BNP

Brain natriuretic peptide was originally isolated from porcine brain (Sudoh *et al.*, 1988). However, it was later discovered that the highest concentrations of this peptide were found in the heart. BNP, like ANF, is a potent natriuretic, diuretic, vasorelaxant, antimitotic factor as well as an antagonist of the renin–angiotensin–aldosterone axis (Burger, 2005; Dhingra *et al.*, 2002; Mukoyama *et al.*, 1991; Vanderheyden *et al.*, 2004). Of interest, however, BNP may have functions not associated with ANF. BNP has been shown to have antifibrotic properties (Tamura *et al.*, 2000). This effect may be particularly important in cardiovascular diseases in which cardiac fibrosis contributes to the progression to heart failure (Segura *et al.*, 2014). In addition, BNP has immunomodulatory properties (de Bold *et al.*, 2010).

Structure and Biosynthesis of BNP

BNP is synthesized as a 121- to 134-amino-acid preprohormone (**Fig. 3**). In humans, subsequent processing releases a mature biologically active 32-amino-acid carboxy-terminal fragment (Kambayashi *et al.*, 1990). Unlike ANF or CNP, the amino acid sequence of BNP is not as highly conserved and may differ by as much as 50% between species (Potter *et al.*, 2009). The plasma half-life of BNP is approximately 20 min, which is approximately six times longer than that of ANF. The normal circulating BNP level in humans is approximately 0.9 fmol/mL (Mukoyama *et al.*, 1991).

Regulation of BNP Gene Expression

The BNP gene is mapped to chromosome 1 in human and to chromosome 4 in mouse (Yang-Feng *et al.*, 1985; Ogawa *et al.*, 1994). Structurally the BNP gene is similar to the ANF gene in that it is composed of three exons and two introns. However, there are important differences between the regulation of BNP and ANF at the transcriptional and posttranscriptional levels. Hemodynamic overload increases both atrial and ventricular expression of BNP (and ANF) dramatically (Benvenuti *et al.*, 1997; Yokota *et al.*, 1995). In pathological states such as chronic congestive heart failure, the plasma BNP level can increase 1000-fold; Mukoyama *et al.*, 1991.

The 5′ flanking region of the BNP genes have GATA-4 binding sites and AP-1/CRE-like binding sites, which are also seen in the ANF gene (Marttila *et al.*, 2001; Sawada *et al.*, 2010). As mentioned above for ANF, these sites are essential for normal heart development. GATA-4 is also involved in pathological conditions because the elevation of BNP genes in response to AII, ET-1, isoproterenol, and stretch are mediated by GATA-4 (Clark *et al.*, 2006; Grepin *et al.*, 1994; He *et al.*, 2002). The human BNP promoter contains two M-CAT elements and members of the transcriptional enhancer factor-1 (TEF-1) family binds to them (Yoshida, 2008). Mutation of this sequence significantly depresses basal and phenylephrine (PE)-induced gene expression of rat BNP (Thuerauf *et al.*, 1994). Three shear stress-responsiveness elements (SSRE) are found in BNP promoter. Cyclic mechanical stretch increased in NF-κB binding to the SSRE, and mutation of the SSRE or co-transfection with constitutive suppressor of NF-κB activity caused a maximum of 40% decrease in strain-activated BNP (Liang *et al.*, 2001b).

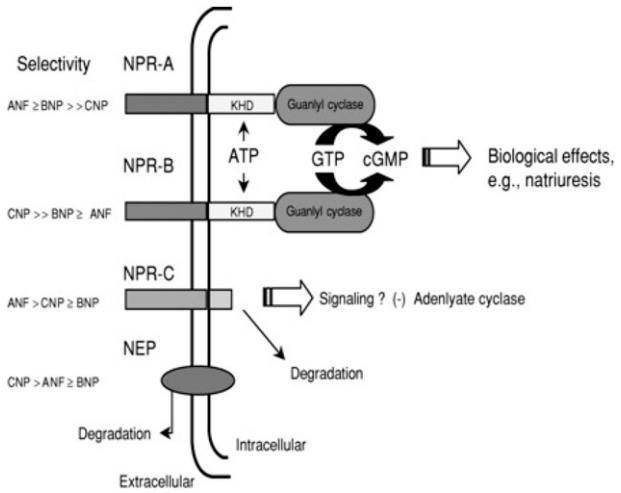

Fig. 4 The natriuretic peptide receptors. Binding of ANF and BNP to NPR-A and CNP to NPR-B stimulates intrinsic guanylyl cyclase activity of the receptor. The transduction of ligand binding to cGMP generation is ATP dependent and requires participation from the KHD portion of the receptor. *NPR-A*, natriuretic peptide receptor-A; *NPR-B*, natriuretic peptide receptor-B; *NPR-C*, natriuretic peptide receptor-C; *KHD*, kinase-like homology domain; *NEP*, neutral endopeptidase 24.11.

In response to certain hypertrophic stimuli, BNP mRNA is rapidly upregulated in a protein synthesis-independent manner with quick turnover (Bruneau *et al.*, 1997). These features are characteristic of an IEG. In support of this, the BNP 3′-untranslated region contains many AU-rich elements that may confer instability to the BNP transcript (mRNA t1/2 ~60 min) not found in ANF mRNA, which is quite stable (Hanford *et al.*, 1994). Interestingly, BNP mRNA stability can be enhanced after treatment with phenylephrine. In addition to neurohumors such as ET-1 and phenylephrine, BNP gene expression and secretion can also be upregulated by pro-inflammatory cytokines, such as interleukin-1β and tumor necrosis factor α (TNFα) (Liang *et al.*, 2001b). In summary, the significant increase in BNP expression during overload may be due a combination of specific transcriptional and posttranscriptional mechanisms.

Physiology, Structure, Biosynthesis, and Regulation of CNP

Physiological Actions of CNP

CNP is found in the cerebellum, hypothalamus, anterior pituitary, kidney, and the vascular endothelial cells but not in the heart (Komatsu *et al.*, 1991; Nishimura *et al.*, 1998; Sudoh *et al.*, 1990; Ueda *et al.*, 1991). The central actions of CNP include antagonizing angiotensin II-mediated increases in vasopressin, which in turn decreases salt and water intake (Nishimura *et al.*, 1998). The natriuretic activity of CNP is only approximately 1% of that of ANF. CNP has potent anti-growth properties on vascular smooth muscle cells, suggesting that CNP may be an important regulator of blood vessels (Furuya *et al.*, 1991).

Structure and Biosynthesis of CNP

CNP is the most conserved of all natriuretic peptides, with 90% homology observed among human, mouse, pig, and rat (Potter *et al.*, 2009). Produced from a 126-amino-acid preprohormone, the bioactive hormone, unlike ANF or BNP, is only 22 amino acids long, because CNP has no carboxy-terminal tail (Barr *et al.*, 1996; Del Ry *et al.*, 2006) (**Fig. 2**).

Regulation of CNP Gene Expression

The gene for CNP is located on chromosome 2 in humans, in contrast to the ANF and BNP genes, which are located on chromosome 1 in humans (Ogawa *et al.*, 1994). The mouse CNP gene consists of least two exons and one intron. The 5′-flanking region of CNP contains numerous cis-acting regulatory elements including dinucleotide CA repeats, cyclic AMP-response element-like, nuclear factor κB, and shear stress recognition sites (Anand-Srivastava, 2005; Sellitti *et al.*, 2011). Cytokines, such as transforming growth factor-β and TNFα, can upregulate CNP (Mendonca *et al.*, 2010).

Natriuretic Peptide Receptors

The biological actions of the natriuretic peptides are mediated through association with specific high-affinity receptors on the surface of target cells and the generation of cyclic guanosine monophosphate (cGMP) (Lowe *et al.*, 1989; Maack *et al.*, 1993; Schulz *et al.*, 1989) (**Fig. 4**). There are three natriuretic peptide receptors (NPR-A, NPR-B, and NPR-C). NPR-A and NPR-B are linked to guanylate cyclase and, on activation of the receptor, cGMP is formed (Gerzer *et al.*, 1985). cGMP targets may include cGMP-dependent protein kinases and cGMP-gated ion channels (Lincoln and Cornwell, 1993). NPR-A binds both ANF and BNP, with preference for ANF. NPR-B binds CNP with far less preference for either ANF or BNP (Koller *et al.*, 1991). NPR-C is the clearance receptor and binds CNP with slightly greater affinity than ANF or BNP (Anand-Srivastava and Trachte, 1993; Murthy and Makhlouf, 1999). Circulating natriuretic peptides are also inactivated by neutral endopeptidases present within renal tubular and vascular cells (Hashimoto *et al.*, 1994).

Natriuretic Peptides as Biomarkers

Because plasma ANF and BNP are increased in various pathological conditions such as heart failure, myocardial infarction, hypertension, left ventricular hypertrophy, and pulmonary hypertension (Buckley *et al.*, 1993; Cody *et al.*, 1986; Cowie *et al.*, 1997; Foy *et al.*, 1995; Nagaya *et al.*, 1998a,b; Nishikimi *et al.*, 1996; Ramos and de Bold, 2006), plasma levels of ANF and BNP have proven useful for the diagnosis and prognosis of these diseases. In addition to ANF99-126 and BNP77-108, the biologically inactive N-terminal fragments, NT-proANP and NT-proBNP also circulate in plasma. Since the N-terminal prohormones half-lives are longer than those of the C-terminal prohormones (Pemberton *et al.*, 2000), in some cases such as mild heart failure or asymptomatic left ventricular dysfunction, the determination of plasma levels of NT-proBNP has better diagnostic ability than BNP (Steiner and Guglin, 2008).

Natriuretic Peptides as Therapeutic Agents

Because ANF and BNP possess diuretic, natriuretic and hypotensive activities, ANF and BNP have been used in the treatment of various cardiovascular conditions. Infusion of carperitide, a recombinant form of human ANF has proven to be effective in patients with acute heart failure and acute myocardial infarction (Kitakaze *et al.*, 2007; Nomura *et al.*, 2008; Sackner-Bernstein *et al.*, 2005). Efficacy of low-dose administration of carperitide for acute heart failure is in progress as a multicenter, randomized, open-label, controlled study (Nagai *et al.*, 2017).

The effectiveness and safety of nesiritide, a recombinant form of human BNP has been questioned. Analysis of five randomized studies demonstrated that administration of nesiritide to acutely decompensated heart failure patients significantly increased the risk of worsening renal function compared to the control group (Sackner-Bernstein *et al.*, 2005). In another study in which nesiritide was administered to acute heart failure patients, no significant changes regarding death rate, rehospitalization rate, and renal function were observed, and hence the authors did not recommend the routine use of nesiritide to acute heart failure patients (O'Connor *et al.*, 2011).

Seventy-two hours of intravenous infusion of recombinant human BNP to ST-elevation myocardial infarction not only corrected cardiac dysfunction and decreased serum level of NT-pro BNP in the course of infusion, but also reduced cardiac dilatation and improved left ventricular ejection fraction 3 month later in comparison with baseline and control group (Gong *et al.*, 2015). A BELIEVE II study, a randomized, double-blind, placebo-controlled trial of 72 h intravenous infusion of nesiritide in humans with first time ST-elevation acute myocardial infarction, is in progress for the assessment of prevention of adverse left ventricular remodeling and preservation of left ventricular function (Sangaralingham *et al.*, 2013).

Recently Sacubitril/Valsartan, a novel angiotensin receptor-neprilysin inhibitor, was approved for the treatment of heart failure with reduced ejection fraction. Although neprilysin inhibition alone did not exert a significant effect because neprilysin inhibition activates RAAS (Richards *et al.*, 1992), combination of neprilysin inhibition and angiotensin inhibition revealed greater blood pressure reduction in patients with hypertension (Kario *et al.*, 2014; Ruilope *et al.*, 2010), and reduced all-cause mortality in heart failure patients compared with valsartan or enalapril alone (McMurray *et al.*, 2014; Solomon *et al.*, 2012).

Natriuretic Peptides in Other Diseases

Natriuretic Peptides in Inflammation

Plasma BNP but not ANF levels increased significantly during rejection episode, and successful treatment of the rejection resulted in a decrease of BNP plasma levels to values observed prior to acute rejection (Masters *et al.*, 1999). Others also have reported an association between plasma BNP and cardia cellular rejection suggesting that plasma BNP is a plasma marker for detecting heart transplant rejection (Almenar *et al.*, 2002; Arnau-Vives *et al.*, 2004; Hammerer-Lercher *et al.*, 2005; Ogawa *et al.*, 2005). Plasma samples taken from rejecting and nonrejecting patients were analyzed by cytokine array (Meirovich *et al.*, 2008). Regulated on

Activation, Normal T Expressed and Secreted (RANTES), Neutrophil Activating Protein-2 (NAP-2), and Insulin Growth Factor Binding Protein-1 (IGFBP-1) had significant correlations with BNP plasma levels during acute allograft rejection as diagnosed by endomyocardial biopsy suggesting that these cytokines may be involved in the rejection of transplanted heart.

Plasma BNP and NT-proBNP are increased in rheumatoid arthritis patients without a history of cardiac disease (Armstrong *et al.*, 2010; Solus *et al.*, 2008). A prospective case-control study revealed that high BNP levels in rheumatoid arthritis are related to inflammation but not to left ventricular abnormalities (George *et al.*, 2014).

Plasma ANF or BNP levels are increased in sepsis and in septic shock patients (Chua and Kang-Hoe, 2004; Nikolaou *et al.*, 2007; Shor *et al.*, 2006; Witthaut *et al.*, 2003). Administration of LPS, the main bacterial component responsible for the immune response to Gram negative bacterial infection, to healthy men increased plasma NT-proBNP without changing heart rate and blood pressure (Vila *et al.*, 2008). In LPS-treated rats, both plasma ANF and BNP levels increased, and gene expression of MCP-1, MMP-8, TIMP-1 CINC-1, TNFα, ICAM-1, and MIP-3 were correlated with gene expression of BNP suggesting that these cytokines might be involved in the plasma BNP elevation in sepsis patients (Ogawa and de Bold, 2012). Because ANF and BNP appear related to many cytokines, plasma levels of these hormones could become good biomarkers of inflammatory diseases other than those mentioned above.

Natriuretic Peptides in Metabolic Disorders

There is increasing evidence of the involvement of NPs in the pathophysiology of metabolic diseases. Recently inverse relation between circulating NPs levels and bodyweight, insulin resistance and type 2 diabetes has been reported (Das *et al.*, 2005; Khan *et al.*, 2011; Olsen *et al.*, 2005; Wang *et al.*, 2004). NPR-C, identified in human adipose tissue, is increased in adipose tissue of obese hypertensive patients compared to nonobese and normotensive individuals (Dessi-Fulgheri *et al.*, 1997). It is also reported that NPR-C expression in adipose tissue is induced by insulin (Nakatsuji *et al.*, 2010). NPs exert metabolic effects in numerous organs. In human adipose tissue, NPs enhance lipolysis as well as the secretion of adiponectin which has anti-atherosclerotic and anti-insulin resistance effects (Birkenfeld *et al.*, 2012; Sengenes *et al.*, 2000). Treating a human-derived adipose cell line with ANF results in the uncoupling of cellular respiration as well as "browning" of white adipose tissue, suggesting that NPs induce thermogenic programs in adipose tissue (Bordicchia *et al.*, 2012; Collins, 2014). Administration of ANF to healthy individuals increased lipolysis, lipid oxidation, energy expenditure (Birkenfeld *et al.*, 2008). Parts of beneficial effects of exercise and low calorie diet on metabolic disorders such as type 2 diabetes or metabolic syndrome may be related to the increase activity of NPs because physical activity alone or low calorie diet are reported to increase plasma ANF and BNP levels or augment NPR-A expression in skeletal muscle cells (Engeli *et al.*, 2012).

Natriuretic Peptides in Cancer

Recently many cancer cells including melanoma, lung, ovarian, and prostate cancers are reported to express NPR-A gene (Kong *et al.*, 2008; Vesely *et al.*, 2005). In the in vitro experiment, ANF decreased the number up to 97% of pancreatic, breast, colon, kidney, prostate, ovarian, and lung carcinoma cells. Administration of ANF to athymic mice bearing human pancreatic adenocarcinomas results in elimination of 80% of the carcinomas (Vesely *et al.*, 2007). The anticancer mechanisms of ANF may be related to RAS—mitogen-activated protein kinase kinase (MEK 1/2)—extracellular signal-related kinase (ERK 1/2) cascade, vascular endothelial growth factor (VEGF), β-catenin, WNT, JNK, and STAT pathways (Vesely *et al.*, 2007). Mean serum levels of ANF in breast cancer patients were significantly elevated compared to control group and the metastatic breast cancer patients showed significant high ANF levels compared to nonmetastatic group (Houssen *et al.*, 2017). The results of these studies suggest that NPs have the potential to become the therapeutic agents or biomarkers of cancers.

Summary

The ANF family of NPs play important roles in regulating blood pressure, extracellular fluid homeostasis, and cardiovascular growth under normal physiological conditions and in diseased states. NPs defend against excess salt and water retention, promote vascular relaxation, inhibit RAAS, inhibit sympathetic outflow, and have potent antimitotic properties. In many pathophysiological cardiovascular conditions, ANF and particularly BNP plasma levels have become important diagnostic and prognostic tools. ANF, BNP, and the combination of angiotensin and neutral endopeptidase inhibition have shown remarkable results for the treatment of cardiovascular diseases such as heart failure and acute myocardial infarction. Recently, extra-cardiovascular roles of NPs systems have been focused on, including the effect of NPs on inflammation, metabolic disorders and cancers, and some of these studies have revealed promising results suggesting that NPs possess potential for becoming biomarkers and therapeutic agents in these fields.

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Pathophysiology

John W Funder, Hudson Institute of Medical Research, Clayton, VIC, Australia

Introduction

In setting the scene it may be useful to define 'mineralocorticoid'. Historically, mineralocorticoid was a primarily effector definition—a steroid hormone secreted from the adrenal cortex in response to sodium deficiency/volume depletion, to restore the status quo by increasing transepithelial retention of sodium in the kidney. This definition was based on studies with deoxycorticosterone (DOC), the initial 'classic' mineralocorticoid, and was complemented decades later by the isolation of electrocortin (by chromatography) and demonstration of its natriferic action. Electrocortin was rapidly renamed aldosterone when its structure was established, in recognition of the unique aldehyde group at carbon 18 instead of the otherwise universal methyl group.

It is more than 60 years since the isolation and characterization of aldosterone, and the hormone remains the central pillar of fluid and electrolyte homeostasis. That said, over that time the context in which such homeostasis is achieved has broadened very widely—from mineralocorticoid receptors (MR) to additional sites of mineralocorticoid action, from selective co-expression of the 'protective' enzyme 11βhydroxysteroid dehydrogenase to a variety of clinical situations which might be described as mineralocorticoid excess syndromes. In this complex context aldosterone still stands as the physiologic mineralocorticoid in terrestrial vertebrates, and as such a necessarily brief overview is in order.

Aldosterone

In evolutionary terms aldosterone is a uniquely terrestrial hormone, first found in lungfish—which, as their name implies, were the transition species from an obligate aqueous environment to the land: they still can be found in South Africa, South America, Australia (and Japanese pet shops). Aldosterone is secreted in response to sodium deficiency, potassium loading, circulating volume depletion and—least well defined—stress: the secretagogues are angiotensin11, elevation of plasma $[K+]$ and—acutely, but not chronically—ACTH. The enzyme aldosterone synthase—also called CYP11B2—is responsible in most species for the conversion of the substrate 18-hydroxyDOC to aldosterone in a three step process. The genes encoding CYP11B2 and CYP11B1 (responsible for glucocorticoid synthesis) lie sequentially on chromosome 8q24. Some species (e.g., bovine) express a single CYP11B enzyme, closer to CYP11B2 than CYP11B1 in sequence, and responsible for both activities: determinants of functional zonation in such species are currently unclear.

In species with both CYP11B1 and CYP11B2 expression of the latter is confined to the outermost layer, the zona glomerulosa of the adrenal gland. In many experimental animals (e.g., rats, mice) the width of the zona glomerulosa varies with the sodium status of the animal—thin and sometimes tenuous in sodium loading, regular and thicker in sodium deficiency. In human adrenals a similar pattern has been presumed, recently challenged by the demonstration—in some but not all adults, and not in subjects under 20—that CYP11B2 expression is confined to isolated and scattered aldosterone producing cell clusters (APCC). Some of these APCC, from apparently normal glands removed from renal transplant donors, harbor mutations found in aldosterone producing adenomas, as will be discussed subsequently. The reasons why some adult adrenals show APCC and others not, and why not all APCC express mutations otherwise responsible for hyperaldosteronism, remain to be established.

Circulating aldosterone levels are normally very low, to some extent reflecting the common sodium-replete diet in most countries. These 'normal' levels are $\sim$3 orders of magnitude lower than those of cortisol; in addition most current assays overestimate levels at the lower end of the 'normal' range. The published ranges are very wide— 4–21 ng/dl in Rochester, 3-31 ng/dl in Ancona, a spread of values unlikely to reflect differences in daily salt intake, plasma $[K+]$ or variable sensitivity to aldosterone. African-Americans are on average more sensitive to aldosterone (lower baseline levels, more marked blood pressure responses to fludrocortisone, with no difference in sodium/potassium daily excretion) but are unlikely contributors to the 5–10 fold ranges noted above.

To some extent offsetting the $\sim$1000-fold difference in plasma concentrations of aldosterone and cortisol are the differences in plasma binding. About half the circulating aldosterone is bound with relatively low affinity to albumin; in contrast, only $\sim$5% of the circulating cortisol is free, the rest bound to albumin and much higher affinity transcortin (cortisol binding protein: CBG). One corollary of this is that the plasma half-time for aldosterone ($\sim$12min) is much lower than that of cortisol ($\sim$30 min). Another difference between the two is the shape of the nocturnal rise in steroid levels, much faster for aldosterone (and decaying faster) than for cortisol, the acuteness of the aldosterone response perhaps reflecting the volume shifts from systemic to pulmonary circulation upon recumbency. There are many more facets of aldosterone physiology that need to be taken into consideration, but this is perhaps better done in the context of its action on target tissues, primarily via mineralocorticoid receptors (MR).

Mineralocorticoid Receptors

Twenty years after the isolation and characterization of aldosterone the receptors whereby they act were demonstrated by incubating kidney slices from adrenalectomized rats with [3H] aldosterone alone or with excess non-radioactive aldosterone, and showing displaceable binding of tracer aldosterone to high affinity sites. Initially these were termed Type 1 corticosteroid receptors, to distinguish them from Type 2, [3H]-dexamethasone–binding sites in various glucocorticoid target tissues. Even though the Type 1/Type 2 nomenclature is non-descriptive, and was rapidly replaced by the familiar mineralocorticoid and glucocorticoid receptor (MR, GR) terminology, it is in fact more precise, in that MR have an affinity for physiologic glucocorticoids 10–30 fold higher than do GR. They were also shown to be what had been previously termed 'corticosterone-preferring' receptors in the hippocampus, distinct from pituitary [3H]-dexamethasone-binding pituitary GR. Imperfect as they are, we are stuck with the terms MR and GR.

Both MR and GR are primarily ligand-dependent nuclear transactivating proteins with effects mediated via DNA-directed, RNA-mediated protein synthesis. In humans there are family of 48 nuclear receptors (steroid/thyroid/retinoid/lipid-binding/orphan, the last without or with as yet undiscovered ligands); in mice there are 49. Within this superfamily MR/GR/progesterone receptors (PR)/ androgen receptors (AR) form a closely knit sub-family, sharing ~90% identity in their DNA-binding sites and ~50% in their steroid-binding sites. They all derive from a single ancestral gene, with MR the first to have branched off from this common ancestor, followed by GR, and then PR/AR. MR are found in both bony (e.g., trout, zebrafish) and cartilaginous (e.g., shark, rays) fish; their delineation as a receptor, presumably for cortisol, thus antedates that of the emergence of aldosterone millions of years later in lungfish. The presumption that the cognate ligand for MR in fish was cortisol is based not only on contemporary studies on fish, but also on the finding that MR in humans and experimental animals have the same high affinity for cortisol as for aldosterone; they are truly promiscuous in that this same high affinity extends to corticosterone, deoxycorticosterone and progesterone.

For several decades deoxycorticosterone was the recognized mineralocorticoid, as previously noted. Its physiologic role as a mineralocorticoid is minimal, for at least three reasons. First, its plasma levels are low, usually similar to those of aldosterone. Second, it is ~98% plasma bound, and experimentally only 2–3% as potent a mineralocorticoid as aldosterone. Finally, the major driver of deoxycorticosterone biosynthesis is ACTH, so that it is essentially out of the homeostatic control (low sodium, high potassium) loop triggering a mineralocorticoid response, in contrast with aldosterone.

Pathophysiologically, however, deoxycorticosterone may play a major mineralocorticoid role, in at least two circumstances. One is that of the ectopic secretion of ACTH, which is unconstrained by the normal feedback controls on pituitary ACTH secretion; the other is in patients with defects in 11β oxidation, where levels of deoxycorticosterone and 11-deoxycortisol rise in response to compromised feedback regulation of ACTH secretion. That progesterone—which is a mineralocorticoid receptor antagonist—does have effects via MR is seen in pregnancy, when plasma aldosterone levels rise to levels 3–10 times baseline to counter the MR antagonist action of the very high progesterone levels. The first (spironolactone, canrenone) and second (eplerenone) generation MR antagonists are variously elaborated progesterone derivatives, and drospirenone used as an oral contraceptive is a very potent MR antagonist.

Aldosterone Specifically Activates Epithelial Mineralocorticoid Receptors: The Role of 11βhydroxysteroid Dehydrogenase Type 2

An obvious corollary of the 1000-fold (total)/100-fold (free) plasma concentrations of cortisol (corticosterone in rats and mice) is the question of how aldosterone can specifically activate epithelial MR in the face of the equivalent affinity and far higher concentrations of the physiologic glucocorticoids. This enigma appears to have been solved, with one caveat, by the finding of co-expression with MR of the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) in epithelia, and its ability to metabolize cortisol into cortisone (which does not bind to MR). Aldosterone is not a substrate for 11βHSD2, in that its hydroxyl group at carbon 11 cyclizes with the very reactive (and unique) aldehyde group at carbon 18, to form an 11,18 complex (and sometimes an 11, 18, 20 complex): together these forms constitute ~99% of circulating aldosterone.

These studies from almost 3 decades ago are still interpreted as evidence that 11βHSD2 action does not allow cortisol to *occupy* MR in the principal cells of the distal renal tubule, an interpretation which appears to be buttressed by the unrestrained mineralocorticoid action of cortisol when the enzyme is congenitally absent or impaired (in the condition known as apparent mineralocorticoid excess) or blocked by glycyrrhizic/glycyrrhetinic acid in licorice abuse. Inconveniently, however, studies on adrenalectomized rats showed that what 11βHSD2 did was to reduce intracellular corticosterone levels by an order of magnitude —levels, however, still ~10-fold higher than those of aldosterone. What this suggests is that most principal cell MR are normally *occupied but not activated* by normal levels of glucocorticoids. The ten-fold increase in sensitivity in the Kagawa bioassay when rats are adrenalectomized is in accordance with this scenario.

How then, can it be that when 11βHSD2 is operating to metabolize cortisol MR occupied by cortisol are inactive, but when the enzyme is deficient or blocked cortisol can mimic aldosterone and act as a mineralocorticoid? There really can be no question that the metabolism of cortisol by the enzyme is so complete that it can not occupy the receptors. The intracellular concentrations of cortisol are (presumably, like plasma free levels) ~100 times higher than those of aldosterone. To reduce them to 'noise' in the system, let us say they need to be reduced to ~10% of those of aldosterone: reduced only to equality, for instance, would constitute a very unfortunate inappropriate signal. What this requires is that 999 of every 1000 cortisol molecules would need to

be metabolized to cortisone, in an organ that receives 20–25% of the cardiac output and through which the entire blood volume passes every 5 min.

So how does 11βHSD2 block the mineralocorticoid activity of cortisol mineralocorticoid receptor complex? The answer appears to lie in NAD, the commonly disregarded obligate co-substrate for 11βHSD2. For every molecule of cortisol converted to cortisone, one molecule of NAD is converted to NADH. Levels of NAD vary between cell compartments, but under resting conditions are $\sim$600-fold those of NADH. This disparity means that major changes in NADH concentrations—say 100-fold — are possible with minimal change in substrate levels: in other nuclear receptor systems, increased NADH levels have been shown to act as a brake on their transactivational activity.

Cortisol as an MR Agonist

That this effect reflects changes in redox state has been shown in studies on cardiomyocytes (which do not express 11βHSD2). In patch clamp studies on rabbit cardiomyocytes, cortisol normally acts as an aldosterone antagonist. When, however, the cardiomyocytes are perfused with oxidized glutathione (GSSG) to mimic redox change, cortisol becomes a mineralocorticoid receptor agonist, mimicking aldosterone. Studies using Lagendorf preparations of rat hearts confirmed and extended this effect of cortisol. Under ischemia-reperfusion conditions, aldosterone increased the infarct size/area at risk, an effect blocked by spironolactone. Under such conditions (tissue damage, reactive oxygen species generation, redox change) cortisol proved equivalent to aldosterone in aggravating infarct size/area at risk: its effect was blocked by spironolactone, but not by the GR, PR antagonist RU486.

Cortisol is thus a bivalent steroid: an antagonist of MR under 'normal' conditions, but an agonist absent 11βHSD2 in the kidney, or in tissue damage in other organs. In one cell type, however, it appears an unreserved mineralocorticoid receptor agonist. The intercalated cells in the renal tubule do not express 11βHSD2, but do express mineralocorticoid receptors. Normally these receptors cannot bind steroids, in that they are phosphorylated at serine 843 in the ligand binding site. In conditions of sodium deficiency, however, these S^{843} mineralocorticoid receptors are dephosphorylated by angiotensin, and thus able to bind ligand, with cortisol proving to be as active as a mineralocorticoid as aldosterone in promoting Na^+ and Cl^- transport. This, incidentally, answers the conundrum of the different effects of aldosterone synthase and mineralocorticoid receptor gene deletion in mice. MRKO is essentially lethal: CYP11B2 $-/-$ mice have low BP, but survive under low salt conditions, presumably due to corticosterone acting as a mineralocorticoid receptor agonist in renal intercalated cells.

Finally, it should be noted that non-epithelial unprotected MR are cortisol-occupied, and have a life of their own, independent of aldosterone, in tissues such as the hippocampus and cardiomyocyte.

Rapid Effects of Aldosterone

While the classic effects of aldosterone on its target tissue involve DNA-directed RNA-mediated protein synthesis, there is clear evidence for rapid aldosterone effects. Most but probably not all of the acute non-genomic effects of aldosterone are mediated via classical MR: the most salient of these is the rapid secretion and action of aldosterone in response to orthostasis. Experimentally, aldosterone can be shown in vitro to activate the membrane receptor GPER, so called despite its affinity for estradiol being many orders of magnitude lower than circulating estradiol concentrations. Conversely, in some studies it appears to have a very, very high affinity ($K_d \sim 10^{12}$) for aldosterone, with that for other corticosteroids to be determined: its (patho) physiologic significance remains to be established.

Mineralocorticoid Excess Syndromes

The first two cases of successful unilateral adrenalectomy for hypertension and hypokalemia were published in the Polish literature in 1953. Jerome Conn reported his findings in the following year: he had the twin advantages of aldosterone having been isolated and characterized and publishing in English. Primary aldosteronism (hyperaldosteronism, Conn Syndrome: PA) is so-called in that the overproduction of hormone may be driven not by the classic secretagogues but by circumstances intrinsic to the adrenal cortex. This appears to be certainly the case for the minority of cases, those caused by a unilateral aldosterone producing adenoma (APA): whether it is also the case for bilateral adrenal hyperplasia (BAH) is moot, given the possibility that the process may be driven by external input (e.g., leptin, AT_1 R antibodies). In both cases the hypersecretion of aldosterone is outside the recognized feedback control—renin and angiotensin are suppressed, and plasma [K+] low normal or in the hypokalemic range. Secondary aldosteronism is a physiologic response to a low intravascular volume, as occurs in ascites.

Although Jerome Conn predicted that PA may be the cause of elevated blood pressure in $\sim$20% of hypertensives, for many years it was thought (and taught) that PA was rare ($<1\%$) and responsible for a mild form of hypertension, both of which we now know not to be true. At that time diagnosis required obligate hypokalemia: we now know this to be the case in only half of the patients with APA, the more florid form of PA, and fewer than 20% of patients with BAH. Today screening of at-risk hypertensives (30–100% in various guidelines) is by determination of the plasma aldosterone to renin ratio (ARR), followed by one or more of half a dozen confirmatory tests. Currently the prevalence of PA is reckoned as 5–13% of hypertensives, the range largely

representing variation between laboratories in renin and aldosterone assays, and the 'cut-offs' used to distinguish PA from so-called low renin hypertension. The unfortunate prolixity in confirmatory/exclusion testing notwithstanding, once the diagnosis of PA is made the pathway is straightforward albeit taxing.

Patients undergo a CT scan, ostensibly to exclude the very rare aldosterone-secreting carcinoma, actually to find (or not) an adenoma, thus to help in defining the source of the hyperaldosteronism. In patients able and willing to possibly undergo surgery lateralization is by bilateral adrenal venous sampling, to determine whether one or both glands are responsible. Patients who do not undergo adrenal venous sampling, and those who do not lateralize, are treated with a mineralocorticoid receptor antagonist, preferably at low dose, plus amiloride/triamterene and conventional antihypertensives as required: surprisingly, a lowered salt intake appears uncommon as a recommendation. If the patient lateralizes on adrenal venous sampling the recommended pathway is unilateral laparoscopic adrenalectomy, which essentially always cures the hyperaldosteronism, and restores the elevated blood pressure to normal in over half the patients, reducing it in the remainder. In the latter it would be sensible to include a mineralocorticoid receptor antagonist with the conventional antihypertensives, given that normal levels of cortisol mimic the vasoconstrictor effect of aldosterone under conditions of tissue damage: such is the monist view of spironolactone as purely 'an aldosterone antagonist' that this is never considered.

The past decade has seen a remarkable surge in both interest and advances in primary aldosteronism. A landmark study from Paris reported a much higher cardiovascular risk profile (4.2 fold higher risk of stroke, 6.5 fold higher risk of non-fatal myocardial infarct, 12.1 fold higher risk of atrial fibrillation) in patients with PA than in age-, sex-, and BP-matched essential hypertensives. Guidelines for the management of PA were published by the Endocrine Society in 2008, the Japanese Endocrine Society in 2011, and a revised version by the Endocrine Society in 2016. What is remarkable in the Guidelines is the thinness of what would be conventionally recognized as a true evidence base, rather than an (inevitable) reliance on consensus re best practice. This is at its most stark, and least impressive, in the plethora of confirmatory/exclusion tests currently in use. Continuing use of one or another test reflects history, familiarity and fears that a 'broken series' may affect acceptance for publication. Currently an inexpensive, rapid, physiologically appropriate seated saline suppression test is being trialed against the laborious 4-day fludrocortisone suppression test, often considered the 'gold standard'. Even if the very encouraging results are confirmed, it will take a revolution in the field to have it uniformly adopted.

Somatic and Germline Mutations

One revolution in the field has been the finding that more than half—and still counting—of APA carry a somatic mutation responsible for over secretion of aldosterone and (less well established) adenoma formation. The prismatic study reported that 8/22 APA were positive for one of two point mutations in the gene encoding KCNJ5, a subunit of the Kir3.4 potassium channel. The mutation-bearing adrenals were larger than wild type, more florid in terms of plasma aldosterone to renin ratio, more common in women and occurred at a younger age. A subsequent study on over 300 patient samples from the ENS@T archive confirmed and extended the initial observations, with two exceptions: the relative frequency of the two mutations was reversed, and no difference in size of APA was found between the two groups. Subsequently there have been described a series of different point mutations in KCNJ5, and a variety of less common somatic mutations in ATPase (ATP1A1, ATP2B3), calcium channels (CACNA1D, CACNA1H) and the intracellular protein catenin beta 1(CTNNB1). At the time of writing mutation-bearing APA constitute 50–60% of all APA in most series, with higher levels in Japan, China and Korea; whether this represents a real ethnic difference or particularities of patient selection remains to be established.

In addition to somatic mutations, germline mutations are responsible for a relatively small percentage of PA. Familiar hyperaldosteronism Type 1 (FH-1) was first described almost 50 years ago, is rare, and reflects a chimeric gene comprising the 3′ end of CYP11B1 with the 5′ end of CYP11B2. The chimeric gene is expressed ectopically throughout the zona fasciculata and is continually ACTH responsive: FH-I is diagnosed by long PCR, and treated by the minimum doses of dexamethasone required to moderate ACTH release. FH-II is PA in two or more first degree (parent–child, sibling-sibling) family members, appears to be heritable with a genetic locus around chromosome 7P22 in several families, with no specific gene shown responsible; this constitutes the minority of cases of FH-II, and whether the remainder are truly heritable remains moot. FH-III is caused by germline mutations in KCNJ5, and a possible FH-IV by germline mutations in CACNA1D. All of these are rare, and if florid need to be treated by bilateral adrenalectomy and replacement therapy.

Public Health Issues

What is slowly being recognized is that primary aldosteronism is a major public health issue, given its higher, blood-pressure independent cardiovascular risk profile. There are two main reasons for this. First is the possible upward revision of its prevalence, from 5 to 13% of hypertension to ~50%. Second is the fact that in no country are more than 1% of hypertensives ever screened for PA, let alone diagnosed and appropriately treated. Reflecting capacity constraints and the relatively high costs of the diagnostic and therapeutic workup, patient referrals from primary care physicians are uncommon, and so the current estimates of 5–13% understandably constitute the most florid cases, the 'low hanging fruit'. In addition the current work up pathway ignores the acute stimulatory effect of ACTH on aldosterone secretion, increasingly obviously to its detriment. A prediction can be confidently made,

once a series of largely ignored historical studies are acknowledged, and recent studies from Athens repeated and validated, that inappropriate aldosterone levels for sodium status will be gradually recognized as responsible at least in part for BP elevation in 50% of 'essential' hypertensives.

Whether the prevalence of PA is 10% or 50%, the fact remains that fewer than 1% of hypertensives are ever screened for PA. The 2008 Endocrine Society Guidelines recommended ~30% of hypertensives, the Japanese Guidelines 100%, and the 2016 Endocrine Society Guidelines ~50%. All these are counsels of perfection, impossible to put into effect in the foreseeable future. In contrast, MR antagonists have been shown to be safe and efficacious in essential hypertension, and specific in lowering BP and cardiac hypertrophy when added to standard therapy in low renin hypertension. They are similarly specifically efficacious when added to current therapy (3 conventional agents, including a diuretic) in so-called resistant hypertension—and game-changing in primary aldosteronism.

In studies on diabetic hypertensives spironolactone 6.25 mg (one quarter of the current smallest tablet) added to existing therapy significantly lowered BP and halved urinary albumin to creatine ratio over 3 months. *Primum non nocere*: but one day perhaps we will see a 6.25 mg spironolactone (or canrenone) tablet recommended for inclusion in first line therapy for hypertension. This would be a breathtakingly effective public health measure—but don't hold your breath waiting for it to happen.

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Clinical Aspects☆

Ellen Marie Freel, Queen Elizabeth University Hospital, Glasgow, United Kingdom

Introduction

Classic mineralocorticoid-induced hypertension develops due to increased distal renal tubular sodium reabsorption, leading to raised body sodium content and plasma volume expansion. In addition, increased urinary potassium and hydrogen ion secretion leads to a reduction in body potassium content, metabolic alkalosis. Finally, increased plasma volume and sodium causes suppression of renin production by the juxtaglomerular cells of the kidney (and correspondingly low levels of angiotensin II).

Autonomous and excessive production of aldosterone, the most potent and prevalent of the human mineralocorticoid hormones, is now accepted to be the commonest cause of secondary hypertension. Although the incidence of primary aldosteronism (PA) varies according to the population studied and diagnostic methods employed, the most robust recent clinical studies consistently suggest that PA accounts for 5%–15% of cases of hypertension within European populations (Rossi *et al.*, 2006). Moreover, it is increasingly recognized that aldosterone excess is associated with disproportionate cardiovascular morbidity further highlighting the importance of accurate diagnosis.

In addition to aldosterone excess, there are a number of other (less common) causes of mineralocorticoid hypertension that will also be considered within this article. In order to enhance the understanding of aldosterone excess as well as these rarer mineralocorticoid excess syndromes, however, it is first necessary to revise mineralocorticoid synthesis, regulation and action as outlined below.

Mineralocorticoid Biosynthesis and Regulation

Aldosterone is produced from cholesterol by a series of hydroxylation and dehydrogenation reactions within the outermost zona glomerulosa of the adrenal cortex (Fig. 1). Aldosterone synthase (encoded by the gene) carries out two unique biosynthetic

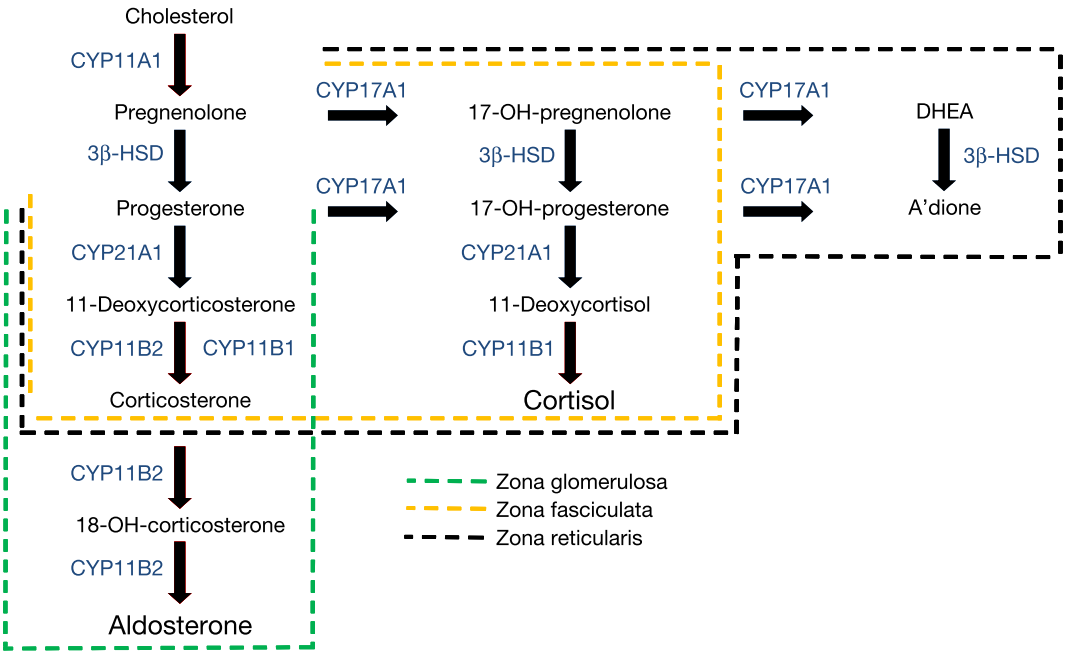

Fig. 1 Corticosteroid biosynthesis within the adrenal cortex. *DHEA*, dehydroandrosterone; *A'dione*, androstenedione.

☆*Change History*: March 2018. E Marie Freel has altered and updated sections (1) Extra section of prevalence of PA, (2) New section on genetic mutations in APA, (3) New section of familial aldosteronism, (4) Section on diagnosis rewritten to include the update American Endocrine Society Clinical Practice Guideline, (5) New section detailing the excess cardiovascular morbidity with aldosterone excess, (6) New section on Gordon Syndrome. Table 1 is new and Table 2 is updated, Figs. 1 and 2 are updated, Figs. 3–6 are new.

This article is an update of John M.C. Connell and Marie Freel, Mineralocorticoids and Mineralocorticoid Excess Syndromes, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 242-251.

 doi:10.1016/B978-0-12-801238-3.65415-6

reactions to generate aldosterone (Rainey, 1999). In brief, corticosterone undergoes hydroxylation to form 18-hydroxycorticosterone which, following a second hydroxylation reaction, is spontaneously dehydrated to form aldosterone. Aldosterone synthase also converts the mineralocorticoid precursor, 11-deoxycorticosterone to corticosterone in zona glomerulosa cells.

In the adjacent zona fasciculata of the adrenal cortex, the 11β-hydroxylase enzyme converts 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone. 11β-Hydroxylase is encoded by the *CYP11B1* gene which is highly homologous to *CYP11B2* (Mornet *et al.*, 1989).

The renin–angiotensin system is the principal regulator of aldosterone production (**Fig. 2**; Connell and Davies, 2005). Loss of sodium (and reduced plasma volume) leads to reduced renal perfusion and activation of the renin–angiotensin system whereas reduced plasma volume suppresses it. Potassium is also a powerful direct stimulus to aldosterone secretion; very small increments (insufficient to cause a significant rise in plasma concentration) raise aldosterone secretion rate. In normal subjects, ACTH can acutely provoke aldosterone release, but chronic pharmacological doses of ACTH given over several days results in suppression of aldosterone synthesis by poorly understood mechanisms.

Mineralocorticoid Action

The mineralocorticoid receptor belongs to the nuclear receptor superfamily of proteins and consists of an N-terminal domain, a DNA-binding domain, and a C-terminal ligand-binding domain (Arriza *et al.*, 1987). Aldosterone binds to this latter domain and causes a conformational change to the mineralocorticoid receptor, whereupon it translocates to the cell nucleus. The ligand–receptor complex interacts directly with hormone response elements of aldosterone-responsive genes in order to activate or repress relevant gene transcription (the so-called "classical genomic effect" of aldosterone) (**Fig. 3**).

The most important physiological action of aldosterone is to increase the activity of the epithelial sodium channel (ENaC) in the apical membrane of the distal convoluted tubule of the nephron (Rossier *et al.*, 1994). This leads to reabsorption of sodium in the kidney and other epithelial sites at the expense of potassium and hydrogen ions (Horisberger and Diezi, 1983). Hydrogen ion excretion by the kidney in the distal nephron is also regulated by aldosterone via an effect on the activity of the ATP-dependent apical hydrogen ion pump and parallel regulation of the basolateral membrane Cl^-/HCO_3^- exchanger (Hays, 1992).

The net effect of aldosterone on the renal tubule is therefore to promote sodium retention at the expense of potassium and also to promote hydrogen ion excretion by the kidney. This explains the clinical features observed in classic cases of autonomous aldosterone excess, that is, plasma hypokalemia, alkalosis, an increased exchangeable sodium content, and low total body potassium.

The 11-β Hydroxysteroid Dehydrogenase System

Aldosterone and cortisol have equal affinities for the mineralocorticoid receptor. Given that cortisol is found at much higher levels in plasma (up to 1000-fold in comparison to aldosterone levels) it would be expected that the vast majority of these receptors

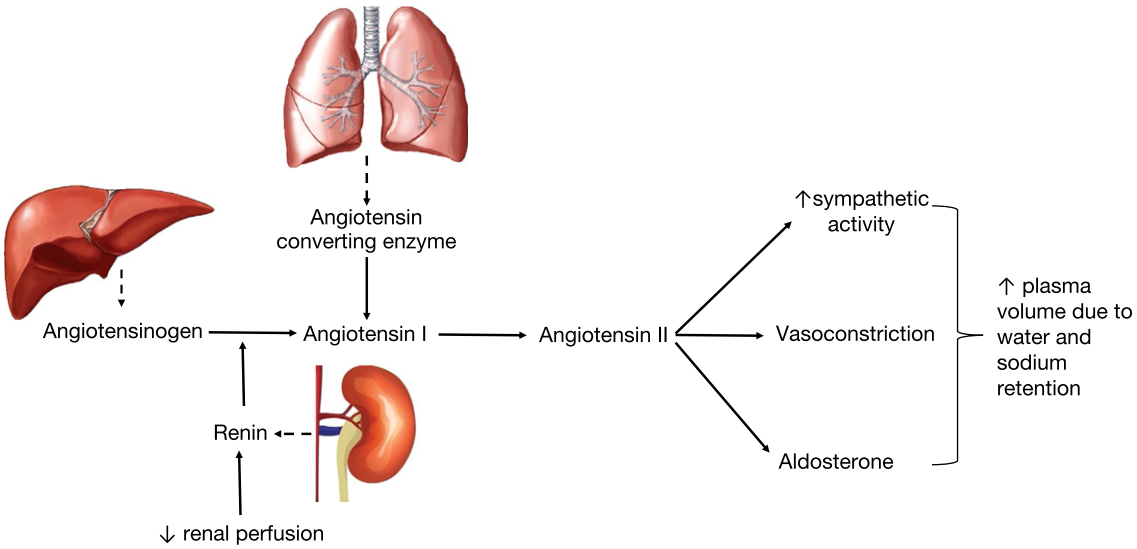

Fig. 2 The renin angiotensin system and the influence of angiotensin II on blood pressure. Renin is produced from the cleavage of pro-renin by the juxtaglomerular apparatus of the kidney in response to reduced circulating plasma volume or sodium. Circulating plasma renin then cuts a short, 10 amino acid long, peptide angiotensinogen (synthesized by the liver) to create angiotensin I. Angiotensin I is then converted, by the removal of two amino acids, to form an octapeptide known as angiotensin II, by the angiotensin-converting enzyme (ACE) found in the capillary endothelial cells especially in the lungs and the epithelial cells of the kidneys. Angiotensin II is a potent vaso-active peptide that causes arteriolar vasoconstriction as well as stimulating aldosterone biosynthesis by the adrenal cortex.

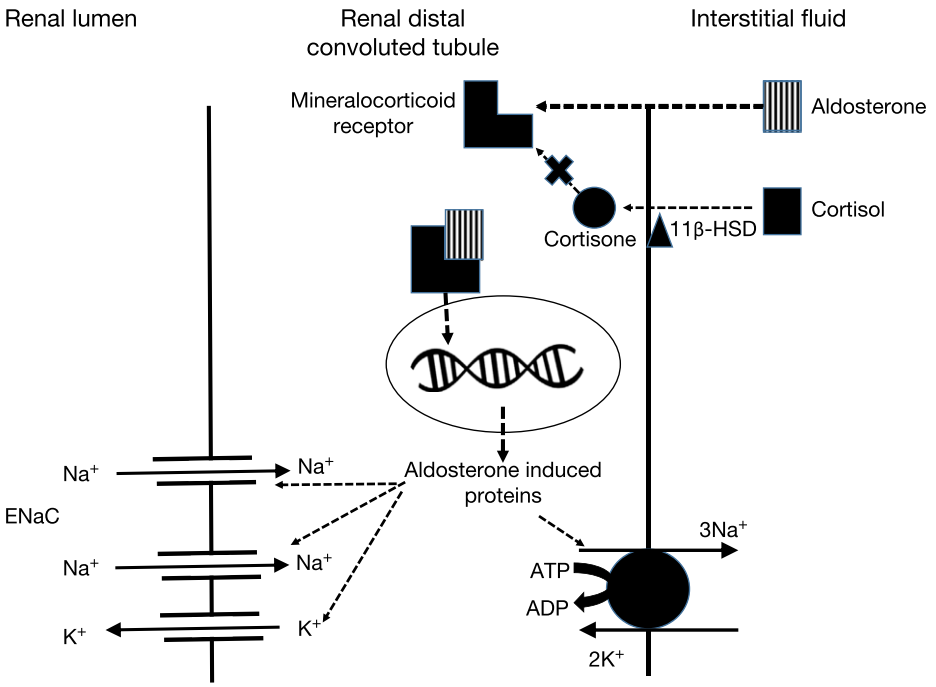

Fig. 3 Mechanism of action of aldosterone in epithelial cells. Aldosterone binds to mineralocorticoid receptor (MR) and leads to alteration in gene transcription by direct binding of the receptor/ligand complex to hormone responsive elements in relevant genes. The MR is protected from activation by cortisol by the 11β-hydroxysteroid dehydrogenase enzyme which converts cortisol to cortisone which has no affinity for the MR. The major effect of aldosterone is to increase availability of ENaC on the apical membrane of the distal convoluted tubule as well as increase activity of the NA-K ATPase pump. Thus, the net effect is increased renal reabsorption of sodium with increased potassium excretion. ENaC, epithelial sodium channel; 11β-HSD2,11β-hydroxysteroid dehydrogenase.

would be expected to be occupied and activated by glucocorticoid. This does not occur as a consequence of the activity of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD), which acts as a gatekeeper to prevent the mineralocorticoid receptor being overwhelmed by much higher available levels of cortisol (**Fig. 3**) (Funder *et al.*, 1988). The type 2 isoform of this enzyme is found in the renal distal nephron as well as other aldosterone-sensitive target tissues (colon, salivary glands, and placenta) and converts cortisol to its inactive metabolite, cortisone, which has no affinity for the mineralocorticoid receptor (Edwards *et al.*, 1988). Whenever protection of the mineralocorticoid receptor is compromised by impairment of 11β-HSD2 activity cortisol causes widespread activation of the mineralocorticoid receptor leading to mineralocorticoid hypertension. The clinical consequences of this are described later in this article.

Mineralocorticoid Hypertension

As a result of an understanding of mineralocorticoid biosynthesis and action, mineralocorticoid excess syndromes can be thought of under the following headings:

1. Activation of the mineralocorticoid receptor by excess levels of its normal agonist, aldosterone (primary aldosteronism)
2. Activation of the mineralocorticoid receptor by an alternative ligand (either cortisol in the Syndrome of Inappropriate Mineralocorticoid Excess or mineralocorticoid precursors in rare forms of Congenital Adrenal Hyperplasia)
3. Abnormality within the mineralocorticoid receptor altering sensitivity to other agonists (progesterone induced hypertension)
4. Abnormality within renal ion channels resulting in inappropriate activation (Liddle syndrome and Gordon Syndrome)

Activation of the Mineralocorticoid Receptor by Excess Levels of Its Normal Agonist, Aldosterone-Primary Aldosteronism (PA)

As outlined previously, PA is the commonest cause of secondary hypertension. The current accepted prevalence rates are strongly supported by a seminal Italian study in a large series of unselected patients with hypertension. Using careful confirmatory tests for the disorder, this study reported a prevalence of 11% for primary aldosteronism in such a cohort, with 4.8% of subjects harboring an aldosterone-producing adenoma (Rossi *et al.*, 2006). Another comprehensive study in Greece of patients with resistant hypertension reported an incidence of 11.3% (Douma *et al.*, 2008). Thus, the recently reported frequency rates are consistent with

a previous multicenter retrospective review where more widespread use of the plasma aldosterone to renin ratio (ARR) as a screening test in hypertensive patients resulted in a marked increase (up to sixfold) in the annual detection rate of PA as well as in the proportion of hypertensive patients in whom PA was detected (1%–2% before and 5%–10% after screening) (Mulatero *et al.*, 2004). This apparent increased PA prevalence can mainly be accounted for by increasing recognition and earlier diagnosis of more subtle cases of aldosterone excess through use of the aldosterone to renin ratio as a screening tool (see below).

PA presents with hypertension, which is often severe and resistant to "conventional" antihypertensive therapy. Although hypokalemia had historically been considered to be a prominent clinical feature less than half of all patients have demonstrably low plasma potassium levels (Funder *et al.*, 2016; Mulatero *et al.*, 2004).

Causes of Primary Aldosteronism

Sporadic primary aldosteronism

The relative prevalence of causes of primary aldosteronism varies by geographical location, but in all cases the vast majority are sporadic. In Caucasian populations, the most common cause of sporadic PA is bilateral adrenal hyperplasia, accounting for approximately 60% while an aldosterone-producing adenoma (APA) consists of 35% of patients with PA; unilateral micronodular hyperplasia (caused by micronodular or macronodular hyperplasia of the zona glomerulosa of predominantly one adrenal gland) is an uncommon cause. In contrast, in a Japanese cohort, APA accounts for the majority of primary aldosteronism cases (around 80%) (Omura *et al.*, 2004). Aldosterone-producing adrenal carcinoma is an extremely rare cause of aldosterone excess associated with a poor prognosis.

The precise etiology of these conditions remains largely unknown, and whether APAs arise from nodular adrenal glands, or whether the two conditions are independent is still debated. It has previously been shown that tissue around the resected adenoma differs from normal adrenal tissue and has undergone remodeling with reduced vascularization and zona glomerulosa hyperplasia (Boulkroun *et al.*, 2010). However, a comparison of the transcriptome of tissue adjacent to APA, APA tissue itself and normal adrenal tissue suggests that it this is not an intermediate step in the formation of APAs.

Genetic mutations in APA

Major advances have been made during the past 6 years in understanding the pathophysiology of aldosterone production in patients with PA with the discovery that somatic mutations are found in up to 50% of patients with APA; the most prevalent of these are summarized in **Table 1**. The breakthrough was the identification of somatic mutations in the potassium channel GIRK4 (encoded by *KCNJ5*) in APA and the simultaneous discovery, by the same authors, of a germline mutation within this gene responsible for familial hyperaldosteronism type III (Choi *et al.*, 2011). This was followed by the identification of further somatic mutations in APAs in two ATPases (Na^+/K^+-ATPase 1 and Ca^{2+}-ATPase3,encoded by *ATP1A1* and *ATP2B3*, respectively) and in a subunit of an L-type voltage-gated Ca^{2+}-channel, Cav1.3 (encoded by *CACNA1D*) (Beuschlein *et al.*, 2013; Scholl *et al.*, 2013; Azizan *et al.*, 2013).

Somatic mutations in *KCNJ5* appear to be present in approximately 40% of patients with APAs (Boulkroun *et al.*, 2012; Azizan *et al.*, 2012; Åkerström *et al.*, 2012; Monticone *et al.*, 2012) (**Table 1**). However, the prevalence of such mutations seems to vary according to geographical location with one Chinese study reporting the presence of KCNJ5 mutations in 77% of all tested APA (Zheng *et al.*, 2015). All mutations identified so far affect the selectivity filter of the potassium channel GIRK4 (*KCNJ5*) producing increased sodium conductance and cell depolarization, leading to calcium entry into glomerulosa cells resulting in aldosterone production and cell proliferation.

In one of the first studies to estimate mutation frequency, *KCNJ5* sequencing was performed on somatic (APA, $n = 380$) and peripheral (APA, $n = 344$; bilateral adrenal hyperplasia, $n = 174$) DNA of patients with primary aldosteronism (Boulkroun *et al.*, 2012). Somatic *KCNJ5* mutations (G151R or L168R) were found in 34% (129 of 380) of APAs. They were significantly more common in women (49%) than men (19%, $P < 0.001$) and associated with higher preoperative aldosterone levels. Germline *KCNJ5* mutations were not found in patients with bilateral adrenal hyperplasia. Similar genotype and phenotypic findings have been reported in multiple subsequent studies of APA.

Other somatic mutations in *ATP1A1*, *ATP2B3*, and *CACNA1D* have also subsequently been identified; albeit at a lower frequency than *KCNJ5* mutations. In a study using exome sequencing of 308 APA, somatic mutations of *ATP1A*1 (encoding an Na^+/K^+ ATPase alpha subunit) were found in 16 (5.2%) and of *ATP2B3* (encoding a Ca^{2+} ATPase) in 5 (1.6%) (Beuschlein *et al.*, 2013). Similar results were noted in a subsequent study of 112 APA (Williams *et al.*, 2014).APA harboring these mutations were more common in mean and associated with increased plasma aldosterone concentrations, and lower potassium concentrations compared with mutation-negative cases (Beuschlein *et al.*, 2013).

Additional somatic APA mutations have been identified in *CACNA1D*, encoding a voltage-gated calcium channel. In one study, such mutations were identified in 11% percent of APA (Scholl *et al.*, 2013); patients carrying these mutations had smaller tumors and were older than those with KCNJ5 mutations. In two cases with early onset of PA, de novo germline mutations of *CACNA1D* were identified and associated with complex, severe neurologic and neuromuscular abnormalities (cerebral palsy, seizures, athetosis, spastic quadriplegia).

Table 1 Summary of most significant APA mutations and their relative frequencies

Gene	*Reference*	*Number of APA*	*% somatic mutations*	*Mutations identified*

Inherited forms of PA

Familial syndromes are a rare cause of PA (so-called "familial hyperaldosteronism; FHA"). However, as is often the case with Mendelian disease, understanding their etiology gives insight into the control and regulation of aldosterone in both health and disease.

FHA1 (glucocorticoid remediable aldosteronism; GRA)

This is an autosomal dominant monogenic disorder caused by a hybrid gene comprising the regulatory element of 11β-hydroxylase, which catalyzes the final steps of cortisol synthesis and is normally expressed in the zona fasciculata, and the coding region of aldosterone synthase, which catalyzes the final steps of aldosterone production in the zona glomerulosa (**Fig. 1**). This leads to mineralocorticoid hypertension that typically presents in young adults (Lifton *et al.*, 1992). Aldosterone is produced in response to ACTH rather than its usual trophins of potassium and angiotensin II, but importantly, the chimeric gene is expressed ectopically in the fasciculata, which allows the gene product inappropriate access to greater quantities of 11-deoxycorticosterone as a substrate for excessive aldosterone production.

The diagnosis of glucocorticoid-remediable hyperaldosteronism should be suspected in any patient who presents with early onset of PA and/or a positive family history of aldosterone excess. Genetic testing using molecular biologic techniques to detect the chimeric gene is now preferred over dexamethasone suppression testing for making the diagnosis of GRA. Given its relative rarity, the genetic screen should be performed only on selected patients. Indications include primary aldosteronism patients with onset at a young age (e.g., $<$20 years), or a family history of primary aldosteronism or of stroke at a young age (e.g., $<$40 years).

Treatment of GRA can be with either low dose oral glucocorticoid therapy (to suppress ACTH mediated aldosterone excess) or mineralocorticoid receptor antagonists.

FHA2

FHA2 is also an autosomal dominant disorder presenting as PA with a positive family history. While the gene defect causing FHA2 has not been discovered, linkage analysis of affected families have suggested an association between markers within cytogenetic band 7p22 and this phenotype (Lafferty *et al.*, 2000). It is currently diagnosed if patients have at least two relatives with hyperaldosteronism and screening for FHA1 (GRA) is negative.

FHA3 (KCNJ5)

FHA3 has recently been characterized in a single affected family where three members had severe, early onset hypertension and massive bilateral adrenal hyperplasia (Choi *et al.*, 2011). The discovery that germ line mutations in the *KCNJ5* gene lead to autosomal dominant hyperaldosteronism has provided a clear genetic cause of this condition in a small cohort of patients. More importantly, as discussed above, it has provided novel mechanistic insights into the normal control of aldosterone and possible pathogenic mechanism in patients with nonfamilial APAs.

Diagnosis of Primary Aldosteronism

As PA is a relatively common secondary cause of hypertension, with excess cardiovascular mortality compared to hypertensive controls and specific management issues, there is a clear case for identification of PA within hypertensive cohorts. However, the diagnosis of PA can be obtuse, as there are few specific clinical symptoms, and the biochemical tests can be obscured by confounding factors and technical factors. The Endocrine Society's recently published updated guideline (Funder *et al.*, 2016) suggests screening for PA using simultaneous measurements of plasma renin and aldosterone (to give a ratio, the ARR) in patients with moderate to severe or resistant hypertension, those with hypokalemia (spontaneous or in response to diuretic treatment), those with an adrenal incidentaloma and those with a family history of PA. If this initial test is positive then confirmatory testing followed by the subtype diagnosis should proceed. Their approach to diagnosis is summarized in **Fig. 4**.

Screening test

The initial screening test of ARR can be performed without the need for stopping antihypertensive medication if patients have severe hypertension (with the exceptions of spironolactone, eplerenone and amiloride), as these agents have predictable effects on renin and aldosterone measurements (**Table 2**). The ARR should be measured in the context of an unrestricted sodium intake (which should not require adjustment from normal for the majority of patients). Previously plasma renin activity (PRA) was measured using a radioimmunoassay. More recently, the measurement of plasma renin concentration (PRC) has been adopted in many centers as this method is less technically demanding although this assay in general is less sensitive, particularly at lower concentrations (Dorrian *et al.*, 2010). Therefore, adding cut-off of minimum plasma aldosterone concentration (>15 ng/dL or 410 mmol/L) before further confirmatory testing has been proposed to minimize false positive results. This recommendation, however, this is not universally accepted (Dorrian *et al.*, 2010; Funder *et al.*, 2016). The cut-off values for aldosterone and ARR are dependent on local assays and conditions: an aldosterone (pmol/L)/PRC (microIU/mL) ratio of >30, aldosterone (pmol/L)/PRA (ng/mL/h) ratio of >750 are commonly used.

Confirmatory test

Levels of ARR above a threshold require further confirmatory testing for the diagnosis of PA. The exception to this is when there is clear PA (spontaneous hypokalemia with plasma renin below detection levels and plasma aldosterone above 20 ng/dL (550 pmol/L)) when confirmatory testing is unnecessary.

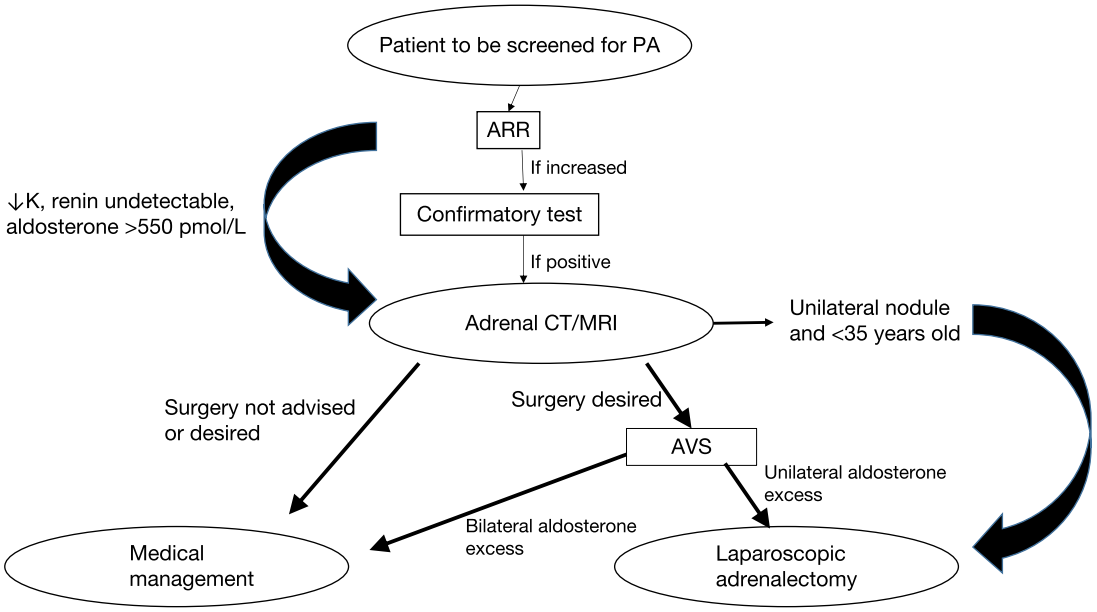

Fig. 4 Diagnostic algorithm for primary aldosteronism. *AVS*, adrenal vein sampling; PA, primary aldosteronism; ARR, aldosterone to renin ratio.

Table 2 Influence of commonly used antihypertensive agents on the renin–angiotensin–aldosterone axis

Medication	*Plasma aldosterone*	*Plasma renin*	*ARR*
Beta-blocker	Reduced	Significantly low	Increased
Loop or thiazide diuretics	No effect or increase	Significantly increased	Reduced
Potassium-sparing diuretics (spironolactone/amiloride)	Increase	Significantly increased	Reduced
ACE inhibitors/ARB	Reduced	Significantly increased	Reduced
Ca channel blockers (dihydropyridine)	No effect or reduced	Increased	Reduced

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blockers.

The purpose of the confirmatory test is to confirm autonomous secretion of aldosterone which is freed from control by its conventional trophins. There are a number of ways this can be investigated, and the choice of which confirmatory test is a matter of local preference/expertise; no "gold standard" currently exists. It is recommended that, for confirmatory testing, medications with significant effects on the renin–angiotensin–aldosterone axis be avoided (**Table 2**).

Oral sodium loading test

This test requires an increase in oral sodium intake (with sodium chloride tablet if necessary) to >200 mmol (6 g) per day, for 3 days. As with all confirmatory tests, it is important to ensure plasma potassium remains normal as hypokalemia can lead to a false suppression of plasma aldosterone. A 24 h urine aldosterone is measured after 3 days. Autonomous secretion of aldosterone is confirmed if urinary aldosterone excretion exceeds 33 nmol/day (12 μg/24 h). This test is of limited value in patients with renal disease, as aldosterone 18-oxo-glucuronide is a renal metabolite, and its excretion may not rise in patients with renal disease. However, the main limitation of this test is mainly due to the difficulties encountered in organizing 24 h urine collections in most patients.

Intravenous saline infusion test

In this test, 2 L of 0.9% sodium chloride solution are infused over 4 h into the recumbent patient with monitoring of blood pressure and heart rate throughout. After 4 h, plasma aldosterone is measured; levels <139 pmol/L (5 ng/dL) make PA less likely, values between 139 and 277 pmol/L (5 and 10 ng/dL) are indeterminate and levels >277 pmol/L (10 ng/dL) make a diagnosis of PA highly likely. The main disadvantage of this test is the volume of intravenous fluid infused, which may be contraindicated in patients with cardiac failure as well as ongoing debate over the optimal postsaline infusion aldosterone level used to confirm aldosterone excess.

Fludrocortisone suppression test

Fludrocortisone acetate (0.1 mg every 6 h) is administered for 4 days and in addition, the oral sodium intake maintained at an intake of >200 mmol per day using sodium chloride supplementation. Plasma renin should be suppressed and the upright aldosterone in the morning of day 4 should be suppressed to <166 pmol/L (6 ng/dL). While the fludrocortisone suppression test is considered by some to be the most sensitive of the confirmatory tests, it has several limitations which mean its use should be restricted to centers with expertise and facilities to cope with complications (such as hypokalemia and cardiac dysrhythmia). In light of this, most centers undertake this test as an inpatient, which has cost and resource implications.

Captopril challenge

The captopril challenge consists of measurement of plasma renin and aldosterone before and 2 h after a single dose of captopril (25 mg). This would normally be expected to suppress aldosterone by >30% but, in PA, aldosterone will remain high. However, this test has been reported to be less sensitive than salt suppression methods and as such it is now rarely used.

Subtype characterization: Further tests

Only once autonomous secretion of aldosterone has been confirmed should there be an attempt to differentiate between APA and bilateral forms of aldosterone excess. Further imaging is important in order to exclude an aldosterone secreting carcinoma as well as to inform management, which is clearly different depending on the underlying cause of hyperaldosteronism. Lateralizing the site of excess aldosterone production is the next step, and this requires adrenal vein sampling.

Imaging

The preferred imaging modality is computerized tomography (CT) which demonstrates superior spatial resolution over MRI. On the other hand, MRI does not involve radiation exposure which, to some patients, may be more advantageous.

An APA is usually a small (<2 cm) lipid-rich tumor with a typical appearance on CT, corresponding to <10 Hounsfield units with a rapid wash-out phase following the administration of contrast agent. Adrenal hyperplasia can consist of either micro (<1 cm) or macro (>1 cm) adenomas, or a combination of the two (**Fig. 5**).

Importantly, in the majority of cases, CT alone should not be used to distinguish between unilateral disease, amenable to adrenalectomy, and bilateral or idiopathic disease, which should be managed medically. For example, nonfunctioning adrenal

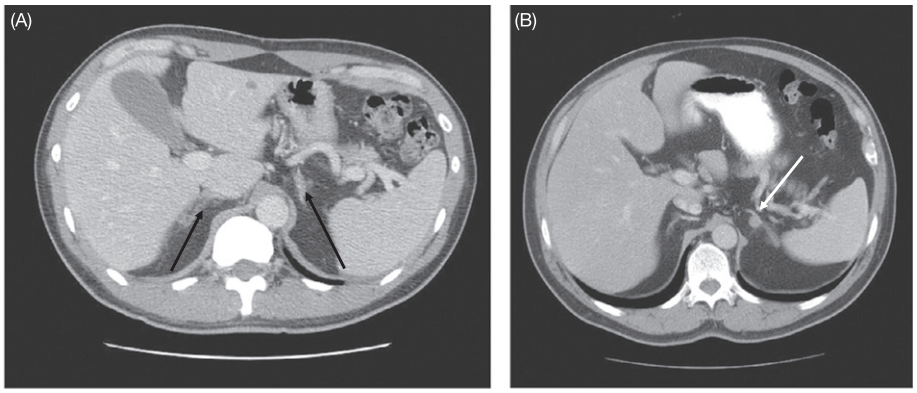

Fig. 5 CT scan of adrenals demonstrating bilateral adrenal hyperplasia (A, *black arrows*) and a unilateral adrenal adenoma (B, *white arrow*).

adenomas are relatively common in older patients and radiologically indistinguishable from APAs. Moreover, small APAs may not be seen on CT and the incorrect diagnosis of idiopathic hyperaldosteronism reached, and conversely, areas that look like microadenomas may in fact represent area of hyperplasia. Consequently, a more accurate method of lateralization of aldosterone secretion is required in order to avoid inappropriate surgery in patients with bilateral disease or withholding curative surgery to patients who may benefit. The exception to this sequence of investigations is in patients under the age of 35, in whom an adrenal adenoma is identified of >1 cm. In these patients, it would be reasonable to proceed to adrenalectomy without further investigation in accordance with The Endocrine Society Clinical Practice Guideline (**Fig. 4**; Funder *et al.*, 2016).

Lateralizing aldosterone secretion

The gold standard investigation to confirm aldosterone excess is adrenal vein sampling (AVS). This is a technically demanding procedure which is difficult to access outwith tertiary referral centers and, as such, is likely to be performed less frequently than is clinically indicated. This notion was supported by the Adrenal Vein Sampling International Study (AVIS which explored AVS practice in 20 centers from Asia, Australia, United States and continental Europe (Rossi *et al.*, 2012). This important study confirmed that AVS was under-utilized with significant variation in techniques and interpretation of results and therefore highlighted a requirement for definitive guidance on the use and interpretation of AVS in identifying unilateral aldosterone excess. This requirement was subsequently addressed by the publication of an expert consensus statement on the use of AVS, based on data collected in the AVIS study, by Rossi and coauthors published in 2014 (Rossi *et al.*, 2014). This now provides a convenient reference to allow standardization of AVS techniques and protocols as well as in interpretation of results.

While there is no doubt that AVS remains a technically challenging procedure, success can be directly correlated with clinical experience. In the AVIS study, 2604 AVS procedures were performed by seven radiologists, with an average of 2.6 radiologists performing the procedure at each center. Unsurprisingly, the complication rate was inversely proportional to the number of radiologists performing AVS at each center (Rossi *et al.*, 2012).

Given these difficulties, the prospect of another tool to differentiate unilateral, surgically curable disease from bilateral disease is appealing. The use of 11^{C}-Metomidate as a radiotracer in positron emission tomography (PET-CT) could be a useful in this situation. Previous data have demonstrated sensitivity and specificity of 76% and 87% using this technique (Burton *et al.*, 2012) which is noninvasive and requires less technical expertise. The use of 11C-Metomidate PET would currently be limited to centers with access to a cyclotron, but this promising diagnostic test may be used more frequently in the future.

Treatment of Primary Aldosteronism

Surgical management

In suitable patients with unilateral disease, laparoscopic (when possible) surgical resection of the affected adrenal gland is the treatment of choice. Adrenalectomy offers the possibility of curing hyperaldosteronism, although it is important to be aware that not all patients achieve complete remission of hypertension. This has been illustrated most recently in a very careful study examining surgical outcomes after adrenalectomy for PA in 12 centers of excellence in 9 countries (Williams *et al.*, 2017). Using a set of criteria agreed in advance by a cohort of international experts, it was reported that surgery resulted in cure of hypertension in 259/705 (37%) of cases; although this varied between centers. An additional 334/705 (47%) of patients demonstrated partial success with reduction in blood pressure or antihypertensive use after surgery. Factors which were associated with cure were found to be younger age, fewer antihypertensives preoperatively and female sex. Interestingly, while clinical cure was only seen in one third of patients, complete biochemical resolution of aldosterone excess was found in 94% which illustrates that primary hypertension and PA often coexist.

Medical therapies

In patients with bilateral disease, or those with APA and unsuitable or unwilling for a surgical procedure, medical therapy with aldosterone antagonists is the mainstay of therapy. Spironolactone is an effective mineralocorticoid antagonist, although it lacks specificity and acts as an antagonist for the androgen and progesterone receptor. These properties account for the side effects which can limit its use, particularly at high doses (gynecomastia and erectile dysfunction in males and menstrual irregularity in women). Eplerenone is more specific for the mineralocorticoid receptor but is less potent, requiring higher doses. Both should be started at low dose and titrated slowly with monitoring of plasma potassium. Once aldosterone action is appropriately suppressed, plasma renin should rise, and this can be a helpful way to monitor the titration regime. If adequate control of hypertension is not achieved with mineralocorticoid antagonists alone, amiloride is a relatively effective additional antihypertensive through its action on blocking the epithelial sodium in the distal convoluted tubule. Calcium channel blockers and diuretics are also reasonable to use in combination with MR antagonists, however, unless plasma renin (and angiotensin II) is released from the inhibitory effects of excessive action of aldosterone, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) are unlikely to improve blood pressure control.

Importance of targeting aldosterone excess

Animal studies in stroke prone hypertensive rats have demonstrated that aldosterone (and salt) results in vascular damage and fibrosis which can be prevented by small doses of spironolactone that do not lower blood pressure (Rocha *et al.*, 1998, 2000). Subsequently, a variety of clinical studies have demonstrated that aldosterone exerts adverse cardiovascular consequences which cannot be attributed to hypertension alone. For instance, a landmark observational study in 2005 comparing cardiovascular events in subjects with PA with those with primary hypertension demonstrated a marked increase in stroke, myocardial infarction and atrial fibrillation in PA patients despite similar severity and duration of hypertension (Milliez *et al.*, 2005). A number of subsequent studies have demonstrated similar results (Savard *et al.*, 2013).

Taken together, both animal and clinical studies suggest that targeting of aldosterone excess (by surgical or medical means) as well as lowering of blood pressure is an effective treatment strategy to reduce cardiovascular morbidity in PA. It has been demonstrated that both mineralocorticoid-receptor blockade and adrenalectomy are effective in reversing adverse target organ damage seen in aldosterone excess (Catena *et al.*, 2008; Sechi *et al.*, 2010).

Activation of the Mineralocorticoid Receptor by an Alternative Ligand

Syndrome of Inappropriate Mineralocorticoid Excess

Apparent mineralocorticoid excess (AME) is a rare syndrome of hypertension and hypokalemia associated with suppression of plasma renin activity and low plasma concentrations of aldosterone and other known mineralocorticoids (Stewart *et al.*, 1988). In this autosomal recessive syndrome, 11β-HSD2 activity (**Fig. 6**) is reduced or absent such that cortisol overwhelms the mineralocorticoid receptor leading to cortisol-mediated mineralocorticoid hypertension.

AME usually presents in childhood with failure to thrive, short stature, significant hypertension, and hypokalemia. Biochemical diagnosis of AME can be made by measuring the ratio of cortisol (compound F) to cortisone (compound E) as indicated by the ratios of their tetrahydro (allo)-urinary metabolites (THF + alloTHF:THE) (Palermo *et al.*, 1996). In AME, however, urinary free cortisone excretion is extremely low compared to normal subjects, leading to an increased THF + alloTHF:THE ratio in urine.

Milder cases of AME, so-called "type II apparent mineralocorticoid excess" with isolated hypertension and normal or low-normal potassium have been described in Italian patients (Li *et al.*, 1998). In these subjects, a homozygous mutation in the 11β-HSD2 gene (R279C) has been identified which causes a reduction but does not completely ablate 11β-HSD2 activity. Therefore, AME comprises a spectrum of mineralocorticoid hypertension with a good correlation between enzyme activity and clinical phenotype.

The most effective treatment of AME is amiloride, although high doses (up to 40 mg daily) can be required in order to be effective. Mineralocorticoid receptor antagonists can also be used but their safety and tolerability may be limited by the relatively high doses required to competitively antagonize the agonist effects of cortisol in this circumstance. Dexamethasone has also been

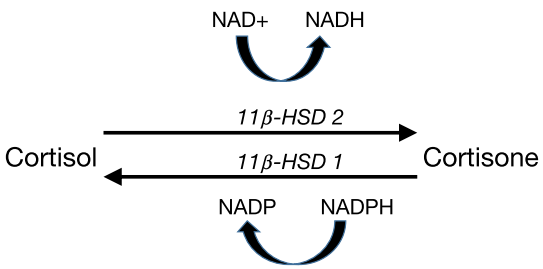

Fig. 6 The 11β-hydroxysteroid dehydrogenase system.

used but its therapeutic benefit is similarly limited by the need to give doses sufficiently high to inhibit endogenous cortisol production, exposing patients to unwanted glucocorticoid side effects.

Deficiency of 11β-HSD and consequent mineralocorticoid hypertension can also occur due to ingestion of liquorice or carbenoxolone (previously used for the treatment of peptic ulcer disease). The active component of liquorice is glycyrrhizic acid and its hydrolytic product glycyrrhetinic acid, which have been shown to inhibit the activity of 11β-HSD2 in the renal tubule allowing cortisol-driven mineralocorticoid hypertension (Stewart *et al.*, 1987). Carbenoxolone is a semisynthetic hemisuccinate derivative of glycyrrhetinic acid and has its effect through a mechanism analogous to that of liquorice.

Congenital Adrenal Hyperplasia

Other mineralocorticoids rarely circulate in sufficient levels to cause hypertension. For example, the aldosterone precursor deoxycorticosterone, which also binds and activates the mineralocorticoid receptor, circulates at concentrations around 2% of those of aldosterone and so, under normal circumstances, does not contribute to electrolyte and blood pressure regulation.

However, excessive plasma levels of deoxycorticosterone can be found in patients with rare inborn errors of adrenal steroid synthesis due to defective 17α-hydroxylase or 11β-hydroxylase activity (**Fig. 1**). In both of these circumstances, low plasma cortisol leads to increased ACTH drive to the adrenal and chronic excess of corticosteroid precursors including deoxycorticosterone (White, 1996). In turn, sodium retention causes suppression of renin release and, as a consequence, aldosterone levels are generally low. Most cases present shortly after birth or in early childhood. While both conditions result in early onset mineralocorticoid hypertension and glucocorticoid deficiency, there are important differences in the associated symptoms. For instance, adrenal androgens are produced in excessive amounts in patients with 11β-hydroxylase deficiency, leading to virilization of female subjects. In contrast, 17-hydroxylase deficiency results in an inability to synthesize sex hormones, with the result that affected males fail to develop normal masculine external genitalia, while females fail to progress through adrenarche or puberty. Diagnosis of either condition is confirmed by measurement of corticosteroid metabolite excretion in the urine.

Abnormality Within the Mineralocorticoid Receptor Altering Sensitivity to Other Agonists (Progesterone Induced Hypertension)

This rare disorder is characterized by constitutive activation of the mineralocorticoid receptor as well as an alteration in receptor sensitivity (Geller *et al.*, 2000). An autosomal dominant mis-sense mutation in the MR gene (S810L) means that the receptor is able to be occupied by a range of steroids, including those that have not undergone 21 hydroxylation, for example, progesterone. Subjects with this mutation develop early onset of severe hypertension with suppression of aldosterone and plasma renin. As progesterone levels increase by up to 100-fold in pregnancy, carriers of the S810L tend to develop severe pregnancy-associated hypertension.

Abnormality Within Renal Ion Channels Resulting in Inappropriate Activation

Liddle Syndrome

This is a rare autosomal dominant condition which presents with significant hypertension in childhood, arising from increased activity of the epithelial sodium channel (ENaC). In common with PA, patients have hypokalemia with a metabolic alkalosis and low plasma renin but in this disorder plasma aldosterone concentrations are also low. The genetic abnormality lies on chromosome 16 leading to "gain of function mutations" within the β- and γ-subunits of ENaC (Shimkets *et al.*, 1994; Rossi *et al.*, 2008). These mutations prevent the interaction of these subunits with intracellular ubiquitin protein ligase (Nedd4) that normally removes the luminal sodium channel from the cell surface. This results in constitutive activity of the ENaC in the cortical collecting duct and a failure to downregulate in response to volume expansion-mediated reduction in renin secretion and aldosterone. Importantly, in this condition, spironolactone is not a useful treatment because activation of ENaC is independent of the mineralocorticoid receptor. However, the ENaC is amiloride-sensitive and this is the treatment of choice in these patients.

Gordon Syndrome (Pseudohypoaldosteronism Type 2)

Pseudohypoaldosteronism Type 2 or Gordon syndrome is characterized by hypertension, hyperkalemia, metabolic acidosis, normal renal function, low or low-normal plasma renin activity and normal or elevated aldosterone concentrations (Gordon, 1986). In addition, patients with this autosomal dominant condition are extremely sensitive to thiazide diuretics suggesting a gain of function mutation in the thiazide-sensitive sodium–chloride transporter in the distal convoluted tubule. However, the mutation lies not within the gene encoding the transporter itself, but rather on chromosomes 12 and 17 each of which encode a With No Lysine Kinase (WNK). WNK1 and 4 localize to the distal convoluted tubule and cortical collecting duct and are involved in the regulation of the sodium–chloride transporter acting via a kinase cascade, leading to loss of inhibition of the sodium chloride transporter and increased expression at the apical surface (Wilson *et al.*, 2001). WNK4 normally inhibits the thiazide-sensitive

Na–Cl cotransporter of the distal nephron; thus somatic mutations increase its activity, leading to thiazide-sensitive hypertension. As a result, systolic and diastolic blood pressure fall significantly after treatment with low dose thiazide diuretic such as hydrochlorothiazide (Mayan *et al.*, 2002). The mechanism of hypertension in subjects with WNK1 mutations is less clear.

Summary

Primary aldosteronism is easily the commonest secondary cause of hypertension. Whilst universal screening for this condition among subjects with hypertension is not yet advocated, its prevalence and relative ease of screening mean it should be considered far more commonly and earlier in hypertensive cohorts (especially if young, presenting with resistant hypertension, presenting with spontaneous or diuretic-induced hypokalemia). Earlier identification of PA means that more targeted treatment (and even cure) can be offered; this is particularly relevant given strong evidence demonstrating blood pressure independent adverse effects of aldosterone excess.

However, it should be noted that PA is not the sole cause of mineralocorticoid hypertension, although other causes, as demonstrated in this article, are extremely rare. Whatever, the cause, baseline measurement of plasma renin and aldosterone can be used as a starting point to guide further investigations. If both are low, then this should trigger a search for more obscure causes of mineralocorticoid hypertension.

Primary Aldosteronism; Epidemiology and Screening

Michael Stowasser, University of Queensland Diamantina Institute, Brisbane, QLD, Australia

Abbreviations

ACE	Angiotensin converting enzyme
AngII	Angiotensin II
APA	Aldosterone-producing adenoma
ARB	Angiotensin receptor blocker
ARR	Aldosterone/renin ratio
BAH	Bilateral adrenal hyperplasia
CCB	Calcium-channel blocker
DRC	Direct renin concentration
FST	Fludrocortisone suppression test
PA	Primary aldosteronism
PRA	Plasma renin activity

Epidemiology

Primary aldosteronism (PA) is currently considered to be the most common secondary endocrine form of hypertension. This represents a marked change in understanding of the prevalence of PA which, throughout the 1970s to early 1990s, was considered to be rare (accounting for $<1\%$ of patients with hypertension) and not worth looking for in the absence of hypokalemia. During the preceding decade, Conn had strongly argued that PA was much more common, having recognized that patients with PA (including those with aldosterone-producing adenoma, APA) need not be hypokalemic (Conn, 1964) and was able to report that 14 of 45 patients diagnosed by his group as having PA and found to have adrenal cortical tumors at the time of surgery were normokalemic preoperatively (Conn, 1966) and that 13 (93%) of these demonstrated either cure or improvement of hypertension postoperatively. Despite these observations, Conn's proposal that normokalemic PA may be a common cause of hypertension was generally rejected by the medical community of that time.

A major advance in the ability to detect patients with PA was the application of the plasma aldosterone/renin ratio (ARR) as a screening test, first reported on in 1981 by Hiramatsu *et al.* (1981). By measuring the ARR in 348 "unselected" hypertensives, these workers were able to detect and remove APAs from 9 (2.6%) patients, only 3 of whom were hypokalemic. Since they used a very high diagnostic cut-off for the ARR, and relied on adrenal venography and scintigraphy to confirm the diagnosis of APA, it is highly probable that they would have missed patients with relatively small APAs, and all with bilateral adrenal hyperplasia (BAH), meaning that the true prevalence of PA was probably much higher than the figure of 2.6% they reported.

From the early 1990s, reports began to emerge of even higher detection rates for PA resulting from the use of the ARR and its wider application among hypertensive populations. At the Greenslopes Hospital Hypertension Unit in Brisbane, Australia, adoption of the policy to apply the ARR to all referred hypertensives, and not just those with hypokalemia or resistant hypertension, led to a tenfold increase in the detection rate of PA (confirmed in each case by fludrocortisone suppression testing [FST]) (Gordon *et al.*, 1992b, 1994a; Stowasser and Gordon, 2004). The proportion who were hypokalemic fell from two-thirds to just one-fifth, the rest being normokalemic and therefore masquerading as "essential hypertension" (Gordon *et al.*, 1992b, 1994a; Stowasser and Gordon, 2004).

What is the prevalence of PA among the hypertensive population? While rates vary across series according to the population screened and the diagnostic methods and cut-offs used, the majority of studies since the 1990s have reported prevalence rates between 5% and 15%, with most patients being normokalemic (Fardella *et al.*, 2000; Gordon *et al.*, 1993, 1994b; Lim *et al.*, 2000; Loh *et al.*, 2000; Mulatero *et al.*, 2004; Nishikawa *et al.*, 2007; Rossi *et al.*, 2006; Young, 1997). In the earliest of these, 6 (12%) of 52 respondents to advertisements seeking volunteers for antihypertensive drug trials and who were screened by ARR testing were found to have PA (confirmed by FST) (Gordon *et al.*, 1993); and (2) PA was confirmed in 19 (8.5%) of 199 consecutively referred normokalemic hypertensive patients who underwent ARR testing (Gordon *et al.*, 1994b). Although the patients in the studies were "selected," similar prevalence rates were reported among relatively unselected hypertensive patients (e.g., those randomly chosen for ARR testing from a general practice database in the United Kingdom; Lim *et al.*, 1999). Such prevalence rates make PA probably the most common specifically treatable and sometimes curable cause of hypertension. In resistant hypertensive cohorts, the prevalence rates appear to be even higher and at least 20% (Calhoun *et al.*, 2002; Eide *et al.*, 2004; Gallay *et al.*, 2001; Strauch *et al.*, 2003). Not unexpectedly, this new understanding has led to a marked increase in the number of ARR tests ordered by treating physicians. There is therefore currently a critical need to better understand the strengths and weaknesses of the ARR, the factors that can complicate interpretation of results, and the steps that can be taken to maximize its performance as a means of screening for PA.

Screening

The diagnostic workup for PA involves (1) screening, (2) confirmatory testing, and (3) determining the subtype of PA. Unlike screening, procedures utilized for confirmatory testing and subtype differentiation are relatively invasive, time-consuming, and

 doi:10.1016/B978-0-12-801238-3.64331-3

expensive. Screening of at-risk populations for the possible presence of PA is therefore important as it serves to minimize the number of patients who should then be considered for the subsequent steps of diagnostic assessment.

Who Should Be Screened?

An Endocrine Society Guideline has recommended screening for all but the mildest forms of hypertension, and for patients with hypertension and spontaneous or diuretic induced hypokalemia, hypertension and adrenal incidentaloma, hypertension and sleep apnea, and (in recognition of familial forms) hypertension and a family history of early onset hypertension or cerebrovascular accident at a young age (<40 years) and all hypertensive first degree relatives of patients with PA (Funder *et al.*, 2016).

Could an argument be made for screening all hypertensives? While the majority of authorities would not support this view, proponents point out that: (1) PA is common among the hypertensive population, (2) ARR testing is relatively inexpensive, (3) early diagnosis may be preferable to waiting until hypertension becomes severe and resistant because the degree of benefit achieved from specific treatment of PA (including chance of cure of hypertension following unilateral adrenalectomy for unilateral forms of PA) appears to be inversely related to duration of hypertension at the time of treatment institution (Citton *et al.*, 2015; Gockel *et al.*, 2007; Lumachi *et al.*, 2005; Wachtel *et al.*, 2014; Zarnegar *et al.*, 2008; Zhang *et al.*, 2013), and (4) screening patients before they are commenced on antihypertensive medications avoids potentially confounding effects of treatment on plasma renin and aldosterone levels which could lead to false-positive or -negative ARR results.

Choice of Screening Test

Once relied upon as the main "trigger" for further workup, it is now well established that the demonstration of hypokalemia by measurement of plasma potassium lacks sufficient sensitivity to serve as a sole means of screening for PA. Furthermore, unless great care is taken to avoid factitious rises in potassium due to release from muscle and blood cells during collection, the presence of hypokalemia can sometimes be missed. This involves (1) avoiding fist clenching and releasing the tourniquet after venepuncture has been achieved, (2) waiting (at least 10 s) before withdrawing blood, (3) using a syringe and needle rather than a vacuumed sample container to permit slow and careful blood withdrawal and discharge down the side of the opened sample tube, (4) using lithium heparin (i.e., plasma) rather than plain (serum) tubes so that clot formation (which is associated with release of potassium) does not occur, and (5) separating plasma from cells within 30 min of collection.

Reliance on frankly elevated plasma aldosterone levels also lacks sensitivity for PA. In many patients, levels lie within the wide normal range (Rutherford *et al.*, 1998; Stowasser and Gordon, 2004; Stowasser *et al.*, 2003), but could be viewed as "inappropriately normal" in the face of suppression of the renin which, in individuals without PA, should result in plasma aldosterone levels that are frankly low. Raised plasma aldosterone levels also lack specificity as they may result from raised renin/AngII (secondary hyperaldosteronism), as in renovascular forms of hypertension or in patients receiving diuretic agents.

Plasma renin levels, measured by plasma renin activity (PRA) or direct active renin concentration (DRC), are almost always suppressed in PA. They are therefore superior to plasma potassium and aldosterone in terms of sensitivity. Levels can be normal however in patients who habitually ingest a low sodium diet or are on medications such as diuretics, angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), or dihydropyridine forms of calcium-channel blockers (CCBs) which can result in renin production. Rarer causes of "false normal" renin levels include concomitant "accelerated" or malignant hypertension (Beevers *et al.*, 1976; Kaplan, 1963; Murphy *et al.*, 1985), or renovascular hypertension (Stowasser *et al.*, 1993).

While a suppressed renin is highly sensitive for PA, it lacks specificity. Hence, reliance on plasma renin alone to screen for PA would lead to frequent false-positive results. Situations (other than PA) in which renin levels may be suppressed include (1) treatment with medications (including beta-adrenoceptor blockers, clonidine, or alpha-methyldopa) which reduce beta-sympathetic stimulation of renin release (Ahmed *et al.*, 2010; Buhler *et al.*, 1972; Gordon *et al.*, 1992a; Oparil, 1982); (2) treatment with nonsteroidal antiinflammatory agents which promote salt-retention (Mitnick *et al.*, 1980); (3) high dietary sodium intake (Gordon, 1995); (4) advanced age (Crane and Harris, 1976; Luo *et al.*, 2016); (5) chronic renal impairment, in which renal renin-producing capacity is reduced and salt-retention contributes to renin suppression (McKenna *et al.*, 1991); and (6) the presence of other salt-dependent, low-renin forms of hypertension of either known (listed in **Table 1**) or unknown cause (Arai and Chrousos, 1995); Geller *et al.*, 2000; Gordon *et al.*, 1970; Irony *et al.*, 1987; Kater and Biglieri, 1994; Stewart, 1996; Walker *et al.*, 1992; Warnock, 2001; White, 2001; Wilson *et al.*, 2001).

Unlike in PA, chronic suppression of renin/angiotensin II (AngII) leads to suppression of aldosterone and hence the ARR is normal in all of the low-renin forms of hypertension listed in **Table 1** with the exception of familial hyperkalemic hypertension, in which elevated plasma potassium levels prevent aldosterone suppression. Because of this, the ARR is more specific than isolated renin measurements while at the same time being much more sensitive than plasma potassium or isolated measurement of plasma aldosterone. As a result, it has become the preferred method of screening for PA.

Despite its superiority over other currently available methods of screening, the ARR can be affected by numerous physiological and pharmacological factors, leading to the potential for false positives and negative results (see what follows). Accordingly, although such factors can often be controlled or at least taken into account when interpreting the ARR, the ratio should still be regarded as a screening test only. Furthermore, given the greater complexity and invasiveness associated with subsequent steps in

Table 1 Low-renin forms of hypertension (other than PA) of known cause

Condition	*Cause/mechanism*	*ARR*	*References*
Liddle syndrome	Activating mutations of ENaC subunits causing excessive distal renal tubular sodium retention	Normal	Warnock (2001)
Syndrome of apparent mineralocorticoid excess	Mutations in gene encoding, or inhibitors (e.g., carbenoxolone or licorice) of, 11β-HSD2, resulting in lack of "inactivation" of cortisol, which thereby gains access to and activates the MR	Normal	Stewart (1996)
DOC-secreting tumors	Excessive DOC (has intrinsic mineralocorticoid activity)	Normal	Irony *et al.* (1987)
Hypertensive forms of CAH	Mutations in gene encoding either 11β-hydroxylase or 17α-hydroxylase leading to reduced cortisol production, hence increased ACTH secretion and, in turn, increased production of DOC	Normal	Kater and Biglieri (1994) and White (2001)
Primary glucocorticoid resistance	Mutations in gene encoding the GR leading to increased ACTH secretion and, in turn, increased production of DOC	Normal	Arai and Chrousos (1995)
Ectopic ACTH syndrome	Excess ACTH leads to DOC excess and "overload" of 11β-HSD2 by very high levels of cortisol	Normal	Walker *et al.* (1992)
Activating mutations of MR	Leads to constitutive activation of MR and anomalous activation by other ligands (e.g., high concentrations of progesterone during pregnancy and spironolactone)	Normal	Geller *et al.* (2000)
Familial hyperkalemic hypertension	Mutations in *WNK1*, *WNK4*, *CUL3* and *KLHL3* which are thought to lead to activation of NCC and excessive sodium and potassium retention in the distal renal tubule	Normal or high	Boyden *et al.* (2012), Glover *et al.* (2014), Gordon *et al.* (1970), and Wilson *et al.* (2001)

ENaC, epithelial sodium channel; 11β-HSD2, 11β-hydroxysteroid dehydrogenase type 2; DOC, deoxycorticosterone; CAH, congenital adrenal hyperplasia; ACTH, adrenocorticotrophic hormone; MR, mineralocorticoid receptor; NCC, sodium chloride cotransporter.

diagnostic workup for PA, it is advisable to measure the ARR more than once before deciding whether or not to go on to confirmatory testing to definitively confirm or exclude PA.

In addition to an elevated ARR, some investigators require the absolute plasma aldosterone concentration to be above a minimum level (e.g., 15 ng dL^{-1} or 410 pmol L^{-1}) before a screening test is considered positive. This is because the ARR is highly dependent on renin (Montori *et al.*, 2001), and therefore, in the presence of very low-renin levels (e.g., at PRA values of $\leq$0.1 ng ml^{-1} h^{-1} or DRC $<$2 mU L^{-1}), the ARR can be elevated even when plasma aldosterone is also very low (e.g., 4 ng dL^{-1} or 120 pmol L^{-1}) and clearly not consistent with PA. Others argue that this approach would lead to many patients with PA (including some with APA and hence potentially curable by surgery) being missed because their plasma aldosterone concentrations fall below this cut-off level (Stowasser and Gordon, 2004). The risk of missing APA at plasma aldosterone levels of $<$10 ng dL^{-1} ($<$277 pmol L^{-1}) is probably low. In such situations, however, if the decision is made not to proceed to confirmatory testing, it would seem prudent to at least continue to follow the patient and periodically repeat the ARR and consider, from time to time, further diagnostic workup depending on the clinical scenario and patient's wishes.

Factors That Affect the ARR

Posture

In normal subjects, plasma aldosterone rises in response to the assumption of upright posture (Tuck *et al.*, 1975). It is likely that this is due primarily to the associated translocation of blood into the lower limbs, which in turn results in (1) an increase in renin, released in response to both a fall in renal perfusion pressure and an increase in sympathetic output and beta-adrenergic receptor stimulation (Gordon, 1995), and (2) a reduction in metabolic clearance of aldosterone due to reduced hepatic blood flow (Balikian *et al.*, 1968; Nowaczynski *et al.*, 1977). Most patients with PA similarly demonstrate a rise in plasma aldosterone in response to upright posture. Such patients have been termed "angiotensin II-responsive" (AngII-R), meaning that their aldosterone levels rise in response to rising renin-AngII and thus to upright posture, and includes all patients with AngII-R APA, which make up 20%–50% of APAs, and most (at least 70%) with BAH (Espiner *et al.*, 2003; Gordon *et al.*, 1987; Mulatero *et al.*, 2008; Stowasser *et al.*, 2003). AngII-unresponsive (AngII-U) forms of PA, in which plasma aldosterone fails to rise in response to upright posture, include AngII-U APA, familial hyperaldosteronism type I, and the remaining up to 30% of BAH (Espiner *et al.*, 2003; Gordon *et al.*, 1987; Mulatero *et al.*, 2008; Stowasser *et al.*, 2003). However, despite the failure of aldosterone to rise in those subjects, upright levels in AngII-U PA are similar to those of patients with AngII-R forms (whose recumbent levels are usually much lower). Taking

all the above into account, performance of the ARR in the upright position is less likely to miss patients with PA, and most centers therefore use a midmorning upright sample for ARR testing, usually while seated for 5–15 min.

Time of day

Upright posture tends to have a greater stimulatory effect on renin and aldosterone in the early morning than in the afternoon (Gordon *et al.*, 1966). Hence, levels obtained midmorning from seated patients will tend to be higher than those measured in the afternoon (Gordon, 2004; Vagnucci *et al.*, 1974). Furthermore, plasma aldosterone levels in PA (in which levels are chronically suppressed) are strongly influenced by ACTH (Kem *et al.*, 1973), levels of peak at around 0800 h and fall rapidly thereafter as part of its normal circadian rhythm (Ney *et al.*, 1963). As a result, ARR levels in patients with PA are more likely to be elevated during the morning rather than in the afternoon (Gordon, 2004).

Age

In the elderly, renin levels fall in association with gradually falling renal function (Crane and Harris, 1976), while the fall in aldosterone is less marked. This leads to rising ARR levels and the possibility of false positives (Luo *et al.*, 2016).

Gender

Administration of exogenous estrogen stimulates production of the renin substrate angiotensinogen (Derkx *et al.*, 1986; Goldhaber *et al.*, 1984). The resulting rising angiotensin levels lead, by negative feedback on the juxtaglomerular apparatus, to falls in renin release and therefore in DRC. However, because PRA measures the generation of angiotensin I by the action of renin (levels of which are reduced) on angiotensinogen (levels elevated), the net effect on PRA is minimal (Fischer *et al.*, 2002). Falling DRC will tend to raise ARR, whereas stable PRA will not. Progesterone, secreted during the luteal phase of an ovulatory menstrual cycle, has mineralocorticoid-antagonist activity (Oelkers, 1996) and can cause natriuresis, leading to a reduction in plasma volume and a compensatory increase in plasma renin and aldosterone. Higher levels of estrogen and progesterone in women, and fluctuations of these levels during the menstrual cycle, thus have the potential to lead to differences in ARR levels between the genders and between different menstrual phases (Ahmed *et al.*, 2011b; Fommei *et al.*, 2008; Pizzolo *et al.*, 2010).

ARRs in females have been reported to be significantly higher than those of males (Ahmed *et al.*, 2011b) and, in another study (Pizzolo *et al.*, 2010), elevated ARR (using DRC) was more prevalent in hypertensive women than men (13.6% vs. 2.3%), but seldom associated with confirmed PA. In females, ARR levels are the lowest (and closest to those of males) during the menses and follicular phase and highest during the luteal phase, during which false positives can occur, but only if DRC (and not PRA) is used to measure renin (Ahmed *et al.*, 2011b). These observations suggest that PRA may be preferable to DRC in the determination of ARR and new reference ranges for ARR may be required which take into account gender and sex hormone levels (Ahmed *et al.*, 2011b).

Dietary sodium intake

Habitual dietary salt restriction raises renin and aldosterone levels, and because the ARR is more dependent on renin than aldosterone (Montori *et al.*, 2001), has the potential to lower the ARR and cause false negatives in patients with PA (Baudrand *et al.*, 2016; Gordon, 1995; Stowasser *et al.*, 2001). On the other hand, occasional false positives might arise in patients without PA who consume very large amounts of salt (Gordon, 1995; Stowasser *et al.*, 2001).

Plasma potassium level

Potassium is a potent chronic regulator of aldosterone secretion. Severe, uncorrected hypokalemia can lower aldosterone secretion in PA (Cain *et al.*, 1972) and therefore has the potential to cause false-negative ratios (Gordon, 1995; Stowasser *et al.*, 2001). Although it is less likely that this could also occur with milder hypokalemia, it is probably safest not to exclude PA on the basis of a normal ARR until it has been measured after correcting plasma potassium with supplemental slow-release potassium chloride tablets.

Medications potentially causing false-positive ratios

Treatment with beta-adrenergic blocking medications, which inhibit beta-adrenoceptor-mediated stimulation of renin production by JG cells (Gordon *et al.*, 1992a; Oparil, 1982), raise the ARR (Ahmed *et al.*, 2010). Methyldopa (Oparil, 1982) and clonidine (Manhem *et al.*, 1982) have a similar effect on renin by reducing central sympathetic outflow. Nonsteroidal antiinflammatory agents not only suppress renin levels by inducing renal sodium and water retention and suppressing renal prostaglandins which normally stimulate renin release, but also promote retention of potassium, which leads to stimulation of aldosterone production and further elevation of the ARR (Mitnick *et al.*, 1980).

Patients receiving oral contraceptive agents or hormone replacement therapy containing estrogen may demonstrate falsely elevated ratios when measurements of DRC are used rather than PRA (Ahmed *et al.*, 2011c, 2017a). This is presumably because the increased hepatic production of angiotensinogen, induced by estrogen, results in increased negative feedback by angiotensin suppressing active renin production (Derkx *et al.*, 1986; Goldhaber *et al.*, 1984; Steingold *et al.*, 1991). This usually prevents PRA from rising significantly but will lead to suppressed DRC and increased aldosterone/DRC ratio. Use of PRA may be preferable to DRC when screening women for PA by ARR measurement without ceasing estrogen-containing agents.

Table 2 Medications and the ARR

Medications that cause false-positive ARR	*Medications that cause false-negative ARR*	*Medications that have relatively little effect on ARR*
Beta-adrenergic blockers	Potassium-sparing diuretics	Verapamil SR
alpha-Methyldopa	Potassium-wasting diuretics	Hydralazine
Clonidine	ACE inhibitors	Prazosin, doxazosin, terazosin
NSAIDs	ARBs	Moxonidine
E2-containing OCPs and HRT[a]	Dihydropyridine CCBs	
Renin inhibitors[b]	SSRI antidepressants	
	Renin inhibitors[a]	

[a]Only if renin is measured as DRC.
[b]Only if renin is measured as PRA.
ARR, aldosterone/renin ratio; NSAIDs, nonsteroidal antiinflammatory drugs; E2, estrogen; OCPs, oral contraceptive preparations; HRT, hormone replacement therapy; ACE, angiotensin converting enzyme; ARBs, angiotensin receptor blockers; CCBs, calcium-channel blockers; SR, slow-release; SSRI, selective serotonin receptor uptake inhibitor.

Medications potentially causing false-negative ratios

False negatives may be encountered in patients taking medications that stimulate renin production. Examples include diuretics, both potassium-wasting and potassium-sparing (such as spironolactone, eplerenone, amiloride, and triamterene) (Gordon, 1995; Young, 1997), which induce volume contraction and sympathetic nervous system stimulation. Potassium-wasting diuretics (such as thiazides), by lowering plasma potassium levels, may also result in reduced aldosterone secretion. Dihydropyridine CCBs stimulate renin (Brown and Hopper, 1999; Mulatero *et al.*, 2002), probably through reflex sympathetic stimulation induced by falling blood pressure and natriuretic effects, and can reduce aldosterone production by interfering with intracellular, calcium-dependent steps in biosynthesis (Anderson *et al.*, 1986). ACE inhibitors (Mulatero *et al.*, 2002) and ARBs (Mulatero *et al.*, 2002) reduce negative feedback of AngII on renin production and may inhibit aldosterone production in patients with AngII-R forms of PA (Atkinson *et al.*, 1980).

Antidepressants are frequently prescribed agents, including among patients with hypertension. Administration of the selective serotonin uptake inhibitors (SSRIs) sertraline and escitalopram was recently reported to be associated with rises in aldosterone, PRA, and DRC and, because renin rose more than aldosterone, falls in the ARR (Ahmed *et al.*, 2011a), raising the potential for SSRIs to be associated with false-negative ARRs in patients with PA.

Renin inhibitors

Renin inhibitors have complex effects on renin levels, which depend on how renin is measured (Campbell *et al.*, 2009), being likely to raise the ARR (and cause false positives) if renin is measured as PRA, and lower it (causing false negatives) if measured as DRC (**Table 2**).

Presence of impaired renal function

Renin levels tend to fall in patients with chronic kidney disease (CKD), presumably because of both reduced renin secretory mass and salt and water retention. Furthermore, potassium retention due to CKD may lead to hyperkalemia and thereby elevate aldosterone. These influences on renin and aldosterone may result in false-positive ratios (McKenna *et al.*, 1991).

Effects of coexisting and other hypertensive conditions

Coexistence (with PA) of conditions in which previously suppressed renin is released from suppression, such as pregnancy (Gordon and Tunny, 1982), malignant hypertension (Beevers *et al.*, 1976; Kaplan, 1963; Murphy *et al.*, 1985), and renal artery stenosis (Stowasser *et al.*, 1993), may cause ARRs to become falsely negative.

False-positive ratios occur in the syndrome of familial hyperkalemia and hypertension, in which a primary defect in distal renal tubular function appears to result in upregulation of the sodium chloride cotransporter, leading to excessive resorption not only of sodium (leading to hypertension and renin suppression) but also of potassium (causing chronic hyperkalemia and thereby counteracting suppression of aldosterone) (Gordon *et al.*, 1970).

Aldosterone and Renin Assays

Accurate measurement of both aldosterone and renin is required for reliable ARR results, making highly reproducible assays essential. Reliable aldosterone quantification is also critical during subsequent confirmatory testing (to definitively confirm or exclude PA) and adrenal venous sampling (used to differentiate unilateral forms, potentially curable by unilateral adrenalectomy, from bilateral forms which are usually managed medically with agents that block aldosterone action) (Gordon, 1995; Stowasser *et al.*, 2001).

Concerns have been raised about currently available immunoassay methodology (Schirpenbach *et al.*, 2006; Stowasser and Gordon, 2006) and have led to development of high-throughput mass spectrometric methods of measuring aldosterone which demonstrate excellent reliability and reproducibility (Taylor *et al.*, 2009). As the required methodology becomes more price-competitive and widely available, it is likely that the use of this approach will gradually move from highly specialized to more general clinical service laboratories, with the potential to improve diagnostic accuracy and optimize clinical outcomes.

Faster, more convenient methods of measuring DRC (Ferrari *et al.*, 2004; Gordon, 2004) using immunometric techniques and automated machinery have rapidly been adopted in large, busy laboratories in recent years and have evolved to include measurement of aldosterone in the same sample (Burrello *et al.*, 2016), but uncertainty exists about their reliability (Gordon, 2004), particularly at the lower end of the reference range. Efforts are underway to develop and validate high-throughput assays of angiotensin I (PRA) and AngII using mass spectrometry and results are awaited with great interest.

An Approach to the Measurement of the Aldosterone/Renin Ratio

A. Prior to ARR measurement
   1. Correct hypokalemia (if present) with oral slow-release potassium tablets. To determine if hypokalemia is present, measure plasma potassium in blood collected slowly using a syringe and needle, avoiding fist clenching during collection, waiting at least 10 s after torniquet released (if used to achieve needle insertion), and ensuring separation of plasma from cells within 30 min of collection.
   2. Encourage a liberal (rather than restricted) dietary sodium intake.
   3. Where possible, withdraw medications which are known to significantly affect the ARR:
      a. Beta-blockers, clonidine, methyldopa, nonsteroidal antiinflammatory drugs (cause false positives)—for at least 2 weeks
      b. ACE inhibitors, ARBs, dihydropyridine calcium blockers (cause false negatives)—for at least 2 weeks
      c. Diuretics including spironolactone, eplerenone, and amiloride (cause false negatives)—for at least 4 weeks

      N.B. Ceasing medications in nonhospitalized patients to attain washout is not without risk and sometimes potentially hazardous. Although complete cessation of interfering anithypertensives can be achieved safely in mildly hypertensive patients who are seen frequently, it is more often necessary to commence in their place a relatively renin-neutral drug alone or in combination (see (A) (4)).
   4. Where necessary, commence other antihypertensive medications which have lesser effects on the ARR (verapamil slow-release ± hydralazine, prazosin or doxazosin, moxonidine; Ahmed *et al.*, 2017b) in order to maintain hypertension control.
   5. Estrogen-containing oral contraceptive agents may cause false-positive ARRs when DRC (rather than PRA) is measured. Do not withdraw unless confident of alternative, effective contraception.

B. Blood collection
   1. Midmorning, after patient ambulant for at least 2 h, seated for 5–15 min
   2. Careful collection of blood sample avoiding stasis and hemolysis [see (A) (1)]

C. Factors to consider when interpreting results
   1. Age—in patients over 65 years, renin can be lowered more than aldosterone, leading to a raised ARR
   2. Gender (ARR higher in females) and phase of menstrual cycle (false positives may occur during luteal phase, but only if calculated using DRC rather than PRA)
   3. Time of day, posture, and length of time in that posture, recent dietary sodium intake
   4. All medications—in cases where a potentially interfering medication cannot be withdrawn, useful information can still be obtained by taking into account its known effects. For example, a raised ratio in patients receiving a diuretic, ACE inhibitor, ARB, dihydropyridine calcium blocker, or SSRI antidepressant would make PA very likely, whereas a normal ARR in the presence of beta-blocker treatment or an estrogen-containing oral contraceptive agent or hormone replacement therapy would make the diagnosis very unlikely.
   5. Method of blood collection including any difficulty
   6. Potassium level
   7. Level of creatinine (false-positive ARR can occur in CKD).

Because of the innate variability of both aldosterone and renin, and the implications for further management (including more invasive diagnostic workup) if the ARR is deemed to be positive, it is important that management decisions not be based on a single ratio. The ratio should be repeated as required until confident that the ARR is raised or otherwise, meanwhile adjusting medications and conditions of collection if indicated.

Primary Aldosteronism; Diagnosis and Treatment

Franco Mantero, University of Padua, Padua, Italy
Maria Verena Cicala, South Tyrolian Academy of General Practice, Bolzano, Italy

Introduction

Primary aldosteronism (PA) is a common form of endocrine hypertension in which aldosterone production is inappropriate and at least partially autonomous of the renin–angiotensin system. The inappropriate production of aldosterone results in sodium retention and suppression of the secretion of renin. PA is commonly caused by an adrenal adenoma (APA) or bilateral hyperplasia (IHA) of the adrenal zona glomerulosa, less common forms include: unilateral adrenal hyperplasia, aldosterone-producing carcinoma, ectopic aldosterone-producing tumors and the familiar forms of hyperaldosteronism (Type I-II-III-IV).

Epidemiology

PA was previously believed to account for $<1\%$ of hypertensive patients. In addition, hypokalemia was considered a prerequisite for pursuing diagnostic tests for PA. However, several studies applying the plasma aldosterone(PAC)/plasma renin activity (PRA) ratio (ARR) as a screening test among both hypokalemic and normokalemic hypertensives have reported a much higher prevalence of this disease, with PA accounting for up to 12% of hypertensive patients of whom only a minority of patients with PA (9%–37%) had hypokalemia (Mulatero *et al.*, 2004). Thus, normokalemic hypertension constitutes the most common presentation of the disease, with hypokalemia probably present in only the more severe cases (Rossi *et al.*, 2006).

Therefore, PA could be the most common identifiable, specifically treatable and potentially curable form of hypertension. It has been suggested that it is only worthwhile to perform diagnostic workup for PA in hypokalemic patients in the belief that the great majority of patients with normokalemic PA have bilateral adrenal hyperplasia (BAH) rather than aldosterone-producing adenoma (APA) and are therefore rarely surgically curable (Young, 2007) but even in APA around 50% of patients was found to be normokalemic (Rossi *et al.*, 2006; Käyser *et al.*, 2016).

Pathophysiology

Elevated plasma aldosterone levels promote excessive preservation of sodium, by increasing the number of open sodium channels in the cell's luminal membrane of the cortical collecting tubules at the expense of hydrogen and potassium loss in the lumen. Sodium retention promotes water retention and an expansion in extracellular volume, resulting in hypertension and suppression of plasma renin, but not in oedema due to the so-called aldosterone escape. This phenomenon, not yet completely understood, is due in part to the increase of atrial natriuretic peptide (ANP), changes in the Na-Cl cotransporter in the distal tubule and to pressure_natriuresis and leads to a new steady state, in which the extracellular fluid volume is increased but stable (Pedrinelli *et al.*, 1988).

Hypokalemia can be absent or present in different grades, sometimes with metabolic alkalosis, mostly depending on the degree and duration of aldosterone excess. Also for plasma potassium concentration there is a mechanism of stabilization at lower level unless some other factor is added, such as the use of diuretic therapy.

Increased levels of aldosterone have also deleterious effects on the cardiovascular system, partly independent on its effect on BP and potassium, including left ventricular hypertrophy, myocardial fibrosis, increased carotid intima-media thickness and endothelial dysfunction (Savard *et al.*, 2013).

Genetics of Primary Aldosteronism

Somatic mutations of APA have been described in the last few years in around 50% of the tumors, constitutively altering the function of potassium and calcium channels and ion pumps. This topic is specifically discussed in an other chapter of the Encyclopedia.

Familiar forms of primary aldosteronism (FH) are also known: FH type I (glucocorticoid-remediable aldosteronism (GRA), Type II (familiar occurrence of APA or IHA, due germline mutation of CLCN2 chloride channel gene), Type III (germline mutations in the KCNJ5 potassium channel), FH IV (germline mutations in CACNA1H gene) (Williams *et al.*, 2016; Zennaro *et al.*, 2018).

This topic is extensively covered in an other chapter of this Encyclopedia.

Diagnosis

Primary aldosteronism has made it into the headlines over the last decade mainly due to the notion that it might be more frequent than previously assumed. Thus previous diagnosis rates would not reflect the entirety of a very rare disease but perhaps only the "tip of iceberg," with many others also affected, but currently undiagnosed. With this perceived paradigm change came a new attitude towards screening for primary aldosteronism (Funder *et al.*, 2008). While we previously aimed to establish this diagnosis mainly in patients presenting with hypokalaemic hypertension, more and more physicians took to actively screening their hypertensive patients for the presence of primary hyperaldosteronism.

The Endocrine Society USA published clinical practice guidelines for the diagnosis and treatment of patients with primary hyperaldosteronism in 2008 (Funder *et al.*, 2008) and a more updated version in 2016 (Funder *et al.*, 2016). Systematic reviews of available evidence were used to formulate the key treatment and prevention recommendations. Those guidelines are the most used consensus criteria for the management, diagnosis and treatment of primary aldosteronism. However, there remains a number of unresolved issues, which unfortunately require more of a detour guide and cannot be easily addressed by a straight forward guideline.

Clinical Aspects

Clinical features might be more severe in patients with APA than in the other forms of PA. Moreover, patients with APA are usually younger than those with IHA, with age at presentation typically being <50 years.

Hypertension is often substantially elevated, but PA may be present also in Stage I and II, and occasionally in normotensives. On the other end, PA is relatively more frequent in patients with resistant hypertension (Funder *et al.*, 2016).

Hypokalemia is present in about half of patients with APA and less frequently in patients with IHA. When severe, symptoms or signs related to metabolic alkalosis, such as tetany or positivity of Chvostek or Troussea sign, symptoms or signs related to myopathy, such as weakness, or to nephrogenic diabetes insipidus, such as polyuria and nocturia, can be present.

In addition, cardiovascular/renal complications such as atrial fibrillation, myocardial infarction, stroke and chronic kidney disease may occur with relative more frequency than in age-BP matched essential hypertensives.

Case Detection

The guidelines recommend case detection of primary aldosteronism "in higher risk groups of hypertensive patients and those with hypokalemia by determining the aldosterone-renin ratio under standard conditions."

The guidelines panel clearly defined the patients perceived at higher risk of hyperaldosteronism and this is important to avoid mass screening for primary hyperaldosteronism in all hypertensive patients.

However, if one looks carefully to this indications it becomes evident that quite a large number of patients are expected to be screened, and this may have some impact on the cost/benefit ratio.

They recommend to determine "the aldosterone-renin ratio under standard conditions," but those are difficult to obtain (Funder *et al.*, 2016; Stowasser and Gordon, 2004). The table reported in the guidelines outlines only "a suggested approach" to measurement of the ARR. The major problem is that patients who are screened for primary aldosteronism may suffer from moderate to severe hypertension and may need to be on antihypertensive drugs which could interfere both with aldosterone and renin (Funder *et al.*, 2016; Mulatero *et al.*, 2002). The guidelines recommend to correct hypokalemia and to remove for at least 2 weeks those drugs which could cause false-positive or false-negative ARR. This comes with significant costs as this approach will require a major monitoring effort in a severely hypertensive patients, and a certain degree of risk. In such case, indeed the switch to a few drugs with minimal effects on ARR is recommended (verapamil, hydralazine, doxazosin, terazosin).

There remains uncertainty, however, about the effects of some of these agents on the ARR. For example, although Mulatero *et al.* (2002) found β-blockers to lead to an elevation in the ARR in some patients with PA, Young (2007) has argued that β-adrenoceptor blockers, despite inducing renin suppression, are not likely to lead to false-positive ARR values because aldosterone levels fall in parallel. Further evaluation of the effects of these drugs in hypertensive patients without PA is required to settle this issue (Gallay *et al.*, 2001).

Moreover, the effects of many other commonly used medications, such as oral contraceptive agents and antidepressants, have received little attention. Because estrogen-containing preparations induce angiotensinogen production by the liver, the resultant rise in angiotensin II levels chronically inhibits renal renin secretion by a negative feedback mechanism. Consequently, plasma renin concentration, measured as "direct active renin" (DRC), would be expected to fall in patients taking estrogen preparations, and there is therefore the potential that the ARR could become elevated if renin is measured in this way. Whether this could be avoided by using plasma renin activity (PRA; which normally shows little change and if anything a rise rather than a fall) remains uncertain as well as whether the phase of the menstrual cycle needs to be taken into account when considering ARR testing.

Furthermore the newly introduced renin inhibitors have complex effects on renin levels, which depend critically on how renin is measured. Put in simplistic terms, these agents are likely to raise the ARR (and cause false-positives) if renin is measured as PRA and to lower it (causing false-negatives) if measured as DRC.

Once measured the ARR the diagnosis is not confirmed. A substantial problem, not really clarified by the guidelines, is to define a corrected cut-off level for the ARR. In the guidelines there is a "substantial variability in cutoff values" for the ARR, and not all researchers agree. Lack of uniformity in diagnostic protocols and assay methods for ARR measurement has been associated with substantial variability in cutoff values used by different groups. Most groups, however, use cutoffs of 20–40 when using PRA as ng/mL/h and aldosterone as ng/dL, when testing is performed in the morning on a seated ambulatory patient.

Certainly it should be accept that the likelihood of a false-positive ARR becomes greater when renin levels are very low. A related issue are the assays that actually where used to measure aldosterone and specifically renin. Most centers currently measure plasma renin activity, but the measurement of direct renin concentrations (DRC), which has the potential to be more accurate and less cumbersome, is becoming more popular, both with regard to accessibility and methodology. On the other side, given the variability in immunometric assays for plasma aldosterone, the move to tandem mass spectrometry for its measurement is almost mandatory.

Case Confirmation

Although The Endocrine Society guidelines were clear in their recommendation that confirmatory testing be performed to definitively confirm or exclude PAL in patients with elevated ARR results, the choice of test remains a matter of debate (Giacchetti *et al.*, 2006). The guidelines enumerate four confirmatory test to definitively confirm or exclude the diagnosis including: oral sodium loading, saline infusion (SIT), fludrocortisone suppression (FST), and captopril challenge (CCT). These four tests are in common use, and there is currently insufficient direct evidence to recommend one over the others. Rossi *et al.* (2007) found SIT and CCT to have similar, but only moderate, accuracy for confirming PAL. By contrast, Mulatero *et al.* (2007) found CCT to be misleading in four of the 11 patients in whom PAL had been confirmed (in six) and excluded (in five) by both FST and SIT. Proponents of the fludrocortisone suppression testing argue that it is the most sensitive approach, being more "physiological" than SIT, and it avoids the problems associated with 24-h urinary aldosterone estimation required for the oral salt loading test used at several major institutions. However, it is also the most labor-intensive and requires admission to hospital for several days, making it the least practical.

Although it is acknowledged that these tests may differ in terms of sensitivity, specificity, and reliability, the choice of confirmatory test is commonly determined by considerations of cost, patient compliance, laboratory routine, and local expertise. The search for the ideal confirmatory test is still on. Indeed, two additional confirmatory tests have been recently suggested. The first is the dexamethasone-enhanced FST, whereby roughly 30% of referred hypertensives show PAC values above the range found in normotensive controls (Funder *et al.*, 2016). The second is a seated variance of the SIT (usually performed with the patient recumbent) which has been sown to have a remarkable agreement with the reliable but less practicable FST (Ahmed *et al.*, 2014).

Another matter of debate is whether it is necessary to perform a confirmatory test really in al patient. For example a young patient with severe hypokalemic hypertension, unequivocal ARR and an unilateral adrenal nodule >1 cm can go straight to surgery as the likelihood that his nodule represents an endocrine inactive adenoma is extremely low. However, we certainly have to take a different view when looking at older patients as the likelihood of a nonfunctioning adrenal adenoma is 3% in 40-year-olds and even 10% in 70-year-olds (Mansmann *et al.*, 2004).

Subtype Classification

As mentioned by the guideline panel also all other published dates agreed that all patients with primary aldosteronism should undergo adrenal computed tomography (CT) as the initial study in subtype testing and to exclude large masses that may represent adrenocortical carcinoma.

However adrenal CT has several limitations. Small APAs may be interpreted incorrectly by the radiologist as IHA on the basis of CT findings of bilateral nodularity or normal-appearing adrenals. Moreover, apparent adrenal microadenomas may actually represent areas of hyperplasia, and unilateral adrenalectomy would be inappropriate. In addition, nonfunctioning unilateral adrenal macroadenomas are not uncommon, especially in older patients (>40 years) and are indistinguishable from APAs on CT. Unilateral UAH (unilateral adrenal hyperplasia) may be visible on CT, or the UAH adrenal may appear normal on CT.

In several studies, in which patients with PAL were evaluated with both CT and adrenal venous sampling (AVS) CT resulted to be accurate in only about 50% of patients. Thus about ¼ of the patients would have been incorrectly excluded from surgery and an other ¼ might have had inappropriate surgery (Rossi *et al.*, 2008a; Mansmann *et al.*, 2004; Rossi *et al.*, 2001; Young *et al.*, 2004).

NMR has no clearcut advantage over CT, except for less irradiation in case of prolonged follow-up.

However CT (or NMR) may be useful in detecting larger tumors with malignant potential, as well as in showing even small tumors (but at least >1 cm) in young patients with marked PAL, thus possibly avoiding the need of AVS in such cases, as well for localizing adrenal veins in order to aid the cannulation during AVS.

In most of the other cases, AVS is essential to direct appropriate therapy in patients with PAL who seek a potential surgical cure.

The guidelines in fact made firm recommendations about the need for AVS for confident differentiation of unilateral from bilateral forms of PA. This insistence on the currently existing "gold standard" approach was based on well-documented limitations in reliability associated with computed tomography (Young *et al.*, 2004; Kempers *et al.*, 2009) and other approaches, but it recognized the need for an experienced, dedicated radiologist to ensure optimal cannulation success rates. A new innovation

designed to improve rates of cannulation success has been the real-time estimation of adrenal and peripheral venous cortisol levels by rapid assay techniques, permitting calculation of adrenal/peripheral venous cortisol gradients (upon which success or otherwise is based) at the time of the procedure (Mengozzi *et al.*, 2007). Debate exists as to the value of ACTH stimulation, which has been used by several groups to maximize adrenal/peripheral venous cortisol gradients, reduce fluctuations in steroid secretion resulting from changes in endogenous ACTH levels during nonsequential AVS, and stimulate aldosterone production by APAs and thus avoid sampling during a relatively quiescent period of secretion (El Ghorayeb *et al.*, 2016; Young *et al.*, 2004). Rossi *et al.* (2008b), however, in a recently reported study examining the effects of different currently used ACTH stimulation protocols, found that the higher doses resulted in a higher proportion of samples that would be regarded as "successful," but they also had the potential to result in incorrect lateralization of aldosterone overproduction. Further sources of debate that remain to be addressed and clarified include the lack of standardization of criteria used for defining success of cannulation (with cortisol gradient cutoffs varying from 1.1 unstimulated to over 5.0 with ACTH stimulation) and for defining lateralization (criteria that variably compare aldosterone/cortisol ratios between side and peripheral, or between one side and other side, with a range of cutoff ratios) (Rossi *et al.*, 2014; Young and Stanson, 2009).

Maybe it should be made careful use of AVS in patients who are suitable and willing to undergo surgery and after stratifying by age. Some form of patient stratification is required, possibly firstly identifying which patients should proceed to surgery set against those who can be managed on effective medical therapy with mineralocorticoid receptor antagonists. The use of AVS must be justified on a case-by-case basis, asking how it will improve patient care and outcome, and be undertaken in centers of excellence to achieve optimal sensitivity.

For a detailed discussion on the role of AVS in making the distinction between unilateral and bilateral adrenal disease please refer to the specific chapter on this Encyclopedia.

Other less reliable tools to distinguish between APA and IHA (Funder *et al.*, 2016; Kempers *et al.*, 2009; Phillips *et al.*, 2000):

- The postural response of plasma aldosterone, which is almost always present in IHA and may be absent in APA (except in the so-called Angiotensin II sensitive adenoma).
- The levels of 18 OH corticosterone,18 OH cortisol and 18 Oxo cortisol, which are significantly higher in patients with APA.
- The scintigraphy with radiolabeled iodocholesterol or nor cholesterol (controllare) under dex suppression.
- The C11 Metomidate PET-CT. This is a promising imaging technique, especially if more specific tracers for aldosterone synthase will be available in the next future.

Treatment

Unilateral adrenalectomy is the treatment of choice in patients with APA (or in more general term in patients who lateralize on AVS), resulting in normalization of the serum potassium in 100% of those who were hypokalemic preoperatively, and cure of hypertension in about 50% of the cases and significant improvement in most of the remainder, allowing a reduction of antihypertensive medications. Laparoscopic adrenalectomy has supplanted open adrenalectomy, due to lower intra- and postoperative risks and faster recovery. Partial adrenalectomy (removing of the adenoma leaving the remaining adrenal intact) is not indicated because of the frequent presence of clusters of aldosterone-producing cells within the apparently normal adjacent adrenal (Funder *et al.*, 2016; Williams *et al.*, 2017; Duncan *et al.*, 2000).

If surgery is declined or the patient is not an appropriate candidate for surgery due to coexisting medical conditions, long-term medical therapy with mineralocorticoid receptor antagonists (MRA) can be successfully undertaken.

In patients undergoing surgery, if already treated with MRA and/or K supplements, the treatment should be discontinued and other antihypertensive agents should be decrease. In addition to BP, also serum K and creatinine should also be carefully monitored, since transient hyperkalemia and increased creatinine may occur, especially in patients with marked preexisting renal damage (Chiang *et al.*, 2013).

Patients with IHA (or demonstrating bilateral aldosterone production on AVS) should be treated chronically with mineralocorticoid receptor antagonists (MRA: spironolactone or canrenone/potassium canrenoate). Relatively low doses (25–50 mg/daily) can significantly reduce blood pressure and normalize serum potassium, if hypokalemia preexists, although the effect may not be immediate (Funder *et al.*, 2016).

At these dosages side-effects (gynecomastia, menstrual irregularities, and reduced libido) are infrequent, but may be still present. In that case, eplerenone, a more selective antagonist with less affinity for sex steroid receptors, can be used, but an higher dosage and a t.i.d. schedule may be needed to obtain a full effect (Parthasarathy *et al.*, 2011). As an alternative, the sodium channel blocking agent amiloride (5–10 mg/daily) may also be administered (Griffing *et al.*, 1982). In a number of cases, however, the addition of conventional antihypertensive agents such as Ca-channel blockers, alpha-antagonists or even ACE inhibitors/ARBs or thiazide diuretics might be necessary to fully control blood pressure.

In the genetic form FH-I hypertension should first tentatively treated with low dose dexamethasone but spironolactone/amiloride may be needed in combination or substitution in case of Cushingoid side effects.

Finally, it should be stressed that the purpose of treatment of PA is not only aimed at controlling hypertension and *K* values but also to reduce the excess cardiovascular risks and renal toxicity which are at least in part due to a direct effect of aldosterone. Several studies have shown that adrenalectomy and medical therapy with MRA are both very effective not only in reducing BP but

also in decreasing the occurrence of cardiovascular events. However, at short term the surgical approach seems to have a more rapid effect in reducing the LVH, and at long term its efficacy in reducing the incidence of atrial fibrillation appears also to be greater (Catena *et al.*, 2008; Sechi *et al.*, 2006; Rossi *et al.*, 2013; Mulatero *et al.*, 2013; Marzano *et al.*, 2015).

Adrenal Venous Sampling for Primary Aldosteronism

Gian Paolo Rossi, University of Padua, Padua, Italy

Abbreviations

APA	Aldosterone-producing adenoma
ARB	Angiotensin II type 1 receptors blockers
AVIS	Adrenal Vein Sampling International Study
AVS	Adrenal vein sampling
CT	Computed tomography
IHA	Idiopathic hyperaldosteronism, bilateral idiopathic hyperplasia
IVC	Inferior vena cava
MR	Mineralocorticoid receptor
PA	Primary aldosteronism
PAC	Plasma aldosterone concentration
PCC	Plasma cortisol concentration

Introduction

Compelling evidence indicates that primary aldosteronism (PA) constitutes the most common endocrine form of hypertension: it is highly prevalent among patients with drug-resistant hypertension (Douma *et al.*, 2008), and may be diagnosed in more than 11% of the patients referred to the specialized hypertension centers (Rossi *et al.*, 2006a). Albeit usually unrecognized, because it is not searched for, PA is also quite common, in the unselected hypertensive patient population seen by general practitioners (Olivieri *et al.*, 2004). As PA carries an increased risk of damage to target organs of high blood pressure with ensuing cardio-renal complications (Milliez *et al.*, 2005; Rossi *et al.*, 2013), early identification of affected patients followed by an early institution of specific treatment are key measures for prevention of cardiovascular events and reversal of cardiovascular damage (Rossi *et al.*, 2013; Reincke *et al.*, 2012).

Most PA patients have either bilateral idiopathic hyperplasia (IHA), which is treated with life-long mineralocorticoid receptor (MR) blockade (with spironolactone, canrenone, potassium canrenoate, or eplerenone), or a unilateral aldosterone-producing adenoma (APA), which is optimally treated with unilateral adrenalectomy (Rossi *et al.*, 2013). Hence, the distinction between the cases of PA due to IHA and those due to an APA is essential for selecting the most appropriate treatment (Funder *et al.*, 2008; Rossi, 2011a). To this aim the current clinical practice guidelines advocate use of adrenal vein sampling (AVS) (Funder *et al.*, 2008; Nishikawa *et al.*, 2011), a procedure that was introduced for the first time by Masoni in 1957 (Masoni, 1957). Theoretically the concept behind this test is very simple: to demonstrate that the excessive aldosterone production is caused by one adrenal and not the other by measuring plasma aldosterone concentration (PAC) and plasma cortisol concentration (PCC) in adrenal vein blood. However, as the procedure is technically demanding and many factors can confound the interpretation of results, it was soon realized that this is not a simple undertaking and that erroneous conclusions may lead to remove the wrong adrenal or to undertake unnecessary adrenalectomy For example, besides a number of potential confounders unrelated to the blood sampling per se, large factitious gradients of aldosterone can be generated by the collection of blood closer or farther from the adrenal, by the pulsatile pattern of secretion of aldosterone, by sampling accessory hepatic veins on the right side or phrenic vein on the left side. Thus, even though AVS is a straightforward diagnostic test (Davidson *et al.*, 1975; Rossi, 2007), it remains markedly underutilized worldwide even at major referral centers and even in patients with an unambiguous indication to the procedure, as shown by a recent large survey, the Adrenal Vein Sampling International Study (AVIS) (Rossi *et al.*, 2012). This underutilization is likely due to multiple misconceptions, mostly based on anecdotal experiences and/or on retrospective observational studies (Rossi, 2007), that AVS is technically challenging, invasive, risky, and not always necessary, despite abundant evidence to the contrary (Rossi *et al.*, 2012). Furthermore, the lack of accepted standards for the performance of AVS and of established criteria for interpretation of its results creates additional hesitancy for appropriate use in many patients with PA. Therefore, notwithstanding the guidelines recommendations (Funder *et al.*, 2008; Nishikawa *et al.*, 2011), too many PA patients are denied curative adrenalectomy, or undergo removal of a functionally normal adrenal gland because of the lack of demonstration of lateralized aldosterone excess (Funder *et al.*, 2008; Rossi *et al.*, 2012; Magill *et al.*, 2001).

Recently a panel of internationally recognized experts, which was assembled with the aim of providing updated practical suggestions on how to select the patients for AVS, how to perform the procedure, and on how to interpret its results, published a consensus statement. The publication of this document was followed by several studies, which have provided a good deal of novel data that are useful to further refine multiple issues concerning the performance and interpretation of AVS for the diagnosis of surgically curable subtypes of PA. The purpose of this chapter is, therefore, to update the information on the clinical use of AVS moving from the aforementioned consensus statement (Rossi *et al.*, 2014), and on data published afterward.

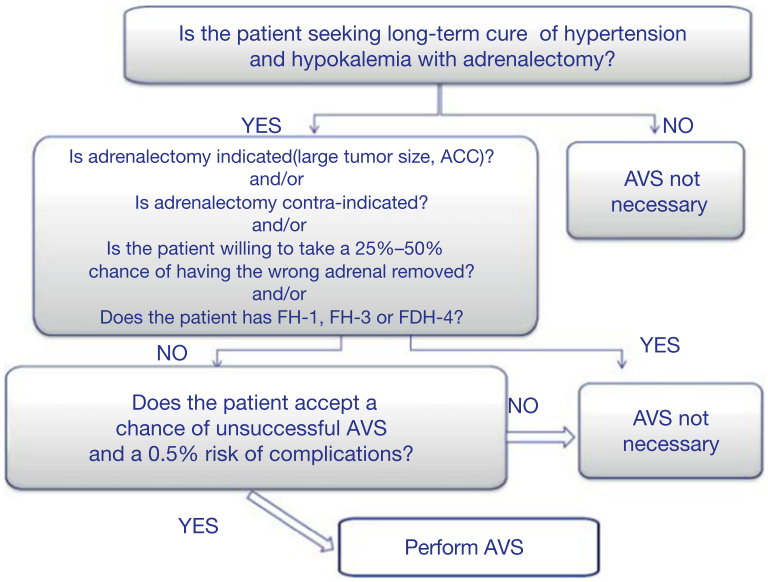

Fig. 1 The flow chart shows the algorithm to be used to select the patients for AVS.

Selection of Patients for Adrenal Venous Sampling

Appropriate selection of the patients is essential beforehand, because AVS is an invasive and expensive test (**Fig. 1**). To this end it is key to remember that an unequivocal biochemical diagnosis of PA must be made before considering AVS, because AVS is aimed at subtyping of PA and not at confirming this diagnosis. Multiple studies have in fact shown that the accuracy of imaging tests, adrenal computed tomography (CT), and magnetic resonance imaging (MRI) in localizing the source of aldosterone excess is poor as aldosterone-producing microadenoma and the majority of bilateral lesions are CT-and MR-undetectable (Kempers *et al.*, 2009). Therefore, in line with international experience that AVS is key to distinguish between unilateral and bilateral aldosterone excess both the U.S. Endocrine Society and the Japan Endocrine Society guidelines recommend AVS in all patients who have the diagnosis of PA and who want to pursue surgical cure (Funder *et al.*, 2008; Nishikawa *et al.*, 2011; Kempers *et al.*, 2009).

As a prerequisite for adrenalectomy, AVS is not indicated when either the patient prefers life-long medical treatment, or the physician considers the risks of surgery to outweigh the benefits—for example, because of the patient's age or general conditions contraindicate general anesthesia and/or surgery (**Fig. 1**). AVS is also not generally required in a patient with PA if surgery is already mandated by the size of the adenoma and/or other radiological features suspicious of adrenocortical carcinoma.

On the premise that nonfunctioning adrenocortical adenoma (so called "incidentaloma") is rare in young people, another subgroup in which AVS might not be needed can include patients <35 years of age with a florid PA—as evidenced by spontaneous hypokalemia, very high plasma aldosterone concentration (PAC), and very low active renin—and a clear-cut unilateral cortical adenoma with a seemingly normal contralateral adrenal gland on imaging (Kupers *et al.*, 2012). However, unilateral aldosterone excess from a small CT-undetectable APA in the adrenal gland contralateral to a CT-detectable adrenal mass cannot be identified without performing AVS, even in such patients. Moreover, bilateral aldosterone secretion, which occurs in those with IHA or familial hyperaldosteronism type I, III, and IV (FH-I, FH-III, FH-IV), and can coexist with incidentaloma, cannot be excluded without AVS. Nonetheless, as the patients with FH usually have bilateral aldosterone excess, AVS is generally not indicated if FH has been genetically proven.

Prediction of Outcome as a Guide for Selecting Patients

In municipalities where health resources are limited, a selection strategy is necessary, as both AVS and the surgical approach are simply not feasible for the multitude of PA patients (Funder, 2012). To this end it is worth remembering that several studies have documented preoperative characteristics associated with cure of hypertension following unilateral adrenalectomy. For example, surgical cure of hypertension has been associated with: young age (Harris *et al.*, 2003; Pang *et al.*, 2007), shorter duration of hypertension (e.g., <5–10 years); fewer antihypertensive medications (e.g., ≤ 2), higher preoperative blood pressure; preoperative normal renal function; body mass index ≤ 25 kg/m^2, female gender, lack of a family history of hypertension (Wang *et al.*, 2000; Sawka *et al.*, 2001), and no evidence of vascular remodeling (Rossi *et al.*, 2008a). These features should be considered when discussing with the patient realistic expectations of surgical outcomes and evaluating the risk benefit ratio. If selected based on AVS results nearly all patients with unilateral PA benefit from the surgical approach, as evidenced by biochemical cure of the aldosteronism and improved hypertension control even if hypertension is not cured (Wang *et al.*, 2000; Sawka *et al.*, 2001;

Zarnegar *et al.*, 2008) and by long-term regression of left ventricular hypertrophy (Rossi *et al.*, 2013). Realistically, however, in most public healthcare systems, priority should be given to young women, who are the most likely to be cured and gain the most in life-years off treatment, and to all the patients with resistant hypertension (or antihypertensive drug intolerance), whose absolute risk of CV complications is the highest.

Preparation of the Patient and Performance of AVS

Performing AVS requires an interdisciplinary team and exploitation of standard operational procedures, including preparation of the patient for the procedure and standardization of the conditions for its performance, as key steps to the success. The following recommendations are based on knowledge of the factors that influence technical success and accuracy and that might confound interpretation of its results.

When preparing the patient for AVS it is generally neither necessary nor advised to withdraw completely the antihypertensive treatment; however, careful adjustment of the antihypertensive agents before and during AVS is fundamental. Peripheral α_1-adrenergic receptor blockers (e.g., doxazosin mesylate, prazosin hydrochloride, and terazosin hydrochloride), and/or the long-acting dihydropyridine or nondihydropyridine calcium-channel blockers (verapamil) are recommended as these agents negligibly affect renin secretion (Rossi, 2011b). In stage 3 and/or drug-resistant hypertensive patients, successful AVS can be achieved notwithstanding the multiple agents that are necessary for minimizing risks of severe and/or uncontrolled blood pressure control. Thus, if angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, diuretics, and beta-adrenergic blockers need to be used, AVS can be performed in these patients as long as renin is suppressed. If the patient lateralizes the result is usually valid regardless of medications or serum potassium status; however, one should have to be concerned that the test might not be valid if AVS does not lateralize in patients treated with these agents. Thus, the AVS results should be interpreted with caution, because the feasibility of using these agents during AVS has not been proven, keeping in mind that when renin is not suppressed, aldosterone secretion can be stimulated in the nonculprit adrenal gland (see also later).

Consensus exists that in patients previously on MR antagonists or amiloride, these agents should be withdrawn (for MR antagonists at least 6 weeks, probably less for amiloride) before AVS, and this entails a small clinical risk in patients with resistant hypertension. MR antagonists should be avoided because they have the potential to allow a rise in renin secretion, which can stimulate aldosterone secretion from the unaffected side, thus minimizing the lateralization. Therefore, some centers use plasma renin measurement to decide whether to perform AVS without withdrawing, or downtitrating, the MR antagonists: the finding of low renin (e.g., a direct renin <10 mIU/L or a PRA <0.60 ng/mL/h) as evidence for unlikely stimulation of the contralateral adrenal cortex at a level sufficient to confuse interpretation of lateralization, and were able to use an independent measure of lateralization.

Some centers conduct AVS in outpatients, in which case time should be allowed for the patient to rest in the supine position for at least 1 h prior to AVS (Rossi, 2007; Daunt, 2005). We prefer to perform AVS with a 1-day hospital stay because complications can occur even after 12–24 h. AVS is best performed in the morning to avoid false-negative results, which can be due to diurnal fluctuation in ACTH having a more variable effect on many APAs than on the contralateral adrenal. Hypokalemia, if present, can blunt differences between sides because it decreases aldosterone secretion, and may potentially mask a unilateral aldosterone production. Thus, it should be corrected with oral or intravenous potassium supplements before AVS.

Catheterization of the left adrenal vein is achieved in almost 100% of the cases if the catheter's tip is positioned either at or distal to the orifice of the left inferior phrenic vein to avoid sample dilution from nonadrenal venous blood. In contrast, that of the right adrenal vein is much more difficult owing to its small size and its draining directly into the inferior vena cava at various angles or directly into a small accessory hepatic vein (Davidson *et al.*, 1975; Daunt, 2005). As prior knowledge of the right adrenal vein anatomy can facilitate catheterization in difficult cases (Miotto *et al.*, 2009), CT is important before AVS not only for detecting adrenocortical nodules but also for identifying the right adrenal vein and delineate its anatomy (in venous phase), including position and relationship to surrounding structures. This is also because in about 10% of the patients, the success rate of AVS achieving in selectivity can be affected by dilution from accessory vein blood flow. Prior identification on CT of the right adrenal vein draining into accessory hepatic vein in these cases allows selective cannulation with suitable catheters of the right adrenal vein, instead of the common trunk made by accessory hepatic vein and right adrenal vein or of small independent accessory hepatic veins instead of the right adrenal vein (Rossi, 2011b; Miotto *et al.*, 2009; Matsuura *et al.*, 2008).

Minimizing Stress During AVS

Emotional and pain-related stress, which activates the hypothalamic pituitary adrenal axis with ensuing ACTH-induced cortisol release from both adrenal glands, can confound interpretation of AVS results, as it might lower the PAC to PCC ratio, and thus obscure lateralization to the culprit adrenal. Stress was recently shown to affect the selectivity index (SI), and the ratio of PCC in an adrenal vein and in the infra-adrenal inferior vena cava. This study showed that a stress reaction: (i) occurs in most patients when starting AVS; (ii) waned rapidly, for example, over 15 min; (iii) increases the SI on both sides at the beginning of the procedure (Seccia *et al.*, 2012).

A more recent study simulating sequential AVS showed that this stress reaction influences also the LI values, particularly in patients who do not have APA, thus leading to a factitious diagnosis of lateralization (Rossitto *et al.*, 2017). Therefore, unless sequential catheterization can be performed within 5 min on both sides, which can be challenging in many cases, particularly if there are anatomical variations, bilaterally simultaneous catheterization should be preferred, and precautions to minimize stress should be systematically exploited (Rossi *et al.*, 2012; Seccia *et al.*, 2012).

To the latter goal, measures to be adopted both before and during AVS entail explanation of the procedure to the patient, reassurance by the doctor and nurses, and use of benzodiazepines and local anesthesia before venipuncture. Allowing the patient to rest quietly for at least 15 min before the blood sampling in a friendly environment with psychological assistance can also be useful but, at variance with this, the AVIS study showed that only one of the 20 participating centers used systematically some of these measures (Rossi *et al.*, 2012). Additional measures aimed at either overriding stress effects by maximally stimulating cortisol release from both adrenals, or minimizing stress effects on the PAC to PCC ratio by simultaneously sampling from both adrenal veins are discussed later.

In summary, available evidence indicates that a stress reaction can affect both the SI and LI, and therefore that stress minimization measures should be taken when starting AVS.

Pharmacologic Stimulation During AVS

Stimulation with a continuous infusion of synthetic ACTH (cosyntropin) (50 μg/h started 30 min before sampling) or a bolus (250 μg i.v.) during AVS was introduced in 1979 and is currently used at many centers (Weinberger *et al.*, 1979; Young *et al.*, 2004). There are three reasons for using this stimulation: (i) enhancing the PCC gradient between the adrenal vein and the inferior vena cava, and thus increasing the SI values and confidence of successful sampling; (ii) reducing stress-induced fluctuations in cortisol and aldosterone secretion during sequential AVS; (iii) increasing aldosterone secretion from APA (Weinberger *et al.*, 1979; Young *et al.*, 2004).

Because of the clear-cut increase of success in demonstrating bilateral selectivity, the administration of cosyntropin has become a standard procedure even despite no proof for increased success in ascertaining lateralization.

To assess the value of pharmacologic stimulation during AVS original papers that investigated patients with PA, before and after exposure to pharmacologic agents, were reviewed in terms of impact of cosyntropin on the selectivity index (SI), the lateralization index (LI, see later), and/or of the decision to perform adrenalectomy. Potentially relevant reports were identified that mostly used cosyntropin. These papers are briefly summarized below. Seccia *et al.* showed that high-dose (250 μg i.v. as a bolus) and intermediate-dose (50 μg/h) cosyntropin increased the percentage of patients with selective studies (using 1.10 as cutoff for SI), while the very low dose (250 pg i.v.) was totally ineffective. The increase of the SI occurred at the cost of a reduced accuracy of the LI, which pointed to the incorrect side in 3% and 13% with high-dose and intermediate-dose cosyntropin, respectively (Seccia *et al.*, 2009). Three studies have confirmed that cosyntropin administration, either as bolus or continuous infusion, increased the SI and thus the successful adrenal veins cannulation rate (Nakamura *et al.*, 2011). At the same time the LI was unaffected by either mode of cosyntropin administration using a high LI cutoff value. By no means these studies provided evidence that cosyntropin stimulation improves decision-making in PA, as there were no AVS-independent success criteria. Cosyntropin was also found to decrease the LI, albeit only in subsequently operated patients (Satoh *et al.*, 2007), or even to invert the LI, thus pointing to the wrong adrenal (Rossi *et al.*, 2008b), leading the authors to not recommend systematic cosyntropin stimulation during AVS. Another study on bilaterally simultaneous AVS with cosyntropin stimulation showed also an increase in bilaterally successful catheterization from 21% to 44%. However, in this study neither the effects of cosyntropin on LI nor the rationale for adrenalectomy could be assessed since most patients did not have a successful AVS.

At variance with all these findings and the theoretical expectations, Mathur *et al.* reported that the SI fell after cosyntropin on both sides, and that the LI values remained unchanged in the cases that lateralized on the right, but increased in the cases that lateralized to the left: overall the proportion of patients that could be defined as lateralized increased only slightly (from 95% to 98%). This study was unique in that it provided no evidence that cosyntropin stimulation improves the assessment of selectivity (Mathur *et al.*, 2010). In a more recent study of 47 patients, 85% of which had successful bilateral catheterization, Wolley *et al.* confirmed the highly significant increase of the SI with cosyntropin both on the right and the left sides; however, only 31 of 40 patients had the same diagnosis pre- and postcosyntropin. Moreover, among those with an inconclusive diagnosis precosyntropin only 50% were diagnosed as unilateral postcosyntropin and in 6% of all patients the diagnosis changed (Wolley *et al.*, 2016).

Two further studies using cosyntropin were either too small (Tanemoto *et al.*, 2009), or only reported the precosyntropin SI and LI values (Carr *et al.*, 2004), thus precluding any conclusions in favor or against use of this stimulation. Likewise, the studies with metoclopramide, a mixed DA_2 dopaminergic antagonist and serotoninergic agonist (Rossitto *et al.*, 2018) that increases aldosterone but not cortisol release, showed that this agent does not increase the PCC-based SI, and the LI to the culprit adrenal, but can be useful to unmask factitious contralateral suppression in non APA cases (Wu *et al.*, 2001).

In a more recent study we used the relative aldosterone secretion index (RASI) (**Table 1**), a way to assess aldosterone secretion by each adrenal gland, and also measured the melanocortin type 2 Receptor (MC2R) mRNA in APA and the normal adrenal cortex (Rossitto *et al.*, 2018). Besides conforming that cosyntropin increases the SI, we could provide key information for a better understanding of the effect of cosyntropin as we found that it lowers significantly the RASI, which explains the previously reported decrease, or even inversion of the LI. The fact that compared to cortisol cosyntropin stimulates less potently aldosterone, along

Table 1 Indexes currently used for the interpretation of AVS results

	Formula	*Meaning*
Selectivity index (SI)	$\frac{PCC_{side}}{PCC_{IVC}}$	Values above the cut-off confirm that the sample was obtained in the adrenal vein
Relative secretion index (RASI)	$\frac{(PAC_{side}/PCC_{side})}{(PAC_{IVC}/PCC_{IVC})}$	Estimates aldosterone secretion of each of adrenal gland relative to cortisol
Contralateral suppression index (CLSI)	$\frac{(PAC_{nondominant}/PCC_{nondominant})}{(PAC_{IVC}/PCC_{IVC})}$	Values below the cut-off (generally 1.00) indicate suppression of aldosterone secretion in the contralateral gland
Lateralization index (LI)	$\frac{(PAC_{dominant}/PCC_{dominant})}{(PAC_{nondominant}/PCC_{nondominant})}$	Values above the cut-off indicate lateralized aldosterone excess

PCC, plasma cortisol concentration; *PAC*, plasma aldosterone concentration. Dominant, side with higher PAC; Nondominant, contralateral side.

with the finding that the MC2R is less expressed in APA than in the normal adrenal cortex, provided a straightforward explanation for the fall of the LI and thus for the confounding effect of cosyntropin in identifying the culprit adrenal.

In summary, the bulk of the data indicate that cosyntropin increases the SI, thus facilitating the ascertainment of selective catheterization, which explains why in the AVIS study centers that systematically used cosyntropin were found to use higher cutoff values for the SI than centers that used baseline (unstimulated) values. However, because there was no conclusive evidence on whether use of cosyntropin stimulation is associated with improved or worsened outcome, defined as remission of hypertension and hypokalemia as endpoints, these major referral centers were almost equally split into those that use and those that do not use cosyntropin stimulation (Rossi *et al.*, 2012). In the absence of definitive data, the following suggestions are provided: (i) if cosyntropin stimulation is not used, then bilateral simultaneous AVS should be performed; (ii) if cosyntropin stimulation is used, then higher SI and LI values are indicated; (iii) cosyntropin could be used only at centers that show a low success rate in achieving successful bilateral catheterization and do not have access to measurement of androstenedione instead of PCC; (iv) in the APA patient with less florid biochemical phenotype cosyntropin likely invert lateralization to the nonculprit adrenal.

Bilaterally Simultaneous or Catheterizations Should Be Preferred

The AVIS study showed that almost two-thirds of the centers used the sequential technique with cosyntropin stimulation, while the rest used the bilaterally simultaneous technique with no stimulation (Rossi *et al.*, 2012). This finding could be anticipated since when cortisol secretion is maximally stimulated during cosyntropin infusion, the time difference between blood sampling from one side and the other is irrelevant, at least for the assessment of selectivity.

Given that secretion of aldosterone is pulsatile and highly variable there are chances of creating artificial gradients between the adrenals when using the sequential blood sampling technique, particularly if the interventionist is not proficient and fast enough. Undoubtedly bilaterally simultaneous AVS can avoid this (Rossi *et al.*, 2008b), and therefore if AVS is performed without cosyntropin stimulation the simultaneity of blood sampling is crucial and should be systematically used. The results of a recent study where bilaterally simultaneous AVS was systematically used at different time points, for example, at time -15, for example, when starting the procedure, and at time 0 for example, 15 min after, support this conclusion. Simulation of sequential AVS by combining the samples obtained on each side at the different time points was compared with the simultaneously obtained samples at time 0. The latter furnished a more accurate identification of lateralization than those obtained sequentially, which, moreover, produced a higher chance for creating factitious lateralization to the last sampled size, regardless of it being right or left. This bias was particularly evident in the cases without on APA, likely because of the waning of the waning of the aforementioned stress reaction (Rossitto *et al.*, 2017).

Assessment of Successful Catheterization

In the early years of AVS retrograde injection of contrast medium in the adrenal vein was used to confirm the success of catheterization and to visualize the abnormal vascular tree that can be a feature of an APA. This carries an increased risk of adrenal vein rupture, and should not be done (Rossi, 2007; Daunt, 2005), because with improved adrenal gland imaging by CT and MR, adrenal venography is no longer needed. Nevertheless, injection of a small amount of dye with a gentle pressure is still used to visualize the adrenal vein, and thus confirms the correct positioning of the catheter's tip inside the adrenal vein.

For the left side, the tip of the catheter should be placed distal to the orifice of the left inferior phrenic vein. For the right side, adrenal vein should be distinguished from accessory hepatic vein and when the right adrenal vein drains into accessory hepatic vein, the tip of the catheter should be confirmed to be located in the right adrenal vein instead of hepatic venous tributaries by injection of a single amount of contrast just before and after blood collection. The most popular technique to confirm the success of selective adrenal vein catheterization entails calculation of the ratio of concentrations of a hormone from an adrenal vein and the infra-adrenal inferior vena cava or a peripheral vein, defined as selectivity index (SI, **Table 1**) (Rossi *et al.*, 2008b), based on the theoretical premise that this hormone is exclusively made in the adrenal cortex and, is not overproduced in APA. Therefore, the finding of a concentration gradient between a blood sample in a vein draining the adrenal cortex and the IVC, or a peripheral vein,

is a proxy for the correct placement of the catheter's tip into the adrenal vein. To this aim the hormone most widely used is cortisol, because of its high rate of production and easy assay although attempts to use epinephrine (Freel *et al.*, 2010), metanephrine, and also chromogranin A have been made (Seccia *et al.*, 2012). While the use of SI might seem straightforward, and is being used to assess selectivity in most major international referral centers, the AVIS study showed that some of these centers still analyze their results using absolute hormonal values without prior assessment of the selectivity and correction for the degree of sample dilution, a practice that is no longer acceptable and should be abandoned.

In a recent study we used 17 α—OH progesterone and androstenedione, two steroids that have a higher step-up than cortisol between the adrenal vein and the peripheral blood to determine selectivity in a series of AVS samples judged to be nonselective by using PCC. The SI values calculated using 17 α—OH progesterone and androstenedione were on average 1.6-fold and 12-fold, respectively, higher than those based on PCC (Ceolotto *et al.*, 2017). Thus, this study provided conclusive evidence that these steroids, and particularly androstenedione, should be used instead of PCC.

Some general considerations need, however, to be made as there was a considerable variability in the SI cutoff values used (Rossi *et al.*, 2012): the cutoffs are lower at centers that perform AVS under unstimulated conditions than at those that use cosyntropin stimulation, which is not surprising given the considerations made above. It is altogether intuitive that the higher the SI cutoff values chosen to establish selectivity, the lower the proportion of AVS studies that could be defined as bilaterally selective and vice versa: too restrictive criteria lead to exclude a proportion of successful studies from diagnostic use, while, conversely, too permissive SI cutoffs could limit the diagnostic accuracy of AVS. Moreover, as the SI increases, so does the confidence of the interpretation. In some cases where unilateral aldosterone production is extremely high, a low SI can give the correct interpretation, but in cases when the production is modest it may lead to the wrong conclusion. As the need for a trade-off between too restrictive and too permissive cutoffs was clearly shown (Rossi *et al.*, 2008b), and then repeatedly confirmed (Seccia *et al.*, 2009; Mulatero *et al.*, 2008) these considerations need to be kept in mind rather than adhering strictly to a specific value. It has also to be considered that cutoffs depend on the accuracy (within-assay coefficient of variation, CV) with which hormones can be measured in that specific laboratory. For instance, considering PCC, if the CV is above or around 10%, low SI cutoffs, for example 1.1, are unusable, while if the assay CV is less than 10% a SI cutoff of 1.1 may be a reasonable choice (Rossi *et al.*, 2001, 2006b).

When using PCC for the SI calculation, use of an SI >2.0 for AVS performed under unstimulated conditions, and >3.0 during cosyntropin stimulation are reasonable options according to the AVIS study (Rossi *et al.*, 2012). However, the choice of the SI cutoff should be center-dependent and based on the accuracy with which the laboratory can measure PCC as mentioned above. The caveat to be made is, however, that while an unambiguous diagnosis of APA should be used as reference and guide in validating the findings and selecting the cutoffs, several studies were biased by a circular type of reasoning in that they used the AVS results to validate the diagnosis and justify the choice of their cutoff values (Seccia *et al.*, 2009; Rossi *et al.*, 2001).

In summary, use of absolute hormonal concentrations should be discouraged and AVS studies that are not bilaterally successful should not be used to establish lateralization as prior verification of bilateral selectivity is a prerequisite to the use of the data for diagnostic purposes (**Fig. 2**). Nonetheless, recognizing the fact that many studies are not bilaterally selective and/or can provide equivocal results, a following section has been devoted to the clinical decision-making in these difficult cases.

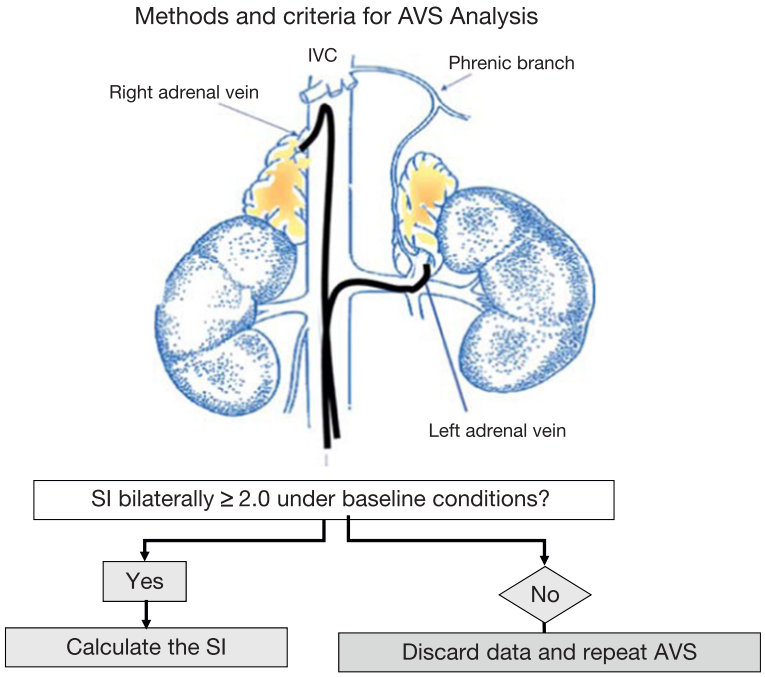

Fig. 2 Methods and interpretation of AVS: only bilaterally selective studies should be used for diagnostic purposes.

Intraprocedural PCC Assay

Given that the hormonal data are available after AVS, and therefore allow judging on the achieved selectivity only retrospectively, some centers have exploited use of extemporaneous, for example, during AVS, PCC measurement. This has the advantage of furnishing to the radiologist the immediate feedback on whether selective blood sampling from each adrenal vein was achieved and to permit further attempts of before removing the catheters, if selective catheterization was not initially obtained, thus avoiding the need for a further catheterization (Mengozzi *et al.*, 2007; Rossi *et al.*, 2011). Unfortunately, this approach that can improve the success rate, particularly during the radiologist's learning curve, is feasible only at centers where PCC can be measured rapidly, which implies a suitable logistic organization and a dedicated laboratory technician standing by Auchus *et al.* (2009) and Betz *et al.* (2011). Thus far, the usefulness of the rapid intraprocedural cortisol assay for increasing the success rate of AVS has been supported mainly by observational studies (Mengozzi *et al.*, 2007; Rossi *et al.*, 2011; Auchus *et al.*, 2009), and one randomized study carried out in Japan (Yoneda *et al.*, 2016), which, however, was performed in some centers that had scant or no experience in performing AVS where, therefore, the observed improvement in the success rate could be anticipated. The hypothesis that the rapid intraprocedural assay of cortisol, and androstenedione, can be useful will therefore be tested prospectively in the Intra-Procedural Cortisol Assay During Adrenal Vein Sampling: Rationale and Design of a Randomized Study I-Padua (Cesari *et al.*, 2017).

Interpretation of AVS and Assessment of Lateralization

The operational diagnostic index to assess the lateralization of aldosterone hypersecretion is the LI, which is calculated as the higher (dominant) over the lower (nondominant) adrenal vein PAC/PCC ratio (**Table 1**). PCC in adrenal venous blood is used for correction of the adrenal aldosterone levels because of inevitable dilution of the samples by nonadrenal blood, which occurs even if efforts are made to avoid blood dilution from accessory hepatic vein and inferior phrenic vein as discussed above. As mentioned above, PCC will probably be replaced by androstenedione for the assessment of selectivity. Therefore, as it is likely that as the LI will make use of this steroid in the future optimal cutoffs should be recalculated.

Ideally, evidence for optimal diagnostic accuracy of LI cutoffs should come from prospective studies in patients undergoing unilateral adrenalectomy regardless of the AVS results, and in which the different LI are thereafter linked to postsurgical cure of hyperaldosteronism rather than only high blood pressure, which is a composite phenotype. Unfortunately, no such prospective studies are available (Funder *et al.*, 2008); the only randomized study in this area performed with the aim to compare on AVS-based with a CT-based strategy for PA patients subtyping (Mengozzi *et al.*, 2007), unfortunately was totally underpowered to furnish any solid information and used a suboptimal AVS technique, for example, sequential blood sampling and cosyntropin stimulation (Funder and Rossi, 2016).

Observational data from the AVIS study showed that most referral centers use arbitrarily chosen LI cut-offs with values that ranged between 2.0 and 4.0 depending on cosyntropin stimulation, higher cutoffs being selected after cosyntropin stimulation (Rossi *et al.*, 2012). At present, an LI of 2.0 for unstimulated AVS and of 4.0 during cosyntropin stimulation are probably the best criteria to document lateralization of aldosterone excess, with the caveat that given the lack of prospective randomized studies, information is only based on observational studies, which show that outcome in terms of cure/improvement of blood pressure is similar for LI values varying between 2.0 and 5.0 (Young *et al.*, 2004; Mathur *et al.*, 2010; Ishidoya *et al.*, 2011; Nwariaku *et al.*, 2006). In fact, a recent study comparing 10 different LI criteria to determine lateralization (Mulatero *et al.*, 2010) found no significant differences in clinical outcome for all criteria: the most accurate criterion for correctly identifying lateralization was an LI >2.0 in combination with an SI >2.0 without cosyntropin, and >4.0 during cosyntropin stimulation.

It is worth considering that the choice of more restrictive (higher) cutoffs, with and without stimulation, undoubtedly leads to selection of a population with a higher chance of being cured with adrenalectomy. Precluding the chances of cure to some potentially curable patients, who have LI below these high cutoffs, is the obvious drawback of this.

To allow use of AVS studies that were not bilaterally selective, in which the LI cannot be calculated, attempts to use a contralateral aldosterone suppression index (PAC/PCC ratio of the nondominant adrenal vein less than the peripheral PAC/PCC ratio, Table 2) as an additional criterion to assess lateralization have been made (Wolley *et al.*, 2015), based on the theoretical premise that the secretion of aldosterone should be suppressed from the side contralateral to an APA. This interesting approach has, however, not been sufficiently validated thus far.

The following considerations need to be made: to assess the accuracy of AVS criteria the outcome after adrenalectomy, defined as normalization of both aldosterone and renin, which consistently occurs after adrenalectomy (Rossi *et al.*, 2013; Quillo *et al.*, 2011) (and not as fall of blood pressure, which may not occur if the patient has concomitant essential hypertension and/or vascular remodeling, (Funder, 2012), should be used. Instead only few studies have used this outcome as reference. Moreover, verification of postadrenalectomy outcome is obviously impossible in the patients who were not operated because they show no lateralization of aldosterone secretion at AVS (Rossi *et al.*, 2006a; Graham *et al.*, 2012). These caveats explain why the quality of evidence is low in this area.

Decision-Making in Equivocal AVS Results

In the AVIS study the most commonly used cutoff values for AVS performed with cosyntropin stimulation were SI of >3.0–5.0 for successful sampling, and an LI of >4.0 for lateralization, with no centers using LI cutoff <2.0 (Rossi *et al.*, 2012). For studies without cosyntropin, these cutoff values were generally lower by a value of 2, but the decision-making principles were the same. Consequently, AVS studies with cosyntropin are considered equivocal when the LI is 2.0–4.0, and the study is technically unsuccessful when one or both SI values are <3.0.

But Is This Conclusion Right? Should All of These Patients Be Managed Medically?

As the "true" result will never be known in the cases not submitted to unilateral adrenalectomy, accuracy of AVS is particularly hard to assess, for the reasons mentioned above and also because false negatives are rarely reinvestigated; the aldosterone/renin ratio falls when any adrenal is removed and, moreover, persisting hypertension can be blamed on many factors. Thus, only persistent hypokalemia with suppressed renin and high aldosterone after adrenalectomy are regarded as definitive evidence of incorrect lateralization. On the other hand, it has to be considered that because APAs are mostly benign, and many patients can be controlled medically, false negatives are held to be less serious than false positives, which led to suggest use of generally high diagnostic thresholds as appropriate. Ambiguous cases can often be resolved by repeating the AVS. If medical control of blood pressure and hypokalemia is poor, the benefit/risk from surgery is increased, and therefore the clinician should lower the threshold for recommending surgery.

Safety and Management of Complications

It is advised that AVS be performed in the specialized referral centers with sufficient throughput and expertise. However, the limited number of specialized centers that can perform for this technically demanding procedure results in missed opportunities for optimal surgical management (Rege *et al.*, 2016), training programs and certification of proficiency in performing AVS for radiologists should be implemented.

The most common and major complication of AVS includes adrenal vein rupture (Daunt, 2005), a complication that is only occasionally followed by complete and permanent adrenal insufficiency, but can be curative if occurring in the adrenal gland harboring the APA. Clinically, adrenal vein rupture is characterized by onset of persistent pain during or after catheterization, which increases in intensity and requires large doses of analgesics over 24–48 h (Daunt, 2005). Confirmation of the diagnosis, by CT and/or MRI, and careful monitoring of vital signs should be applied. The complications usually resolve with conservative treatment (Monticone *et al.*, 2016) and do not carry any sequelae, although they can render subsequent laparoscopic adrenalectomy more difficult due to extensive retroperitoneal adhesions.

Early studies suggested a wide range of complication rates varying between less than 0.2% and 13% (Daunt, 2005; Young *et al.*, 2004; Betz *et al.*, 2011; Vonend *et al.*, 2011). Compared to those higher rate of complications reported in the aforementioned AVIS study, the rate of adrenal vein rupture was 0.61, only at major referral centers (Rossi *et al.*, 2012). This decrease is likely attributable, at least in part, to avoiding routine adrenal venography and minimizing the injection volume for anatomical confirmation of the adrenal vein catheterization. Complications are more common in the right than left adrenal vein, mainly because of the anatomical diversity and complexity. While they do not seem to depend on the methods of catheterization, such as sequential or bilateral simultaneous, and the use of cosyntropin stimulation (Rossi *et al.*, 2012), it was found that they differ significantly even among major referral centers. Regression analysis demonstrated that adrenal vein rupture was inversely related to the number of AVS performed by each radiologist and the number of AVS performed per centers, thus clearly indicating that the complication rate depends on the expertise of the radiologist and the experience of each center (Rossi *et al.*, 2012).

Conclusions

AVS should serve as the "gold standard" diagnostic test for the subtyping of PA because of its high diagnostic accuracy and the very low rate of complications. With few exceptions, this procedure should be systematically used before referring a PA patient PA to the surgeon. Following the suggestions that are herein summarized will render AVS a rewarding diagnostic test both for the doctor and, more importantly, for the patient.

Genetics of Familial Hyperaldosteronism

Silvia Monticone, Martina Tetti, Isabel Losano, Franco Veglio, and Paolo Mulatero, University of Turin, Turin, Italy

Glossary

Next generation sequencing A DNA sequencing technology which performs sequencing of millions of small fragments of DNA in parallel.

Introduction

Primary aldosteronism (PA) is a group of disorders comprising both sporadic and familial forms and characterized by aldosterone overproduction by the adrenal glands, at least partially independent from its physiological regulators, angiotensin II, ACTH, and plasma K^+.

The recent introduction of affordable large scale methods of gene sequencing (e.g., next generation sequencing) has had a profound impact on mutation discovery in both sporadic and familial PA. Four forms of familial hyperaldosteronism (FH-I to FH-IV) (Monticone *et al.*, 2015a) and one form of genetic, but non familial, PA (Scholl *et al.*, 2015) (**Table 1**) have been reported and will be reviewed in detail.

Familial Hyperaldosteronism Type I

FH-I, also known as glucocorticoid remediable aldosteronism (GRA), was first described in 1966 in a father and son as a clinical syndrome characterized by hyperaldosteronism, which could be suppressed by the administration of dexamethasone (Sutherland *et al.*, 1966). Moreover, affected patients displayed high levels of the so-called "hybrid steroids" 18-hydroxycortisol (18OHF) and 18-oxocortisol (18oxoF) (Gomez-Sanchez *et al.* 1988; Ulick *et al.*, 1990), which suggested the hypothesis that FH-I could represent a disorder of the adrenal transitional zone, where it is likely that 17α-hydroxylase and aldosterone synthase coexists (Gomez-Sanchez *et al.*, 1988).

The molecular basis of FH-I remained unknown until 1992, when Lifton *et al.* identified the chimeric *CYP11B1/CYP11B2* gene as the genetic determinant of this disorder (Lifton *et al.*, 1992). *CYP11B1* and *CYP11B2* genes, encoding for 11β-hydroxylase and aldosterone synthase respectively, are located on 8q24 and share a 95% homology in the coding region. 11β-hydroxylase catalyzes the conversion of 11-doxycortisol to cortisol, while aldosterone synthase can catalyze three different reactions: 11β-hydroxylation of DOC to corticosterone (B) 18-hydroxylation of B to 18OHB, and, finally, 18-oxidation of 18OHB to aldosterone.

The chimeric *CYP11B1/CYP11B2* gene results from an asymmetrical crossing over between the two genes and comprises sequences derived from *CYP11B1* at the 5′ end (including ACTH regulatory sequences) and sequences from *CYP11B2* at the 3′ end (Pascoe *et al.*, 1992) (**Fig. 1**, panel A). The hybrid enzyme retains the 18-oxidase activity of CYP11B2 and can therefore produce aldosterone under ACTH control. In addition, it is expressed through the entire adrenal cortex (including the adrenal *zona fasciculata*, where 17α-hydroxylase is expressed) determining the abnormal production of the hybrid steroids (Pascoe and Curnow, 1995) (**Fig. 1**, panel B). Further studies demonstrated that the point of recombination is always comprised between intron 2 and exon 4 (Dluhy and Lifton, 1995) and Gly288 and Ala320 are the two residues indispensable for 18-hydroxylase and 18-oxitase activity respectively (Curnow *et al.*, 1997).

Originally, the diagnosis of FH-I was made on a clinical basis and relied exclusively on the complete suppression of aldosterone production after a 2–4 days dexamethasone suppression test (Liddle and Grant, 1960), together with the hybrid steroids

Table 1 Familial forms of primary aldosteronism

Familial hyperaldosteronism			
Type	Molecular basis	Prevalence	Treatment
Familial hyperaldosteronism, type 1 (or glucocorticoid remediable aldosteronism, GRA)	Chimeric *CYP11B1/CYP11B2* gene	<1% of PA	Dexamethasone, MR antagonists
Familial hyperaldosteronism, type 2	Unknown (possibly heterogeneous)	5% of PA	Unilateral adrenalectomy or MR antagonists
Familial hyperaldosteronism, type 3	*KCNJ5* mutations	Rare (12 affected families reported so far)	Bilateral adrenalectomy or MR antagonists
Familial hyperaldosteronism, type 4	*CACNA1H* mutations	Very rare	MR antagonists
PASNA syndrome	*CACNA1D* mutations	Very rare (two affected subjects)	CCBs, MR antagonists

PA, Primary aldosteronism; *MR*, mineralocorticoid receptor; CCBs, calcium channel blockers.

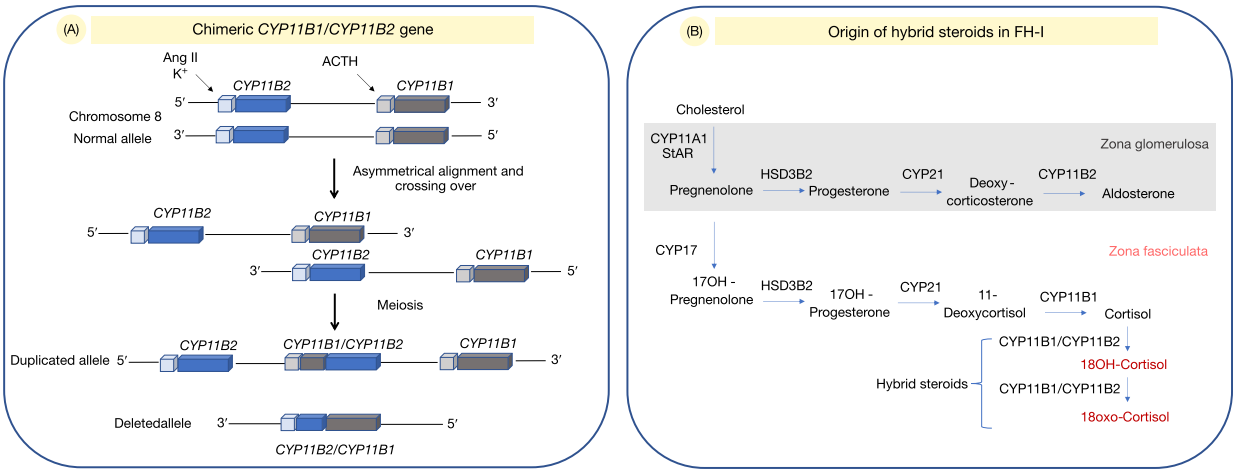

Fig. 1 (Panel A) Asymmetrical crossing over between *CYP11B1* and *CYP11B2* genes on chromosome 8, leading to the chimeric *CYP11B1/CYP11B2* gene in FH-I. (Panel B) Adrenal steroidogenesis in *zona glomerulosa* and *zona fasciculata*, showing the origin of the hybrid steroids in FH-I.

measurement. However, both tests, lacking specificity for FH-I diagnosis, have been replaced by the long PCR amplification of the chimeric gene (Stowasser *et al.*, 1995; Mulatero *et al.*, 1998a). It has infact been shown that a variable proportion of patients with sporadic aldosterone producing adenomas (APAs) show dexamethasone suppressible aldosterone production (Mulatero *et al.*, 1998b) and can produce a certain amount of hybrid steroids (Mulatero *et al.*, 2012a; Williams *et al.*, 2016). Moreover, extremely high levels of hybrid steroids have also been reported in one family affected by FH-III (Geller *et al.*, 2008).

According to the 2016 Endocrine Society guideline (Funder *et al.*, 2016), genetic testing for FH-I should be performed in all patients with the onset of PA earlier than 20 years of age and in those who have a family history of PA or of strokes at young age (<40 years). However, due to the lack of invasiveness and the undoubted benefit of an early diagnosis together with the requirement of a specific therapy, some authors suggest to systematically test all PA patients (Stowasser and Gordon, 2004; Mulatero *et al.*, 2010). Hypertensive children should also be considered for FH-I screening since it has been shown to be relatively frequent in this subgroup of patients (3.1% in untreated hypertensive Chilean children 4–16 years old) (Aglony *et al.*, 2011). In agreement with the data of Aglony *et al.*, the long-PCR test should be performed in all pediatric patients with low PRA and normal/high aldosterone (and, thus, high ARR) and normal/low potassium levels (Aglony *et al.*, 2011; Mulatero *et al.*, 2011a).

The clinical phenotype of FH-I is extremely heterogeneous and varies widely across affected families or even between members of the same pedigree (Fallo *et al.*, 2004), ranging from resistant hypokalemic hypertension to asymptomatic normotension (Mulatero *et al.*, 2002; Fardella *et al.*, 2000). The possible mechanisms underlying such a wide variation in clinical phenotype have been extensively investigated. Both the site of the crossing over (Pascoe *et al.*, 1992) and the Na^+ intake (Stowasser *et al.*, 2000) were not shown to play a role; an inverse relationship between urinary kallikrein levels and blood pressure in patients affected by FH-I was demonstrated in some families (Dluhy and Lifton, 1995), but not in an Italian pedigree (Mulatero *et al.*, 2002). Similarly, a significant correlation between the levels of the hybrid steroids 18OHF and 18oxoF) levels (as an index of the hybrid enzyme activity) was observed in some families (Mulatero *et al.*, 2002; Wyckoff *et al.*, 2000; Stowasser *et al.*, 2000) but not in others (Dluhy and Lifton, 1995).

With respect to target organ damage, normotensive FH-I affected patients display concentric remodeling and reduced diastolic left ventricular function compared with age- and sex-matched normotensive controls, indicating that aldosterone excess is associated with organ damage at least in part independent from the effects on blood pressure (Stowasser *et al.*, 2005).

FH-I affected patients also display an increase cerebrovascular morbidity and mortality at young age (Litchfield *et al.*, 1998). A large retrospective study including 27 GRA pedigrees, for a total of 167 affected patients, showed that a cerebrovascular complication occurred in 48% of the pedigrees and in 11% of patients with GRA, mainly hemorrhagic strokes, related intracranial aneurysms rupture. The mean age at the occurrence of the event was 32 years. It has been hypothesized that early onset of high blood pressure levels and/or the inappropriate amount of aldosterone during vascular development could determine the formation of cerebral aneurysms (Litchfield *et al.*, 1998). Interestingly, pregnant women affected by FH-I display an increased prevalence of pregnancy-aggravated hypertension but not of preeclampsia (Wyckoff *et al.*, 2000).

Glucocorticoids, which inhibits ACTH-driven aldosterone production, are the cornerstone of FH-I treatment and should be administered at the minimum dose necessary to control blood pressure to avoid iatrogenic Cushing syndrome. According to the ES Guideline (Funder *et al.*, 2016) synthetic glucocorticoids that are longer acting than hydrocortisone, such as dexamethasone or prednisone should be preferred and administered at bed time to suppress the morning ACTH peak. If glucocorticoid administration is not sufficient to control blood pressure a MR antagonist can be added. In case of affected children, in whom there might be concerns related to growth retardation and the antiandrogenic effects of glucocorticoids and spironolactone respectively, eplerenone may be considered the first-line therapy (Funder *et al.*, 2016).

Familial Hyperaldosteronism Type II

Familial hyperaldosteronism type II (FH-II) is an inheritable form of PA transmitted as an autosomal dominant disorder in most of the affected families and not associated to the presence of the chimeric *CYP11B1/CYP11B2* gene. This condition was described for the first time by Gordon *et al.* (1991) at the Greenslopes Hospital Hypertension Unit in Brisbane (Australia). Six relatives from three different families were diagnosed with PA (either APA or BAH) and since none of these patients was positive to the dexamethasone suppression test, the authors named this condition FH-II, to distinguish it from FH-I (Stowasser *et al.*, 1992). In one of the families, two second cousins presented with hypertension and hypokalemia at age of 31 and 29 years, both underwent excision of a left APA and the disease was cured. The second family presented two affected members: a 37-year-old female with hypertension and spontaneous hypokalemia and her 63-year-old father affected by poorly controlled hypertension. Both were diagnosed with APA and underwent surgery. The last family displayed a 46 year-old female with bilateral adrenal hyperplasia (BAH) and her 25 year-old hypertensive daughter; both were hypertensive and hypokalemic (Gordon *et al.*, 1991).

The genetic basis of the disease is still unknown. The study of potential genetic abnormalities causing FH-II has been based on both candidate gene approach and genome-wide search. The involvement of many genes has been excluded: *CYP11B2* (Torpy *et al.*, 1998), the gene coding for the angiotensin II receptor type 1 (Klemm *et al.*, 1995), the locus MEN1 (Stowasser and Gordon, 2001) and the gene coding for oncosuppressor p53 (Ballantine *et al.*, 1996). In 2000, through linkage studies, the FH-II causing gene was mapped to chromosome 7p22 (LOD score 3.26) (Lafferty *et al.*, 2000) and subsequent studies confirmed this locus (LOD score 4.61) (So *et al.*, 2005). Afterwards, the linkage has been demonstrated also in other families belonging to three different continents (Australia, Europe and South America) (Sukor *et al.*, 2008). Sequencing analysis has excluded the involvement of several genes within 7p22, including *PRKAR1B* (Elphinstone *et al.*, 2004), *RbaK*, *PMS2*, and *GNA12* (Jeske *et al.*, 2008). However, for two affected Australian families the linkage with locus 7p22 could not be demonstrated (So *et al.*, 2005) and the role of 7p22 is debated because of the genetic heterogeneity of the families. Moreover, in a recent European multicentric study (Mulatero *et al.*, 2012b) including 21 families with suspected FH-II, one family resulted to be affected by FH-III and in two APAs removed from patients belonging to two different families, a somatic *KCNJ5* mutation was identified, indicating that FH-II is very likely to be a heterogeneous disease.

Since the molecular basis remains unknown, the diagnosis of FH-II is clinical and requires two or more family first-degree members affected by PA together with the exclusion of FH-I and FH-III through long-PCR for chimeric gene *CYP11B1/CYP11B2* and *KCNJ5* sequencing, respectively (Mulatero *et al.*, 2011b; Stowasser *et al.*, 2000).

Clinical, biochemical and morphological features of patients affected by FH-II are indistinguishable from sporadic PA (Mulatero *et al.*, 2011b). In the PATOGEN study, including 27 FH-II patients from 12 different families, 92% of patients presented with arterial hypertension and hypokalemia was present in 35% of the patients (50% of index cases and 18% of relatives with PA). Morphologically patients presented with APA in nearly 18% of cases, in other cases they had bilateral hyperplasia (Mulatero *et al.*, 2011b).

It has been shown in two large series of PA patients from Italy (Mulatero *et al.*, 2011b) and Australia (Stowasser *et al.*, 2011), that FH-II is at least five times more common than FH-I and accounts for around 6% of PA patients. However, the prevalence could be even higher because patients who present with low-renin hypertension could evolve in overt PA over time (Mulatero *et al.*, 2011b). Due to its relatively high prevalence, the Endocrine Society guideline recommend that all hypertensive first-degree relatives of patients with PA should undergo screening test (Funder *et al.*, 2016). Thus, the identification of FH-II in the relatives of PA patients is fundamental in order to establish an appropriate therapy, surgical with unilateral adrenalectomy or medical with mineralocorticoid receptor antagonists (Mulatero *et al.*, 2011b).

Familial Hyperaldosteronism Type III

Familial hyperaldosteronism type III (FH-III) is an inheritable autosomal dominant disorder caused by a germline mutation in the *KCNJ5* gene.

FH-III has been described as a distinct clinical entity by Geller *et al.* (2008) in an American family affected by a non-glucocorticoid-suppressible form of familial hyperaldosteronism. The index case of this family was previously reported by Therien *et al.* (1958) as affected by severe hyperaldosteronism and hypokalemia associated with arterial hypertension, polyuria, polydipsia, and myalgia since childhood. Geller *et al.* (2008) described the biochemical and clinical phenotype of the two daughters of the index case, which presented at the age of 7 and 4 respectively, because of severe resistant arterial hypertension (188/140 mmHg and 148/114 mmHg respectively) and profound hypokalemia (< 2 mEq/L). Furthermore, the two patients showed markedly increased levels of 18-hydroxycortisol, 18-oxocortisol, deoxycorticosterone, and 18-hydroxycorticosterone) (Geller *et al.*, 2008). Both the father and the two daughters required bilateral adrenalectomy in order to normalize aldosterone and potassium levels and to control hypertension (Therien *et al.*, 1958; Geller *et al.*, 2008). Adrenal glands showed bilateral hyperplasia and subverted histological architecture of the adrenal cortex (Gomez-Sanchez *et al.*, 2017). Recently, an immunohistochemical and immunofluorescence study described the distribution of the main steroidogenic enzymes (CYP11B1, CYP11B2, and CYP17) in the adrenal cortex of the glands removed from the two girls. The results showed an unexpected co-expression of CYP11B2 and CYP11B1, CYP11B2 and CYP17 or even all the three enzymes in some cells (Gomez-Sanchez *et al.*, 2017).

Initially, causative mutations remained unknown despite the DNA sequencing of candidate genes. The genetic basis of this disorder has been uncovered through the application of the next generation sequencing, which allowed the identification of the germline p.T158A *KCNJ5* mutation in the affected members (Choi *et al.*, 2011).

KCNJ5 is located on chromosome 11q24 and encodes for GIRK4 (also known as Kir3.4), an inward rectifying potassium channel. This channel forms homotetramer and heterotetramer with GIRK1, encoded by *KCNJ3* gene (Corey and Clapham, 1998). *KCNJ5* is a widely expressed gene and, among the adrenal gland, GIRK4 is expressed in the *zona glomerulosa* and in the outer part of *zona fasciculata* and it shows heterogeneous expression in APA (Choi *et al.*, 2011; Monticone *et al.*, 2012). Physiologically, GIRK4 contribute to maintain a state of hyperpolarization of the cell through a potassium outflow. All the mutations described are localized near or within the selectivity filter of the channel, a highly conserved domain across species (**Fig. 2**). The consequent alteration of the filter causes the loss of ion selectivity, sodium influx and depolarization of the cell membrane which activates voltage-dependent calcium channels. (Oki *et al.*, 2012; Monticone *et al.*, 2015b). The increase in intracellular Ca^{2+} concentration stimulates *CYP11B2* transcription through the transcriptional factor *NR4A2* (Monticone *et al.*, 2012), which finally results in an autonomous and excessive aldosterone production (Oki *et al.*, 2012) (**Fig. 3**).

After the identification of the first mutation (p.T158A) by Choi *et al.*, additional 5 *KCNJ5* mutation and 11 FH-III families have been described. In vitro studies conducted on HAC15 adrenocortical cells demonstrated that p.Y152C substitution caused a milder electrophysiological effect compared to other KCNJ5 mutations (Monticone *et al.*, 2013). Whereas, p.G151E substitution caused cell lethality due to a massive sodium influx and the consequent osmotic shock. However the surviving cells can produce large amount of aldosterone (Scholl *et al.*, 2012; Mulatero *et al.*, 2012b): these results explain the normal size of the adrenals and the less severe clinical phenotype in comparison with patients with other mutations.

According to the Endocrine Society guideline, the diagnosis of FH-III should be ruled out in all patients presenting with PA at very young age (Funder *et al.*, 2016), through *KCNJ5* sequencing of DNA obtained from a peripheral blood sample.

Initially the diagnosis was based on the particular clinical features displayed by the family described by Geller *et al.* (2008), but it became evident that these characteristics are not present in all FH-III families. Clinically, the majority of the patients displayed an early onset of PA, hypokalemia, polyuria, polydipsia, and resistant hypertension. However it is important to underline that the clinical phenotype is influenced by the type of *KCNJ5* mutation.

In addition to p.T158A (Choi *et al.*, 2011; Geller *et al.*, 2008; Therien *et al.*, 1958) five other germline mutations (p.G151E, p. G151R, p.I157S, p.Y152C, and p.E145Q) have been identified.

The p.G151E mutation has been reported in three different families, affecting a total of seven patients (Scholl *et al.*, 2012; Mulatero *et al.*, 2012a; Mussa *et al.*, 2012; Greco *et al.*, 1982; Bartter and Biglieri, 1958), who were all diagnosed with PA because of high aldosterone levels and suppressed renin activity. The affected members of the family from Italy showed mildly increased levels of the hybrid steroids within the range of sporadic PA (Mulatero *et al.*, 2012a,b) and they did not show any changes in aldosterone after dexamethasone suppression test. All patient except two showed severe hypertension and low potassium levels with onset in early childhood, which were well controlled by pharmacological therapy with spironolactone and amiloride (only two patients underwent bilateral adrenalectomy) (Scholl *et al.*, 2012). Moreover, none of the affected patients showed adrenal hyperplasia at adrenal imaging.

The p.G151R substitution (Scholl *et al.*, 2012; Adachi *et al.*, 2014; Monticone *et al.*, 2017) has been identified in six patients from four different families. The clinical phenotype was similar to that observed in patients carrying the p.G151E mutation, with early onset of the disease but in this case PA was progressive. Only in the patient reported by Adachi *et al.* (2014) hypertension and

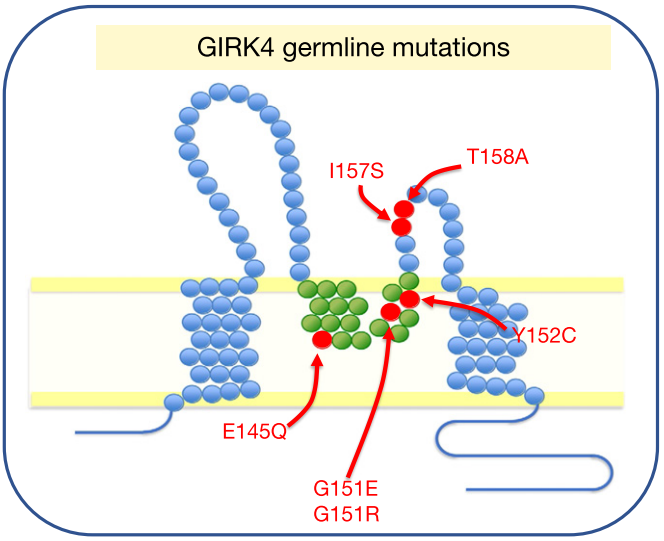

Fig. 2 GIRK4 structure and summary of the germline mutations leading to FH-III. All the mutations are located near or within the selectivity filter of the channel (represented in *green*).

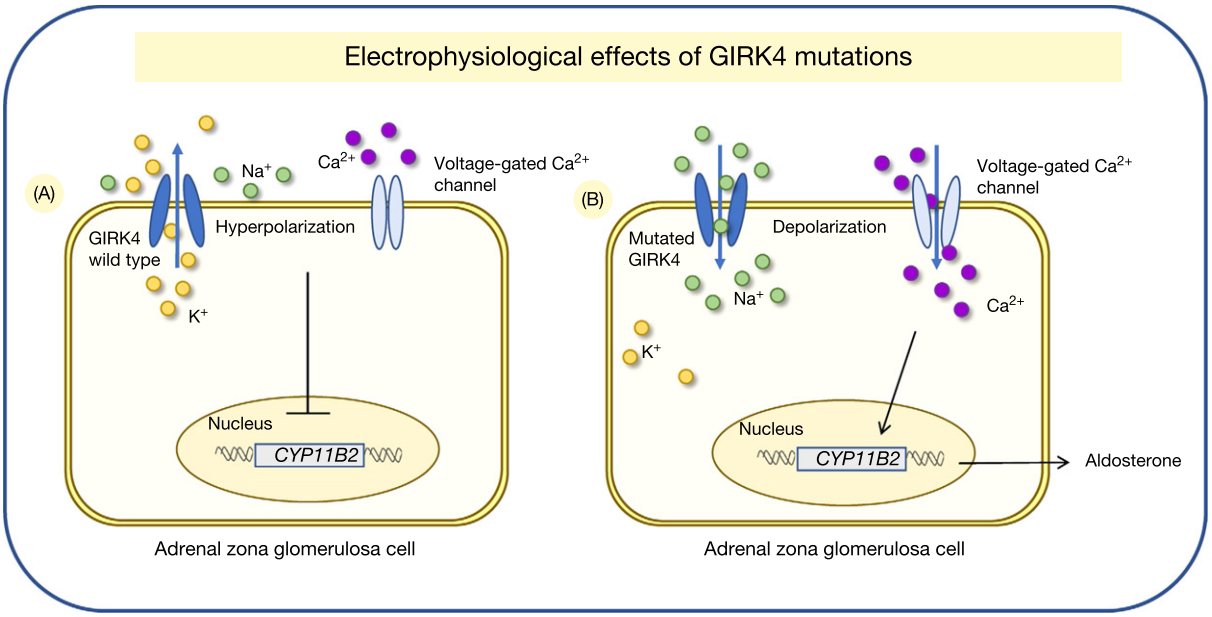

Fig. 3 (Panel A) In adrenal zona glomerulosa cells, GIRK4 wild-type is responsible for K^+ outflow and the cell membrane is maintained in a hyperpolarized state. (Panel B) The mutations, located in proximity of the selectivity filter of the channel result in loss of ion selectivity, Na^+, cell membrane depolarization, opening of voltage-gated Ca^{2+} channels and finally autonomous aldosterone overproduction.

hypokalemia were controlled by spironolactone and adrenal imaging was normal (Adachi *et al.*, 2014). All the other patients required bilateral adrenalectomy in order to control blood pressure, hypokalemia and symptoms mimicking diabetes insipidus. Moreover, histological analysis confirmed nodular hyperplasia in one patient and diffuse hyperplasia of adrenal cortex of three out of four patients who underwent surgery.

The p.I157S mutation (Charmandari *et al.*, 2012) has been identified in two members of a single family displaying resistant hypertension, marked hypokalemia and severe adrenal enlargement which required bilateral adrenalectomy.

The p.Y152C mutation (Monticone *et al.*, 2013) was reported in an African-American woman who was diagnosed with arterial hypertension when she was 48 year old. She had left adrenalectomy on the basis of adrenal CT scanning, but the intervention was not curative and serum aldosterone levels did not normalize.

Finally, the p.E154Q substitution (Monticone *et al.*, 2015b; Tong *et al.*, 2016) has been reported in two patients from two different families: a Caucasian girl who presented with severe PA requiring bilateral adrenalectomy and a Chinese boy who was diagnosed with PA and Cushing syndrome and had left adrenalectomy.

This condition is rare and its prevalence has not been evaluated in large population; Mulatero *et al.* (2012a,b) reported a 0.3% prevalence among patients with PA and 8% prevalence among familial forms.

Familial Hypertension Hyperaldosteronism Type IV

FH4 is a familial form of primary aldosteronism due to germline mutations in the *CACNA1H* gene, encoding a T-type calcium channel, Cav3.2. *CACNA1H* is expressed in kidney, liver, heart, brain (Cribbs *et al.*, 1998) and it is the second most expressed Ca^{2+} channel in the adrenal zona glomerulosa (Scholl *et al.*, 2013), where it is activated at small depolarizing potentials (Perez-Reyes 2003). Cav3.2 is composed by four homologous repeats (I-IV) and each of them has six transmembrane segments (S1–S6).

Using whole exome sequencing in patients with hypertension and onset of PA by the age of 10 years), a novel germline heterozygous *CACNA1H* mutation (p.Met1549Val) has been identified in five unrelated subjects (Scholl *et al.*, 2013). The index cases carrying the p.Met1549Val substitution showed early onset hypertension and PA with normal appearing adrenal glands at adrenal CT scanning, without any other distinctive clinical or biochemical feature. Targeted sequencing of *CACNA1H* in first- and second-degree relatives of the index cases, identified five more subjects carrying the p.Met1549Val substitution, among four families (in one case it was a de novo mutation). The substitution segregated with the disease in one kindred, but, in two other families, two mutation carriers did not display the PA phenotype and were normotensives, indicating an incomplete penetrance. Histological examination of an adrenal gland removed from a FH-IV patient (because of difficult to control hypertension) revealed microscopic hyperplasia of the zona glomerulosa with micronodular invasion of the capsule (Scholl *et al.*, 2013; Korah and Scholl, 2015).

Following the original finding by Scholl *et al.*, four other germline *CACNA1H* mutations have been identified in PA patients (p.Met1549Ile, p.Ser196Leu, p.Pro2038Leu, and p.Val1951Glu) (Daniil *et al.*, 2016). The index case carrying the p.Met1549Ile

showed early onset PA with mild mental retardation at the age of 7 and a diagnosis of multiplex developmental disorder was made 3 years later. The patients carrying the p.Ser196Leu, the p.Pro2083Leu, and the p.Val1951Glu were diagnosed with arterial hypertension between the age of 32 and 48, in two cases there was a familial history of hypertension and PA and in one case (p.Val1951Glu) the patient was affected by apparently sporadic APA (Daniil *et al.*, 2016). Adrenal CT scanning was normal in patients carrying the p.Met1549Ile and in two patients carrying the p.Pro2083Leu mutations; the index case carrying the p.Ser196Leu showed bilateral nodules at adrenal CT scanning; one patient carrying the p.Pro2083Leu mutation had left adrenal hyperplasia and the patient carrying the p.Val1951Glu mutation had a single 8 mm left adrenal nodule (Daniil *et al.*, 2016).

Under physiological conditions, Cav3.2 is activated in response to physiological small changes in aldosterone, angiotensin II and potassium serum levels and the activation threshold is -60 mV, followed by a very fast inactivation. Met1549 lies in a conserved position in the S6 helix of repeat 3 (Marksteiner *et al.*, 2001) and functional studies on the paralogous CACNA1G showed that it regulates channel inactivation. Electrophysiological studies on HEK293T cells demonstrated that p.Met1549Val Cav3.2 showed loss of normal inactivation together with a shift of activation to more hyperpolarized potentials (Scholl *et al.*, 2013). To examine these electrophysiological effect on aldosterone production, the p.Met1549Val channel was expressed in the adrenocortical cell lines HAC15 (Reimer *et al.*, 2016). As expected, overexpression of the mutant Cav3.2 resulted into a sevenfold increase in aldosterone levels compared with vector-transfected cells and this effect was mediated by the increased expression of *CYP11B2*, thereby linking the presence of this mutation to the clinical PA phenotype (Reimer *et al.*, 2016).

In conclusion, *CACNA1H* seems to represent a susceptibility gene that may predispose to PA development, which in turn could present with a wide range of clinical phenotypes (Daniil *et al.*, 2016).

PASNA Syndrome

PASNA (primary aldosteronism with seizures and neurologic abnormalities) is a new mendelian syndrome characterized by primary aldosteronism and neurological manifestations, such as seizures and neuromuscular disease. The molecular basis of PASNA is represented by gain of function mutations in the *CACNA1D* gene (Scholl *et al.*, 2013), which encodes the $\alpha 1$ subunit of a L-type voltage gated calcium channel, Cav 1.3, expressed in adrenal glomerulosa cells, heart and neurons (Baig *et al.*, 2011). Cav 1.3 is formed by four repeated domains with six transmembrane segments (S1–S6) and a membrane associated loop between S5 and S6, which line the channel pore. In normal quiescent adrenal glomerulosa cells, the cell membrane is maintained in a hyperpolarized state, preventing the opening of voltage-gated calcium channels. Mutations in *CACNA1D* alter the cytoplasmatic end of the S6 segment of domains I and II, causing channel activation at less depolarized potentials and altered channel inactivation. As a consequence, the channel opens at more hyperpolarized potentials, closer to the glomerulosa resting potentials, causing an increase in intracellular calcium concentration. Increased calcium influx in glomerulosa cells leads to aldosterone production and cell proliferation, while neurological manifestations are due to abnormal neuronal calcium signaling (Scholl *et al.*, 2013, 2015).

CACANA1D (somatic) mutations have been identified through exome sequencing studies in sporadic APA (Azizan *et al.*, 2013; Scholl *et al.*, 2013; Monticone *et al.*, 2015a) and, subsequently, the Gly403Asp and the Ile770Met substitution have been found as germline mutations in two individuals affected by severe hypertension and neurological manifestations. Both the index cases had healthy parents, demonstrating that de novo germline mutations occurred (Scholl *et al.*, 2013).

The affected children manifested early onset severe hypertension, hypokalemia and seizures. The first patient is a female of European ancestry who suffered from severe hypertension at birth (119/78 mmHg), biventricular hypertrophy, ventricular septal defect, pulmonary hypertension and second degree heart block. Laboratory testing revealed high aldosterone levels, (128.6 ng/dL), low PRA (0.78 ng/mL/h) and hypokalemia. At 7 months the patient had her first generalized tonic-clonic seizures. Other neurological manifestations include apparent cerebral palsy, cortical blindness, neuromuscular abnormalities. Interestingly, blood pressure was normalized by the calcium channel blocker amlodipine and ventricular hypertrophy regressed (Scholl *et al.*, 2013, 2015).

The second patient is an African American female, with cerebral palsy, spastic quadriplegia, mild athetosis, severe generalized intellectual disability, complex and partial seizures at birth. She developed severe hypertension (132/90 mmHg) at the age of 5 years. The diagnosis of primary aldosteronism was made on the basis of hypokalemia, metabolic alkalosis, high serum aldosterone levels (36 ng/dL) and suppressed PRA with elevated ARR. Echocardiography demonstrated mild left ventricular hypertrophy. The patient was treated with clonidine and then spironolactone. CT scan shows normal adrenals.

Different mutations lead to variable calcium conductance, resulting in variable cell lethality. Individuals with mutations causing cell lethality do not develop adrenal hyperplasia (Scholl *et al.*, 2013).

The response of the first patient to a calcium channel blocker may lead to the possibility of a specific treatment for individuals affected by APAs and *CACNA1D* mutations. These drugs are weak antagonists of wild type Cav 1.3, but more specific inhibitors could represent a possible treatment of individuals with *CACNA1D* mutations (Scholl *et al.*, 2013).

Conclusions

The recent advances in the genetics of familial hyperaldosteronism have provided new insight in the molecular mechanisms responsible for autonomous aldosterone overproduction. The identification of a familial form of PA is of outmost importance, in order to establish an early diagnosis, plan a close follow-up of the affected subjects and promptly start a targeted therapy, in order to prevent the cardio- and cerebrovascular complications associated to aldosterone excess.

Aldosterone-Producing Adenomas; Genetics

Livia Lenzini, Sofia Zanin, and Gian Paolo Rossi, University of Padua, Padua, Italy

Mutations in K + Channel in Aldosterone-Producing Adenoma

In 2011, using exomes sequencing Choi *et al.* in about 34% of 22 aldosterone-producing adenoma (APA) discovered mutations in the selectivity filter of the KCNJ5 gene, which codes for the Kir3.4 K^+ channel (Choi *et al.*, 2011). This channel is highly expressed in the aldosterone-producing cells of the zona glomerulosa (ZG) and plays a key role in maintaining cell hyperpolarized (Choi *et al.*, 2011) (**Fig. 1**, Panels A and B). The Authors identified two recurrent functional variants (G151R and L168R) in this highly conserved region of the K^+ channel, which allows the exit of K^+ from the cells in a selective fashion, which means with exclusion of other ions. Using cloning techniques and site-directed mutagenesis they could show that mutant-transfected cells in vitro exhibit perturbation in both size and charge of the selectivity filter, resulting in permeability to Na^+, Na^+ influx, and membrane depolarization (**Fig. 2**, Panel A).

After this first report several other mutations were identified, both in the same "hot spot" region of the gene and also outside this region (for review see Zennaro *et al.*, 2017). All were found to impair the selectivity of the filter for K^+ and to allow Na^+ influx, leading to ZG cell membrane depolarization, opening of T type Ca^{2+} channels, Ca^{2+} influx and activation of aldosterone synthesis and secretion. A further novel somatic mutation consisting of a 3 bp insertion (446insAAC) outside of the selectivity filter, thus differing from all previously known mutations, which are located in the selectivity filter, was identified by our group (Kuppusamy *et al.*, 2014). The phenotype associated with this mutation featured severe drug-resistant hypertension that had been previously complicated by an ischemic stroke, and evidence of prominent target organ damage, including left ventricular hypertrophy. At the cellular level this mutation behaved like the other known mutations in that caused increased permeability for Na^+, cell membrane depolarization, and increased Ca^{2+} influx. However, with use of specific inhibitors we could show that this occurred not only via voltage-dependent T Type Ca^{2+} channels opening, but also via the Na^+/Ca^{2+} exchanger working in the reverse mode, for example, Na^+ out and Ca^{2+} in. These changes resulted in overexpression of the aldosterone synthase (CYP11B2) gene and constitutive over-production of aldosterone by the tumor. A different mutation in the same region (445-446insGAA) was thereafter found in a cohort of Chinese APA patients that exhibited a very high prevalence (77%) of KCNJ5 mutations (Zheng *et al.*, 2015). Thus, it seems that the selectivity of the pore can be affected also by mutations located outside of the filter region through mechanisms discussed in details in our paper (Kuppusamy *et al.*, 2014).

Why these mutations occur in this region of the gene is unclear; similarly, unclear is why these KCNJ5 mutations are found to be more common in patients from Asia (Japan and China) than in other continents. In fact, the overall prevalence of KCNJ5 mutations was 43% (range = 12%–80%), but in studies done in Europe, USA, and Australia (35%) their rate was lower ($P < 0.003$) than in Japan and China (63%), as reported in a large meta-analysis (Lenzini *et al.*, 2015).

The latter also showed that the phenotypic features of APA patients with KCNJ5 mutations comprised more pronounced hyperaldosteronism, young age, female gender and larger tumors, but no significant differences in blood pressure and serum K^+. Hence, the latter clinical features do not help in identifying KCNJ5-mutated APA patients.

Effect of Somatic Mutations in K + Channel on Cell Growth

Notwithstanding all these novel discoveries, it remains unclear whether these mutations play any mechanistic role in adenoma growth. This is because, when transfected with mutated KCNJ5 (T158A) channels, adrenocortical cells did show a decreased, rather the hypothesized increase of rate proliferation compared to the wild type cells (Oki *et al.*, 2012). Moreover, cells with mutations in the same codon, the G151R and the G151E mutation, showed an altogether different lethality, which was higher in the former than in the latter and in wild type cells, and was shown to depend on the enhanced conductance for Na^+ (Scholl *et al.*, 2012). It was contended that this latter finding might explain why this mutation did not associate with signs of adrenal hyperplasia and translated in a milder form of familial hyperaldosteronism (Scholl *et al.*, 2012; Mulatero *et al.*, 2012) that responded well to antihypertensive therapy.

The discrepancy between the antiproliferative effect of KCNJ5 mutations, due to the high intracellular concentrations of Na^+ and Ca^{2+}, and the development of the adenoma was suggested to be explained by the observation that APA cells are protected against Ca^{2+}-induced cell death by the calcium-sensor protein Visinin-like 1 (VSNL1). Consistently with this hypothesis VSNL1 would seem to be more expressed in KCNJ5 mutated than in wild type APAs; moreover, its silencing rendered H295R cells sensitive to Ca^{2+}-induced apoptosis (Williams *et al.*, 2012).

Mutations in ATP1A1 and ATP2B3 Genes

In Caucasians, only a minority of APA show KCNJ5 mutations, which seem to predominate in zona–fasciculata-like than in zona glomerulosa-like APA cells (Azizan *et al.*, 2012). Hence, a search for further candidate genes by exome sequencing in non

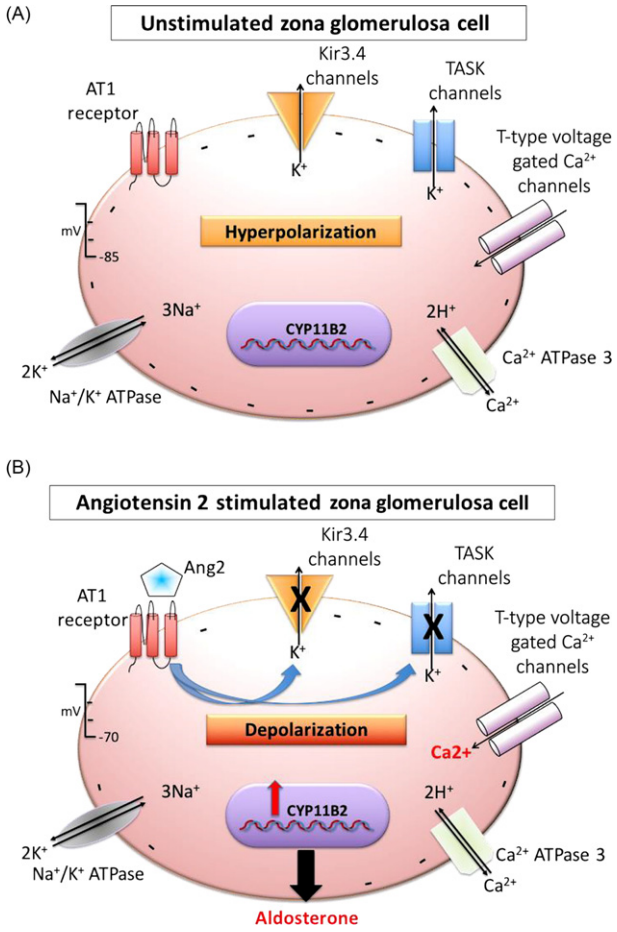

Fig. 1 *Regulation of aldosterone production in normal adrenocortical zona glomerulosa (ZG) cells and effects of aldosterone secretagogue.* Under normal condition, ZG cells have a resting potential of about −85 mV, which means that they are hyperpolarized, through the activity of the TASK and Kir K^+ channels. This hyperpolarization state maintains voltage gated T-type Ca^{2+} channels in a low open state probability. Therefore, the ZG cells do not produce aldosterone (*Panel A*). In the presence of an aldosterone secretagogue stimulus, such as Angiotensin 2, the activity of the TASK and Kir K^+ channels is blunted and the cell is depolarized. This opens the voltage gated T-type Ca^{2+} channels with an increase of intracellular Ca^{2+} and the stimulation of aldosterone biosynthesis (*Panel B*).

KCNJ5-mutated APA composed of zona glomerulosa cells led to the discovery of mutations in ATP1A1 and ATP2B3 genes (Azizan *et al.*, 2013; Beuschlein *et al.*, 2013; Scholl *et al.*, 2013).

ATP1A1, located on chromosome 1p21, encodes the alpha-1 subunit of the Na^+/K^+-transporting ATPase; the ATB2B3 gene, located on chromosome Xq28, encodes the plasma membrane Ca^{2+}-transporting ATPase 3. The former regulates the resting membrane potential by exchanging three cytoplasmic Na^+ ions for two extracellular K^+; the latter is involved in Ca^{2+} homeostasis by exchanging one cytosolic Ca^{2+} with two H^+ (**Fig. 1**, Panels A and B).

Loss-of-function variants of the Na^+/K^+ ATPase gene ATP1A1 were found in 5.2% of APA (Beuschlein *et al.*, 2013). In vitro models of these mutations exhibit abnormal leak currents of H^+ leading to intracellular acidification (L104R, V332G) and/or of Na + ions (L104R, V332G, G99R) (**Fig. 2**, Panel A) (Stindl *et al.*, 2015). Mutations of the Ca^{2+}-ATPase gene ATP2B3 were discovered in 1.6% of APA and reported to increase intracellular Ca^{2+} concentration (**Fig. 2**, Panel D) (Beuschlein *et al.*, 2013).

Mutations in CACNA1D Gene

Gain-of-function somatic mutations of the CACNA1D gene, coding for the voltage-gated calcium channel Cav1.3, were reported in 5%–9% of APA (Azizan *et al.*, 2013; Scholl *et al.*, 2013; Fernandes-Rosa *et al.*, 2014). These mutations cause Cav1.3 activation at less depolarized potentials with ensuing increased Ca^{2+} influx (**Fig. 2**, Panel C). According to two small studies, APA carrying these mutations would be mainly composed of zona glomerulosa cells (Tan *et al.*, 2017; Monticone *et al.*, 2015), but larger studies are obviously necessary.

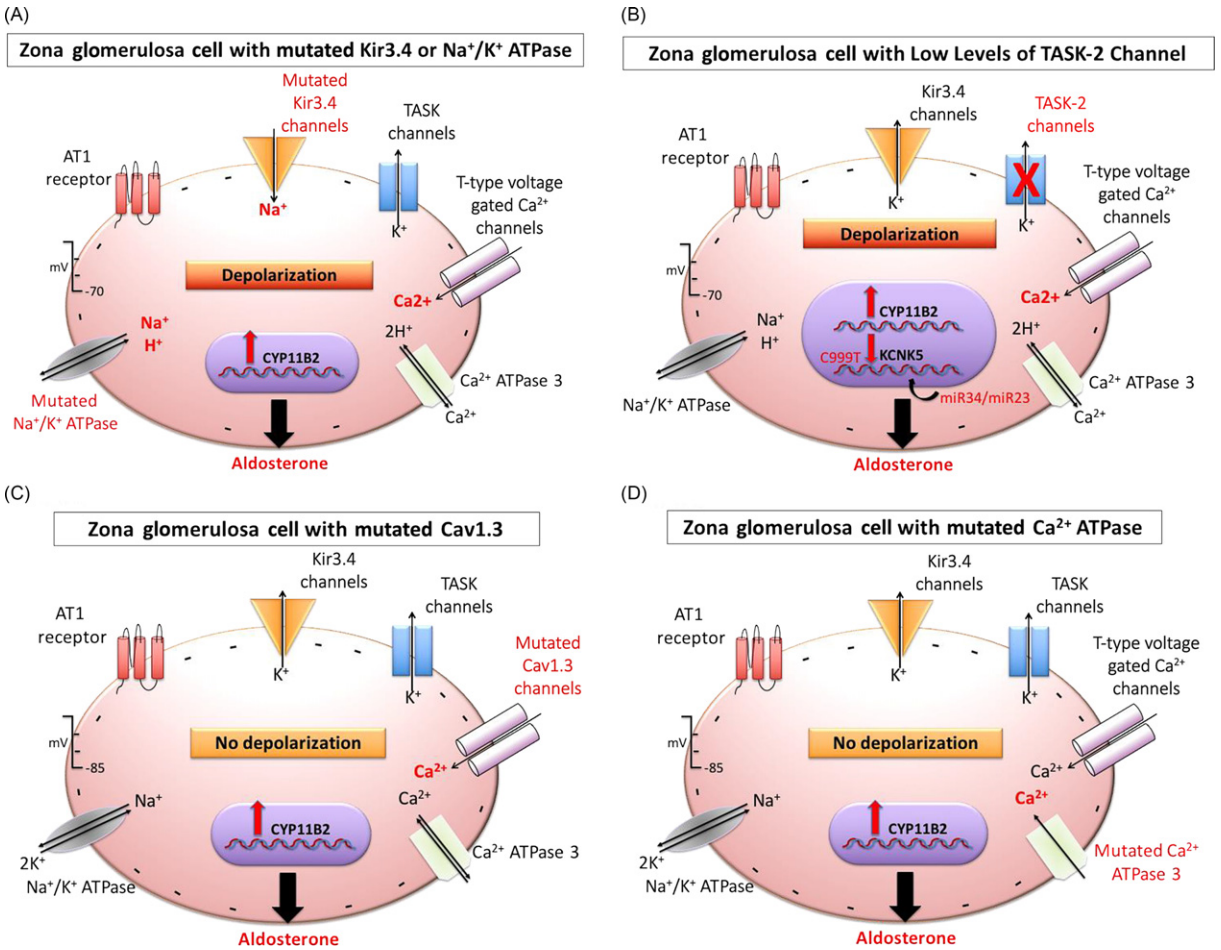

Fig. 2 *Genetic causes of aldosteronism in aldosterone-producing adenoma (APA).* In a percentage of sporadic APA (12%–80%) mutations lead to depolarization of the cell, with ensuing entry of Ca^{2+} via Voltage Gated T-type Ca^{2+} channels and autonomous production of aldosterone. This can occur as a result of Kir3.4 (KCNJ5) mutations, which cause a loss of selectivity for K^+ and Na^+ influx, or of functional mutations in the Na^+/K^+ ATPase leading to abnormal leak currents of H^+ and/or of Na^+ and increased intracellular acidification. (*Panel A*). The TASK-2 channel is expressed at very low levels as compared to normal adrenocortical tissues in all APA, due to multiple molecular mechanisms, including degradation of TASK-2 RNA by the miR23 and miR34 in about 25% of the cases and functional mutations in the promoter region of the TASK-2 gene in another 25% of the cases (*Panel B*). Panels C and D illustrate two additional genetic causes of aldosteronism in APA in which intracellular Ca^{2+} levels are increased without changes in the membrane potential as the cell remain hyperpolarized, either because of the presence of mutated Cav1.3 (*Panel C*), or because of Ca^{2+} ATPase 3 (*Panel D*), in both cases with ensuing augmented Ca^{2+} influx and subsequent stimulation of aldosterone synthesis.

Genetic Heterogeneity of APA

The recent development of a specific antibody able to discriminate aldosterone synthase from the highly homologous 11β hydroxylase (Gomez-Sanchez *et al.*, 2014) has made possible to achieve a more precise immunochemical characterization of the APA. This led to the discovery that nodules expressing the aldosterone synthase and coexisting in the same explanted adrenal gland can express two different KCNJ5 mutations (Dekkers *et al.*, 2014), and/or mutations in KCNJ5 and CACNA1D (Fernandes-Rosa *et al.*, 2015). Moreover, up to seven different mutations in KCNJ5 and CACNA1D were detected in macro-dissected nodules in CT cross-sectional image–negative cases (Yamazaki *et al.*, 2016).

Role of the Twik Related Acid Sensitive K^+ (TASK) Channels in Primary Aldosteronism

The crucial role of K^+ in regulating aldosterone secretion confirmed by the studies described above stands also on the well-established notion that zona glomerulosa cells are exquisitely sensitive to extracellular K^+ in that small elevations in serum K^+, even within the physiological range, are known to increase cell sensitivity to angiotensin II and other aldosterone secretagogue stimuli (**Fig. 1**, Panels A and B) (Spat and Hunyady, 2004). Hence, K^+ represents a key modulator of aldosterone secretion not

only due to its direct effects, but also because of its permissive role on the action of other agents that stimulate aldosterone secretion. Compelling evidences indicate that K^+ channels activity sets the resting membrane potential of aldosterone-producing zona glomerulosa cells and that the intrinsic oscillations of these cells, due to Cav3.2 Ca^{2+} currents, could explain the remarkable sensitivity of aldosterone production in vivo to small incremental changes (0.1 mEq/L) in plasma K^+ (Hu *et al.*, 2012).

Three TASK channels (TASK-1, 2 and 3) are primarily expressed in the adrenal gland (Bayliss and Barrett, 2008). They are coded by the KCNK genes and form active channels through homo- and hetero-dimerization, and show persistent activity at negative membrane potentials, generating background, or "leak," K^+ currents (**Fig. 1**, Panel A).

Of note, the TASK channels are considered to be essential for maintaining a negative resting membrane potential, and therefore for keeping the T-type-calcium channels closed, thus preventing Ca^{2+} influx. Mice knocked-out for both the TASK-1 and TASK-3 genes developed a phenotype resembling human PA in that it features sodium-dependent hypertension with low plasma renin and K^+ and hyperaldosteronism (Davies *et al.*, 2008). The mice with homozygous knock-out of only one channel generated two distinct forms of hyperaldosteronism: the TASK-1 knock-out caused a severe hyperaldosteronism with low-renin hypertension, and a defective adrenocortical zonation. These alterations were glucocorticoid-remediable, albeit only in females (Heitzmann *et al.*, 2008), thus resembling familial hyperaldosteronism type 1 (FH-1) (Lifton *et al.*, 1992). At variance, the TASK-3 knock-out caused a low-renin, salt-sensitive hypertension (Penton *et al.*, 2012; Bandulik *et al.*, 2013; Guagliardo *et al.*, 2012).

In humans, TASK channels are expressed in both the normal adrenal cortex and in APA tissues (Nogueira *et al.*, 2010), but we found the TASK-2 gene KCNK5 to be consistently under-expressed in APAs at both the transcript (**Fig. 2**, panel B) and the protein levels, as compared to the normal human adrenal cortex (Azizan *et al.*, 2012), a finding confirmed in a larger group of consecutive APAs with a low (23%) rate of KCNJ5 mutations (Lenzini *et al.*, 2014). This consistent under-representation in APA than in the normal adrenal cortex was an unexpected and striking finding given the known marked molecular heterogeneity of APAs (Lenzini *et al.*, 2007), but was, however, reported also in the public expression profiles of the GEO Profile Database on human normal adrenal cortex and APA, (Profile 1: GDS3912/219615_s_at; Profile 2: GDS2860/219615_s_at).

Therefore, the blunted expression of this channel can be a common molecular hallmark of these tumors. To prove this hypothesis a dominant-negative mutant of TASK-2 was stably transfected in H295R cells, an approach that allowed to show the involvement of TASK-2 channel in the regulation of aldosterone production in humans: compared to cells transfected with an empty vector, those carrying the dominant negative mutant exhibited a higher CYP11B2 and STAR expression and an increased production of aldosterone. By integrating the transcriptome analysis with microRNA profiling and using a site-directed mutagenesis technique combined to a reporter gene assay it was proven that two microRNAs (hsa-miR-23 and hsa-miR-34a), which were highly expressed in a percentage of APA but not in the zona glomerulosa surrounding the tumor, bind to the 3′ UTR of the TASK-2 gene and modulate its expression. Therefore, an up-regulation of the hsa-miR-23 and hsa-miR-34a microRNAs could lead to enhanced degradation of the TASK-2 channels, and thereby to cell membrane depolarization, with ensuing increased of Ca^{2+} influx and stimulation of steroidogenesis (**Fig. 2**, Panel B).

Since the under-expression of TASK-2 could be explained by enhanced expression of hsa-miR-23 and hsa-miR-34a in only 25% of APA, we investigated in a further study if variations in the promoter sequence of KCNK5 gene can lead to a low expression of TASK-2 in the remaining two third of APA (Lenzini *et al.*, 2017). To this end, the promoter region of KCNK5 was sequenced in APAs ($n = 76$), primary hypertensive patients ($n = 98$) and 20 years-old healthy volunteers ($n = 71$), searching for variants that could affect the expression of this channel. We found TASK-2 promoter mutations in another 25% of the APA: C999T in 6.6%, G595A in 5.3%, G36A in 5.3%, and C562T, Gins468, G265C, C1247T, G1140T and C1399T in 1.3% (each). The C999T mutation was detected in only one of the 98 primary hypertensive patients, but mutations were also in 12% of volunteers: four carried the C999T, three G1288C, one the G1140T mutation and one the 468ins.

The effect of C999T mutation was investigated in H295R cells using reporter vectors with the mutated or the wild-type (WT) TASK-2 promoters. TASK-2 gene expression was decreased by 31% (± 18, $P = 0.01$) in mutated, as compared to WT APA. Likewise, in transfected H295R cells, the C999T mutation decreased TASK-2 transcriptional activity by 35% (normalized luciferase signal fold change: 0.65 ± 0.25 $P < 0.001$).

Thus, mutations in the promoter region of the TASK-2 gene can account for the low expression in 25% of APA (**Fig. 2**, Panel B). After 16 years follow-up none of the healthy subjects developed hypertension or PA, indicating that either the predisposition carried by these gene variants require a very long time and/or may become apparent only late in life and/or other gene variants, yet unknown, are necessary for APA to develop. These variants could act as predisposing factors that, when associated with other genetics variations acquired by the adrenal gland, for example, somatic mutations in other genes involved in the autonomous production of aldosterone, and/or with environmental factors, can eventually concur to the development of PA in a relevant proportion of the cases.

Mutations of the WNT/β-Catenin Pathway

The role of WNT/β-catenin signaling in APA was also considered since transgenic mice with specific activation of β-catenin in the adrenal cortex showed increased aldosterone production due to aberrant adrenal cortex zonation (Berthon *et al.*, 2010). Canonical Wnt signaling has a key role in the development of the adrenal cortex by regulating the translocation of β-catenin to the nucleus, where it controls key gene expression programs through interaction with transcription factors (El Wakil and Lalli, 2011). A constitutive activation of WNT/β-catenin signaling was found in 70% of APA; it was not associated with mutations in the β-catenin

1 gene (CTNNB1), but with low levels of SFRP2 (Secreted frizzled related protein 2), a WNT signaling inhibitor (Berthon *et al.*, 2014). In a cohort of 198 APAs, somatic CTNNB1 mutations were found in 5.1% of the tumors and to be mutually exclusive from the other mutations in KCNJ5, ATP1A1, ATP2B3 and CACNA1D. All known mutations occurred on serine/threonine residues in the GSK3β binding domain in exon 3, suggesting activation of WNT signaling (Åkerström *et al.*, 2016).

According to another study on 219 APA patients, CTNNB1 mutations were found in 8 subjects (3.7%) 6 of whom women. Clinically, these patients had higher risk of postadrenalectomy residual hypertension as compared to the other APA patients, while molecularly they have heterogeneous expression of CYP11B1 and CYP11B2, and of the gonadal receptors LHCGR and GnRHR (Wu *et al.*, 2017). Thus, CTNNB1 mutations and activation of the WNT pathway in APAs seem to be more related to mechanisms causing tumor development, as suggested by the two hit model (Lalli *et al.*, 2016), rather than aldosterone overproduction (Zennaro *et al.*, 2017).

Other Genes Changes

Recently an over-expression of Calneuron -1, a Ca^{2+} binding protein of the endoplasmic reticulum, was reported in APA and found to be associated with increased endoplasmic Ca^{2+} and CYP11B2 expression (Kobuke *et al.*, 2018). As what matters for aldosterone biosynthesis is not endoplasmic Ca^{2+} content, but rather mitochondrial Ca^{2+} content, how this increased endoplasmic Ca^{2+} can lead to increased mitochondrial Ca^{2+} and whether the mitochondrial Ca^{2+} uniporter is involved needs further research.

Another gene seemingly over-expressed in APA is the CXCR4, a chemokine receptor, which was described to be up-regulated in about two thirds of a relatively small series of APA and to correlate with CYP11B2 expression (Heinze *et al.*, 2018). The relevance of this may be that a ligand for this receptor could be used in a PET MR imaging to detect APA noninvasively, which means without performing adrenal vein sampling (AVS). However, the limited data in support of this suggest extreme caution before this strategy can be proposed to replace AVS (Heinze *et al.*, 2018).

Conclusions

There is little doubt that there are no other fields of human hypertension where the progresses in understanding the molecular mechanisms have been so terrific as in primary aldosteronism in the last decades. The detection of expression changes of channels regulating K^+ and Ca^{2+} content has opened a new avenue in the knowledge of mechanisms regulating aldosterone secretion with implications for the development of pharmacological target treatment. The recent report that L168R and G151R KCNJ5 mutated cells are specifically sensitive to inhibition with macrolides and their derivatives (Scholl *et al.*, 2017), followed by our demonstration that clarithromycin blunts aldosterone synthesis and secretion in APA cells ex vivo (Caroccia *et al.*, 2017) testifies the clinical implications of these discoveries that open the way to in vivo studies in the M.A.P.A. trial (Maiolino *et al.*, 2018).

Apparent Mineralocorticoid Excess

Padiporn Limumpornpetch, University of Leeds, Leeds, United Kingdom and Prince of Songkla University, Songkhla, Thailand
Paul M Stewart, University of Leeds, Leeds, United Kingdom

Background

Apparent mineralocorticoid excess (AME) is caused by impairment of the enzyme 11 β-hydroxysteroid dehydrogenase type 2 (11β-HSD2). AME is rare; worldwide less than 100 cases have been reported, typically characterized by early onset of hypertension with hypokalemia, metabolic alkalosis, low renin activity, and low aldosterone level. The first patient, described by Maria I. New and colleagues (New *et al.*, 1977; Ulick *et al.*, 1977), was a 3-year old Zuni Indian girl with the history of failure to thrive, low renin-aldosterone hypertension, hypokalemia, cardiomegaly who responded well to a salt restricted diet, and spironolactone. The condition was termed AME because the excess mineralocorticoid was not found. Later in 1979, Ulick and colleagues proposed that the cause of AME related to a defect in peripheral metabolism of cortisol to cortisone (Ulick *et al.*, 1979). In 1983, New and colleagues demonstrated that hypertension and hypokalemia could be induced in AME patients by infusing variable doses of cortisol; this discovery led to our understanding that cortisol plays a major role as a potent mineralocorticoid in such cases (Oberfield *et al.*, 1983). In 1988, Stewart and colleagues found that 11β-HSD2 deficiency of the kidney is the main pathological cause of this syndrome with excessive cortisol action at the mineralocorticoid receptor (MR) (Stewart *et al.*, 1988). Today we have a clear understanding of pathophysiology and the genetic molecular basis of AME.

Pathophysiology and Molecular/Genetic Basis of AME

Cortisol is a biologically active glucocorticoid which is essential for life. At a prereceptor and cellular level, glucocorticoid action is regulated mainly by 11β-hydroxysteroid dehydrogenase (11β-HSD) isoenzymes and the corticosteroid receptors, glucocorticoid receptor (GR), and mineralocorticoid receptor (MR). The tissue-specific expression of 11 β-HSD's and GR/MR play an important role in regulation of the mineralocorticoid and glucocorticoid effects. In humans, two 11β-HSD isozymes have been described, 11 β-HSD-1 and 11β-HSD2, that interconvert active cortisol and inactive cortisone. 11β-HSD1 is a bidirectional enzyme capable of both 11-oxo reductase and dehydrogenase activity dependent on the available cofactor ($NADP/H^+$). The predominant reaction is the oxoreductase pathway critically dependent on high NADPH concentrations generated by hexose-6-phosphate dehydrogenase (H6PDH) within the endoplasmic reticulum. 11β-HSD1 is found in liver, lung, gonads, pituitary, brain, adipose, bone, muscle, and stromal tissues where activation of cortisol from cortisone facilitates cortisol action via the GR. On the contrary, 11 β-HSD2 is a high affinity nicotinamide adenine dinucleotide (NAD) dependent dehydrogenase that inactivates cortisol to cortisone. Expressed predominantly in mineralocorticoid responsive tissues, such as distal nephron, colon, and salivary glands protects the MR from cortisol (Chapman *et al.*, 2013). Circulating cortisol concentrations are 1000-fold higher than the native MR agonist aldosterone; inactivation of cortisol by 11β-HSD2 enables normal specificity for the MR to be maintained (**Fig. 1**).

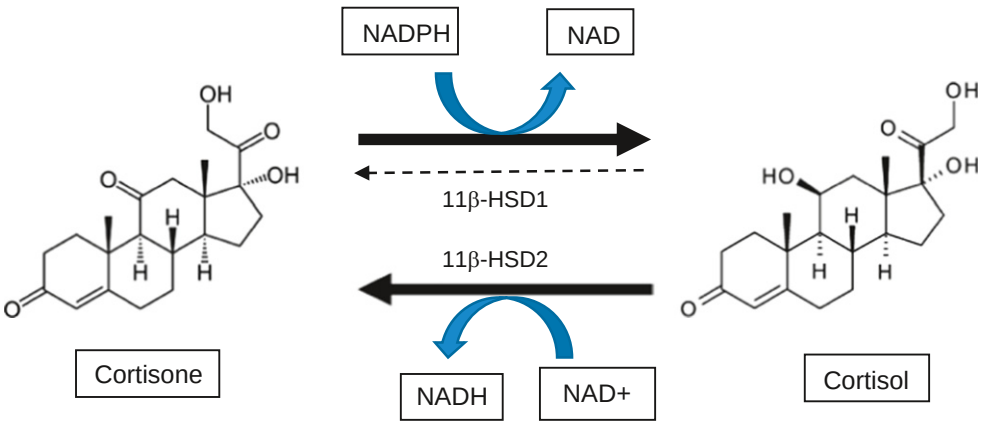

Fig. 1 Biochemical properties of 11β-hydroxysteroid dehydrogenases (11β-HSDs). Type 1 11β-HSD exhibits both oxoreductase (cortisone to cortisol) and dehydrogenase activities (cortisol to cortisone) in vitro, but in vivo it mainly functions as an oxoreductase. The type 2 enzyme exhibits only dehydrogenase activity (cortisol to cortisone).

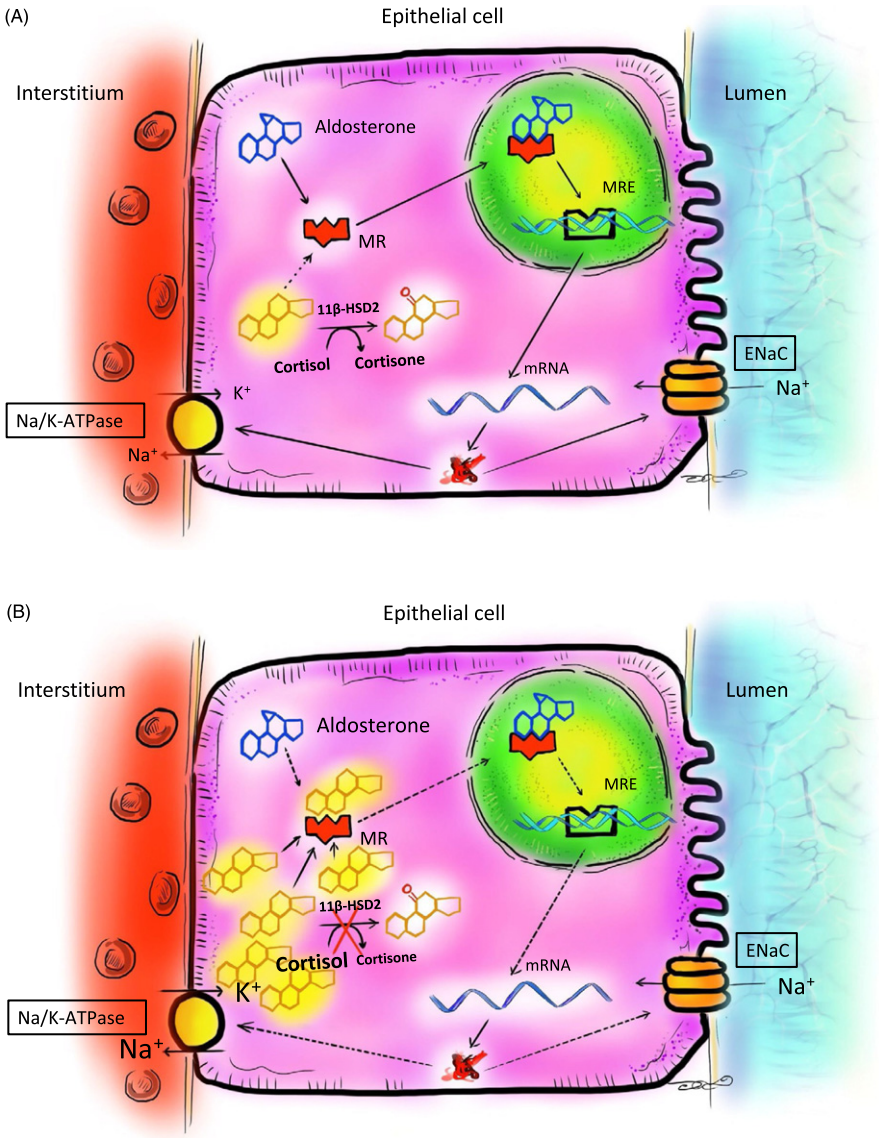

Fig. 2 A renal cortical collecting epithelial cell. (A) Normal physiology showing inactivation of cortisol by 11β-HSD2 and aldosterone binding to MR. (B) In states of 11β-HSD2 deficiency cortisol gains access to the MR. Illustrator Dr. Wisitsak Pakdee, Department of Radiology, Faculty of Medicine, Prince of Songkla University, Songkhla, Thailand.

Mineralocorticoids (aldosterone) play an essential role in intravascular volume control and electrolyte homeostasis through their action at the distal nephron (White, 1994). Indeed the classical well-known effect of MR activation by aldosterone is predominantly in the kidney, especially the renal distal tubules and cortical collecting ducts, called mineralocorticoid responsive tissues. MR activation by aldosterone leads to amiloride-sensitive sodium channel (ENaC) and Na^+–K^+-ATPase activation resulting in increased intravascular volume by Na^+ influx, K^+, and H^+ efflux (Fig. 2A). In vitro, aldosterone and cortisol have the same binding affinity for the MR, however in normal physiology cortisol cannot bind to the MR due to 11 β-HSD-2 inactivation which acts as a main protective role for cortisol-binding MR. Excessive amounts of aldosterone or cortisol, hypersensitivity of MR or decreased activity 11 β-HSD-2 enzyme result in Na^+ retention and urinary K^+ and H^+ loss with mineralocorticoid hypertension, characterized by hypertension and hypokalemic metabolic alkalosis.

In summary the pathogenesis of AME is impairment of 11β-HSD2 enzyme activity leading to cortisol-mediated mineralocorticoid activation of the MR, resulting in hypertension, hypokalemia, and metabolic alkalosis (Fig. 2B).

Inherited Form of 11β-HSD2

We now have a clear understanding of the genetic basis for AME. AME is a rare autosomal recessive condition with loss-of-function mutations of the HSD11B2 gene located on the long arm of chromosome 16 (16q22.1). The HSD11B2 gene is approximately

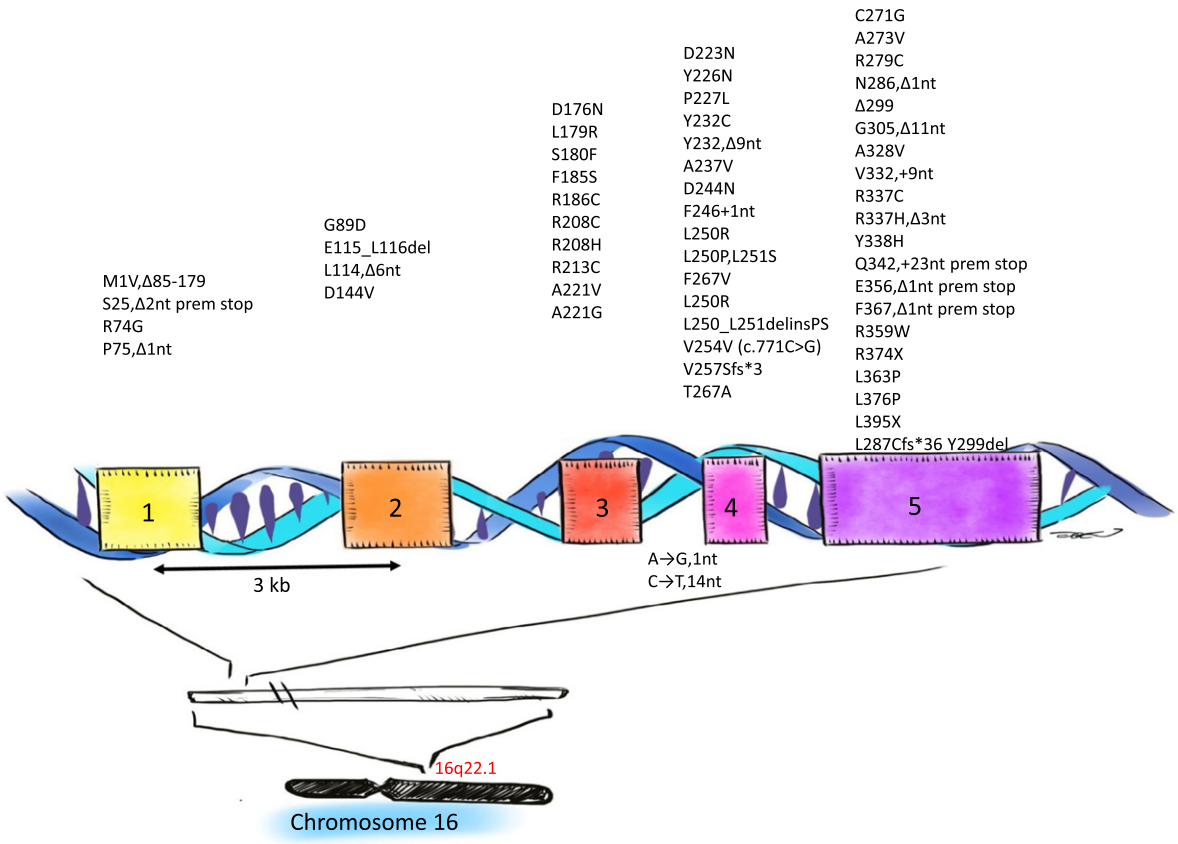

Fig. 3 HSD11β2 gene and the mutations identified in patients with AME. Illustrator Dr. Wisitsak Pakdee, Department of Radiology, Faculty of Medicine, Prince of Songkla University, Songkhla, Thailand.

6.2 kb length and contains five exons (Agarwal *et al.*, 1995). First detailed in the mid 1990s by Perrin White and Paul Stewart's group, **Fig. 3** summarizes the mutations reported to date in patients with AME. There is a close correlation between severity of mutation and the severity of diseases. More severe mutations result in reduced enzyme expression, earlier onset and more severe symptoms. Indeed patients with heterozygous mutation may present with a mild degree of late onset hypertension undifferentiated from essential hypertension. Epigenetic mechanisms such as promotor methylation or DNA methylation have been proposed as a contributor to the degree of 11β-HSD2 enzyme insufficiency and phenotypic expression (Alikhani-Koopaei *et al.*, 2004; Friso *et al.*, 2008; Pizzolo *et al.*, 2015). A family history of consanguinity is a part of autosomal recessive inheritance which is commonly found in some ethnic groups such as Iranian, Omani, and Native American (Dave-Sharma *et al.*, 1998; Quinkler *et al.*, 2004; Razzaghy-Azar *et al.*, 2017; Mune *et al.*, 1995; White *et al.*, 1997).

Acquired Deficiency of 11β-HSD2

An "acquired" form of AME is seen following excessive ingestion of 11β-HSD2 inhibitors such as liquorice. Liquorice contains glycyrrhetinic acid, glycyrrhizic acid and its hydrolysis product GE, both of which are potent competitive inhibitors of 11 β-HSD2 (Stewart *et al.*, 1987; Armanini *et al.*, 1983). The amount of liquorice that can produce hypokalemia was reported to be as low as 150 mg confectionery glycyrrhizic acid per week (Cumming *et al.*, 1980). In Stewart's seminal Lancet paper, 200 g daily of liquorice containing 580 mg of glycyrrhizic acid induced salt retention, hypertension, and hypokalemia. This was reversible after cessation of liquorice. Carbenoxolone was used to treat patients with peptic ulceration in the 1970–80s. As a hemi-succinate derivative of glycyrrhetinic acid it too caused severe mineralocorticoid excess via inhibition of 11β-HSD2. More recently flavonoids found in grapefruit juice can also cause a mild mineralocorticoid excess state. It is good clinical practice in all hypertensive patients to enquire about liquorice intake.

Clinical Characteristics

The common presentation of AME is childhood onset of hypertension with hypokalemia and metabolic alkalosis. The pediatric history of moderate intrauterine growth retardation, postnatal failure to thrive, or short stature are the presenting symptoms of

severe phenotypes. Nephrocalcinosis, nephrogenic diabetes insipidus, myopathy, rhabdomyolysis, and abnormal ECG may also occur, attributed to chronic prolonged hypokalemia. The homozygous mutations present with typical mineralocorticoid hypertension in the young. In youth, heterozygous mutations usually have a normal phenotype (Lavery *et al.*, 2003; Morineau *et al.*, 2006). The consequence of chronic severe hypertension causes target organ damage such as hypertensive retinopathy, chronic renal failure, cerebrovascular accident, and cardiovascular disease, and may lead to decreased life-expectancy in severe untreated patients. Milder forms of AME present with late onset, low renin hypertension which responds well to low salt diet and spironolactone.

Diagnostic Methods

Diagnosis of AME and other 11β-HSD2 deficient states is based on clinical characteristics of early onset of hypertension, hypokalemic metabolic alkalosis with low plasma aldosterone and renin activity. Biochemically urinary deficiency of 11β-HSD2 results in a high urinary cortisol/cortisone ratio, prolonged cortisol half-life, and reduced urine cortisone metabolism excretion (**Fig. 4**A). The assessment can be performed by measuring a 24-h urinary collection analyzed by gas chromatography/mass spectrometry for cortisol and cortisone metabolites and free cortisol/cortisone (**Fig. 4**B). The confirmation for inherited AME is genetic testing of the HSD11B2 gene.

Differential Diagnosis

Mineralocorticoid hypertension with low renin activity is usually caused by aldosterone excess. In patients where aldosterone is also suppressed other causes include Liddle syndrome, Cushing syndrome (both exogenous and endogenous), and activating mutations of the mineralocorticoid receptor and glucocorticoid resistance. Ectopic ACTH Cushing syndrome is another cause of mineralocorticoid excess with the history of rapid onset of low renin hypertension with profound hypokalemia. Here the high cortisol secretion rate swamps the renal 11β-HSD2 enzyme system. Liddle syndrome is a cause of monogenic endocrine hypertension that should be mentioned owing to the same clinical features as AME, early-onset severe hypertension, hypokalemia, metabolic alkalosis with strong family history of hypertension caused by hyperactivity of ENaC in renal epithelial cells. The genetic

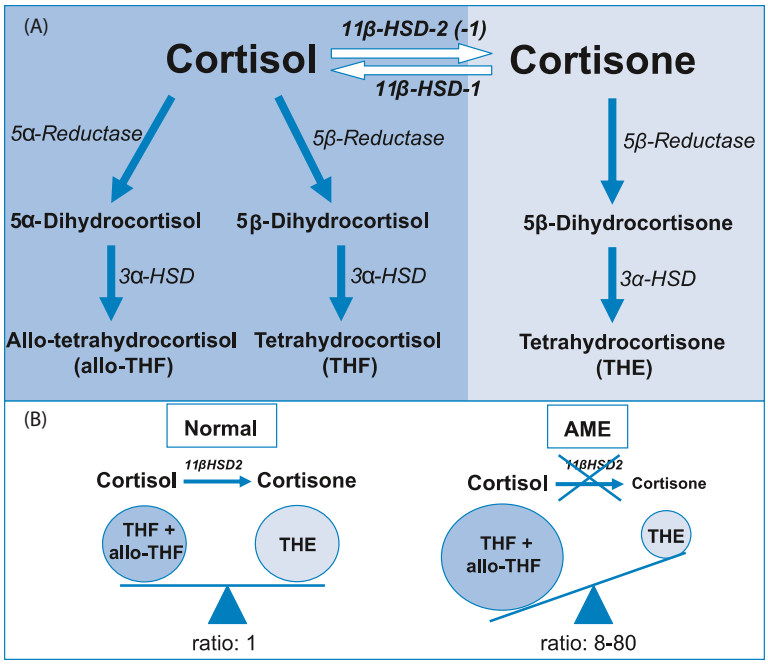

Fig. 4 (A) Schematic depiction of the enzymatic activity involved in glucocorticoid metabolism. Cortisol and cortisone are interconverted by 11β-(11β-HSD's). In the liver, 5- and 5 β-reductases and 3-hydroxysteroid dehydrogenases (HSDs) convert cortisol to 5-tetrahydrocortisol (allo-THF) and 5β-tetrahydrocortisol (THF) and convert cortisone to tetrahydrocortisone (THE). (B) In normal subjects urinary excretion of cortisol metabolites (THF and allo-THF) compared to the cortisone metabolite (THE) is equivalent, resulting in allo-THF, and THF/THE ratio of 1. Inactivation of 11β-HSD2 in apparent mineralocorticoid excess (AME) patients results in a grossly increased urinary excretion of cortisol compounds, whereas THE is dramatically reduced, resulting in a high [THF + allo-THF]/THE ratio. The urinary free cortisol/urinary free cortisone is also dramatically increased. Modified from (2006). *Best Practice & Research Clinical Endocrinology & Metabolism* ***20***(3), 341.

defect is an autosomal dominant disorder with mutations in the genes coding for ENAC at chromosome 16 p that responds well to amiloride that blocks the ENAC activity.

Treatment

The aim of treatment is to maintain normal blood pressure and serum potassium levels. Uncontrolled hypertension and profound hypokalemia causes target-organ damage especially for the brain, heart, retina, and kidneys.

1. Mineralocorticoid receptor antagonists
   1.1 Spironolactone
   Effectiveness of long-term outcome after spironolactone treatment has been shown with normalization of blood pressure, reversal of hypertensive retinopathy, left ventricular hypertrophy and nephrocalcinosis (Dave-Sharma *et al.*, 1998) and decreased morbidity and mortality. There are some concerns about antiandrogenic effects of spironolactone in male patients. The recommended dose is 2–12.5 mg/kg/day.
   1.2 Eplerenone is not approved for use in childhood, but may be given as an alternative.
2. Dexamethasone
   Cortisol is the offending mineralocorticoid in AME. Dexamethasone suppresses endogenous cortisol production by inhibiting the hypothalamic pituitary axis (HPA). Dexamethasone 1.5–2 mg/day as a starting dose followed by 0.5 mg/day is successful in normalizing blood pressure in many patients. There are some controversial issues for long-term treatment because some patients have worsening BP from dexamethasone treatment owing to dexamethasone binding to MR (New *et al.*, 1977; Lan and Baxter, 1982). Other adverse effects are steroid overdose or iatrogenic Cushing syndrome.
3. Low salt diet
4. Renal transplantation
   Patients are reported who have undergone renal transplantation. Disease cure and decreased morbidity, after transplantation, is documented (Razzaghy-Azar *et al.*, 2017; Palermo *et al.*, 2000; Khattab *et al.*, 2014).

Prognosis

The life-threatening condition from hypokalemia is cardiac arrest. Long-term complications of AME without treatment are dissecting aortic aneurysm, left ventricular hypertrophy, cerebrovascular diseases, and end stage renal disease. Long-term treatment with controlled hypertension results in a good prognosis. All of the evidence demonstrates that early detection, tight blood pressure control, and normalized potassium levels are important factors for these patients.

Conclusions

AME is an inherited form of hypertension caused by impaired 11B-HSD2 activity. Clinical clues are early onset of low renin-aldosterone hypertension with hypokalemia. The first recommended screening tools should be urine cortisone/cortisol metabolites with a positive result leading to genetic testing of the 11βHSD2 gene. Therapeutic goal is to maintain blood pressure, normalize serum potassium levels, and prevent long-term morbidity and mortality. Dexamethasone in doses to suppress endogenous cortisol secretion, spironolactone, and salt-restrictive diets are effective treatments.

Glossary

Addison's disease Pathological condition characterized by primary adrenal insufficiency, mainly due to autoimmunitary cause, adrenal surgery, some drugs (like for example mitotane, and ketoconazole), severe bleeding involving both adrenal glands, or infections (especially tuberculosis, and AIDS).

Aldosterone Steroid hormone synthetized by the zona glomerulosa of the adrenal cortex. It is the main mineralocorticoid hormone, involved in the regulation of electrolyte and fluid balance.

Androstenedione Steroid hormone synthetized by adrenal zona fasciculata and reticularis and by ovarian stroma. It is a week androgen and an intermediate precursor of testosterone and estrogens.

Apoptosis Biological process of programmed cell death that occurs in multicellular organisms.

Carbenoxolone Derivate of glycyrrhetinic acid. It is used as antiulcerative and antiinflammatory treatment.

Cortisol Steroid hormone synthetized by the zona fasciculata of the adrenal cortex. It is the main glucocorticoid, involved in several functions in response to stress, inflammation, and energy metabolism.

Deoxycorticosterone Steroid hormone synthetized by the adrenal cortex. It is the precursor of aldosterone and possesses mineralocorticoid activity.

Diamide Chemical compound used as thiol-specific oxidant agent.

Diogenes Laertius Greek historian lived in the third century BC. He was the author of "Lives and Opinions of Eminent Philosophers," a biography of ancient Greek philosophers.

Dioscoride Greek physician, pharmacologist, botanist, lived in the first century BC. He was the author of the "De Materia Medica," an encyclopedia about herbal medicine, widely read for more than 1500 years.

Flavonoids Class of plant and fungus secondary metabolites. They are the most important plant pigments for fruits, vegetables, and flower coloration. There are several groups of flavonoids, with different biological and pharmacological properties, such as antiinflammatory, antioxidant, antibacterial, anticancer, and estrogen-like activity.

Glabridin Chemical compound of licorice root. It is an isoflavane, with antiinflammatory, antioxidant and estrogen-like activity. It is also a natural skin lightener, inhibiting the production of melanin.

Glycyrrhetinic acid Chemical compound of licorice root and derivate of glycyrrhizic acid. It possesses different biological and pharmacological properties, in common with its precursor and it also regulates the activity of 11 beta-hydroxysteroid dehydrogenase.

Glycyrrhizic acid One of the main constituents of licorice and precursor of glycyrrhetinic acid. It possesses a wide range of biological and pharmacological activities, including antiinflammatory and immune regulatory actions, antiviral and anticancer effects, inhibition of hepatic apoptosis and necrosis.

Heraclitus Pre-Socratic Greek philosopher lived in the sixth century BC. His famous aphorism "panta rhei," which means "everything flows," well characterized his thought about a continuous change as fundamental essence of the universe.

Insulin resistance Pathological condition characterized by decreased insulin sensitivity due to an alteration of insulin receptors or at the level of postreceptor signaling pathways. It causes a compensatory hyperinsulinemia to keep the concentration of serum glucose within the normal range. This condition can precede the development of diabetes and it is usually associated to obesity, sedentary lifestyle, hypertension, and many pathological disorders (such as polycystic ovary syndrome, and Cushing syndrome).

Naringenine Component of grapefruit, able to block the enzyme responsible of the activation of cortisone in cortisol.

Plinius Roman natural philosopher, naval and army commander of the early Roman Empire, lived in the first century BC. He was the author of the "Naturalis Historia," considered an editorial model for encyclopedias.

Polycystic ovary syndrome The most common gynecological endocrine disease, affecting about 15% of women in reproductive age. It is mainly characterized by hyperandrogenism, chronic oligo-anovulation and polycystic ovaries. It is also associated with different cardio-metabolic disturbances, in particular insulin-resistance, obesity, diabetes, dyslipidemia, and hypertension.

Pseudohyperaldosteronism Pathological condition characterized by hypertension and hypokalemia. It mimics hyperaldosteronism, but it is associated with low renin and aldosterone levels. It can be due to dietary (such as licorice)

 doi:10.1016/B978-0-12-801238-3.64309-X

or genetic causes (like dysregulation of the epithelial sodium channel).

Receptor Protein molecule that receives chemical signals (ligands) and causes different specific biological response. It can be transmembrane and receives extracellular ligands or intracellular (cytoplasmic or nuclear receptor).

Spironolactone Steroid compound primarily used to treat resistant hypertension and fluid retention due to heart or liver failure, and kidney disease. It is also used as anti-androgen both for women (with acne and/or hirsutism) and for transgender males as hormone therapy. Its pleiotropic action is due to the block of mineralocorticoid and androgen receptors and to some estrogen and progesterone-like effects.

Theophrastus Greek philosopher succeeded to Aristotle in the Peripatetic school and lived in the third-fourth century BC. He is considered the "father of botany," for his work on plants.

11 Beta-hydroxysteroid dehydrogenase Enzyme responsible of the conversion of inert cortisone in active cortisol (type 1), and vice versa (type 2), regulating the interaction of glucocorticoids to the steroid receptors.

Licorice Characteristics

Licorice is a perennial plant, native to Mediterranean area and Asia Minor. Its genus is glycyrrhiza that accounts of 20 species. The most common species in Europe are glygyrrhiza glabra and echinata. Licorice has been studied since long time for its pleiotropic biological and endocrine properties.

The main constituents are triterpene saponins whose principal component is glycyrrhizic acid. Glycyrrhizic acid can be hydrolyzed into 18beta-glycyrrhetinic acid (GA) and two molecules of D-glucoronic acid. Other important constituents are flavonoids that account of 1%–24% of the root weight dependent on the species. The most important flavanoid is glabridin that has estrogen-like effect.

The 2500 Years Long Story of Licorice

Licorice was one of the most widely known medicinal remedies in the ancient history (Armanini *et al.*, 2002). The root had several properties cited by ancient philosophers, botanists and doctors that reported its use for stomach disturbances, cough, female sterility and wounds healing. Licorice medicinal use was known by Assyrians, Chinese, Hindu, Egyptians from around 2500 BC. In the third-fourth century BC Theophrastus reported that licorice root has the property of quenching thirst if one holds it in the mouth (Theophrastus, 1961). He also reported that the Scythians were able to survive 12 days in the desert without drinking water, because they chewed licorice root. Dioscorides in the first century BC gave the plant its botanical name (glukos = sweet, riza = root) and reported that the troops of Alexander the Great were eating licorice roots in order to allay their thirst in situations of water scarcity (Dioscorides, 1958).

In the first century BC, Plinius recommended licorice root to clear the voice and to alleviate thirst and hunger (Plinius, 1987). He mentioned that Roman legionnaires could march up to 10 days without eating or drinking because the licorice properties helped to increase strength and limit hunger. He claimed that licorice was also useful for female sterility.

During the middle age, licorice was popular in Arab medicine and in Avicenna's Canon licorice is reported as a remedy for several diseases (Fiore *et al.*, 2005).

From the middle age until now, the medicinal properties of licorice are known and actually studied to better understand their mechanisms of action.

It is surprising that most of these observations of ancient philosophers, botanists and/or doctors have been now confirmed and validated by scientific studies.

Endocrine and Not Endocrine Effect of Licorice

The most studied side effects of prolonged ingestion of licorice are hypertension and hypokalemia, due to the block of 11 beta-hydroxysteroid dehydrogenase type 2 (11HSD-2). More recently scientific studies have been focused on other endocrine beneficial effect of licorice or of some of its components, such as antiandrogen and estrogen-like effects and as reducer of fat mass. Licorice is also effective as antiviral compound stimulating the secretion of interferon gamma in T cells. Actually it is possible to study not only the extract of licorice root, but also the effect of single components evaluating their individual implications.

Mineralocorticoid Effect and the 11 Beta-Hydroxysteroid Dehydrogenase Enzymatic System

Mineralocorticoid receptors (MR) and glucocorticoid receptors (GR) have a similar structure and they can be bound both by mineralocorticoids and glucocorticoids. The affinity of aldosterone and cortisol for MR is quite similar and considering that the

plasma concentration of cortisol is about thousand fold higher than that of aldosterone, one could derive that MR are only bound by glucocorticoids. In mineralocorticoid target tissues the preferential binding of aldosterone to MR is allowed by the presence in the cytoplasm of the enzyme 11HSD-2 that inactivates cortisol to cortisone (Funder *et al.*, 1988). In tissues lacking 11HSD-2 the MR is occupied by cortisol and in particular in the hippocampus the binding of cortisol to MR is involved in the regulation of circadian rhythm of ACTH (Armanini, 1994).

The interconversion of pharmacologically active cortisol and inactive cortisone is accomplished by two independent 11HSD that exhibit tissue-specific expression (Edwards *et al.*, 1988). Type I isoenzyme (11HSD-1) is expressed at high levels in the liver, where it catalyzes both the dehydrogenation and the reverse reductase reaction, and utilizes NADP+ or NADPH as cofactors. 11HSD-1 is also expressed in central nervous system and in adipose tissue, where it has a reductase function. 11HSD-1 has been characterized also in mononuclear leukocytes (MNL), where it probably modulates the inflammatory and autoimmune reaction (Fiore *et al.*, 2009).

11HSD-2 has a high affinity for related steroids and catalyzes only dehydrogenation utilizing NAD+ as a cofactor. It is mainly expressed in classical target tissues for aldosterone as kidney, salivary and sweet glands, colon, but it was also described in placenta, in some brain areas and in vessels. The enzymatic reaction is synthetically schematized in **Fig. 1**.

When the enzyme is blocked for a genetic or acquired deficiency, the mineralocorticoid effect of cortisol is evidenced by a clinical picture of pseudohyperaldosteronism and by the biochemical evaluation of urinary cortisol to cortisone ratio (Sabbadin and Armanini, 2016). The increased ratio of 5alpha and 5beta reduced metabolites of cortisol and cortisone is another consequence of altered 11HSD activity and therefore the increase of urinary ratio of tetrahydrocortisol + allo-tetrahydrocortisol to tetrahydrocortisone (THF + alloTHF/THE) is an index of impaired activity of 11HSD-2 (White *et al.*, 1997).

Licorice: The Block of 11HSD-2 and the Direct Effect on MR

In 1946 Revers firstly correlated the water retention and the urinary loss of potassium to the licorice ingestion (Revers, 1946). These effects were ascribed to the deoxycorticosterone (DOC)-like activity of licorice, being aldosterone still not discovered.

Following the discovery of aldosterone in 1953, licorice became an important matter of research after the report of hypertension and hypokalemia in subjects eating high amounts of the root or of its preparations.

In 1968 Conn defined the licorice-induced hypertension as a condition of pseudoaldosteronism, characterized by the presence of clinical signs and symptoms of hyperaldosteronism, but with suppression of renin and aldosterone levels (Conn *et al.*, 1968). A lot of reports were published about licorice-induced pseudohyperaldosteronism and actually the prevalence of this disease is sharply reduced due to the knowledge by the doctors and the patients about this risk (Penninkilampi *et al.*, 2017).

Pseudohyperaldosteronism syndrome is not only due to pure extracts of the roots, but it has also been reported during assumption of laxatives (Scali *et al.*, 1990), chewing, tobacco and beverages, where licorice was added for its specific effect or to ameliorate the taste.

The daily amount of licorice responsible for the side effects varies individually and it usually accounts to about 10 g a day of the pure preparation commercially available. However, it depends on individual characteristics of the patient and on the ability to hydrolyze glycyrrhizic acid to GA. In some cases licorice can produce a marked water retention, but not hypertension. Moreover

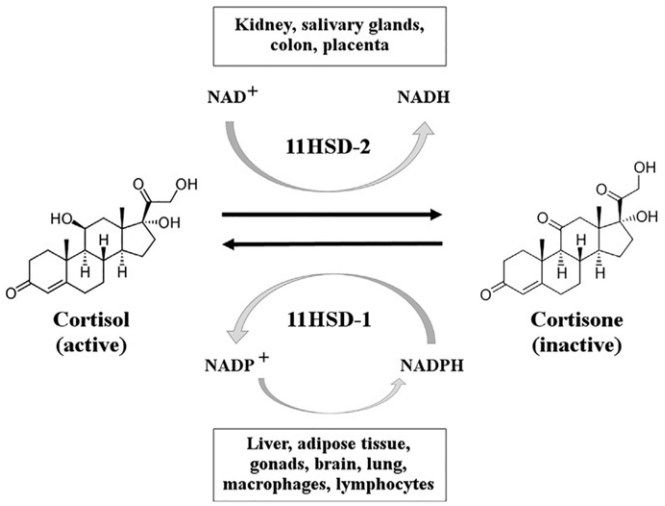

Fig. 1 Intercorversion of cortisol and cortisone by 11HSD. 11HSD-2 is a NAD-dependent dehydrogenase enzyme (that converts active cortisol into inactive cortisone); it is mainly expressed in the kidney, salivary glands, colon, and placenta. 11HSD-1 is a NADPH-dependent reductase (that converts cortisone into cortisol) and a dehydrogenase enzyme too; it is expressed in the liver, adipose tissue, gonads, brain, lung, macrophages, and lymphocytes.

the ingestion of high amounts of licorice could not produce pseudohyperaldosteronism in some subjects, while in other cases the disease could be evident after few days from the beginning of licorice intake at reasonable amounts.

The mineralocorticoid-like effect of licorice usually disappears after 2–3 weeks after the suspension of licorice ingestion in most of the cases, but some patients can also show persistent hypertension (Schambelan, 1994). In some severe cases with marked hypokalemia the treatment with aldosterone receptor blockers is needed to avoid general and in particular cardiovascular complications (Armanini *et al.*, 2014).

The diagnosis is made by the clinical history and eventually by the biochemical evaluation of hypokalemia and suppressed levels of renin and aldosterone. Confirmation derives for the recovery after withdrawal of licorice ingestion.

Therefore it is mandatory to perform an accurate history of all patients with hypertension particularly when potassium is reduced. The specific question about intake of pure licorice or preparations containing the substance is very important to avoid the prescription of exams not necessary, as for example the morphological evaluation of adrenals.

The same pattern of pseudohyperaldosteronism was also subsequently reported for carbenoxolone, a hemisuccinate of GA, used for gastritis and gastric ulcer. Prolonged intake of the drug leads to hypertension, hypokalemia and suppression of renin and aldosterone levels, as shown by in vivo studies in adrenalectomized rats treated with dexamethasone (Armanini *et al.*, 1982). The mechanism of action of carbenoxolone is related to the block of 11HSD-2 and to the direct binding to MR (Armanini *et al.*, 1989a).

It is worth of note that also prolonged ingestion of high amounts of grapefruit can produce a pseudohyperaldosteronism, caused by the component naringenine that blocks 11HSD-2, and the combination of grapefruit and licorice has a synergic effect (Palermo *et al.*, 2003).

When MR was discovered some studies demonstrated a low affinity of GA in kidney-slices MR (Ulmann *et al.*, 1975), in kidney cytosol (Armanini *et al.*, 1983) and later in intact mononuclear leukocytes (MNL) (Armanini *et al.*, 1989b). GA is able to bind to MR with a lower affinity than aldosterone (about 1:10,000 in kidney cytosol and 1:3000 in intact MNL), while carbenoxolone has an affinity of 1:13,000 for kidney MR (Armanini *et al.*, 1982; Armanini *et al.*, 1989a). Despite the low affinity, the chronic ingestion of pure licorice can produce high plasma concentrations of GA consistent with a direct effect at the level of MR (Armanini *et al.*, 1989b). The direct action has been demonstrated measuring the plasma MR active materials in plasma of subjects taking licorice. The study showed an increased binding of plasma mineralocorticoid active substances in adrenalectomized rat kidney cytosol (Armanini *et al.*, 1996).

The mechanism of the reversible block of 11HSD-2 by licorice could be related to a direct enzyme inhibition, to the enzyme saturation with high plasma concentrations of GA, or to a rearrangement of the enzyme structure following the interaction with GA.

In 1978 Epstein reported that cortisol was increased during licorice intake (Epstein *et al.*, 1978). The block of 11HSD-2 by licorice reduces the conversion of cortisol in cortisone in the classical mineralocorticoid target tissues, increasing the urinary cortisol to cortisone ratio.

In 1987 Stewart found that GA and carbenoxolone also inhibit 11HSD-1 (Stewart *et al.*, 1987). The enzyme is particularly expressed in adipose tissue and liver, but it has been found in other tissues as gonads, brain, lung, macrophages and lymphocytes. 11HSD-1 activates circulating cortisone to cortisol and a partial block of the enzyme could be implicated in some cases of low renin essential hypertension: the decreased cortisol availability due to the block of 11HSD-1 increases ACTH to normalize plasma cortisol values. This slight increase of ACTH could assess at higher levels of ACTH-dependent mineralocorticoids, as for example DOC and corticosterone or other minor mineralocorticoids, causing a pseudohyperaldosteronism (Davies *et al.*, 2009).

Licorice can also affect other enzymatic systems as 5beta-reductase in liver (Tamura *et al.*, 1979). This enzyme plays an important role in the regulation of the metabolism of cortisol and aldosterone in the liver. The inhibition of the enzyme leads to a reduction of corticosteroid clearance and to an increase of the biologic half-life of cortisol. Therefore, the increase of cortisol during licorice ingestion seems to be related to the block of 11HSD-2 and 5beta-reductase, while the effect on 11HSD-1 seems to be less relevant.

Licorice also binds to plasma binding proteins, as sex hormone binding globulin, corticosteroid binding globulin (Tamaya *et al.*, 1986) and albumin, displacing the physiological binders. By this mechanism the free fraction of the related steroids can be higher thus interfering in the clinical picture and in the mineralocorticoid, glucocorticoid and sex hormone concentration and function.

All these interactions between GA and steroid receptors, binding proteins, 11HSD and other enzymes have several clinical implications and are involved in the synergic increase of the mineralocorticoid effector mechanism.

All these studies confirm the observation of Theophrastus and other ancient authors about the effect of licorice of quenching thirst in situation of water scarcity. Theophrastus's observation was utilized during the Second World War for acclimating the American soldiers destined to Africa. These soldiers were exercised in a warm humid ambient taking DOC for resisting to the hot and humid climate of the African desert. This kind of adaption is the same used by the Roman soldiers and the Scythians, who ingested licorice roots to resist to climate adversities (Fiore *et al.*, 2006).

An interesting observation was also suggested about the death of Heraclitus. Diogenes Laertius reported that Heraclitus retired in the desert in Asia eating only roots and he became dropsy and subsequently dead. This condition could be related to the ingestion of licorice roots which grow everywhere in that region (Fiore *et al.*, 2008b).

Aldosterone Licorice and Inflammation

From the late 1980 aldosterone was studied as a potent proinflammatory hormone involved in atherosclerosis, fibrosis, and cardiovascular and cerebral risk (Pitt *et al.*, 1999). The administration of aldosterone receptor blockers was able to prevent these effects even in patients with normal aldosterone concentration, demonstrating that the inflammatory effect is not only caused by the high plasma aldosterone concentration, but also to different factors related to the individual ability of aldosterone to bind to MR and GR (Armanini *et al.*, 2014).

This new area of investigation of aldosterone was already hypothesized and validated in 1953, before the discovery of aldosterone, by Selye, who considered DOC having an inflammatory effect opposite to the antiinflammatory effect of cortisol (Selye, 1953). This concept was later lost and aldosterone was studied for several decades only as involved in the electrolyte balance and hypertension or in primary aldosteronism.

From the 1980 the inflammatory and profibrotic effect of aldosterone was studied and aldosterone became a dangerous hormone for its side effects at the level of heart and vessels. In the recent years the prescription of aldosterone receptor blockers became quite mandatory not only in patients with resistant but also with essential hypertension (Pitt *et al.*, 1999; Armanini *et al.*, 2014).

After the characterization of MR in MNL (Armanini *et al.*, 1985) and the demonstration of an effect of aldosterone on the regulation of intracellular electrolytes via genomic and nongenomic mechanisms (Wehling *et al.*, 1987; Wehling and Kuhls, 1989), studies have shown that GA is able to mimic the effect of aldosterone in MNL, leading to regulation of intracellular electrolytes (Armanini *et al.*, 1989b) and activation of oxidative stress (Calò *et al.*, 2004). In fact, incubation of MNL with a concentration of GA related to its affinity for MR had the same effect of the incubation with aldosterone, increasing the expression of two oxidative stress-related proteins, PAI-1 and p22 (phox). Both the effect of aldosterone and GA are reversed by coincubation with canrenone, the active principle of spironolactone (Calò *et al.*, 2004). These in vitro experiments confirmed also the importance of a direct effect of aldosterone at the level of MR independent from 11HSD-2.

Possible interactions between genomic and nongenomic effects of aldosterone and GA were also hypothesized and validated by in vivo and in vitro studies on plasma membrane of erythrocytes. Incubation of red cells with aldosterone induced well-characterized cell-membrane alterations (Bordin *et al.*, 2013), while GA prevented diamide induced band 3 Tyr-phosphorylation in a dose-dependent manner, showing high resistance to proteolysis (Fiore *et al.*, 2008a). From these studies, GA is proposed to strengthen membrane integrity against both oxidative and proteolytic damage. These studies have focused on the opposite effect of GA and aldosterone on plasma membrane of erythrocytes: high concentrations of aldosterone have negative effects reducing the life and increasing the apoptosis of erythrocytes, while GA has an opposite effect. It is interesting to note that canrenone is able to block the effect of aldosterone also in these anucleated cells, in agreement with a nongenomic effect of aldosterone mediated by MR (Bordin *et al.*, 2016). Maybe the direct effect at the level of plasma membrane of GA is due to a mechanism different than the binding to cytoplasmatic MR.

This effect on MNL and erythrocytes validates the concept that GA has an inflammatory effect due to the increased mineralocorticoid activity, but also an antiinflammatory effect due the action on plasma membrane.

All these studies confirm the ancient observation of a beneficial effect of licorice in ameliorating wounds and as antiinflammatory.

Glucocorticoid and Mineralocorticoid Effects

In 1951, before the discovery of cortisol, Groen reported a beneficial effect of licorice in Addison's disease (Groen *et al.*, 1951). Some affected patients were using spontaneously the licorice root, experiencing an amelioration of the symptoms and the clinical picture allowing a survival to the disease. In 1953 Borst demonstrated that licorice did not act directly but enhances the effect of even low concentrations of cortisol, producing better results on the survival of patients with Addison's disease (Borst *et al.*, 1953). In 1978 Epstein reported that cortisol was increased during licorice ingestion (Epstein *et al.*, 1978).

The effect of licorice in Addison's disease seems to be due to the block of 11HSD-2, increasing the effect of the small amount of cortisol secreted by the affected adrenals. Based on our studies, a direct effect of GA also via GR could be implicated, considering the low affinity of GA for GR and the high amount of GA measured in serum after long time consumption (Armanini *et al.*, 1989b). From all these reports GA has both a glucocorticoid-like action by binding to GR and blocking 11HSD-2 and an antiglucocorticoid action in tissues harboring 11HSD-1.

11HSD-1 is highly expressed in fat and therefore licorice can have a role in the modulation of fat mass. A previuos experiment evaluated the effect of topical application of a cream containing GA in the thickness of subcutaneous thigh fat: after 1 month the circumference of the leg and the fat thickness (measured by ultrasound analysis) was significantly reduced with the application of the cream (Armanini *et al.*, 1989b). This effect is probably due to the block of 11HSD-1 by GA in fat, thus decreasing the incorporation of triglycerides into the adipocytes mediated by cortisol. The same experiment showed that after 2 months of topical application the values of renin and aldosterone were not suppressed and blood pressure was unchanged, probably due to the low vascularization of fat and to a direct effect on the volume of adipocytes mediated by the reduced availability of cortisol. Moreover, in subjects eating licorice fat mass measured by bioelectrical impedance analysis was reduced, but weight did not decrease. This discrepancy could be explained by the fact that licorice reduces the fat mass by interacting with 11HSD-1 and increases the water reabsorption by interacting with 11HSD-2.

Licorice can have different effects at different levels depending on 11HDS-1 and −2, 5beta-reductase and the relative affinity for MR and GR. Obesity is often related to the genetic hyperactivity of 11HSD-1. Stewarts reported a higher 11HSD-1 expression in the visceral fat tissue (Stewart *et al.*, 1987). This situation has been called Cushing syndrome of the adipose tissue.

Licorice or carbenoxolone treatment could be useful in reducing local and visceral fat but in all cases the water retention can masque the reduced fat tissue.

Medical Uses of the Mineralocorticoid-, Glucocorticoid- and Antiglucocorticoid-Like Properties of Licorice

Licorice has a positive effect in patients with orthostatic hypotension linked to primary and secondary hypoaldosteronism. As already reported, it can be used in patients with Addison's disease when fludrocortisone in not available, having a mineralocorticoid-like action. In diabetic patients with severe microangiopathy the sclerosis of the juxtaglomerular apparatus can limit renin secretion particularly in orthostatic position, inducing a secondary hypoaldosteronism and orthostatic hypotension, which can be ameliorated by the administration of licorice or fludrocortisone (Basso *et al.*, 1994).

In patients on hemodialysis, Farese *et al.* reported that inhibition of the enzyme 11HSD-2 by GA reduces serum potassium levels and the frequency of hyperkalemia through the enhanced intestinal potassium loss (Farese, 2009). This finding could be an important tool to maintain predialysis serum potassium concentrations within safe limits in some dialysis patients at risk of hyperkalemic arrhythmias.

Licorice is also used in the treatment of patients with polycystic ovary syndrome (PCOS) in association with spironolactone (Armanini *et al.*, 2007; Armanini *et al.*, 2016). The daily amount of pure commercial licorice extract is about 5 g in fractioned doses associated with 100 mg of spironolactone.

Spironolactone is a blocker of MR, but it also acts as an antiandrogen: the drug binds to androgen receptor as an antagonist, blocks 17-hydroxysteroid dehydrogenase at the level of adrenals and gonads 5alfa-reductase, activates aromatase and increases sex hormone binding globulin (Sabbadin *et al.*, 2016). The association with licorice is very useful in the treatment of PCOS, since it reduces the side effects related to the diuretic activity and hyperkalemia of spironolactone; moreover, it potentiates the antiandrogen effect of spironolactone, reducing secretion of testosterone and androstenedione by blocking the 17 hydroxysteroid dehydrogenase and 17–20 liase (Takeuchi *et al.*, 1991; Armanini *et al.*, 1999). These patients show a systemic chronic inflammatory state and an increased cardiovascular risk, partially linked to increased aldosterone levels and aldosterone to renin ratio compared with healthy controls (Armanini *et al.*, 2012): this combined treatment could prevent and reduce this risk due to the antiinflammatory effect of both spironolactone and GA. Finally, the intake of licorice has also a positive action on the ovulatory rate due to its estrogen-like effect, especially in PCOS patients who want to get pregnant (Armanini *et al.*, 2007).

Licorice is effective in the chronic fatigue syndrome and its flavonoid constituent glabridine can be useful for reducing the menopause related affects of estrogen depletion (Baschetti, 1995).

Other beneficial effects of licorice are its use as antiviral remedy, stimulating beta interferon secretion by T lymphocytes, and as antimycotic, blocking the growth of vaginal candida (Fiore *et al.*, 2005).

Conclusive Remarks

Licorice is still a fascinating plant and an interesting topic of research, considering its multiple effects. Many reports have shown that licorice have an antibacterial, antiviral and antimycotic effect. In addition to the well-known hypertensive and antiinflammatory properties, licorice is very useful in some endocrine and gynecological disorders as antiandrogen and estrogen-like agent, and to blunt the potassium increase and/or hypotensive effect due to some drugs such as spironolactone in normotensive patients. The complex interaction of GA with 11HSD-1 and 11HSD-2 could be also useful in reducing fat mass by topical application and by oral administration.

Synthetic derivatives without mineralocorticoid-like properties have been recently developed, such as deglycyrrhizinated licorice, which seems to find a safe long-term application in gastroenterology, virology and in protection of atherosclerosis.

Its millennial use and the actual interest related to the beneficial and side effects of licorice are the reason for which a lot of research work is still in progress in many laboratories.

Glossary

Acid-sensing ion channels (ASICs) H^+-activated sodium channels.

Nedd4-2 A member of the Nedd4 (neural precursor cell expressed developmentally downregulated protein 4) family of the ubiquitin-protein ligases which ubiquitinates ENaC.

SCNN1A The gene encoding αENaC subunit.

SCNN1B The gene encoding βENaC subunit.

SCNN1G The gene encoding ɣENaC subunit.

Serum and glucocorticoid regulated kinase 1 (SGK1) An aldosterone-induced serine/threonine kinase.

Introduction

In 1963, Grant W. Liddle, a physician at Vanderbilt University (US-TN), reported on a family in which some members had severe hypertension and low plasma K^+ levels. The proband, a 16-year-old girl, and her adolescent brother, had hypertension, high urinary K^+ excretion, hypokalemic metabolic alkalosis, and negligibl
e urinary aldosterone excretion. Moreover, aldosterone administration resulted in a prompt decrease in urinary Na^+ excretion, which was consistent with the maintenance of the renal response to aldosterone. Spironolactone was ineffective on renal Na^+ and K^+ excretion. Conversely, triamterene, together with dietary sodium restriction, decreased urinary K^+ excretion, increased Na^+ excretion, and corrected both hypertension and hypokalemia. Proband's mother and grandmother had been hypertensive and died prematurely (Liddle *et al.*, 1963). Liddle hypothesized that the syndrome was a familial "disorder in which the renal tubules transport ions with such abnormal facility that the end result simulates that of a mineralocorticoid excess," but molecular mechanisms responsible for the disorder remained elusive for a long time.

About 30 years after the seminal work by Liddle, David G. Warnock, a nephrologist at the University of Alabama at Birmingham, serendipitously found that the proband reported by Liddle had developed end-stage renal disease and had successfully undergone deceased-donor kidney transplantation. This provided the opportunity to study the proband's extended pedigree, resulting in the finding of 18 family members suffering from Liddle syndrome (LS), with an autosomal-dominant inheritance pattern (Botero-Velez *et al.*, 1994). Around the same time, the subunits of the epithelial sodium channel (ENaC) were cloned and characterized by Cecilia Canessa and Bernard Rossier at the University of Lausanne, Switzerland (Canessa *et al.*, 1993, 1994b). Eventually, the collaboration between Warnock's group, Bernard Rossier's group, and Richard P. Lifton's group at Yale University led to the discovery of the genetic basis of LS. Genetic linkage analysis in the extended pedigree revisited by Warnock showed the complete linkage of LS with the locus encoding the β subunit of ENaC (Shimkets *et al.*, 1994). In addition, functional expression analysis in the *Xenopus laevis* oocyte system demonstrated an increase in the activity of the mutant compared with the wild-type ENaC (Schild *et al.*, 1995). Later, a gain-of-function mutation of the ɣ subunit of ENaC was identified in another LS kindred (Hansson *et al.*, 1995a).

Afterward, genetic testing of other LS kindreds identified several other mutations of either β or ɣ subunit of ENaC.

Lastly, a gain-of-function mutation of the α subunit of ENaC has recently been identified in a kindred with LS (Salih *et al.*, 2017).

Definition

LS is a rare hereditary condition, transmitted with an autosomal-dominant mode of inheritance, due to gain-of-function mutations in either *SCNN1A* or *SCNN1B* or *SCNN1G* genes, which encode the three ENaC subunits (α, β, γ). Clinical features include early-onset salt-sensitive hypertension, increased incidence of premature cardiovascular events, hypokalemic metabolic alkalosis, suppression of both renin and aldosterone secretion, and unresponsiveness to mineralocorticoid receptor antagonists, as opposed to ENaC blockers responsiveness (i.e., amiloride and triamterene) (Liddle *et al.*, 1963; Botero-Velez *et al.*, 1994; Warnock, 2001). Since the main clinical and biochemical features of LS, such as hypertension, hypokalemic metabolic alkalosis, and suppressed plasma renin activity, are typical of primary aldosteronism, LS has also been termed "pseudoaldosteronism," as aldosterone secretion is reduced in LS. This term, however, is inappropriate since it could be extended to any other form of Mendelian low-renin, low-aldosterone hypertension.

The Epithelium Sodium Channel and its Regulation

So far identified causative mutations of LS lead to constitutive activation of ENaC, a member of the epithelial sodium channel/degenerin family of cation-selective ion channels, which also includes the acid-sensing ion channels (ASICs). ASICs are H^+-

 doi:10.1016/B978-0-12-801238-3.65187-5

activated sodium channels composed of different subunits assembled as trimeric structures, mainly expressed in the central and peripheral nervous system where they are involved in mechanoreception, chemoreception, and nociception. They share <20% identity with the ENaC subunits (Hanukoglu, 2017). ENaC is a heteromeric protein composed of three homologous subunits, α, β, and γ, sharing around 30%–40% sequence identity. Each subunit is encoded by a specific gene (*SCNN1A*, *SCNN1B*, and *SCNN1G*, respectively) containing 13 exons. *SCNN1A* is located on 12p13.31, while *SCNN1B* and *SCNN1G* reside within a 400-kb fragment on 16p13-p12. Each ENaC subunit consists of two transmembrane domains (TM1 and TM2), a large extracellular loop, and short cytoplasmic amino and carboxyl termini (Canessa *et al.*, 1993, 1994a,b) (**Fig. 1**).

Despite the lack of direct data about the three-dimensional structure of ENaC, it is proposed as a heterotrimer (1α:1β:1γ) according to the high-resolution crystallographic structure of ASIC-1 (Kashlan and Kleyman, 2011; Rossier *et al.*, 2015). Based on this homology model, the three subunits would be arranged around a central ion-pore, lined by the TM2 domains of the subunits. ENaC is highly selective for Na^+ and Li^+ ions, which are smaller than K^+, and is blocked by amiloride and triamterene, which share a common binding site proximal to TM2 domain and interact competitively with Na^+ ions. The specificity of ENaC for Na^+ depends on the size of the selectivity filter, which allows only the passage of the smallest ions (Na^+ and Li^+) and accounts for a Na^+-to-K^+ selectivity ratio between 100 and 1000. A molecular model based on the site-directed mutagenesis of ENaC subunits hypothesizes that the selectivity filter is formed by nine amino acid residues to which each subunit contributes a conserved sequence of three residues, differing between subunits (Gly560-Ser561-Ser562 for the α subunit, Gly531-Gly532-Ser533 for the β subunit, and Ser540-Cys541-Ser542 for the γ subunit) (Hanukoglu, 2017).

ENaC is expressed mostly in salt absorbing epithelia, that is, in the kidney, colon, lung, sweat, and salivary glands, but also in blood vessels, brain, and taste receptors of the anterior tongue (Kellenberger and Schild, 2015). In contrast to ASICs, ENaC is constitutively active, since it is neither ligand- nor voltage-gated (Hanukoglu, 2017).

In the kidney, ENaC is expressed in the apical (i.e., luminal) membrane of the principal cells of the aldosterone-sensitive-distal nephron (ASDN), which comprises the late distal convolute tubule (DCT2), the connecting tubule (CNT), and the entire collecting duct (CD). ENaC mediates the rate-limiting step in Na^+ absorption in the ASDN. Although ASDN reabsorbs <5% of the filtered load of Na^+, ENaCs are the final Na^+ transporters along the nephron, and their activity is finely regulated by hormones and local factors (**Fig. 2**). As a result, ASDN may reabsorb from zero to nearly 100% of the Na^+ entering the ASDN to precisely match the Na^+ excretion to the daily Na^+ intake (Kellenberger and Schild, 2015; Rossier *et al.*, 2013; Palmer *et al.*, 2012).

ENaCs at the apical membrane fluctuate between an open and a closed state, with an average open probability (Po) of 0.5 (Palmer *et al.*, 2012). The activity of ENaC, as assessed by electrophysiologic measurement of the amiloride-sensitive Na^+ current in cell expression systems, depends on Po and on the number (density) of channels expressed at the apical membrane of ASDN principal cells. The latter is determined by the balance between the rate of transfer of ENaC from intracellular sites to the apical membrane and the rate of ENaC internalization from the apical membrane. Proteolytic cleavage of ENaC is one of the mechanisms affecting the ENaC gating and Po. Indeed, the α and γ subunits exhibit either a high molecular weight form (uncleaved) or a lower molecular form (cleaved), and ENaC is fully active only in its cleaved state. The shift from the uncleaved to the cleaved form is the result of two cleavages by serine-proteases, which release imbedded inhibitory peptides within the extracellular domains of α and γ subunits. Furin, a serine-protease residing in the Golgi apparatus, cleaves the α subunit twice, releasing the inhibitory fragment of the subunit, and cleaves the γ subunit only once. The release of the inhibitory tract of the γ subunit requires a second cleavage by a membrane-bound serine-protease acting on the ENaC already inserted in the apical membrane (Shi *et al.*, 2013).

Aldosterone is the main regulator of ENaC, by interfering with the transcription, the redistribution of ENaC subunits from intracellular sites to the apical membrane, the retrieval of ENaC from the apical membrane, and the Po of the channels. Indeed, aldosterone induces *SCNN1A* transcription with a resulting increase in the expression of the α subunit, associated with the

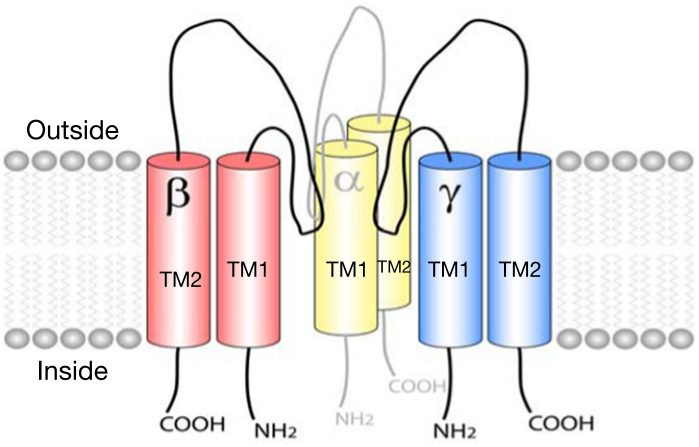

Fig. 1 Composition of the ENaC expressed on the luminal plasma membrane of ASDN.

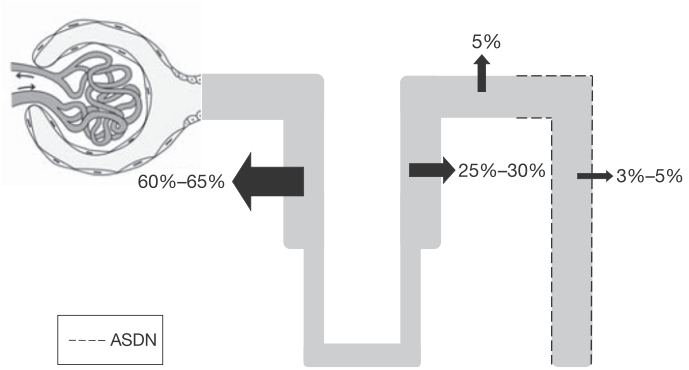

Fig. 2 Percent reabsorption of filtered Na^+ in the different segments of the nephron.

assembly of the whole ENaC. In addition, aldosterone induces the expression of other genes involved in regulating posttranslational modifications of ENaC subunits which result in an increase in both the number and the Po of ENaCs expressed at the apical membrane. In particular, aldosterone-induced serine/threonine kinase SGK1 increases ENaC activity through various pathways. In fact, SGK1 inhibits the removal of ENaC from the apical membrane by phosphorylating the ubiquitin ligase Nedd4-2 (see the next section). In addition, SGK1 directly phosphorylates the carboxyl terminus of the α-subunit of ENaC, resulting in increased Po of apical membrane ENaCs. Moreover, SGK1 also plays a role in promoting ENaC trafficking from intracellular compartments to the apical membrane (Kellenberger and Schild, 2015; Lou *et al.*, 2016).

Aldosterone regulates ENaC activity mainly in the collecting duct, while ENaC activity in the most proximal parts of ASDN (DCT2 and CNT) is partly aldosterone independent (Nesterov *et al.*, 2012).

Genetics and Molecular Mechanisms Responsible For LS

Thirty different LS-causing heterozygous mutations have been reported to date, occurring in familial or sporadic cases (Cui *et al.*, 2017; Salih *et al.*, 2017). Apart from αENaC C479R, βENaC R563Q, and γENaC N530S mutations (Salih *et al.*, 2017; Jones *et al.*, 2011; Hiltunen *et al.*, 2002), all other mutations cluster within exon 13 of either SCNN1B or SCNN1G, and consist of frameshift or nonsense or missense mutations that delete or alter a proline-rich PY motif, corresponding to the conserved sequence PPPXY (where X is any amino acid) in the cytoplasmic C-terminus of the β or γ subunit.

Only one αENaC mutation (C479R) responsible for LS has been reported so far (Salih *et al.*, 2017). Of the other 29 described mutations, 6 concern the γ-subunit. Of these, five cause deletion of the PY motif and one is a missense mutation (γ-N530S) located in the TM2 domain of the subunit, far from the PY motif (Hiltunen *et al.*, 2002; Hansson *et al.*, 1995a; Yamashita *et al.*, 2001; Wang *et al.*, 2007; Shi *et al.*, 2010; Wang *et al.*, 2015). Of the 23 β-subunit mutations, 12 cause deletion of the PY motif, 10 alter the sequence of the PY motif, and 1 (R563Q) is a missense mutation altering a sequence proximal to PY motif (Wang *et al.*, 2015; Shimkets *et al.*, 1994; Jeunemaitre *et al.*, 1997; Jackson *et al.*, 1998; Inoue *et al.*, 1998a,b; Melander *et al.*, 1998; Kyuma *et al.*, 2001; Nakano *et al.*, 2002; Hansson *et al.*, 1995b; Tamura *et al.*, 1996; Uehara *et al.*, 1998; Furuhashi *et al.*, 2005; Freundlich and Ludwig, 2005; Wang *et al.*, 2006; Rossi *et al.*, 2008; Sawathiparnich *et al.*, 2009; Gao *et al.*, 2013; Yang *et al.*, 2015; Cui *et al.*, 2017; Jones *et al.*, 2011).

No explanation has been proposed yet as to why differences in both frequency and mutation type between α, β, and γ subunits occur. Indeed, most mutations affect βENaC, and missense mutations altering the sequence of the PY motif exclusively concern this subunit (**Table 1**).

The PY motif plays a fundamental role in the internalization of ENaCs. PY motifs of all three ENaC subunits are the recognition site for the ubiquitin-protein ligase Nedd4-2, which binds these motifs and ubiquitinates N-terminal lysine groups of the α and γ subunits. Ubiquitination targets the ENaC for internalization and degradation by the lysosomal and proteasomal pathways, thus decreasing the number of ENaC expressed in the apical membrane (Staub *et al.*, 1997). In addition, ENaC ubiquitination decreases proteolytic cleavage of the channel, thus reducing the ENaC Po. Mutations causing deletion or alteration of the PY motif prevent Nedd4-2 binding to ENaC. As a consequence, internalization/degradation of ENaC fails to occur, resulting in an increased density of ENaCs at the apical membrane of the ASDN. Moreover, the inhibition of ENaC ubiquitination increases the fraction of cleaved ENaCs at the luminal membrane, thus increasing channel Po (Knight *et al.*, 2006). Although supported by abundant data, the above paradigm has recently been challenged by findings in genetically engineered mice with selective deletion of Nedd4-2 in kidney tubules. In this model, Nedd4-2 deletion leads to ENaC accumulation in the intracellular ENaC pool, but not at the plasma membrane, as expected. These results suggest that LS mutations might inhibit the Nedd4-2 mediated degradation of ENaC inside the cell and not the retrieval of ENaC from the cell surface (Ronzaud and Staub, 2014). Therefore, these findings suggest that the defective ubiquitination of ENaC by Nedd4-2 may not fully explain LS.

The inhibitory effect of LS mutations on Nedd4-2-mediated ENaC ubiquitination would be similar to one of the mechanisms mediating the aldosterone regulation of ENaC. Aldosterone induces the expression of SGK1 that phosphorylates Nedd4-2 on

Codon numbers correspond to the positions in *Homo sapiens*. In the literature, human β subunit mutations are sometimes numbered according to the sequence of *Mus musculus*, which is shifted down by two positions. The first nine mutations are missense mutations, while the last one is a frameshift mutation due to insertion of an additional cytosine between codons 618 and 619, which changes Tyr620 to Leu620 and introduces a stop codon at 621. Substituent amino acid residue and mutated codon for each mutation are indicated in italics.

serine residues, causing the binding of Nedd4–2 to 14-3-3 adaptor proteins that prevent Nedd4-2 interaction with ENaC, thus decreasing ENaC ubiquitination (Kamynina and Staub, 2002).

A transgenic LS mouse model carrying the same mutation (βENaC R566stop) identified in the original kindred observed by Liddle reproduces the human LS phenotype and exhibits an increase in both cell surface density and activity of ENaC in ASDN, which is consistent with the results of functional expression of LS mutations in heterologous cell systems (Rossier *et al.*, 2013; Pradervand *et al.*, 1999; Nesterov *et al.*, 2016). On the basis of the LS mouse model, the primary site of increased ENaC expression and activity corresponds to the most proximal parts of the ASDN, that is DCT2 and CNT, where ENaC activity is largely aldosterone independent. Moreover, LS mice exhibit increased responsiveness to aldosterone in the distal part of ASDN, which accounts for the persistence of residual ENaC expression and activity in the cortical CD, notwithstanding the low plasma levels of aldosterone that characterize LS. Thus, the failure to downregulate ENaC activity in the CD in response to enhanced Na^+ reabsorption in the proximal parts of ASDN, even when aldosterone level is maximally decreased, may contribute to Na^+ retention and salt-sensitive hypertension (Nesterov *et al.*, 2016; Dahlmann *et al.*, 2003). Furthermore, the maintenance of aldosterone responsiveness confirms the clinical observation by Liddle that aldosterone administration leads to a decrease in sodium excretion (Liddle *et al.*, 1963).

The three missense mutations altering sequences far from the PY motif (γENaC N530S, βENaC R563Q, and αENaC C479R) increase ENaC activity less than mutations which delete or alter the PY motif. Indeed, expression of either the mutant γENaC N530S or αENaC C479R in *Xenopus* oocytes demonstrated a twofold increase in ENaC activity, while mutations which delete or alter the PY motif increase the amiloride-sensitive sodium current from three to more than eightfold compared with the wild-type ENaC. In fact, both γENaC N530S and αENaC C479R mutations increase the channel Po, without changing the cell surface expression of ENaC (Hiltunen *et al.*, 2002; Salih *et al.*, 2017). As to the βENaC R563Q mutation, it may cause hypertension in affected subjects, but is associated with the full-blown LS phenotype only in a minority of patients (Jones *et al.*, 2011).

Interestingly, LS is the mirror image of the autosomal recessive form of pseudohypoaldosteronism type-1 (PHA-1), which is caused by loss-of-function mutations of either SCNN1A or SCNN1B or SCNN1G, leading to defective ENaC. The clinical picture of PHA-1 actually encompasses salt wasting, volume depletion, low blood pressure, metabolic acidosis, hyperkalemia, and high levels of plasma renin and aldosterone (Chang *et al.*, 1996). Thus, these two rare human diseases clearly confirm the fundamental role of ENaC in regulating electrolyte balance and blood pressure.

Pathophysiology of LS

In LS, the increased ENaC activity in the apical surface of ASDN leads to a greater Na^+ reabsorption, plasma volume expansion, high blood pressure, and consequent decrease in renin and aldosterone secretion. In addition, the increased Na^+ reabsorption through ENaC generates a transepithelial lumen-negative voltage that drives K^+ secretion across ROMK channels in the apical membrane of the principal cells of ASDN and facilitates the proton secretion by the proton pump in the intercalated cells of ASDN, resulting in hypokalemic metabolic alkalosis (**Fig. 3**).

Thus, LS should be regarded as a tubulopathy. Indeed, the proband reported by Liddle developed end-stage renal disease afterward, and 26 years after the original report she underwent deceased-donor kidney transplantation, which led to the normalization of plasma potassium level and improvement of hypertension (Botero-Velez *et al.*, 1994). Correction of hypokalemia and hypertension after kidney transplantation was also found in another patient with clinical features consistent with LS (Noblins *et al.*, 1992). However, emerging evidence suggests that in addition to renal Na^+ retention other factors contribute to hypertension in LS: ENaC may play an important role in BP regulation or dysregulation not only by virtue of its activity in the kidney, but also in the brain and in the vasculature. In the brain, ENaC is expressed in cardiovascular regulatory centers within the hypothalamus and

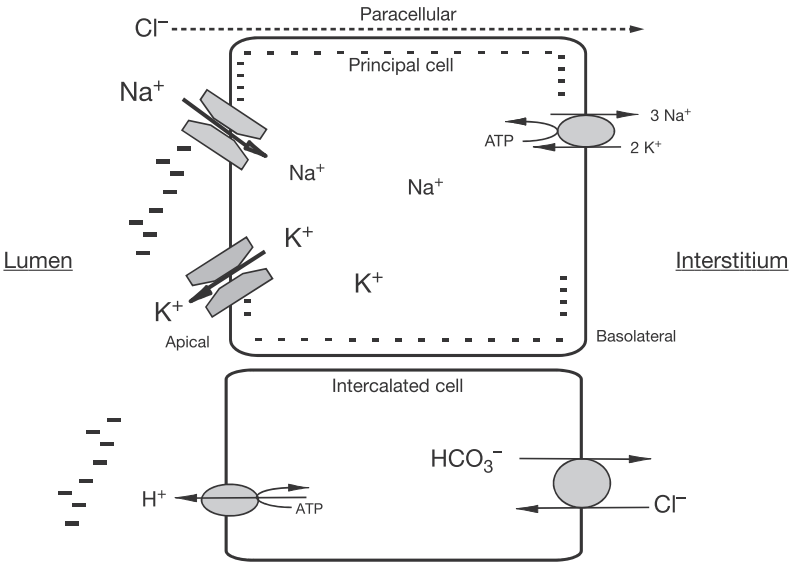

Fig. 3 Handling of Na^+ and K^+ in the cortical collecting duct (CCD). ENaC expressed in the cells of CCD allows Na^+ transport from the lumen into the cell along a favorable electrochemical gradient. Reabsorbed Na^+ is extruded from the principal cell of the CCD into the interstitium through Na^+/K^+ ATPase, and from the interstitium to peritubular capillaries via Starling forces. Both Na^+ flow through ENaC and Na^+ transport through Na^+/K^+ ATPase are electrogenic, and generate a lumen-negative transepithelial voltage, which leads to K^+ diffusion through K^+ channels (ROMK) from the cell to the lumen and facilitates the active H^+ secretion into the lumen associated with HCO_3^- generation in the intercalated cell.

in the choroid plexus epithelium. The increased ENaC expression in cardiovascular regulatory centers in the brain has been associated to sympathetic hyperactivity and hypertension in rat models of salt-sensitive hypertension (Fujita and Fujita, 2013).

In the Nedd4-2 knockout mouse, which may be considered an animal model of Liddle syndrome, increased expression of ENaC has been found in both choroid plexus and neurons. Moreover, intracerebroventricular (IVC) infusion of sodium-rich cerebrospinal fluid (CSF) caused an increase in blood pressure threefold higher than in wild-type animals, and this response was abolished by IVC infusion of an ENaC blocker. Therefore, it has been suggested that the increased ENaC expression in the brain may play a role in the hypertensive response to a high-salt diet through an increase in CSF Na^+ concentration and enhanced responsiveness to CSF sodium (Van Huysse *et al.*, 2012).

As to the role of ENaC in the vasculature, endothelial cells express amiloride-sensitive ENaCs. In contrast to the tight epithelium of ASDN, the endothelium is a leaky barrier, where the ENaCs do not play a role in Na^+ and H_2O transport, which instead is driven by Starling forces. At this level, ENaC is involved in regulating the mechanical properties of endothelial cells. Indeed, an increased expression of ENaC in the luminal membrane of the endothelial cells causes an increase in endothelial stiffness, which in turn decreases nitric oxide (NO) release. An increased endothelial ENaC expression causing endothelial stiffness, which is reversed by amiloride, has been observed in ex vivo vascular preparations from the LS mouse model carrying the βENaC R566stop mutation. Therefore, in LS the increased expression of endothelial ENaC may result in endothelial dysfunction, increase in vascular tone and blood pressure (Jeggle *et al.*, 2013).

These findings challenge the prevailing theory on the common pathways mediating the development of hypertension in the Mendelian human forms of salt-sensitive hypertension. In fact, on the basis of the classic Guyton theory, the expansion of intravascular volume due to the increased renal reabsorption of salt, with the resulting increase in cardiac output, would be the unique necessary and sufficient requirement for the initiation of salt-dependent hypertension. Increased peripheral resistance would contribute to hypertension only in the phase of stabilization of high blood pressure, through the autoregulation of tissue blood flow, which reestablishes a normal cardiac output at the cost of long-term persistence of hypertension resulting from the increase in systemic vascular resistance. In contrast with this prevailing theory, abnormalities in vascular function, resulting from increased expression of ENaC in the brain and in the vessels, would also be at play in both the initiation and stabilization of hypertension in LS, and presumably in other forms of salt-sensitive hypertension (Kurtz *et al.*, 2015).

This emerging paradigm is not at odds with the reversal of hypertension and hypokalemia after kidney transplantation in LS patients, as both Na^+ retention and vascular dysfunction are required for the development of salt-sensitive hypertension. Renal transplantation would normalize renal Na^+ and K^+ handling, with the correction of hypertension and hypokalemia as a result. However, endothelial dysfunction would not be reversed, with the possible persistence of an increased risk of cardiovascular events.

Lastly, ENaC is expressed in the taste bud cells of the anterior tongue, where it serves as the sodium taste receptor, activated by salt and inhibited by amiloride. Moreover, engineered mice lacking ENaC in taste bud cells lose any appetite for salt (Chandrashekar *et al.*, 2010). Even in nonhuman primates, an amiloride-sensitive component has been demonstrated in taste responses to salt stimuli (Hellekant *et al.*, 1997). In humans, the effects of amiloride in the perception of saltiness are controversial (Stahler *et al.*, 2008; Halpern,

1998; Heck *et al.*, 1984). Therefore, in LS patients an increased expression of ENaC in taste receptors could hypothetically lead to attraction to sodium salt, thus leading to high dietary sodium intake, which could contribute to hypertension.

Considering the emerging evidence that an increased expression and activity of ENaC in LS involves not only the ASDN but also the vasculature, the brain, and salt taste receptors, the canonic theory that LS exclusively represents a tubulopathy evidently turns out to be incomplete.

Epidemiological and Clinical Features of LS

LS occurs worldwide, with no ethnic or sex predilection, and is classified by Orphanet as a "rare disease", with a roughly estimated prevalence of $<1/10^6$ within the global population. Actually, no more than about 100 kindreds or sporadic cases have been reported so far, and most of them as case reports (Cui *et al.*, 2017). Though LS is considered a very rare condition, its prevalence in large cohorts of hypertensives has not been investigated so far. However, in a small cohort of 330 Chinese hypertensives aged between 14 and 40 years, LS was diagnosed and confirmed by genetic testing in five patients carrying different ENaC mutations, which corresponds to a prevalence of 1.52% (Halpern, 1998). In another Chinese cohort of 766 subjects with early-onset hypertension, 7 unrelated patients (0.91%) were diagnosed with genetically confirmed LS, with a prevalence of 1.72% among 407 patients with a diagnosis of hypertension before the age of 30 (Liu *et al.*, 2017). Genetic screening of the probands' relatives identified further patients with LS (12 and 10, respectively) in these study cohorts. These findings suggest that the prevalence of LS may not be as low as is commonly believed.

Probands with LS are most often diagnosed between the ages of 10 and 30 years, but some cases have been reported with an earlier onset, at the age of 4, 5, and 8, respectively (Freundlich and Ludwig, 2005; Ciechanowicz *et al.*, 2005; Polfus *et al.*, 2016). However, the diagnosis of LS in the affected relatives of LS probands is commonly delayed, with an interval between the ascertainment of hypertension and LS diagnosis ranging from years to decades, suggesting that LS is currently underdiagnosed and undertreated. Probands' family history often shows early-onset hypertension and premature cardiovascular events in several members across multiple generations of either maternal or paternal lineage, which is consistent with an autosomal-dominant inheritance pattern (**Fig. 4**).

The full-blown LS phenotype includes early-onset salt-sensitive hypertension, increased urinary K^+ excretion, hypokalemic metabolic alkalosis, suppression of both renin and aldosterone secretion, and unresponsiveness to mineralocorticoid receptor antagonists, as opposed to the response to ENaC blockers.

LS is associated with an increased risk of premature stroke, myocardial infarction, and sudden death. These complications are commonly attributed to longstanding misdiagnosed and undertreated hypertension. Indeed, early-onset hypertension is in itself associated with a greater cardiovascular risk than in those with late-onset hypertension, regardless of the cause of hypertension (Niiranen *et al.*, 2017). However, endothelial dysfunction due to increased expression of mutant ENaC in the endothelial cells might contribute as well. Moderate-to-severe hypokalemia (serum K^+ <3 mmol/L) may cause serious complications due to its effects on myocardium and skeletal muscle (**Table 2**).

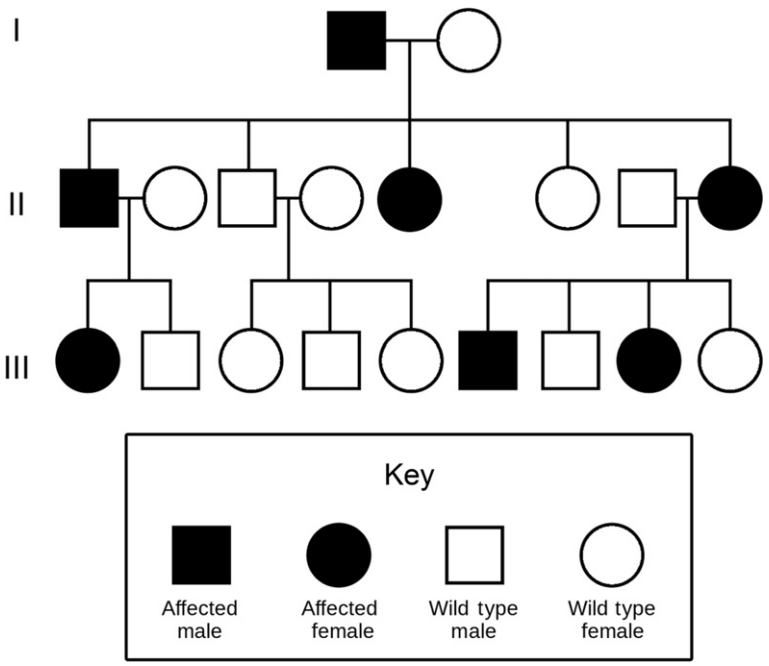

Fig. 4 Autosomal-dominant inheritance pattern.

Actually, LS exhibits remarkable phenotypic variability in age at presentation, degree of hypertension, and plasma potassium concentration. Hypertension may range from mild to severe and plasma potassium from very low to completely normal levels among patients within the same pedigree or unrelated patients with the same mutation, presumably as a result of both allelic variants of other genes and different dietary habits concerning sodium and potassium intake (Botero-Velez *et al.*, 1994; Hiltunen *et al.*, 2002; Tamura *et al.*, 1996; Rossi *et al.*, 2011). The variability of plasma K^+ concentration is reminiscent of other conditions characterized by increased ENaC activity, in primis primary aldosteronism. Indeed, screening of hypertensives for primary aldosteronism regardless of the plasma potassium values has impressively increased the prevalence of this condition from $<1\%$ to $>10\%$ among hypertensives, and showed that the majority of patients with primary aldosteronism are actually normokalemic (Rossi *et al.*, 2006). By contrast, a diagnosis of LS is currently considered exclusively in hypokalemic hypertensives, while normokalemic patients with LS are identified only following the genetic screening of the relatives of hypokalemic probands. Thus, the current approach may overlook many normokalemic patients with LS.

On the contrary, reduced plasma levels of renin associated with either low or normal values of plasma aldosterone are a constant finding in LS patients.

Diagnosis of LS

LS should be considered in all patients with early-onset hypertension, regardless of plasma K^+ concentration, even in the absence of a family history of early-onset hypertension, since de novo mutations may be responsible for sporadic cases of LS. The basal biochemical and hormonal alterations associated with LS are indicated in **Table 3**.

The following functional tests may confirm the increased activity of ENaC.

Cosyntropin (ACTH 1–24) stimulation test. The test is performed in the morning on the fasting patient. Blood samples for plasma aldosterone are taken before and 30 min after intravenous injection of Cosyntropin [ACTH 1–24] 250 μg. In LS patients, the aldosterone response is blunted or absent.

Transmucosal nasal potential difference. Since ENaC is also present in the nasal epithelium, its activity may be quantified by transmucosal electrical potential difference. Higher basal lumen-negative potential difference and greater change in potential difference after topical amiloride application have been observed in few related patients with LS compared with controls (Baker *et al.*, 1998). This test, which explores the ENaC activity "in vivo", has not been performed in other LS kindreds, thus leaving its diagnostic accuracy undefined.

Table 2 Clinical manifestations of moderate-to-severe hypokalemia

Neuromuscular system	Cramp Myalgia Paresthesia Weakness Paralysis Rhabdomyolysis
Cardiovascular system	EKG changes • prominent U waves • flattened or inverted T waves • S-T segment depression • T- and U-wave fusion (pseudo-prolonged QT interval) Arrhythmias • Ectopic supraventricular and ventricular beats • Atrial tachycardia with or without atrioventricular block • Ventricular tachycardia • Ventricular fibrillation • Torsades de pointes Sudden death
Kidney	Polyuria (acquired nephrogenic diabetes insipidus) Hypokalemic tubulo-interstitial nephropathy
Gastrointestinal tract	Constipation Paralytic ileus
Endocrine system	Insulin resistance Impaired insulin release

Table 3 Biochemical and hormonal features of Liddle syndrome

Plasma [K^+]	Low or normal
Plasma renin	Low
Plasma aldosterone	Low or normal
Plasma [HCO_3^-]	Increased or normal
Urinary K^+/24 h[a]	High or normal
Urinary aldosterone/24 h	Low
Urinary aldosterone-to'potassium ratio (ng/mmol)[b]	<60

[a]In the case of hypokalemic LS, a potassium excretion >30 mmol/24 h indicates an increased secretion of K^+ in the ASDN.
[b]A reduced ratio reflects an increased K^+ secretion resulting from an increased sodium reabsorption independent of the aldosterone drive.

However, both basal and functional tests cannot discriminate LS from other Mendelian forms of low-renin, low-aldosterone hypertension, also characterized by an increased ENaC activity independent of the aldosterone drive.

Comparison of the responses to spironolactone and triamterene. LS patients exhibit unresponsiveness to mineralocorticoid receptor antagonists, as opposed to the efficacy of ENaC blockers in correcting hypokalemia and reducing blood pressure. A 3-week trial of spironolactone 100 mg/day does not have effects on both plasma potassium and blood pressure. In contrast, a 3-week trial of either triamterene 100 mg/day or amiloride 10 mg/day corrects hypokalemia (at least partially) and reduces blood pressure. This test actually discriminates LS from other low-renin, low-aldosterone forms of hypertension. However, it is time-consuming, and not appropriate in the case of normokalemic LS patients.

DNA sequence analysis. Direct sequencing of the PCR-amplified final exons of both SCNN1B and SCNN1G is the most accurate tool to identify a causal mutation of LS. Since most mutations causing LS are clustered in a short DNA sequence, screening by direct sequencing of the exon 13 of both SCNN1B and SCNN1G is relatively simple, rapid, and feasible. In the event that no mutation of either SCNN1B or SCNN1G is found, genotyping SCNN1A may be needed, since a causative mutation responsible for LS has been recently identified (Salih *et al.*, 2017).

Restriction fragment length polymorphism (RFLP). Some LS mutations may create a restriction site for specific endonucleases which cut DNA within their recognition sequences (**Fig. 5**).

In this case, the enzymatic cleavage of exon 13 generates DNA fragments only in the mutant allele (**Fig. 6**). RFLP may represent a more rapid way to genetically screen the proband's relatives.

In view of the autosomal-dominant inheritance pattern of LS, each child has a 50% chance of inheriting the disease from an affected parent. Therefore, genetic testing of the offspring of affected patients is advisable, even in asymptomatic children or adolescents, since they may later develop the LS phenotype. Indeed, the finding of a LS mutation in asymptomatic children or adolescents warrants for a continued surveillance and appropriate lifestyle changes recommendations (such as dietary sodium restriction) aimed at delaying the clinical onset of LS.

Functional expression of the mutant ENaC. The genetic discovery of a novel ENaC mutation in patients with the LS phenotype does not necessarily imply its causal role. The conclusive proof of the mutation's pathogenicity comes from studying the activity of the mutant ENaC in expression systems, of which the *X. laevis* oocytes expression system is the most standardized. It consists of the injection of the mutant and the wild ENaC cRNA in oocytes, followed by the electrophysiological measurement of the amiloride-sensitive Na^+ current in the oocytes expressing mutant ENaCs compared with those expressing wild-type channels. However, these techniques are available only in few research laboratories.

Differential diagnosis. LS must be differentiated from other Mendelian forms of low-renin, low-aldosterone hypertension. While some of them exhibit a clearly specific clinical phenotype, mild forms of familial apparent mineralocorticoid excess syndrome (AMES) may be indistinguishable from LS. The autosomal-dominant inheritance pattern may help distinguish LS from AMES, which is an autosomal recessive disorder. As mentioned, however, LS may affect even patients without a family history of early-onset hypertension, since de novo mutations may occur (Uehara *et al.*, 1998; Yamashita *et al.*, 2001; Nakano *et al.*, 2002). In contrast to LS, AMES patients respond to both mineralocorticoid receptor antagonists and ENaC blockers. A key diagnostic marker of AMES is the increased urinary ratio of free cortisol to cortisone, or of reduced metabolites of cortisol to reduced metabolites of cortisone ([THF + αTHF]/THE), which definitively differentiates it from LS.

Therapy

Both hypertension and hypokalemia are corrected in most patients with LS by the use of an ENaC blocker associated with dietary sodium restriction.

ENaC blockers. Both triamterene and amiloride bind a specific site at the extracellular entry of the ENaC pore, where they block Na^+ flow into the cell. In the kidney, ENaC inhibition results in increased Na^+ excretion and decreased K^+ excretion, which normalize plasma volume, and plasma K^+ level. In addition, blocking the ENaCs expressed in the brain and vasculature might contribute to the correction of hypertension and reduction of cardiovascular risk.

Triamterene is a pteridine derivative (**Fig. 7**). Daily doses ranging from 100 to 300 mg are usually effective.

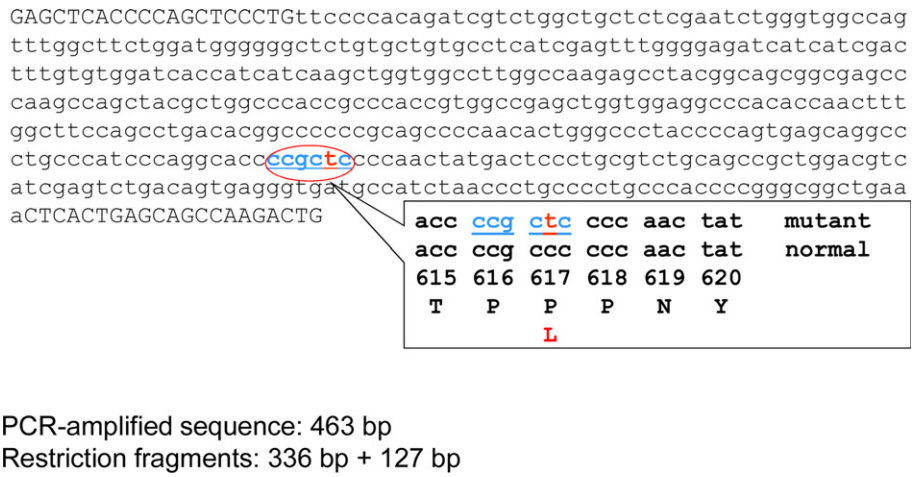

Fig. 5 Recognition site (ccgctc) for the *Bsr*BI endonuclease within the exon 13 of the mutant *SCNN1B* (βP617L). The BsrBI endonuclease recognizes a sequence containing the mutated codon 617 (ctc), resulting in the cleavage of the 463 bp exon 13 of *SCNN1B* into two fragments of 336 and 127 bp.

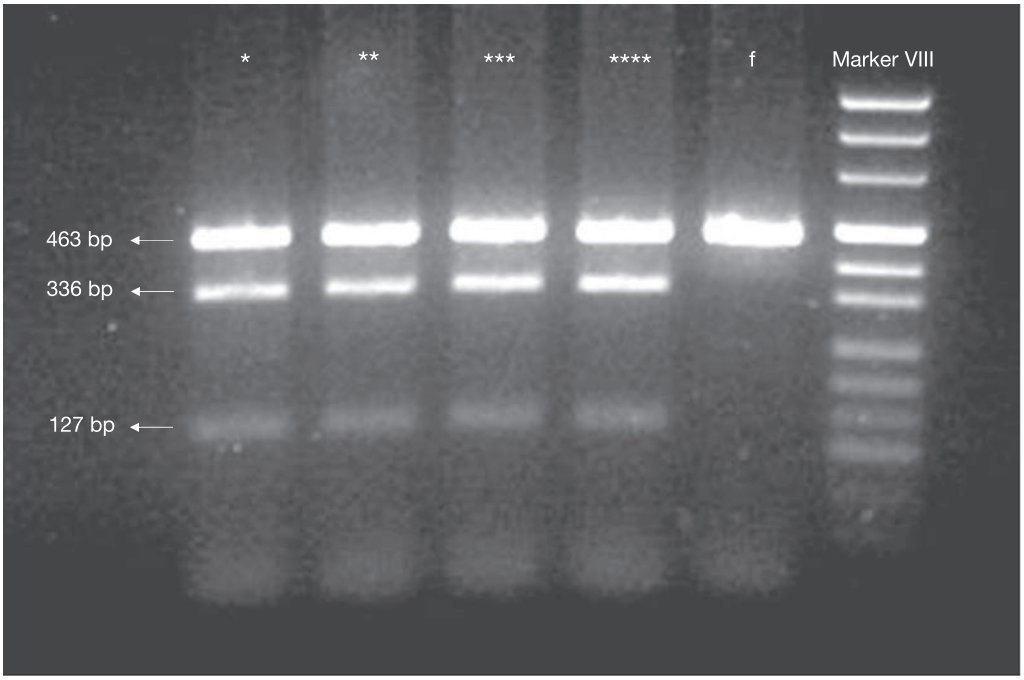

Fig. 6 Restriction fragment length polymorphism (gel electrophoresis) in a kindred carrying the βENaC P617L mutation. A band corresponding to the wild-type allele (463 bp) is present in all subjects. The bands of 336 and 127 bp (resulting from the enzymatic cleavage of the mutant 463 bp allele) are present only in the affected members of the family. *, proband; **, proband's mother; ***, proband's maternal uncle; ****, proband's grandmother; f, proband's father.

Amiloride, an aminopyrazine derivative, is an open-chain analog of triamterene (**Fig. 7**). Its potency is much greater than that of triamterene, and effective daily doses vary from 10 to 30 mg.

The dose of either triamterene or amiloride needs to be titrated based on the effects on serum potassium level and blood pressure values. In addition, the use of an ENaC blocker should be associated with dietary sodium restriction, since these drugs compete with Na^+ ions at the level of the ENaC pore. Therefore, an excessive dietary intake of salt, through an increase in sodium delivery to ASDN, limits the effects of ENaC blockers and maintains both plasma volume expansion and renal potassium wasting.

Both plasma renin activity and plasma aldosterone levels may remain low after several months of treatment with an ENaC blocker, despite the normalization of BP and serum K^+. Indeed, chronic volume expansion caused by the activation of ENaC might lead to a sort of "disuse atrophy" of juxtaglomerular cells in the kidney and glomerulosa cells in the adrenal cortex.

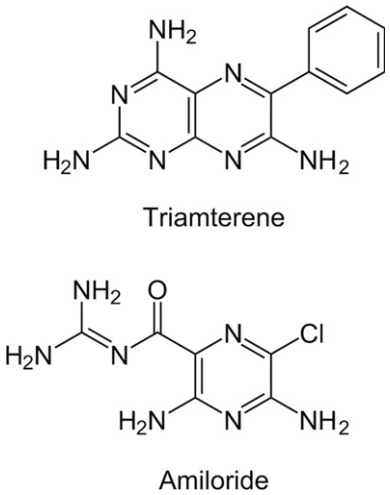

Fig. 7 Chemical structure of triamterene and amiloride.

Amiloride or triamterene alone are often adequate to normalize blood pressure and plasma K^+ concentration. However, in several LS patients, conventional antihypertensive drugs (such as calcium-channel blockers) need to be added for achieving optimal blood pressure control.

Treatment of moderate–severe hypokalemia associated with LS. Severe and symptomatic hypokalemia may require oral or intravenous potassium replacement. Potassium chloride must be preferred to other K^+ salts, since both K^+ and Cl^- administration contribute to correct the coexisting metabolic alkalosis.

Treatment of LS during pregnancy. Hypertension in pregnancy is a major cause of maternal, fetal, and neonatal morbidity and mortality. However, although LS affects women of childbearing age, the optimal management of hypertensive pregnant women with LS is unclear and entails several challenges. Commonly recommended antihypertensive drugs in pregnancy (such as methyldopa, sustained-release nifedipine, and labetalol) may be ineffective in patients with LS. Moreover, diuretics are discouraged in pregnancy, since the sodium retention and the resulting increase in maternal plasma volume, progressively occurring throughout normal pregnancy, ensure an optimal uteroplacental perfusion. Indeed, pharmacological blockade of ENaC in a late pregnant rat prevents sodium retention and maternal volume expansion, with fetal growth restriction as a result (West *et al.*, 2014). On the other hand, in the setting of LS, the volume expansion associated with pregnancy would be excessive and responsible for hypertension, given the basal constitutive activation of ENaC in ASDN.

No randomized trial evaluating the safety profile of ENaC blockers during gestation has been performed to date.

Triamterene is a folic acid antagonist, and its use in pregnancy, at least in the first trimester, may be associated with an increased risk of congenital malformations, such as neural-tube defects, cardiovascular defects, and oral clefts (Hernandez-Diaz *et al.*, 2000). Therefore, its use is not advisable in pregnancy, especially in the first trimester.

With regard to amiloride, teratogenicity studies in rabbits and mice revealed no evidence of harm to the fetus, although a decrease in rat pup growth was observed at doses five or more times the expected maximum dose for humans.

Only two case reports concerning the use of amiloride in pregnant patients with LS have been reported to date. In both cases, amiloride, which was administered from the 25th and 18th gestational week respectively, proved to be effective with no maternal or fetal adverse effects (Caretto *et al.*, 2014; Awadalla *et al.*, 2017). Moreover, amiloride has also been used in pregnant women with either primary aldosteronism or Gitelman/Bartter syndromes, at daily doses ranging from 15 to 30 mg, started at a gestational age from 1 to 17 weeks, with no maternal or fetal adverse effects (Al-Ali *et al.*, 2007; Krysiak *et al.*, 2012; Morton, 2015; Mathen *et al.*, 2013; Deruelle *et al.*, 2004). Increasing doses of amiloride may be needed to control blood pressure as gestational age advances, possibly due to the progressive increase in the expression of mutant ENaCs. After delivery, the dose of amiloride should be reevaluated in relation to possible and excessive decrease in blood pressure. Although it is not known whether amiloride is excreted in human milk, in rats the drug is excreted in milk in concentrations higher than those found in blood. Because of potential adverse effects in nursing infants, a decision should be made whether to discontinue nursing or to discontinue amiloride, taking into account the importance of the drug to the mother.

Conclusions

Several reasons warrant a more extensive search and earlier diagnosis of LS in hypertensive patients. Prevalence of LS may be higher than that commonly perceived. Patients with misdiagnosed LS are at high risk of premature cardiovascular events. Lastly, ENaC blockers together with dietary salt restriction are impressively efficient in both reversing the clinical manifestations and preventing severe complications.

Secondary Hyperaldosteronism

Aleksander Prejbisz and Andrzej Januszewicz, Institute of Cardiology, Warsaw, Poland

Definition

Secondary hyperaldosteronism is defined as an increased aldosterone production resulting from extra-adrenal stimulation of adrenal gland (Corry and Tuck, 1995; Kaplan and Victor, 2015; Schrier, 2011; Young *et al.*, 2017).

Background and Pathogenesis

Extra-adrenal stimulus for increased aldosterone production can be a single factor or an interplay of a number of regulatory factors. Secondary hyperaldosteronism might be a physiological and pathophysiological consequence of reduced "effective" arterial blood volume arising from a circulatory disorder such a heart failure or severe hypertension, leading to renal hypoperfusion and to augmented renin secretion. As a consequence of renin-angiotensin system activation, angiotensin II, together with known modulators, increases aldosterone secretion. In some of these clinical conditions, for example, electrolyte depletion from vomiting or diuretic use, hyperaldosteronism should be regarded more as compensatory effect, lessening when the triggering factor is relieved (Corry and Tuck, 1995; Kaplan and Victor, 2015; Schrier, 2011; Young *et al.*, 2017).

Renovascular Hypertension

Renovascualar hypertension (RVH) is one of the most frequent causes of secondary hypertension. Renal artery stenosis (RAS) the most frequent cause of RVH leads not only to the development of hypertension, but also results in ischemic nephropathy and chronic kidney disease. De Mast and Beutler reviewed the atherosclerotic RAS and estimated the following prevalence of atherosclerotic RAS in various populations: hypertension and diabetes (20%), coronary angiography (10.5%), coronary angiography in hypertensive patients (18%), coronary angiography and suspected renovascular disease (17%), heart failure (54%), peripheral vascular disease (25%), abdominal aortic aneurysm (31%) and end-stage renal disease (41%). However, the existence of RAS does not inevitably leads to RVH. Therefore, these two terms—RAS and RVH—cannot be paralleled. RVH is much less common than is RAS. Prevalence of RVH is estimated as less than 1% of general hypertensive population. In a study of Anderson *et al.*, which included 4429 hypertensive patients, RVH was found in 3.1% of patients. RVH is more frequent in patients with resistant hypertension and malignant hypertension, as well as in elderly which are characterized by higher incidence of atherosclerotic RAS. In a study of Morganti *et al.* the prevalence of RVH was 6.4% in patients with atherosclerotic RAS and 31.3% in patients with RAS caused by fibromuscular dysplasia (FMD) (Kaplan and Victor, 2015; de Mast and Beutler, 2009; Giavarini *et al.*, 2013; Dzielinska *et al.*, 2007; Anderson *et al.*, 1994; Hansen *et al.*, 2002).

The role of the renin-angiotensin-aldosterone system in the pathogenesis of RVH in patients with atherosclerotic RAS is widely accepted. In the early stage of RVH, significant renal ischemia causes marked rise in renin secretion. This further leads to the activation of the renin-angiotensin-aldosterone system. In spite of subsequent hyperaldosteronism, blood volume remains unchanged because of natriuresis in the contralateral kidney. In the next stage, hypertension induced nephrosclerosis, enhancing kidney failure, leads to a progressive expansion of blood volume, subsequently reducing renin secretion. However, renin and angiotensin II are still inappropriately elevated in relation to blood volume expansion (Kaplan and Victor, 2015; de Mast and Beutler, 2009; Giavarini *et al.*, 2013).

It should be noted, that in addition to the activation of the renin-angiotensin-aldosterone system, several other factors and mechanisms contribute to the elevation of blood pressure and progression of kidney failure in RVH. These include increased sympathetic nervous system activity and increased secretion of endothelin-1. Recently it has been also postulated that natural history of atherosclerotic RAS consists of three stages: (1) reduction of blood flow is compensated by a reduction in GFR what preserves renal tissue oxygenation (2) advancing RAS causes renal cortical hypoxia which in turn induces production of inflammatory cytokines and fibrotic pathways, which may result in (3) irreversible damage to the microvasculature (pruning of renal microvessels) (Chrysochou *et al.*, 2012; Textor and Lerman, 2013; Gloviczki *et al.*, 2010; Saad *et al.*, 2013).

When comparing with atherosclerotic RAS, not all pathophysiological mechanisms causing hypertension described above can be extrapolated to patients with FMD related RAS. Recent data indicate, that in patients with renal FMD pathogenesis of hypertension caused by RAS is complex. On one hand it is believed that decrease in renal blood flow is stimulating the renin-angiotensin system—particularly in the early stage of the disease—and result in increased production of angiotensin II. It has been documented in a small group of FMD patients that successful renal angioplasty followed by decrease in BP and subsequent down-regulation of the renin-angiotensin system may decrease oxidative stress resulting in bioavailability of nitric oxide and inhibition of production of angiotensin II (Higashi *et al.*, 2002; Petruzzelli *et al.*, 2016).

 doi:10.1016/B978-0-12-801238-3.66149-4

On the other hand the recent findings of van Twist *et al.* argue against the hypothesis that FMD induces hypertension via similar pathophysiological mechanism as in atherosclerotic RAS since renal blood flow was significantly higher in FMD as compared with atherosclerotic RAS. In contrast to patients with unilateral atherosclerotic RAS lateralization in renin secretion was not found in unilateral FMD and systemic and local renin secretion was lower in FMD as compared with atherosclerotic RAS (van Twist *et al.*, 2017).

The most common cause of RAS is atherosclerotic ($\approx$85%), FMD is the second most common cause ($\approx$15%). Clinical signs of RVH include resistant hypertension, deterioration of renal function or, rarely, flash pulmonary edema. **Table 1** details clinical situations raising suspicion of RVH (Young *et al.*, 2017; Mancia *et al.*, 2013).

In patients with a clinical suspicion of RAS, doppler ultrasonography is the first-line imaging modality to screen for significant RAS ($\geq$60% stenosis). The sensitivity and specificity of peak systolic velocity in the main renal artery for RAS has been estimated, respectively, as 85% and 92%. Multidetector computed tomography angiography and magnetic resonance angiography for detection of RAS showed equally high sensitivities (64%–100% and 94%–97%) and specificities (92%–98% and 85%–93%). However digital subtraction angiography (DSA) remains the gold standard for the diagnosis of RAS (Aboyans *et al.*, 2018).

Treatment strategies for RAS have been recently summarized in the European Society of Cardiology (ESC) 2017 guidelines (Aboyans *et al.*, 2018):

- Angiotensin converting enzyme inhibitors or angiotensin receptor blockers are recommended for treatment of hypertension in patients with unilateral RAS (class I, level B recommendation);
- Those drugs can be considered also in bilateral severe RASS or in patients with stenosis in a single functioning kidney, if well tolerated and under close supervision (class IIb, level B recommendation);
- Calcium channel blockers, beta-blockers and diuretics are recommended for treatment of hypertension in patients with RAS (class I, level C recommendation);
- In atherosclerotic RAS routine revascularization is not recommended (class III, level A recommendation);
- In FMD RAS in case of hypertension and/or signs of renal impairment, balloon angioplasty with bailout stenting should be considered (class IIa, level C recommendation);
- In selected patients with RAS and unexplained recurrent congestive heart failure or sudden pulmonary edema, balloon angioplasty, with or without stenting, may be considered (class IIb, level C recommendation);
- Surgical revascularization should be considered in patients with indication for revascularization in case of complex anatomy of the renal arteries, after a failed endovascular procedure or during open aortic surgery (class IIa, level B recommendation).

Malignant Hypertension

Malignant hypertension (MHT), also known as accelerated-malignant hypertension or malignant phase hypertension is defined clinically as high blood pressure associated with bilateral retinal flame-shaped hemorrhages, exudates or cotton wool spots, with or without papilledema. It is the most severe form of hypertension. It has been also proposed to replace the term "malignant hypertension" with "hypertensive crisis with retinopathy." Since the presence of retinopathy may allow other target organs to be included, making the description of this type of hypertensive emergency more accurate (Kaplan and Victor, 2015; Mancia *et al.*, 2013; van den Born *et al.*, 2011; Januszewicz *et al.*, 2016).

MHT is associated with failure of blood pressure autoregulation and develops when the mean arterial pressure (diastolic blood pressure + 1/3 of the difference between systolic and diastolic blood pressure) reaches a critical level of 150 mmHg, as reported in experimental animals. Fibrinoid necrosis appears in the arterial walls, which may be caused by vasoactive factor(s) or may be a nonspecific consequence of very high BP (Kaplan and Victor, 2015; Januszewicz *et al.*, 2016).

Possible pathophysiological mechanisms for the development of MHT have been proposed. These include: rapidly increasing blood pressure, pressure diuresis and natriuresis, severe renal vasoconstriction and ischemia. Moreover, activation of the renin-

Table 1 Clinical situation raising suspicion of renovascular hypertension or renal artery stenosis (Mancia et al., 2013)

Clinical situation raising suspicion of renovascular hypertension	
Atherosclerotic renal artery stenosis	*Fibromuscular dysplasia*
Flash pulmonary edema	Early onset HT (especially in women)
	FMD in other vascular beds or history of spontaneous artery dissection
	HT of abrupt onset,
	Worsening or increasingly difficult to treat HT;
	Resistant or malignant HT;
	Abdominal bruit, bruits over other arteries
	Rapid deterioration in renal function (spontaneous or in response to RAA blockers).
	Hypokaliemia

HT—hypertension; RAAS—renin–angiotensin–aldosterone system.

angiotensin-aldosterone system, microangiopathy, hemolytic anemia and development of retinopathy are found in MHT. The vascular lesions of MHT consist of fibrinoid necrosis and myointimal proliferation (Januszewicz *et al.*, 2016).

Various symptoms and complications may accompany MHT, the most typical being microangiopathic lesions or renal failure. In some patients, the presenting manifestation may be an acute oliguric renal failure. In patients with MHT many features of renal dysfunction, including microalbuminuria, proteinuria, may be also present. About half of patients with MHT may have hypokalemia, reflecting secondary aldosteronism from increased renin secretion induced by intrarenal ischemia. Hyponatremia is also common (Kaplan and Victor, 2015; Januszewicz *et al.*, 2016).

Since MHT is a hypertensive emergency, patients with MHT should receive immediate antihypertensive treatment, under continuous supervision, preferably in an intensive care setting, due to a high risk of renal failure, stroke, myocardial infarction and heart failure (Januszewicz *et al.*, 2016).

The 2013 Guidelines on hypertension from the European Society of Hypertension (ESH) and ESC recommend treatment based on agents that can be administered by intravenous infusion and titrated according to response, lowering blood pressure gradually, avoiding abrupt falls in BP and excessive hypotension (Mancia *et al.*, 2013).

Juxtaglomerular Cell Tumor

In 1967, Robertson *et al.* first described the tumor derived from the juxtaglomerular apparatus producing renin. The case report presented a 16-year–old patient with malignant hypertension, hypokalemia and increased urinary potassium excretion. Intraoperative examination revealed a small tumor in the left kidney. It consisted of juxtaglomerular apparatus cells. Nephrectomy resulted in the normalization of blood pressure and serum potassium concentration (Robertson *et al.*, 1967).

The term "primary reninism" for renin secreting tumors (reninomas) was introduced by J. Conn in the early 1970s. Primary reninism is a very rare form of hypertension with a potentially removable cause. In the last half-century 89 cases were described, and according to other authors—119 cases. Renin-secreting tumors provide a rare opportunity to study the renin-angiotensin-aldosterone system in hypertension; as a source of large amount of renin-secreting cells, they were used to obtain prorenin, renin, their polyclonal antibodies and monoclonal cell cultures as well as for genetic tests. Now, instead of the term primary reninism, the term juxtaglomerular cell tumor is more frequently used (Wong *et al.*, 2008; Beevers *et al.*, 2008; Corvol *et al.*, 1988; Prejbisz *et al.*, 2014).

The clinical picture of juxtaglomerular cell tumor is usually dominated by severe hypertension. Hypokalemia, remarkably increased renin activity or renin plasma concentration and elevated serum aldosterone levels (secondary hyperaldosteronism) are characteristic biochemical abnormalities. Among the imaging methods, computer tomography and magnetic resonance imaging enable a precise location of a tumor in the kidney. Renal vein catheterization might be an useful further diagnostic steps, however in some cases it fails to show gradient of renin concentration between renal veins. Functional imaging techniques are seldom applied in patients with juxtaglomerular cell tumor however it has been reported that they might be useful. This is important for the choice of surgical strategy. Surgical removal of the tumor leads to normalization of blood pressure in most cases (Wong *et al.*, 2008; Beevers *et al.*, 2008; Corvol *et al.*, 1988; Prejbisz *et al.*, 2014).

Congestive Heart Failure

Cardiac failure is related with activation of the renin-angiotensin-aldosterone system. This system's components act to compensate for decreased cardiac output, stabilize the circulation and expand extracellular fluid volume. Resulting from persistence stimulation of the renin-angiotensin-aldosterone system, serum aldosterone level is increased in patient with heart failure. This have deleterious effects on cardiovascular system and kidneys (Masoumi *et al.*, 2015; Januszewicz *et al.*, 2016; Robertson *et al.*, 1967).

Cirrhosis and Nephrotic Syndrome

Likewise as in heart failure, there is variable stimulation of the renin-angiotensin system and the activation of aldosterone secretion, depending on severity, preceding treatment and type of organ failure in cirrhosis and nephrotic syndrome. Both activation of the renin–angiotensin–aldosterone system and sympathetic nervous system, shown in several and experimental studies, lead to increased aldosterone secretion. In cirrhosis the increased aldosterone levels are related to sodium loading and delayed clearance. Also in nephrotic syndrome, aldosterone exerts salt-retaining effects on the distal nephron. It is a site implicated in formation of nephrotic edema. Therefore increased aldosterone activity might be an explanation for observed salt retention (Schrier, 2011; Palmer *et al.*, 2013; Soi and Yee, 2017).

Other Conditions

Secondary aldosteronism might be also associated with a few other conditions (Corry and Tuck, 1995):

- Pregnancy—activation of the renin-angiotensin-aldosterone system might occur early in pregnancy. It is related to the decrease of systemic vascular resistance, in spite of the increase in blood volume. However the increase of aldosterone secretion might be counterbalanced by increased progesterone levels, which has antimineralocorticoid effects.
- Estrogen treatment—estrogen treatment leads to increased renin and angiotensin II production, and subsequently to stimulation of aldosterone secretion.
- Bartter syndrome and Gitelman syndrome—hereditary renal tubular disorders characterized by chronic hypokalemia with renal K+ wasting, metabolic alkalosis, renal salt wasting with low to normal BP. These results in secondary increased renin secretion and secondary hyperaldosteronism. Bartter's syndrome is secondary to defective reabsorption of NaCl in the loop of Henle. Gitelman's syndrome is characterized by defective reabsorption of NaCl in the distal convoluted tubule segments (Lin *et al.*, 2010).

Aldosteronism in Congestive Heart Failure☆

Yenal I Harper, Oluwaseun A Akinseye, Salem A Salem, Muhammad Shahreyar, and Karl T Weber, University of Tennessee Health Science Center, Memphis, TN, United States

Introduction

The clinical syndrome, congestive heart failure (CHF), comprises a constellation of symptoms and signs whose origins arise from renal salt and water retention mediated by effector hormones attendant with an activated renin–angiotensin–aldosterone system (RAAS) (Weber, 2001). RAAS activation occurs in response to reductions in renal blood flow and the subsequent release of renin by juxtaglomerular cells. A fall in renal blood flow may accompany heart failure-reduced ejection fraction (HFrEF) or heart failure with preserved ejection fraction (HFpEF). An index of ventricular systolic function, EF does not predict cardiac output, renal blood flow, and therefore the presence or absence of RAAS activation with salt and water retention, and hence EF does not predict the clinical severity of chronic heart failure and is not a marker of CHF (Weber, 2001). In recognition of the importance of neurohormonal activation in determining morbid and mortal events in patients having CHF, its pharmacologic management has come to include inhibitors of angiotensin II and aldosterone hormone formation and their receptor ligand binding, as well as that of the adrenergic nervous system and its effector hormones.

The aldosteronism of RAAS activation has other deleterious systemic consequences, wherein a cycle of chronic homeostatic responses gone awry begets dyshomeostasis (Kamalov *et al.*, 2010). These adverse effects include secondary hyperparathyroidism (SHPT) with abnormal elevations in plasma parathyroid hormone (PTH) that occur in response to the appearance of ionized hypocalcemia which accompanies increased urinary and fecal calcium excretion; and a pathologic remodeling of the cardiovasculature including the heart, arteriolar circulation, and kidneys.

Herein, we focus on these pathologic consequences of aldosteronism in CHF and where aldosteronism is defined as inappropriate elevations in plasma aldosterone relative to dietary Na^+ intake. We finally review the results of clinical trials involving the efficacy of aldosterone receptor blockade in patients with heart failure.

Excretory Ca^{2+} and Mg^{2+} Losses in Aldosteronism

In human studies, Horton and Biglieri (1962) identified the urinary wasting of Mg^{2+} and K^+ that accompanied an infusion of aldosterone and which was then abrogated by cotreatment with its receptor antagonist spironolactone (see **Fig. 1**). These findings underscored Conn's explanation of why hypomagnesemia and hypokalemia represented several of the cardinal metabolic features of primary aldosteronism (Conn, 1963a,b).

In metabolic studies conducted in 8-week-old male Sprague–Dawley rats, urinary and fecal excretion of Ca^{2+} and Mg^{2+} were monitored in response to a 4-week aldosterone/salt treatment. Marked excretory wasting of these cations occurred with milligram quantities lost in stool and microgram quantities in urine (**Fig. 2**) (Chhokar *et al.*, 2004, 2005). The losses of Ca^{2+} and Mg^{2+} led to the appearance of ionized hypocalcemia and hypomagnesemia (**Fig. 3**) and as expected, this invoked the Ca^{2+}-sensing receptor of the parathyroid glands to elaborate PTH (Chhokar *et al.*, 2005). The ensuing SHPT was responsible for bone resorption with a marked loss in bone mineral density and flexor strength (Chhokar *et al.*, 2004). In a paradoxical manner, however, increased plasma PTH promoted intracellular Ca^{2+} overload and induction of oxidative stress in diverse cells, including cardiac myocytes and peripheral blood mononuclear cells (Chhokar *et al.*, 2005).

SHPT in Aldosteronism

Resnick *et al.* (1985) and Resnick (1986) suggested that a calcium-regulating hormone would determine intracellular Ca^{2+} overloading and the cellular deposition of Ca^{2+} in low-renin hypertension. Rossi *et al.* (1995) would identify the role of PTH and SHPT that accompanied primary aldosteronism and which was corrected by adrenal gland surgery or spironolactone treatment.

The role of PTH as the circulating hormone responsible for intracellular Ca^{2+} overload in aldosteronism was therefore implicated by the marked urinary and fecal wasting of Ca^{2+} with ionized hypocalcemia. The ensuing SHPT accounted for a fall in bone mineral density and increased the risk of atraumatic fractures in patients with CHF (vide infra). Massry *et al.* previously identified PTH as the Ca^{2+}-regulating hormone involved in the Ca^{2+} "intoxication" of SHPT that accompanies chronic renal

failure (Chhokar *et al.*, 2005; Massry and Smogorzewski, 1994; Fujita and Palmieri, 2000; Vidal *et al.*, 2006). The rise in cytosolic free $[Ca^{2+}]_i$ includes mitochondrial $[Ca^{2+}]_m$ where there occurs an induction of oxidative stress coupled to an enhanced opening potential of their inner membrane permeability transition pore leading to mitochondrial swelling and destruction. Microscopic myocyte necrosis follows with their replacement by scarring (Cheema *et al.*, 2011; Shahbaz *et al.*, 2011).

Hence, chronic elevations in plasma aldosterone, inappropriate for dietary Na^+ intake, represent a homeostatic response gone awry leading to dyshomeostasis with SHPT accounting for myocyte Ca^{2+} overload, necrosis, and myocardial scarring.

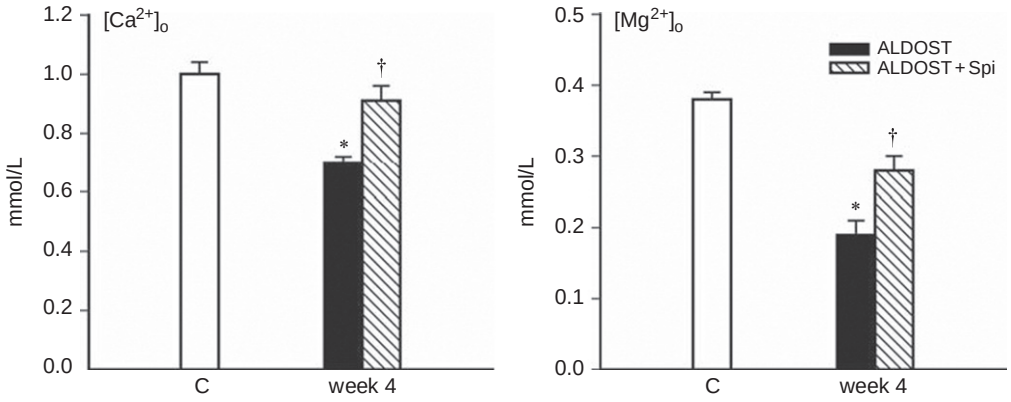

Fig. 3 Compared to controls a fall in plasma ionized $[Ca^{2+}]_o$ and $[Mg^{2+}]_o$ accompanied a 4-week aldosterone/salt treatment (ALDOST) and which was prevented with spironolactone (Spi). $^*P < 0.05$ vs. control, $^\dagger P < 0.05$ vs. ALDOST. Hyperparathyroidism and the calcium paradox of aldosteronism *Circulation* 111, 871–878.

SHPT and Congestive Heart Failure

Abnormal elevations in plasma PTH (>65 pg/mL) were found in consecutively admitted, African-American (AA) patients hospitalized with CHF and HFrEF and who were found to have ionized hypocalcemia (Khouzam *et al.*, 2006; LaGuardia *et al.*, 2006). SHPT would subsequently be documented in a larger AA cohort consecutively hospitalized with decompensated HFrEF and in whom reduced creatinine clearance could not be incriminated as a causal factor (Alsafwah *et al.*, 2008). In patients with intermittent episodes of RAAS activation and CHF, abnormal elevations in plasma PTH range between 150 and 300 pg/mL as contrasted to higher PTH levels of 600–800 pg/mL seen in patients with persistent chronic renal failure. Normal PTH levels (<65 pg/mL) were found in ambulatory AA with compensated HFrEF having comparable EF to their cohorts with decompensated failure, but in whom RAAS activation was absent as was the case in patients with cardiovascular disease, but no heart failure, as well as in healthy AA volunteers. Reduced Ca^{2+} stores due to vitamin D deficiency could predispose to SHPT; however, serum 25OHD levels were reduced (<30 ng/mL) in the entire AA cohort with and without heart failure (Alsafwah *et al.*, 2008).

The association between SHPT in CHF has now been widely recognized. Elevations in plasma PTH predict the need for hospitalization in patients with symptomatic HFrEF and those with advanced symptomatic HFpEF, where RAAS activation is expected in each case (Alsafwah *et al.*, 2008; Lee *et al.*, 1994; Shane *et al.*, 1997; Schmid and Kiowski, 1998; Ogino *et al.*, 2002; Zittermann *et al.*, 2003, 2011; Garakyaraghi *et al.*, 2010; Sugimoto *et al.*, 2009; Altay *et al.*, 2012a,b; Schierbeck *et al.*, 2011). The combination of elevated plasma PTH and brain natriuretic peptide, each surrogates of RAAS activation, confers a poor prognosis in patients with decompensated failure (Gruson *et al.*, 2015).

Factors contributing to the appearance of SHPT in heart failure include hypovitaminosis D with reduced sunlight exposure and senescent skin with its reduced capacity to generate vitamin D; obesity; lactose intolerance with avoidance of dairy products rich in Ca^{2+}; and high dietary Na^+ and loop diuretic, each of which promotes enhanced urinary Ca^{2+} excretion.

PTH is a cardiovascular risk factor for all-cause and cardiovascular mortality and events in patients with heart failure independent of renal function or age (Schierbeck *et al.*, 2011), and this includes a community-based cohort of elderly men and women (Pilz *et al.*, 2010; Hagström *et al.*, 2009, 2010; Björkman *et al.*, 2009). The risk of sudden cardiac death is increased among persons having higher PTH with vitamin D deficiency (Deo *et al.*, 2011).

SHPT reduces bone mineral density and predisposes to atraumatic fractures, particularly of the hip and where the elevation in PTH is related to the severity of RAAS activation and hence symptomatic failure (Lee *et al.*, 1994; Shane *et al.*, 1997; Schmid and Kiowski, 1998; Terrovitis *et al.*, 2012; van Diepen *et al.*, 2008). In men with heart failure treated with spironolactone, an aldosterone receptor antagonist for 6 months or more, the risk of atraumatic fracture was reduced (Carbone *et al.*, 2008).

Aldosteronism and Cardiovascular Remodeling

An adverse structural remodeling of the heart and vasculature accompanies aldosteronism and where an adverse accumulation of fibrous tissue disrupts tissue architecture and organ function (Brilla *et al.*, 1990; Sun *et al.*, 1997). The causality of the cardiac fibrosis in aldosteronism would remain uncertain for some time. Considering arterial hypertension and/or hypertrophy as responsible factors for such remodeling, the pressure-overloaded, hypertrophied left ventricle would only be affected, while the normotensive, nonhypertrophied right ventricle would be spared. Contrariwise, coronary blood flow reaches the entire heart. Hence, the coronary circulation containing a responsible circulating substance would promote fibrosis of the entire heart. Fibrosis was found to involve the right and left atria and ventricles to thereby implicate a circulating substance (Brilla *et al.*, 1990; Sun *et al.*,

1997). Cotreatment with spironolactone prevented SHPT and fibrosis, and this held true when it was given in either a low, nondepressor dose, which did not prevent hypertension or hypertrophy, or a high, pressor dose which achieved these end points (Brilla *et al.*, 1993; Brilla and Weber, 1992). Subsequent studies would identify elevations in plasma PTH as this substance. Overall findings would implicate a cardioprotective role for spironolactone. Moreover, they paved the way for the evaluation of this mineralocorticoid receptor antagonist (MRA) in the overall management of heart failure in placebo-controlled clinical trials.

Aldosterone Receptor Blockade

Heart Failure-Reduced Ejection Fraction (HFrEF). The RALES trial was conducted in patients with advanced symptomatic heart failure (NYHA Class III and IV) receiving an ACE inhibitor and diuretic, together with low-dose spironolactone (12.5–50 mg) compared to placebo (Pitt *et al.*, 1999). All primary and secondary end points were achieved within 3 months of initiating spironolactone treatment with a 30% risk reduction in overall and cardiac mortality, progression of heart failure, cardiac hospitalizations, and sudden cardiac death. In patients randomized to spironolactone serologic markers of collagen synthesis were reduced to suggest the prevention of cardiac fibrosis (Zannad *et al.*, 2000).

Placebo-controlled trials with another receptor antagonist, eplerenone, followed. EPHESUS addressed mortality and morbidity benefit among patients having HFrEF soon after their acute myocardial infarction (Pitt *et al.*, 2003). Combined with an ACE inhibitor and β-blocker, cardiovascular events, including mortality from sudden cardiac death and morbidity with hospitalization, were reduced with low-dose eplerenone. The EMPHASIS trial (Zannad *et al.*, 2011) demonstrated the combination of eplerenone with an ACE inhibitor, and β-blocker reduced the risk of death and hospitalization in patients having HFrEF with mild symptomatic heart failure (NYHA Class II).

Heart Failure-Preserved Ejection Fraction (HFpEF). HFpEF represents an ever increasing population of patients with symptomatic heart failure, who often are hypertensive elderly women and symptomatic African-Americans having evidence of RAAS activation with aldosteronism (Dunlay *et al.*, 2012; Bishu *et al.*, 2012). A randomized, double-blind, placebo-controlled trial with spironolactone (TOPCAT) in the management of symptomatic patients with HFpEF was conducted in six countries. Overall results suggested primary outcome with death from cardiovascular causes, aborted cardiac arrests, or heart failure-related hospitalizations were not reduced (Pitt *et al.*, 2014). However, in a posthoc analysis important differences were found between patients enrolled in the Americas (Argentina, Brazil, Canada, and United States) versus Russia/Georgia (Pfeffer *et al.*, 2015). Spironolactone significantly reduced the composite primary outcome in the Americas (Pfeffer and Braunwald, 2016). In addition, plasma canrenone, a metabolite of spironolactone, could not be detected in one-third of patients enrolled in Russia and Georgia (Mehra and Lindenfeld, 2016).

Summary and Conclusions

In patients with heart failure, the addition of spironolactone or eplerenone to an ACE inhibitor and β-adrenergic receptor antagonist has proven survival benefits with reduced morbid events. Through their interference with cognate receptor binding, these MRA mitigate against the pathophysiologic consequences of inappropriate (relative to dietary Na^+) elevations in plasma aldosterone that occur in CHF, including SHPT and adverse cardiac remodeling (see **Fig. 4**). Cardioprotective properties of these

agents are multiple. We considered several examples herein. Aldosteronism is now recognized as an important pathophysiologic feature of CHF.

Mineralocorticoid Receptor Antagonists

John W Funder, Hudson Institute of Medical Research, Clayton, VIC, Australia and Monash University, Clayton, VIC, Australia

Glossary

Ligand The hormone or drug which binds to the receptor.

MRA Mineralocorticoid receptor antagonist.

PA Primary aldosteronism.

Background

Most children at some stage in their upbringing are asked—usually by the teasing uncle—"which came first: the chicken or the egg?" The same conundrum might be asked of the title of this article, although the answer is very clear: the antagonist (spironolactone) was developed a decade before the first glimmerings of knowledge about the mineralocorticoid receptor, and three decades before it was cloned and sequenced. This was unusual: today a candidate receptor is discovered, a ligand (or ligands) sought, and finally potential antagonists identified, often by sequencing hundreds of thousands of compounds.

The contrast with the development of spironolactone could not be starker. Aldosterone was isolated and characterized in 1953, and recognized to be the major player in renal salt and water metabolism. Aldosterone normally circulates at very low (picomolar) levels, but is 3–10 fold elevated in pregnancy. On the presumption that this reflected a feedback response to the very high progesterone levels somehow blunting the effects of aldosterone in the kidney—subsequently confirmed in animal studies—a series of progesterone derivatives were tested at G.D. Searle in the eponymous Kagawa assay (Kagawa *et al.*, 1957).

Thus was born spironolactone, the first and still by far the most clinically used mineralocorticoid receptor antagonist (MRA). It bears more than traces of its ancestry, in that it retains a measure of progesterone receptor (PR) agonist activity, so that it can interfere with the normal menstrual cycle in premenopausal women, and very occasionally cause breast pain (mastodynia) in women in general. More often, and of more clinical consequence, is that it also has not inconsiderable antagonist activity at androgen receptors (AR). Its affinity for AR is ~one fifth that for mineralocorticoid receptors, and clinically spironolactone may produce dose-related AR-mediated side effects, including male breast enlargement (gynecomastia) and erectile dysfunction.

From the vantage point of 60 years on it is appropriate to begin any account of MRAs with a brief summary of the state of the relevant art in terms of MR. This will be followed by consideration of the current role of MRAs in heart failure, primary aldosteronism, resistant hypertension, low renin hypertension and a miscellany of less common cardiovascular situations. The article will conclude with a brief summary of current potential advances in the MRA field, beyond spironolactone and the second-generation antagonist eplerenone.

Mineralocorticoid Receptors

In this section, and subsequently, MR will be used for both the singular and plural (like sheep). MR are one of a 48 (human)/49 (mouse) member family of nuclear transactivating factors, including receptors for steroid and thyroid hormones, retinoids, lipids and xenobiotics; there remain the so-called orphan receptors, for which no ligand has been found. MR, GR (glucocorticoid receptors), AR and PR share close homology, >50% in the ligand-binding domain, 90% in their DNA binding domain. This subfamily of receptors share a common ancestor in evolution; notably, MR were the first of the four to branch off the ancestral "corticoid receptor," followed by GR, then PR, and finally AR (Kassahn *et al.*, 2011).

Classical, unequivocal MR first appeared in cartilaginous (rays, sharks) and then in bony fish. Millions of years later, the first creature to make aldosterone was lungfish, as its name testifies the species transitioning from an obligate aqueous environment to life on the land. It is important to remember this sequence, in that most people unhesitatingly regard aldosterone as the primary or cognate MR ligand. The primary cognate ligand, as far as it can be established, was cortisol; also, often overlooked, is that ≥90% of the MR in the human body are constitutively occupied by cortisol—the acknowledged and very important role of aldosterone in sodium and water homeostasis notwithstanding.

The issue is that MR are promiscuous. They have equivalent, very high affinity for cortisol, corticosterone, deoxycorticosterone, aldosterone and progesterone. As we have seen, progesterone is an MR antagonist on the basis that aldosterone (and deoxycorticosterone) define agonist activity. The physiologic glucocorticoids circulate at ~1000-fold higher total levels (cortisol, human; corticosterone, rat and mouse) than aldosterone, on a normal salt intake. The obvious question, then, is how does aldosterone ever get to occupy epithelial MR, and to do what we know it does, which is increase transepithelial transport of sodium, and with it water.

Part of the answer is that although the differences in total levels is 1000-fold, the glucocorticoids are much more (~95%) bound in plasma than is aldosterone (~50%), so that the difference in free levels is "only" ~100-fold. What confers specificity on

 doi:10.1016/B978-0-12-801238-3.64323-4

aldosterone in terms of activating epithelial MR (plus those in the vascular wall, and the nucleus tractus solitarius of the brain) is the coexpression at high levels of the enzyme llβHydroxysteroid dehydrogenase (llβHSD2), which converts cortisol to receptor inactive cortisone, and the essential co-substrate NAD (nicotinamide adenine dinucleotide) to NADH.

What was originally thought (Edwards *et al.*, 1988; Funder *et al.*, 1988), and unfortunately is still often being taught, is that this process denies cortisol occupancy of renal MR: certainly, if llβHSD2 is congenitally deficient, or blocked (e.g. in liquorice overindulgence) cortisol is a potent agonist in renal MR. In fact, aldosterone "works" by occupying (and activating) ~10% of the MR in a tubular principal cell; the other ~90% are *occupied but normally not activated* by cortisol. What llβHSD2 does is to debulk intracellular levels to 10-fold, rather than 100-fold those of aldosterone, in the process generating relatively high levels of NADH. It is probable, though not yet proven, that such levels of NADH inactivate MR-cortisol complexes, so that aldosterone can act via the remaining 10%. Harking back to the Kagawa bioassay, prior adrenalectomy shifts the urinary Na^+/K^+ well to the left of that in intact animals maintained on a high salt intake—presumably reflecting all renal MR being unoccupied and thus available to aldosterone.

For terrestrial animals, then, the emergence of aldosterone as a major regulatory hormone acting via a legacy MR (really a very high affinity glucocorticoid receptor) raises a series of questions, few of which have been addressed, and fewer answered. Given the 48 or 49 nuclear transactivating factors that have evolved, one more which was aldosterone-specific would not appear too much of a stretch. Maybe the abruptness of the transition to land was such that the co-expression at high levels of an existing member of an ancient enzyme family, but the twin specificity-conferring mechanisms—debulking and cortisol-MR inactivation by NADH—seem the long way around. This does not appear to be an example of intelligent design, but there it is; it's what we have.

It does not stop there, at least for cortisol. One of the early findings in the MR field is that they are widely expressed, not just in epithelia (kidney/colon/sweat glands/salivary glands), plus blood vessel wall and the nucleus tractus solitarius, but elsewhere. In the elsewhere category are the hippocampus, where MR are expressed at high abundance, and similarly in cardiomyocytes: in these and other non-epithelial tissues MR are not "protected" by llβHSD2, and thus overwhelmingly constitutively occupied by normal circulating levels of glucocorticoids.

In terms of normal physiology very little is known about what effects essentially saturating levels of glucocorticoids have via MR in such tissues. There have been a number of in vitro studies using more or less physiological concentrations of aldosterone on dispersed cardiomyocytes, for example, with the effects shown taken as evidence for a role for aldosterone via cardiac MR in, for example, hypertension or heart failure. The failure to include 100-fold higher concentrations of glucocorticoid with the administered aldosterone makes such studies worthless and, unfortunately, misleading.

Where the cardiomyocyte MR are activated by cortisol is under conditions of tissue damage, reactive oxygen species (ROS) generation and change in intracellular redox status. Under such conditions cortisol becomes an MR agonist, mimicking the effects of aldosterone in in vitro studies. In occlusion-reperfusion studies using the Langendorf perfused heart preparation nanomolar aldosterone increases area-at-risk and infarct size. An identical effect is seen with nanomolar cortisol, blocked by spironolactone but not the GR, PR antagonist mifepristone, clear evidence for a cortisol action via unprotected MR in conditions of tissue damage (Mihailidou *et al.*, 2009).

This of course has major implications for what steroid is activating cardiomyocyte MR in hypertension and heart failure. In the prismatic RALES trial (Pitt *et al.*, 1999) (of spironolactone at low dose added to standard of care) plasma aldosterone levels were in the low normal range: even almost two decades later many authors continue to consider aldosterone as the culprit, with fine disregard for steroids (and science). In the circumstances of tissue damage normal circulating levels of cortisol overwhelmingly occupy MR in the damaged cardiomyocyte, and are thus responsible for the ongoing cardiovascular damage. This can be ameliorated by low-dose MRA: after 18 months the RALES trial was stopped, because the group receiving spironolactone (average 26 mg/day) showed 30% lower mortality and 35% fewer hospitalizations, than the matched control group.

RALES presented two conundrums. One, which is how such a low normal concentration of aldosterone produces such major effects, is solved: it's cortisol in the damaged heart that is the culprit. The second enigma is how can such a low dose of spironolactone have such marked effects? Spironolactone itself has a relatively short half-life, being rapidly converted into active metabolites which have half-lives of 18–24 h. What this means in practice is that effector MRA levels take 8–10 days to reach steady state; the modest daily dose belies steadily increasing plasma concentrations over the first week or so of administration.

The extended pharmacokinetic profile helps, but is not the complete answer: the answer is that spironolactone (and incidentally), eplerenone, of which more later) is not just a blocker, in the normally accepted sense of sitting in the receptor and nothing else can get in, but what is called an "inverse agonist." An inverse agonist is not just a bung, but has a life of its own once it is receptor-bound. In the same Langendorf occlusion/reperfusion model, in the absence of any other added steroid, spironolactone at very low dose reduced infarct size and area-at-risk. For good measure, against the possibility of residual steroids, the same result was found in adrenalectomized rats (Ji *et al.*, 2013).

Given the very low concentrations of aldosterone, in the kidney the pharmacokinetics may be enough to keep aldosterone at bay, so that the classical notion of an MRA as "blocker" may hold. This cannot be the case for the cardiomyocyte, where spironolactone binding to only a percentage of MR exerts its inverse agonist activity to counter the agonist action of much higher concentrations of cortisol than those of aldosterone.

Mineralocorticoid Receptor Antagonists: Congestive Heart Failure

1999 Marked the year that cardiologists recognized aldosterone from among the miasma of "neurohormonal" factors, given the results of the RALES trial. Never mind that it was the wrong MR agonist: what it did was to cement a place for low-dose MRA administration in progressive cardiac failure. The patients under study were selected: normal renal function, modest if any comorbidities. The results were celebrated, over-interpreted and inappropriate patients (much reduced renal function, continued potassium supplements) admitted to emergency departments for hyperkalemia. Now, almost 20 years later, it would be fair to say that spironolactone has been accepted at a low dose as normal practice in the management of progressive, New York Heart Association Stage lll systolic heart failure.

There followed two trials with eplerenone, different not only from one another but also for obvious reasons from RALES. Eplerenone is a considerably less potent MRA in vitro, but much less plasma bound: in vivo, as a single dose it is 50%–60% as potent. Unlike spironolactone eplerenone has no active metabolites, and its plasma half-life is of the order of 4 h, so that even with twice daily dosing levels in plasma do not materially increase over time, unlike those after spironolactone.

The first of these trials (Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study—EPHESUS) was a double-blind, placebo-controlled study on a total of 6632 patients with left ventricular dysfunction after myocardial infarction (Pitt *et al.*, 2003). Eplerenone (25 mg/day) was on average begun a week post MI, and reduced all-cause mortality by 15% after a mean follow-up of 16 months, with its beneficial effect clear 30 days after randomization. The long-term benefit at first sight appears to be ~half that in the RALES trial, a difference that no longer holds when patients with comparably reduced ejection fractions are compared.

The second trial (eplerenone in patients with systolic heart failure and mild symptoms—EMPHASIS-HF) randomized 2737 patients with milder (New York Heart Association Class ll) systolic (ejection fraction $\leq$35%) heart failure to eplerenone (up to 50 mg/day) or placebo (Zannad *et al.*, 2011). After a mean follow-up of 21 months eplerenone lowered mortality by 19% and the risk of hospitalization by 36%. Taken with the data from RALES, the EMPHASIS trial shows that low dose MRA should be an integral component of the drug treatment of systolic heart failure, progressive and mild, with a reduced ejection fraction and due attention paid to plasma $[K^+]$ levels.

The third major trial subsequent to RALES reverted to spironolactone as the MRA (Pitt *et al.*, 2014). The trial was funded by NIH, rather than by pharma, and randomized 3445 patients with diastolic failure and a preserved ejection fraction to spironolactone 15–45 mg daily or placebo. Logged as "spironolactone for heart failure with preserved ejection fraction," it was given as a label rather than as an acronym "TOPCAT." The trial was a disaster, in that whereas in patients from North and South America the expected outcomes were seen, they were nullified by the results from Russia and Georgia, where most randomized patients appeared not to be in heart failure. Subsequently investigators have suggested that despite the overall failure there were sufficient indications from the western hemisphere to use low dose MRA in at least a selection of patients with diastolic heart failure.

Mineralocorticoid Receptor Antagonists: Primary Aldosteronism

Given that the driver of elevated blood pressure and cardiovascular damage in primary aldosteronism (PA) is excessive production of aldosterone, there is a prima facie and essentially universally accepted case for the use of MRAs as cornerstone therapy in bilateral disease. What needs to be borne in mind, in accepting this judgment, are two things. First, in remote areas where populations have very limited access to salt aldosterone levels can be sky-high, above those seen in many cases of PA, with no elevation of blood pressure or cardiovascular damage: aldosterone alone is not the culprit in PA.

The elevated aldosterone levels in chronic sodium deficiency are homeostatic: what causes hypertension and cardiovascular damage is aldosterone levels inappropriate for salt status. To cause hypertension and cardiovascular damage aldosterone needs to operate in a milieu of higher-than-appropriate sodium levels. The second thing to be borne in mind is that an MRA, in promoting natriuresis and an elevation in plasma $[K^+]$, may stimulate the adrenal cortex to produce more aldosterone. The salient example, as previously noted, is pregnancy, when the production of progesterone from the placenta sets in train a 3–10 fold elevation of aldosterone levels from the normal adrenal cortex. Although this level of reflex stimulation is rarely seen with the doses currently recommended for spironolactone in PA (or with eplerenone), increases in plasma aldosterone are not uncommon with higher spironolactone dosage.

There are currently three MRAs used in primary aldosteronism due to bilateral adrenal hyperplasia (BAH)—spironolactone, eplerenone and in Europe canrenone (an active and long-lived spironolactone metabolite). Whereas spironolactone used to be prescribed at high doses, up to 400 mg/day in BAH, today arguably best practice in such patients is to start with as little as 12.5 mg/day, plus an ENaC directed natriuretic agent such as amiloride or triamterene, plus standard antihypertensives if and as required to normalize blood pressure. If clinically indicated, 25 mg/day may be used, but very preferably no higher dose. The reason for using as low a dose as effective is neither economy—spironolactone is very cheap—nor faint-heartedness: it is to minimize the risk of gynecomastia and of exacerbating erectile dysfunction in men, thus minimizing the percentage of non-compliant patients. Non-compliance is a particular problem for patients with PA, as their cardiovascular risk profiles are very significantly higher than those in age-, sex-, and blood pressure matched essential hypertensives (Milliez *et al.*, 2005).

Canrenone is reputed to be less potent in terms of androgen antagonist activity, which can only be the case if at least one of the two long-lived metabolites (7α-thiomethyl spironolactone and 6β, 7α-thiomethyl spironolactone) have equivalently more

androgen receptor activity: it is also not widely available, except in Europe. The third currently available MRA is eplerenone, increasingly in use in patients intolerant of the side effects of spironolactone. There are multiple issues complicating its use, as follows. Although it out of patent, it is difficult and expensive to synthesize, and generics do not yet appear to be widely available. It is expensive for patients, except in Japan where it is a quarter of the global price, and elsewhere not widely recompensable. In terms of efficacy, head-to-head studies have differed markedly, with for example one finding it markedly inferior to spironolactone (Parthasarathy *et al.*, 2011) and another (improbably) as effective at the same dose levels as spironolactone (Karagiannis *et al.*, 2008).

The other group of patients for whom MRAs are currently neglected but should be included in their therapeutic regimen are those with biochemical cure (normal plasma $[K^+]$/aldosterone to renin ratio) after unilateral adrenalectomy for an aldosterone producing adenoma but who remain hypertensive. In these subjects with partial remission of PA the residual hypertension is commonly ascribed to vascular damage and/or underlying essential hypertension. A minority of such patients show post-operatively low plasma aldosterone levels, presumably due to inhibition of aldosterone synthesis in the contralateral adrenal, which resolves over weeks or months.

In those who have, or regain, normal plasma aldosterone levels it would make no sense to include an MRA if we are talking—as many cardiologists still are—about "aldosterone receptors." One of the characteristics of an MR is that it has, as we have seen, equivalent high affinity for aldosterone and cortisol, and that in tissue damage cortisol mimics aldosterone. There are convincing data that this is the case: there are also convincing data that eplerenone, as monotherapy, is a very effective anti-hypertensive in essential hypertensives with normal renin, aldosterone and plasma potassium levels (Levy *et al.*, 2004). In laboratory studies, addition of eplerenone from weeks 5 to 8 in DOC/salt hypertensive rats reversed the cardiac fibrosis and level of vascular inflammatory markers to zero-time control levels (Young and Funder, 2004). Whether the residual elevated blood pressure in partial clinical remission after unilateral adrenalectomy for APA represents underlying essential hypertension or vascular damage there is an excellent, if to date unappreciated, case for a low-dose MRA to be included in post-operative care when aldosterone levels are normal.

Mineralocorticoid Receptor Antagonists: Resistant Hypertension

Resistant hypertension is defined as persistent blood pressure elevation over 140/90 mmHg on three conventional anti-hypertensives including a diuretic, or blood pressure requiring ≥ 4 agents to be brought below 140/90 mmHg. Although earlier estimates of its frequency were put at up to 20% of hypertensives, this figure needs to be discounted reflecting suboptimal compliance, with the true figure around $\sim 12\%$. For over a decade it has become clear that MRAs—spironolactone and eplerenone—included in therapy clearly lower blood pressure; more recently, it has been established that MRAs lower blood reassure more than pharmacologic comparators (bisoprolol, furosemide, doxazosin) and similarly are clearly more effective than renal denervation (Fadl Elmula *et al.*, 2017; Sinnott *et al.*, 2017).

When patients with resistant hypertension are screened, 15%–20% are shown to have primary aldosteronism. What is striking is that the hypertensive response to MRA inclusion does not differ between those with frank primary aldosteronism and those without. It is thus tempting to infer that once again the current cut-offs for the diagnosis of primary aldosteronism may be too strict, and that in many if not all patients with resistant hypertension inappropriate aldosterone secretion is at least in part responsible for the stubborn elevation of blood pressure. Whether or not this is the case, it is now widely accepted that the therapeutic regime in resistant hypertension should include a low dose MRA.

Mineralocorticoid Receptor Antagonists: Low Renin Hypertension

It is similarly becoming clear that many subjects with so-called low renin hypertension—a description, not a diagnosis—may also be in fact be suffering from primary aldosteronism as the victims of straitened cut-offs and definitions. A recent modest but prismatic study (Ori *et al.*, 2013) from Israel very clearly made this point. The authors compared outcomes in 24 patients with established primary aldosteronism (seven with an adenoma on imaging), and 24 of 39 patients sequentially diagnosed with low renin hypertension; the diagnosis was made on the basis of a positive aldosterone to renin ratio, but a plasma aldosterone of <14.5 ng/dL. All 48 patients were treated with low dose MRA (spironolactone 46, eplerenone 2), and monitored at 1 and then 3 years. The results were very substantial lowering of blood pressure, and a similarly substantial fall in left ventricular mass index. The most salient finding was that there were no differences in response to low dose MRA between primary aldosteronism and low renin hypertension patients. It can be anticipated with a fair degree of confidence that many if not most patients with "low renin hypertension" are victims of cut-offs set too high, and in fact suffer from primary aldosteronism.

Mineralocorticoid Receptor Antagonists: Additional Roles?

The previous sections addressed MRAs in three currently accepted areas (heart failure, primary aldosteronism, resistant hypertension) and in low renin hypertension, knocking on the door for over 40 years and finally gaining traction. This section deals with

more or less likely additions to the canon, the first and arguably the most urgent of which is pulmonary hypertension/fibrosis. Again, there is a history going back half a century ago on the use of spironolactone in what was then termed cor pulmonale: much more recently, the focus has been on preclinical studies on efficacy. In models of pulmonary hypertension in mice (hypoxia for prevention, monocrotaline for both prevention and treatment) spironolactone as a preventive measure attenuated a series of adverse effects; more potentially clinically relevant, in established pulmonary hypertension, spironolactone decreased right ventricular systolic pressure and pulmonary vascular resistance (Preston *et al.*, 2013). Parallel studies on rodent models using bleomycin-induced pulmonary fibrosis showed both spironolactone and eplerenone attenuated pulmonary injury and fibrosis (Ji *et al.*, 2013). Given the clinical difficulty in managing pulmonary hypertension and fibrosis, a major well designed clinical trial of low dose spironolactone added to standard of care would be in order.

Two elegant studies from Turkey have demonstrated another major indication for the use of spironolactone. Anthracycline group chemotherapeutic agents are used post-surgery in breast cancer patients. In the first study (Akpek *et al.*, 2015), 83 patients on chemotherapy were randomized to spironolactone or control, and their left ventricular ejection fraction (LVEF) determined. In the control group LVEF fell from 67.7 ± 6.3 to 53.6 ± 6.8 ($P < 0.001$); in the spironolactone group the equivalent values were 67.0 ± 6.1 to 65.7 ± 7.4 (ns): no surprise, the difference between groups was highly significant ($P < 0.001$). The second study (Yavas *et al.*, 2017) complemented the first, using rats to study the known cardiovascular toxicity when trastuzumab and radiotherapy are combined. Chronic treatment with spironolactone significantly lowered both cardiac fibrosis and TGFβ expression over trastuzumab and radiotherapy alone.

Mineralocorticoid Receptor Antagonists: The Next Generation?

None of the currently available MRAs are optimal. Spironolactone is a prodrug with a half-life of $\sim$2 h, and three active metabolites, one of which (canrenone) is marketed as such in Europe. Spironolactone is a potent MRA, but not specific, given its PR agonist and AR antagonist activity. A third, relatively recent second generation MRA is eplerenone, which in vivo is only $\sim$half as potent as spironolactone, and as previously noted has a much shorter half-life. It has the advantage of selectivity, which means it has negligible side effects, but the disadvantage of being difficult to synthesize, and expensive except in Japan. What is often termed a side effect of MRAs is in fact an obligate effect, that of elevation of plasma $[K^+]$. In this regard the shorter half-life ($\sim$4 h) of eplerenone, plus the absence of active metabolites, softens its impact in terms of plasma $[K^+]$ elevation compared with spironolactone. Finally, in terms of generation 1 and 2 MRAs, the trials (and tribulations) of the search for potent, selective MRAs, to replace spironolactone are covered in detail in an excellent recent historical paper (Kolkhof and Bärfacker, 2017), as is the development of the ultimately ill-fated drosperinone, marketed as a progestin-only oral contraceptive, with retained progestational/anti-androgen activity and MRA activity 8-fold that of spironolactone.

Third generation MRAs have been defined as non-steroidal (as synthetic chemists wish), as potent as spironolactone, as selective as eplerenone, with a half-life consistent with once daily dosing, easy to manufacture and with a long patent life; fourth generation MRAs as all of the above, plus tubule-sparing. The latter desideratum reflects clinician fear of hyperkalemia, an obligate side effect of current MRAs. What needs to be borne in mind is that MRA-induced natriuresis is pivotal for its efficacy in hyperaldosteronism: a generation four partial agonist, i.e. tubule-sparing, would be potentially dangerous in PA: as previously noted, in chronic sodium deficiency very high aldosterone levels do not cause hypertension or cardiovascular damage. Given the much higher circulating levels of cortisol, and is equivalent high affinity for MR, it is an open question whether its "agonist" activity in tissue damage is equivalently sodium dependent. The development of generation 4 MRAs to address cardiac, vascular renal or for example hepatic inflammation and fibrosis is crucially dependent on an answer, as yet not forthcoming, to that question.

There are several non-steroidal agents currently in late stage clinical trials. Mitsubishi Tanabe Pharma has conducted a Phase ll trial of *apararenone* in Eastern Europe and Japan for diabetic nephropathy, and has begun a Phase ll trial in patients with non-alcoholic steatohepatitis (NASH) in Japan. Daiichi Sankyo out-licensed *esaxerenone* from Exelisis, a compound which is orders of magnitude more potent an MRA than spironolactone, and significantly more selective than even eplerenone. Two different Phase ll studies have been undertaken in Japanese patients, the first in type 2 diabetes and microalbuminuria, the second a safety and efficacy study in hypertension; more recently the company has announced a Phase lll study against eplerenone in essential hypertension.

The most advanced non-steroidal MRA is *finerenone* from Bayer. This nonsteroidal is more potent as an MRA than spironolactone, and more selective than eplerenone: it is also inactive when tested against 65 other receptors/ion channels. Like spironolactone, it is an inverse agonist as well as a competitor for MR binding. It is substantially less lipophilic, and more polar, than steroidal MRAs; when compared with 3H-eplerenone and 3H-spironolactone, 3H-finerenone is more or less equally distributed between heart and kidney, in contrast to the predominant renal uptake of the steroidal MRAs. This is not a very persuasive basis for possible cardiac selectivity; the rats were not adrenalectomized, and the extent of non-specific binding in the two tissues not determined: it is free, not total concentration, of ligand which determines receptor uptake.

Clinically, in patients with chronic heart failure and kidney disease, finerenone was at least as effective as spironolactone, once daily at one fifth the dose; in addition it produced lower increases in plasma$[K^+]$, less frank hyperkalemia and a lower incidence of worsening renal function. Five Phase ll trials in heart failure plus chronic kidney disease and/or diabetes have shown that neither hyperkalemia nor reduced kidney function limit its use. In patients with type 2 diabetes and diabetic kidney disease a dose-ranging

study on over 800 subjects showed significant reductions in albuminuria progressively with dose (7.5, 10, 15, 20 mg/day) after 90 days of treatment. Currently finerenone is thus being investigated at daily doses of 10–20 mg in two large Phase lll outcome trials in patients with diabetic kidney disease. For an agent thought possibly to be more cardiac-specific, the choice of target for the Phase lll studies is interesting.

Without raising any false hopes, it appears that all three non-steroidal MRAs may prove very useful as treatment for diabetic nephropathy (all three), non-alcoholic steatohepatitis (aparenone), essential hypertension (esaxerenone) and heart failure (finerenone). It is likely that there will be subtle differences between these agents: it is interesting that none of the companies involved appear to have considered a trial in primary aldosteronism.

Mineralocorticoid Receptor Antagonists: A Final Word

Not long after spironolactone was introduced into clinical practice, in addition to its PR- and AR-mediated side effects, there appeared a series of studies which resulted in a black box label on Aldactone (the marketing name for spironolactone). In chronic toxicity studies in rats it appeared to be tumorigenic, leading to a decline in prescription rates. If biological effects can be categorized across four domains—physiology, pharmacology, toxicology and strength of materials (more commonly an engineering term) the doses used in rat studies were toward the latter end—e.g. 100 mg/kg/day for 104 weeks, producing benign hepatocellular, thyroid and testicular adenomas. Despite no tumorigenic or carcinogenic findings in dog and monkey studies, in further rat studies with potassium canrenoate (30/90/270 mg/kg/day) for 52 weeks >50% of the 270 mg/kg/day group died with a spectrum of neoplasia. Based on these findings the UK licensing authority directed manufacturers to stop recommending spironolactone for hypertension and idiopathic oedema.

A recent study (Mackenzie *et al.*, 2017), therefore, must come as a welcome relief to this "the sky is falling" series of messages, in two ways. The study covered 74,272 patients exposed to spironolactone between 1986 and 2013 matched 1:2 with unexposed controls. The outcomes were prespecified as primary (first incidence of ovarian, endometrial, pancreatic, colorectal, prostate, renal cell, pharyngeal and thyroid cancer, plus myelomonoblastic leukemias) or secondary (27 other types of cancer). The results are that there clearly is no evidence for an increased risk of any cancer associated with the use of spironolactone. What there was, however, was strong evidence for a significantly lower risk of prostate cancer in men (hazard ratio 0.69:95% confidence limits 0.60–0.80). The authors conclude that "the possible mechanisms and clinical implications merit further investigation," which is clearly the case. It may well reflect the anti-androgenic activity of spironolactone, but we would do well not to rule out effects via PR, expressed in various organs in men, role(s) totally unknown.

What it also means is that the litany of warning prospective patients of the undesirable side effects of spironolactone, there would appear to be one countervailing—and ultimately more important—side effect, that of protection against prostate cancer.

Diuretics

Claudio Ferri and Rita Del Pinto, University of L'Aquila, L'Aquila, Italy

Glossary

Antiporter A membrane protein that actively transports two or more different molecules or ions at once across a phospholipid membrane in opposite directions.

Cotransporter Membrane transport proteins that couple the favorable movement of one molecule with its concentration gradient and unfavorable movement of another molecule against its concentration gradient. They include antiporters and symporters.

Symporter A membrane protein that transports two compounds simultaneously across a cell membrane in the same direction, one compound being transported down a concentration gradient and the other against a gradient.

Introduction: A Brief History of Diuretics

Diuretics (from the ancient greek word *διουρέω*: to urinate) are therapeutic agents that increase the urinary excretion of sodium and water. They act by decreasing sodium reabsorption at different sites in the nephron. By inducing a negative fluid balance, diuretics find application in different clinical conditions, from high blood pressure to edematous states.

Diuretic properties of specific plants were known since the dawn of medicine: ancient Egyptians used to administer mixtures of diuretic compounds, such as garlic, onion, parsley, juniper and dill, to induce water loss (Nunn, 2002) and Hippocrates also described celery and asparagus as diuretics (Petrovska, 2012). Similarly, diuretic properties of olive, grapes and ivy were known to the ancient Romans (Melillo, 1994). Under the name of cider mixture, an infusion of cider, juniper, mustard seed, ginger, horseradish and parsley-root was still recommended against dropsy in the late 18th century (Biddle, 1889). Among other herbs, digitalis had been discovered as a diuretic agent in 1775 (Withering, 1785), but at that time its inexplicable effectiveness on some, but not all, cases of edema, together with its toxic, occasionally fatal properties, led to the forsaking of the plant for medical use. 40–50 years later, a first distinction between cardiac and renal dropsy was introduced, but the use of digitalis as cardiac stimulator and diuretic in congestive heart failure had to await the middle of the 19th century, when the first animal studies tested the biological effects of digitalis on the heart (Seldin and Giebisch, 1997). Still, its action on the kidney were yet to be elucidated. It was not until the early 20th century, in fact, that the role of the kidney in the pathophysiology of fluid overload and in the functioning of diuretics began to be understood.

In the second half of the 19th century and throughout the first decades of the 20th, the pillar of diuretic therapy was represented by xanthines (Berglund *et al.*, 1935). Caffeine was the first xanthine used for therapeutic purposes, followed by the more powerful, long-lasting, cocoa-derivative theobromine (Richards and Plant, 1922). In 1902 the first synthetic xanthine, theophylline, was developed, followed a few years later by aminophylline. These diuretics revealed particularly effective to sustain diuresis when a decrease in glomerular filtration rate after other strategies was observed (Cragoe, 1983).

Mercury and its compounds represented an additional treatment against edema since the 16th century, following the experience of Paracelsus (Pagel, 1982). In particular, inorganic mercuric compounds were effective diuretics, due to increased chloride excretion, and they were routinely mixed with diuretic herbs, especially digitalis, for further mobilization of water. However, they gradually earned disapproval as a consequence of their toxicity, and it was only after the introduction of the less harmful organomercurials for the treatment of syphilis the 20th century, and the discovery of their effectiveness as powerful injectable diuretics, that these compounds were reintroduced into clinical practice as a mainstay of the treatment of edema at least until the 1950s (Eknoyan and Martínez-Maldonado, 1986). At that time, following the casual discovery of the rheological properties of sulfanilamide and the subsequent demonstration of its action as a carbonic anhydrase inhibitor, the first synthetic diuretics of this class—acetazolamide in 1954, chlorothiazide in 1957—were introduced in clinical medicine (Cragoe, 1983). Soon after the introduction of sulfonamyl diuretics, the progressive understanding of the functioning of the nephron led to the development of loop and potassium-sparing diuretics around the late 1950s to the early 1960s (Maren, 1987). A new era for diuretics had begun, based on the progressive elucidation of the role of the kidney in the management of fluid and ions.

Overview of Electrolytes Transport in the Nephron

To properly discern the mechanism of action of diuretics, it is first imperative to review the renal transport of electrolytes and its regulation. These processes are among the finest in nature and are made possible by the peculiar anatomy of the kidney, supremely condensed in its functional unit, the nephron. Minutely unraveled through the extent of the renal parenchyma, the nephron is composed of the glomerulus, the proximal and distal convoluted tubules (PCT, DCT), and the connecting tubule (CT), all hosted

in the cortex; and the loop of Henle, made of the thin descending and ascending limbs (tDL, tAL) and the thick ascending limb (TAL), which deepens into the medulla. Each tubular section of the nephron has specific properties in terms of permeability to ions and water, and so constitutes the target for a given class of diuretics. In fact, while all the sodium-transporting cells express Na^+/K^+-ATPase pumps in their basolateral membrane, with the duplicate function of returning reabsorbed sodium to the bloodstream and maintaining its intracellular concentration at relatively low levels, the driving force for sodium mobilization changes throughout the tubule, and so does the permeability to water.

Whilst liberally permeable to water, three different mechanisms mediate the sodium reabsorption in the PCT: the electroneutral Na^+/H^+ antiport, the electrogenic Na^+/solute cotransport, and the passive paracellular NaCl absorption (Seldin and Giebisch, 1997; Weinstein, 2013). Thanks to those systems, the reabsorption of the filtered sodium occurs for the greatest extent (around 60%–65%) at the level of the PCT. Such high potential is finely regulated by three key factors: the glomerulotubular balance, consisting in stimulated ions reabsorption following an increase in glomerular filtration rate to prevent massive salt wasting; the cellular pH, which modulates the enzyme activity in response to metabolic disturbances or potassium imbalances; and the effective arterial volume, with salt and water reabsorption representing a primary mechanism to maintain adequate blood pressure (Seldin and Giebisch, 1997).

The progressive change in the composition of the glomerular ultrafiltrate at the level of the loop of Henle exploits the selective permeability of its segments, which also explains the progressive hypertonicity of the interstitium in the medulla and the phenomenon of the countercurrent multiplication. In fact, water permeability is relatively high in the tDL due to the presence of aquaporins, whilst that of solutes is relatively low. As opposite, the tAL has a very low water permeability secondary to the lack of aquaporins, but an extreme passive permeability to salts. In the TAL, which is also impermeable to water, active transport of the intraluminal ions by the Na^+–K^+–$2Cl^-$ cotransporter generates the osmotic gradient that sustains water flow from the tDL into the interstitial space. The consequent selective, passive water absorption at the level of the tDL determines the isotonicity with the interstitial space of the luminal fluid as it advances along the tubule and its subsequent hypotonicity following passive reabsorption of NaCl along the tAL. Thus, water reabsorption in the tDL following active solute reabsorption in the TAL represents the real driving force for passive solute fluxes afterwards. The active Na^+–K^+–$2Cl^-$ cotransport at the level of the TAL is regulated by neurohormonal mechanisms and the glomerulotubular balance. About 20% of the filtered sodium is reabsorbed at the loop of Henle (Alpern *et al.*, 2012; Seldin and Giebisch, 1997).

In the DCT, sodium reabsorption partially mirrors that occurring in the PCT and involving Na^+/H^+ antiport; additional mechanisms include the NaCl coupled cotransport and the electrogenic transcellular Na^+ absorption that also occurs in the CT. As a specific target for mineralocorticoid hormones and vasopressin, the latter is responsible for an additional 3%–5% reabsorption of sodium and is a primary site of potassium transport. Conversely, downregulators of Na^+ absorption in the CT include prostaglandin E2 and bradykinin (Alpern *et al.*, 2012; Seldin and Giebisch, 1997).

The ion exchanges throughout the nephron also encompass other electrolytes, such as calcium and magnesium. We will examine in more detail their involvement when reviewing the single diuretics involved in their mobilization.

Classification and Mechanisms of Action of Diuretics

Based on the site in the nephron where they exert their activity, diuretics are grouped into five classes:

1. Carbonic anhydrase inhibitors;
2. Osmotic diuretics;
3. Loop diuretics;
4. Thiazide diuretics and related compounds;
5. Potassium-sparing diuretics.

The first one acts on the PCT, the second also on the loop of Henle, while the last three at the level of the TAL of the loop of Henle, the DCT-CT, and the aldosterone-sensitive principal cells in the CT, respectively. Vasopressin receptor antagonists, or aquaretics, act as antidiuretic hormone inhibitors and induce a selective water diuresis; they will be examined in a separate section.

Carbonic Anhydrase Inhibitors

The only diuretic of this family still in use in clinical practice is acetazolamide. It acts as a non-competitive inhibitor of the enzyme carbonic anhydrase (CA), which mediates the reversible formation of water and carbon dioxide from carbonic acid in the PCT. The enzyme contributes to the absorption of $NaHCO_3$ and the generation of a Cl^- gradient throughout the PCT that facilitates the passive NaCl absorption in its distal portion. Therefore, the inhibition of CA at that level results in decreased availability of H^+ for the Na^+/H^+ exchanger, with reduced $NaHCO_3$ absorption, and increased NaCl loss after lack of Cl^- gradient formation (Leaf *et al.*, 1954). The net diuresis produced by acetazolamide, however, is residual, mostly because the excess fluid delivered out of the PCT is reclaimed further down the nephron, particularly in the loop of Henle. In addition, a collateral consequence of its action is alkaline diuresis, and the subsequent metabolic acidosis further attenuates its diuretic effect (Leaf *et al.*, 1954).

As a consequence, the clinical uses of acetazolamide are restricted to a few, mainly non-diuretic effects, including the treatment of glaucoma, the CA at the level of the ciliary processes being inhibited, with subsequent reduction of intraocular pressure (Anon, 1955); high altitude illnesses, where it offsets hyperventilation-induced respiratory alkalosis, thus allowing chemoreceptors to better respond to hypoxic stimuli at altitude (Leaf and Goldfarb, 2007; Swenson, 2014); and familial periodic paralysis, where it favors the exchange of Na^+ with H^+ rather than K^+ (Resnick *et al.*, 1968). The main clinical application of acetazolamide as a diuretic remains that in edematous patients with metabolic alkalosis, where its bicarbonate-wasting effects tend to restore acid-base balance (Preisig *et al.*, 1987). This effect may be particularly important in patients with hypercapnic chronic lung disease, especially when posthypercapnic metabolic alkalosis develops and additional diuresis is required. In this case, acetazolamide was found to enhance $NaHCO_3$ excretion and to improve respiratory acidosis (Bear *et al.*, 1977; Miller and Berns, 1977), with shortened ventilator dependence in some (Banga and Khilnani, 2009), but not all (Faisy *et al.*, 2010) studies.

The impact of CA inhibitors on Ca^{++} transport is minimal: in fact, the reduced Ca^{++} reabsorption in the PCT is counter-balanced in the DCT, following increased distal delivery of HCO_3^-.

Acetazolamide can be given orally or intravenous twice a day, since its action lasts about 12 h due to tolerance induced by respiratory compensation for the metabolic acidosis (Wile, 2012).

Osmotic Diuretics

These drugs are filtrable, but non reabsorbable sugar alcohols that owe their diuretic action to the property of attracting water into the lumen of the tubule rather than acting on cellular sodium transport. As such, every solute that is excessively filtered can exert the same action: examples are glucose after severe hyperglycemia, or radiocontrast agents (Seldin and Giebisch, 1997). This class of diuretics is represented by mannitol, a low molecular weight (182 g/mol) isomer of sorbitol (Shawkat *et al.*, 2012). Once filtered, it drives a relative water diuresis in the PCT and the loop of Henle, with consequent increased urinary flow and only modest Na^+ excretion, but intense distal K^+ secretion (Seldin and Giebisch, 1997). Additional actions of mannitol include the induction of renal release of prostaglandins and the scavenging of free-radicals (Seldin and Giebisch, 1997). Based on these properties, mannitol was proposed as a renal protective agent against the risk of developing renal failure, like after cardiac and vascular surgery, renal transplantation, and in case of jaundice and rhabdomyolysis (Shawkat *et al.*, 2012). However, given the inconsistency of results in this field, together with the number of side effects potentially related to the use of mannitol (acute decompensation and pulmonary congestion in patients with heart failure; metabolic acidosis; electrolyte imbalance with hypernatraemia and hypokalaemia), its clinical application is substantially restricted to the treatment of cerebral edema and raised intracranial pressure, based on its immediate effect on plasma expansion, which leads to improved cerebral microvascular flow and oxygenation, and its delayed osmotic effect, which draws water from the cerebral extracellular space into the vasculature, provided the blood–brain barrier is intact (Shawkat *et al.*, 2012). Other uses are, in fact, empiric.

Loop Diuretics

The most powerful diuretics in use are referred to as the loop diuretics, since their site of action is substantially represented by the TAL of the loop of Henle, or high ceiling diuretics, based on their almost linear dose-effect curve as saluretics (Burg *et al.*, 1973). In fact, by competing for the chloride site on the Na^+–K^+–$2Cl^-$ cotransporter, which mediates the greatest NaCl reabsorption, they can induce the excretion of approximately 20%–25% of filtered sodium (Rose, 1991; Wile, 2012). This group includes furosemide, bumetanide, torsemide and ethacrynic acid.

The Na^+–K^+–$2Cl^-$ symporter, located in the TAL and the macula densa cells in the early DCT, is an electroneutral transporter whose action is driven by the low intracellular sodium concentration following its primary active extrusion by the basolateral Na^+/K^+-ATPase pump. The Cl^- gradient is maintained by the ion outflux through the basolateral chloride channel (CLCN), and, together with impermeability to water, the NaCl reabsorption determines urinary dilution and represent the first step for countercurrent multiplication, which is in turn essential for upstream urine concentration. The parallel recycling of K^+ back to the tubular lumen through the ATP-dependent renal outer medullary potassium channel ensures a virtually perpetual reserve of K^+ for coupled Na^+ transportation. In addition, the voltage difference generated by the basolateral Na^+/K^+-ATPase drives the paracellular reabsorption of calcium and magnesium.

In the presence of loop diuretics, the Cl^--binding site gets inactivated, with consequent NaCl loss. In the attempt to retrieve some Na^+, aldosterone-sensitive cells in the CD would exchange it for potassium, which would be wasted in urine. In addition, the transepithelial voltage difference being abolished, calcium and magnesium would be lost as well (Friedman, 1988). Consequent risks of loop diuretics misuse are, therefore, represented by hyponatraemia and possibly some hypokalaemia, hypocalcaemia, hypomagnesaemia, and metabolic alkalosis due to effective volume contraction. The risk of kidney stones and/or nephrocalcinosis after loop diuretics have been primarily reported in premature infants (Hufnagle *et al.*, 1982). The real measure of loop diuretic-induced hypercalciuria depends on the volume depletion secondary to their action: the greatest the latter, less pronounced the former. A clinical condition that mimics side effects of loop diuretics is the Bartter syndrome in its classic form, which develops after mutations in the gene for the symporter.

Among the loop diuretics, the one with uricosuric properties, that is ethacrynic acid, fell into disfavor after its pronounced side-effects of nausea and ototoxicity due to inhibition of an isoform of the Na^+–K^+–$2Cl^-$ cotransporter in the inner ear. The other

loop diuretics decrease urate loss by increasing its net reabsorption and reducing its secretion and, together with thiazides, represent independent risk factors for incident and recurrent gout (Choi *et al.*, 2005; Hunter *et al.*, 2006).

Thiazide Diuretics and Related Compounds

Historically, it was the search for a more powerful AC inhibitor that led to the development of the first thiazide diuretic, chlorothiazide. Accidentally, the latter was found to increase the excretion of NaCl rather than HCO_3^-, and it became subsequently clear that its major site of action was the DCT (Ernst and Moser, 2009). Under the name of thiazide diuretics are, therefore, included those primarily acting on the distal tubule, even though thiazide-type diuretics, namely chlorothiazide and hydrochlorothiazide, present structural differences compared to the thiazide-like compounds, such as metolazone, chlorthalidone and indapamide (Ernst and Moser, 2009).

Thiazide diuretics act by inhibiting the electroneutral Na^+/Cl^- symport located in the DCT after competitively binding its chloride site. The basolateral Na^+/K^+-ATPase represents, once again, the driving force for Na^+ reabsorption. The sulfamyl group on the benzene ring confers to some molecules of this class a limited action as AC inhibitors, but their net diuretic effect is residual, given the subsequent water reabsorption in the loop of Henle. Given the small extent at which Na^+ is reabsorbed at the level of the DCT (3%-5% of the filtered Na^+), the natriuretic effect of thiazide diuretics is limited, with a rapidly flattening dose-effect curve, so that they are also indicated as low ceiling diuretics. As a consequence, their clinical application is primarily represented by the treatment of hypertension, rather than that of edematous states.

Thiazides can also increase potassium and hydrogen losses in the DCT, potentially resulting in hypokalemia and metabolic alkalosis (Lyon and Degraff, 1964). The mechanisms underlying potassium wasting are double and indirect. The first is mediated by the activation of Na^+/K^+-ATPase in the DCT after increased urinary NaCl availability following the inhibition of sodium-chloride symporter. The second involves the activation, secondary to volume depletion, of the renin–angiotensin–aldosterone system, which again boosts Na^+/K^+-ATPase at the level of the CT.

Just as Bartter syndrome and loop diuretics, there is a clinical condition that mimics thiazides-related toxicity, namely Gitelman syndrome (Simon *et al.*, 1996). Also known as familial hypokalemia-hypomagnesemia, or hypomagnesemia-hypokalemia with hypocalciuria, it is a rare, autosomal recessive genetic disorder caused by mutations in the SLC12A3 gene, encoding the thiazide-sensitive NaCl cotransporter and featuring clinical characteristics which are similar to thiazide adverse effects (Simon *et al.*, 1996).

The DCT being the major site of active calcium reabsorption in the nephron, another effect of thiazide therapy is increased Ca^{++} reabsorption, which is thought to be mediated by thiazide-induced hyperpolarization secondary to Na^+ blockade, with consequent activation of voltage-gated Ca^{++} channels, as well as by increased activity of the basolateral Na^+/Ca^{++} exchanger (Costanzo, 1985). Thus, thiazides reveal useful in the management of idiopathic hypercalciuria and related nephrolithiasis (Gesek and Friedman, 1992). The parallel downregulation of the epithelial Mg^{++} channel may explain the observed hypomagnesemia after chronic thiazide use (Nijenhuis *et al.*, 2005).

As anticipated, another metabolic effect of thiazides is hyperuricemia (Healey *et al.*, 1959; Rosch and Sturman, 1962) and the risk of acute gout (Choi *et al.*, 2005; Hunter *et al.*, 2006). Thiazides exploit the organic anion transporter 1 (OAT1) on the basolateral membrane of the PCT to enter the tubular cells, and the apical urate anion exchanger, OAT4, to be released in the tubular fluid. This steps occurs in exchange with urate and drives its reabsorption (Hagos *et al.*, 2007). In addition, by upregulating the Na^+/H^+ exchanger in the PCT, they stimulate pH-dependent OAT4 activity for further urate reabsorption. The inhibition of the luminal multidrug resistance protein 4 also reduces secretion of urate (El-Sheikh *et al.*, 2008).

Additional metabolic effects reported for thiazides include dose-dependent hyperlipidemic (Grimm *et al.*, 1981) and hyperglycemic (Goldner *et al.*, 1960; Zhang and Zhao, 2016) effects. The first, however, is rarely seen at therapeutic doses and its clinical implications are controversial: in fact, it was proven to translate into worst clinical outcomes in some (Zanchetti *et al.*, 2004), but not all (ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial, 2002; Grimm *et al.*, 1981; Kasiske *et al.*, 1995) studies. Thiazide-induced hyperglycemia is thought to develop after potassium depletion, which, in turn, inhibits insulin release from pancreatic beta cells (Barzilay *et al.*, 2006). In support of this hypothesis is the fact that potassium restoration reverses this effect, unlike what seen with the use of other drugs of common use in hypertension (Rapoport and Hurd, 1964; Shafi *et al.*, 2008; Zillich *et al.*, 2006). The long-term impact of thiazide-induced hyperglycemia or diabetes seems, so far, to be residual (Barzilay *et al.*, 2012; Brown *et al.*, 2016). Recent evidence suggests that thiazide-like diuretics are superior to thiazide-type diuretics in the treatment of hypertension in terms of both efficacy and safety, given the lower incidence of hypokalemia and hyponatremia and the neutral glycolipid profile (Liang *et al.*, 2017; Messerli and Bangalore, 2011).

Potassium-Sparing Diuretics

This category includes two groups of drugs with different mechanism of action, sharing the property to reduce potassium excretion at the level of the aldosterone-sensitive sodium channels in the principal cells of the CT, and consisting in the direct inhibitors of the sodium channel (amiloride and triamterene), and the steroidal (spironolactone, eplerenone) and nonsteroidal (e.g., finerenone, apararenone, esaxerenone) mineralocorticoid receptor antagonists (MRAs) (Horisberger and Giebisch, 1987; Kolkhof and

Bärfacker, 2017). This class of diuretics has relatively weak natriuretic power, leading to the excretion of approximately 1%–2% of filtered sodium (Rose, 1991). Therefore, their main use in clinical practice occurs in combination with loop or thiazide diuretics to decrease potassium loss, rather than increase that of sodium (Hropot *et al.*, 1985).

Amiloride and triamterene determine direct inhibition of the Na^+/K^+ channel, thus blocking the reabsorption of sodium occurring at the expenses of potassium. The same action is observed after the use of the antibiotics trimethoprim and pentamidine (Kleyman *et al.*, 1995; Velázquez *et al.*, 1993). Amiloride is safer than triamterene, which is a potential nephrotoxic agent: in fact, crystalluria and cast/stones formation, with the potential risk of acute renal failure, have been reported after its use (Carr *et al.*, 1990; Farge *et al.*, 1986; Sica and Gehr, 1989). An effective clinical application of amiloride occurs in the treatment of polyuria and polydipsia due to lithium-induced nephrogenic diabetes insipidus. Lithium enters the principal cells of the CT through the same sodium channels targeted by amiloride and interferes with the ability of ADH to increase water permeability: the blockade of sodium channels decreases lithium entry into the tubular cells, thus reverting the concentrating defect (Grünfeld and Rossier, 2009; Trepiccione and Christensen, 2010). Amiloride and triamterene also exert a magnesium-sparing activity by reducing its excretion (Devane and Ryan, 1981). Reabsorption of Ca^{++} is also favored, likely as a consequence of cellular hyperpolarization.

MRAs originate from the search for aldosterone antagonists after this molecule was acknowledged as the mainstay of the regulation of Na^+/K^+ transportation. These drugs competitively inhibit the mineralocorticoid receptor that regulates both the number of apical sodium channels and that of active basolateral Na^+/K^+ pumps in the CT (Horisberger and Giebisch, 1987). Both steroidal and non-steroidal MRAs also appear to reduce proteinuria when used alone or in combination with an ACE inhibitor or an ARB in both type 1 and type 2 diabetes (Bakris *et al.*, 2015; Epstein *et al.*, 2006; Mehdi *et al.*, 2009; Rachmani *et al.*, 2004). In addition, there is evidence of beneficial effects of MR blockade in attenuating chlorthalidone-induced sympathetic activation and insulin resistance in humans, independent of blood pressure reduction (Raheja *et al.*, 2012), and also in reducing aldosterone-induced metabolic abnormalities, although not all of these effects (e.g., hyperglycemia, dyslipidemia) are MR-mediated (Baudrand *et al.*, 2016). Primary and secondary (e.g., heart failure, cirrhosis) hyperaldosteronism are specific clinical indications for the use of MRAs antagonists.

The first steroidal MRA to be developed about 50 years ago was spironolactone (Cella and Kagawa, 1957; Cella and Tweit, 1959), a pharmacologically active prodrug. Beside as a diuretic, spironolactone found enthusiastic clinical application in those conditions where the exploitment of its anti-inflammatory, anti-fibrotic properties could be warranted, such as in heart failure (Pitt *et al.*, 1999; Selye, 1955, 1960). However, it also presents undesirable, potentially harmful effects, from painful gynecomastia and menstrual irregularity, secondary to its binding to androgen and progesterone receptors, to possibly life-threatening hyperkalemia, especially among patients with reduced kidney function (Kolkhof and Bärfacker, 2017). Several molecules have been tested with the aim to develop safer alternatives to spironolactone, one being represented by eplerenone, which overcomes the endocrine side effects of spironolactone thanks to its less affinity for androgen and progesterone receptors (Kolkhof and Bärfacker, 2017). Eplerenone is, however, also less powerful as MRA than spironolactone (Garthwaite and McMahon, 2004). A few years after spironolactone was introduced into commerce, the use of its active metabolite canrenone was tested in humans (Kolkhof and Bärfacker, 2017). Together with potassium canrenoate, which is the only MRA clinically available for parenteral administration, canrenone also exerts lower antiandrogen activity.

Boosted by the challenge of identifying and targeting collateral aldosterone-mediated pathways of therapeutic relevance, basic research of the last decades focused on the development of novel non-steroidal MRAs with safer physicochemical profile and reduced incidence of adverse effects. This approach drove the synthesis of at least three molecules, namely apararenone, esaxerenone and finerenone, now tested in late stage clinical trials in patients with nonalcoholic steatohepatitis (apararenone), in those with hypertension or in the presence of type 2 diabetes mellitus and microalbuminuria (esaxerenone), and in individuals with heart failure plus chronic kidney disease and/or diabetes or patients with diabetic kidney disease (finerenone) (Kolkhof and Bärfacker, 2017). The latter is at the most advanced stages of investigation, and it appears as a more selective, efficient and powerful MRA than spironolactone and eplerenone. Its higher polarity allows a balanced distribution into cardiac and kidney tissues, likely explaining the more efficient reduction in cardiac hypertrophy, pro-B-type natriuretic peptide (pro-BNP) and proteinuria than eplerenone and spironolactone, with marginal effects on blood pressure and significantly lower incidence of hyperkalemia and renal failure (Kolkhof *et al.*, 2015; Naegele *et al.*, 2016; Pitt *et al.*, 2013). Lower mortality and less hospitalization for cardiovascular events occurred in patients treated with finerenone compared to eplerenone in a phase IIb trial on 1066 heart failure patients with reduced ejection fraction and concomitant type-2 diabetes mellitus and/or chronic kidney disease (Filippatos *et al.*, 2016). The results of these ongoing trials will better define the future of old and new MRAs.

Special Diuretics

In contrast with the described molecules, which interfere with electrolytes (namely sodium) and water reabsorption, vasopressin receptor antagonists (VPA), or aquaretics, act as antidiuretic hormone (ADH) inhibitors and induce a selective water diuresis. As such, they found application in specific clinical conditions, including the treatment of hyponatremia in the syndrome of inappropriate ADH secretion (SIADH) and in heart failure, and autosomal dominant polycystic kidney disease (ADPKD).

Vasopressin (ADH) acts through three different receptors: V1a, mainly located in blood vessels and liver, responsible for vasoconstriction and glucose metabolism; V1b, which mediates adrenocorticotropic hormone (ACTH) release from the pituitary gland; and V2, located in the basolateral membrane of the CT cells, primarily involved in the antidiuretic response (Greenberg and

Verbalis, 2006). Orally available VPAs, like tolvaptan, satavaptan, and lixivaptan, are selective for the V2 receptor, while conivaptan, the one that is available for injectable use, acts on both the V2 and V1a receptors. By blocking V2 receptors, VPAs prevent recruitment of aquaporin water channels to luminal cell membrane in CT and so promote selective water diuresis, while V1a blockade may improve systemic hemodynamics by decreasing afterload (Greenberg and Verbalis, 2006). Only tolvaptan and conivaptan are currently marketed.

In ADPKD, tolvaptan demonstrated to slow the progression of the disease, with lower decline in glomerular filtration rate (Ong, 2018; Torres *et al.*, 2017). Among patients with heart failure and symptomatic hyponatremia, short-term treatment with vaptans produces a water diuresis and raises the serum sodium concentration, with potential collateral benefit on mental status (Schrier *et al.*, 2006; Udelson *et al.*, 2001). However, no improvement in long-term cardiovascular or renal outcomes was observed in patients with heart failure after the use of vaptans (Inomata *et al.*, 2017; Konstam *et al.*, 2007; Schrier *et al.*, 2006).

The main adverse effects reported after the use of vaptans include thirst, dry mouth, fatigue, pollakiuria, polyuria, and polydipsia (Berl *et al.*, 2010). Tolvaptan should not be used in liver disease/cirrhosis for the risk of acute liver failure and death (Torres *et al.*, 2012), and clinicians must be warned of the risk of irreversible neurologic injury following excessively rapid correction of hyponatremia (Schrier *et al.*, 2006). Caution is recommended for the use of conivaptan in cirrhotic patients, given the risk of adverse hemodynamic effects and of increased variceal bleeding (Greenberg and Verbalis, 2006).

Conclusions

Centuries after the first, intuitive applications in medicine of diuretic compounds, the show offered by this class of drugs is far from over. The multiplicity of mechanisms involved in electrolytes and fluid balance, together with the invaluable resources deriving from advances in genetics, foretell further progress in this field, with the ultimate goal being represented by the patient-tailored, genetic-guided approach.

Calcium Channel Blockers

Stefano Taddei and Rosa Maria Bruno, University of Pisa, Pisa, Italy

General Pharmacology

Calcium-channel blockers (CCBs) or calcium antagonists bind to L-type calcium channels located on the vascular smooth muscle, cardiac myocytes, and cardiac nodal tissue (sinoatrial and atrioventricular nodes) reducing the influx of calcium into muscle cells, leading to relaxation of smooth muscle and cardiac muscular tissue. In cardiac nodal tissue, L-type calcium channels regulate pacemaker currents and phase 0 of the action potentials. Therefore, CCBs cause vasodilation, decrease myocardial inotropism, decrease heart rate and decrease conduction velocity within the heart (negative dromotropy), particularly at the atrioventricular node (**Fig. 1**) (Goodman and Gilman's, 2012).

Therapeutic Indications

CCBs are used to treat hypertension, angina and arrhythmias (Goodman and Gilman's, 2012).

Hypertension

By causing vascular smooth muscle relaxation, CCBs decrease systemic vascular resistance, which lowers arterial blood pressure. These drugs primarily affect arterial resistance vessels, with only minimal effects on venous capacitance vessels (Goodman and Gilman's, 2012).

Angina

The antianginal effects of CCBs are derived from their vasodilator and cardiodepressant actions. Systemic vasodilation reduces arterial pressure, which reduces ventricular afterload (wall stress) thereby decreasing oxygen demand. The more cardioselective CCBs (verapamil and diltiazem) decrease heart rate and contractility, which leads to a reduction in myocardial oxygen demand, which makes them excellent antianginal drugs. CCBs can also dilate coronary arteries and prevent or reverse coronary vasospasm (as occurs in Prinzmetal's variant angina), thereby increasing oxygen supply to the myocardium (Goodman and Gilman's, 2012).

Arrhythmias

The antiarrhythmic properties (Class IV antiarrhythmics) of CCBs are related to their ability to decrease the firing rate of aberrant pacemaker sites within the heart, but more importantly are related to their ability to decrease conduction velocity and prolong

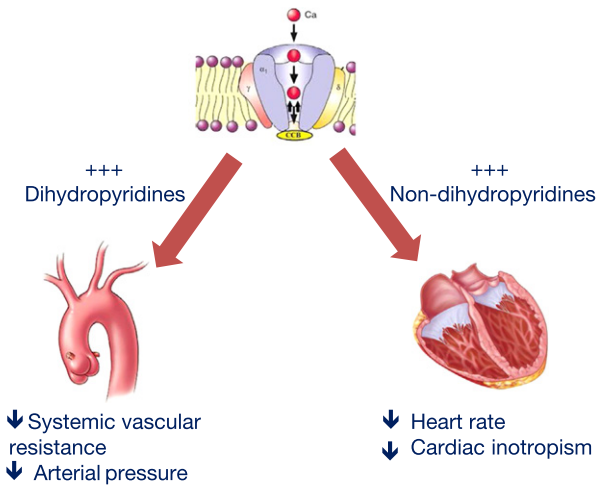

Fig. 1 Main mechanisms of action of calcium channel blockers.

repolarization, especially at the atrioventricular node. This latter action at the atrioventricular node helps to block reentry mechanisms, which can cause supraventricular tachycardia (Goodman and Gilman's, 2012).

Different Classes of Calcium-Channel Blockers

There are three chemical classes of CCBs. They differ not only in their basic chemical structure, but also in their relative selectivity toward cardiac versus vascular L-type calcium channels (**Fig. 1**). The most smooth muscle selective class of CCBs are the dihydropyridines. Because of their high vascular selectivity, these drugs are primarily used to reduce systemic vascular resistance and arterial pressure, and therefore are used to treat hypertension. Extended release formulations or long-acting compounds are used to treat angina and are particularly effecting for vasospastic angina; however, their powerful systemic vasodilator and pressure lowering effects can lead to reflex cardiac stimulation (tachycardia and increased inotropy), which can offset the beneficial effects of afterload reduction on myocardial oxygen demand.

Dihydropyridines include the following specific drugs:

- Amlodipine
- Felodipine
- Isradipine
- Nicardipine
- Nifedipine
- Nimodipine
- Nitrendipine
- Lercanidipine
- Barnidipine
- Lacidipine

Non-dihydropyridines, of which there are only two currently used clinically, comprise the other two classes of CCBs.

Verapamil (phenylalkylamine class), is relatively selective for the myocardium, and is less effective as a systemic vasodilator drug. This drug has a very important role in treating angina (by reducing myocardial oxygen demand and reversing coronary vasospasm) and arrhythmias.

Diltiazem (benzothiazepine class) is intermediate between verapamil and dihydropyridines in its selectivity for vascular calcium channels. By having both cardiac depressant and vasodilator actions, diltiazem is able to reduce arterial pressure without producing the same degree of reflex cardiac stimulation caused by dihydropyridines.

Side Effects and Contraindications

Dihydropyridine CCBs can cause flushing, headache, excessive hypotension, edema and reflex tachycardia. Baroreceptor reflex activation of sympathetic nerves and lack of direct negative cardiac effects can make dihydropyridines a less desirable choice for stable angina than diltiazem, verapamil or beta-blockers. Long-acting dihydropyridines (e.g., extended release nifedipine, amlodipine) have been shown to be safer anti-hypertensive drugs, in part, because of reduced reflex responses. This characteristic also makes them more suitable for angina than short-acting dihydropyridines. The cardiac selective, non-dihydropyridine CCBs can cause excessive bradycardia, impaired electrical conduction (e.g., atrioventricular nodal block), and depressed contractility. Therefore, patients having preexistent bradycardia, conduction defects, or heart failure caused by systolic dysfunction should not be given CCBs, especially the cardiac selective, non-dihydropyridines. CCBs, especially non-dihydropyridines, should not be administered to patients being treated with a beta-blocker because beta-blockers also depress cardiac electrical and mechanical activity and therefore the addition of a CCB augments the effects of beta-blockade (Goodman and Gilman's, 2012).

Cardiovascular Effects of Calcium Channel Blockers

CCBs, especially of the dihydropyridine sub-class, are potent and effective antihypertensive drugs. In the VALUE trial (Julius *et al.*, 2004), performed in high risk patients with essential hypertension, the head-to-head comparison between amlodipine and the angiotensin receptor blocker (ARB) valsartan, demonstrated that after six-month treatment the CCB was significantly more effective in reducing blood pressure values as compared to the ARB (4.3 and 2.5 mmHg for systolic and diastolic blood pressure, respectively). This difference has determined, at the end of the study, a significant reduction in myocardial infarction and a reduction in stroke (very close to be statistically significant) determined by amlodipine as compared to valsartan (**Fig. 2**).

CCBs blockers are very effective on the regression of left ventricular hypertrophy and the prevention of atherosclerosis.

Concerning the left ventricular hypertrophy, common knowledge considers the drugs blocking the renin-angiotensin system as the most potent in determining the regression of this important target organ damage. In contrast the meta analysis from Klingbeil *et al.* (2003) demonstrates that CCBs have the same efficacy as compared to ACE-inhibitors and ARBs.

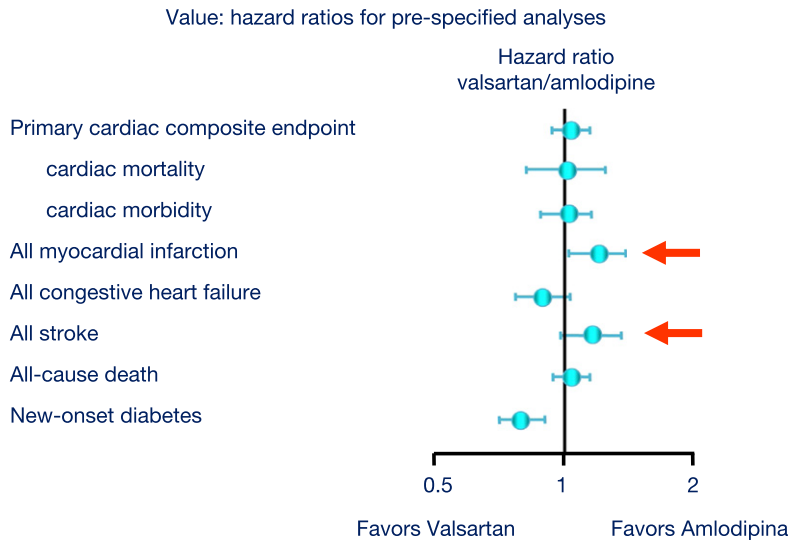

Fig. 2 In the VALUE study, although the effect of Amlodipine and Valsartan was similar on the composite end-point, the CCB significantly reduced the incidence of myocardial infarction as compared to the angiotensin receptor blocker. In addition there was a greater tendency of amlodipine to reduce stroke as compared to valsartan which resulted to be very close to the statistical significance. Adapted from Julius, S., Kjeldsen, S. E., Weber, M., *et al.* (2004). Outcomes in hypertensive patients at high cardiovascular risk treated with regimens based on valsartan or amlodipine: The VALUE randomised trial. *Lancet 363*, 2022–2031.

Moreover CCBs are highly effective in vascular protection, with a specific effect on the prevention of atherosclerosis. Thus, an early event in the atherosclerosis disease process is endothelial dysfunction, which promotes a constellation of processes that contribute to plaque development, including vasoconstriction, thrombosis, inflammation, oxidation and proliferation. In the healthy endothelium, nitric oxide (NO) protects the vessel wall not only by inducing vasodilation, but also through various anti-inflammatory benefits including scavenging of superoxide, inhibition of platelet aggregation, reduced hyper adhesiveness of leukocytes and interference with platelet aggregation (Flammer *et al.*, 2012). Essential hypertension is associated with endothelial dysfunction, which involves enhanced production of oxygen free radicals, that can destroy NO and reduce its availability, and release of endothelium-derived contracting factors including prostanoids and ET-1. In presence of impaired NO availability, a hyperpolarizing factor (EDHF) accounts for endothelium-dependent relaxations (Flammer *et al.*, 2012). It is worth noting that endothelial dysfunction is associated with increased incidence of atherosclerosis and cardiovascular events. In addition, the reversing of endothelial dysfunction can improve the prognosis of essential hypertensive patients, independently from blood pressure control (Flammer *et al.*, 2012). Thus a correct and modern approach to hypertensive patients needs an adequate blood pressure control associated to ancillary properties on organ damage, including restoration of endothelial function and prevention of cardiovascular events (Ghiadoni *et al.*, 2012). However, antihypertensive drugs show contrasting effects in terms of improvement or restoration of endothelial function (Ghiadoni *et al.*, 2012).

CCBs are among the most powerful compounds to interfere with endothelial dysfunction and therefore they can prevent the development of atherosclerosis, an effect mainly mediated by the strong antioxidant activity which characterizes this drug class. Available literature indicates that CCBs act preferentially on endothelial dysfunction at the level of microcirculation, while ACE-inhibitors are very active at the level of large arteries. The effect exerted by CCBs is mediated by strong antioxidant properties which cause a restoration of NO availability (Ghiadoni *et al.*, 2012).

In addition, CCBs are also effective in reversing vascular remodeling in small arteries, one of the most important mechanisms determining the increase in peripheral vascular resistances in hypertensive patients (Schiffrin *et al.*, 2002). Worth of noting is that this effect is independent from blood pressure reduction since it is not observed with other antihypertensive drug classes, including diuretic of beta-blockers (Schiffrin *et al.*, 2002).

Taken together, all this line of evidence supports the antiatherosclerotic properties of CCBs, a finding which is strongly supported by controlled clinical trials.

VHAS (Verapamil in Hypertension and Atherosclerosis Study) (Zanchetti *et al.*, 1998) Study first demonstrated the superiority of the CCB verapamil, as compare to the diuretic chlorthalidone, to inhibit coronary atherosclerosis. Moreover, a subgroup of patients enrolled in the INSIGHT (Intervention as a Goal in the Hypertension Treatment) (Simon *et al.*, 2001) study and ELSA (European Lacidipine Study on Atherosclerosis) (Zanchetti *et al.*, 2002) study, demonstrated that nifedipine or lacidipine, respectively, significantly reduced the progression of carotid artery intima-media thickness as compare to the diuretic hydrochlorothiazide or the beta-blocker atenolol. All the above reported trials were conducted in patients with essential hypertension.

It is worth noting that similar results were observed in patients with coronary artery disease. INTACT (International Nifedipine Trial on Antiatherosclerotic Therapy) study (Lichtlen *et al.*, 1990) demonstrated that nifedipine can inhibit the formation of new atherosclerotic plaques during a 3-year period of observation. In the PREVENT (Prospective Randomized Evaluation of the

Vascular Effects of Norvasc Trial) (Pitt *et al.*, 2000), amlodipine slowed the progression of carotid artery early atherosclerosis while in the CAPARES (coronary angioplasty amlodipine restenosis study) (Jorgensen *et al.*, 2000) the same compound significantly reduced the incidence of re-stenosis after coronary revascularization (4-month follow up).

Finally, in a sub study of CAMELOT (comparison of amlodipine vs. enalapril to limit occurrence of thrombosis) (Nissen *et al.*, 2004), in 274 patients coronary progression of atherosclerosis was assessed by IVUS at baseline and at the end of the study. As compared to baseline, IVUS revealed a significant progression of atherosclerosis in the placebo group ($P < .001$), a tendency to progression in the enalapril group ($P = .08$), but a lack of progression in the amlodipine group ($P = 0.31$).

Thus the well documented antiatherosclerotic effect of CCBs is further reinforced by a meta analysis which demonstrates that this drug class is superior, as compared to ACE-inhibitors, on this specific end-point (Wang *et al.*, 2006).

Effects of Calcium Channel Blockers on Clinical Hard End Points

Controlled clinical trials demonstrate that CCBs have a preferential effect on stroke. This issue is specifically addressed in a meta analysis (Turnbull *et al.*, 2003) demonstrating that CCBs are superior to ACE-inhibitors or beta-blocker/diuretic combination in preventing cerebrovascular disease (**Fig. 3**). Moreover it is worth of mentioning a meta regression from Verdecchia *et al.* (2005) which evaluates the relationship between blood pressure reduction exerted by ACE-Inhibitor or CCBs and coronary artery disease or cerebrovascular disease. While CCBs reduce the incidence of coronary artery disease exclusively by blood pressure reduction, ACE-inhibitor show that part of the beneficial effect (around 38%) is pressure independent. In contrast, concerning the stroke, the beneficial effect of ACE-inhibitors is totally dependent on blood pressure reduction, while around 34% of effect of CCBs is pressure independent.

Thus, it is conceivable that CCBs might be the first choice drug class for the prevention of cerebrovascular disease.

Does an evidence exist supporting the possibility to use CCBs in high risk patients, including patients with coronary artery disease?

Best demonstration that CCBs are effective in patients with coronary ischemic disease (with or without hypertension) derives from the results of CAMELOT study (Nissen *et al.*, 2004). In 1991 patients with documented coronary disease, the effectiveness of 24-month treatment with amlodipine (10 mg/daily), enalapril (20 mg/daily) or placebo was compared. Primary end point was a composite of cardiovascular death, non fatal myocardial infarction, non fatal cardiac arrest, coronary revascularization, angina pectoris hospitalization, heart failure hospitalization, fatal and non fatal stroke, TIA or new diagnosis of peripheral arteriopathy. Patients received concomitant treatment including beta-blockers, statins and antiplatelet drugs.

Incidence of cardiovascular events was 23.1% in the placebo group, 16.6% in the amlodipine group ($P = .003$) and 20.2% in the enalapril group ($P = .16$). Thus while enalapril did not show any superiority as compared to placebo, only amlodipine determined a statistically significant 31% reduction of cardiovascular events.

Thus CCBs are effective drugs in all patients with cardiovascular disease.

Endocrine Effects of Calcium Channel Blockers

A number of dihydropyridine CCBs possess a mineralocorticoid receptor antagonist activity. Nimodipine and felodipine in particular compete with aldosterone binding to the mineralocorticoid receptor "ligand-binding domain" (LBD) with a similar

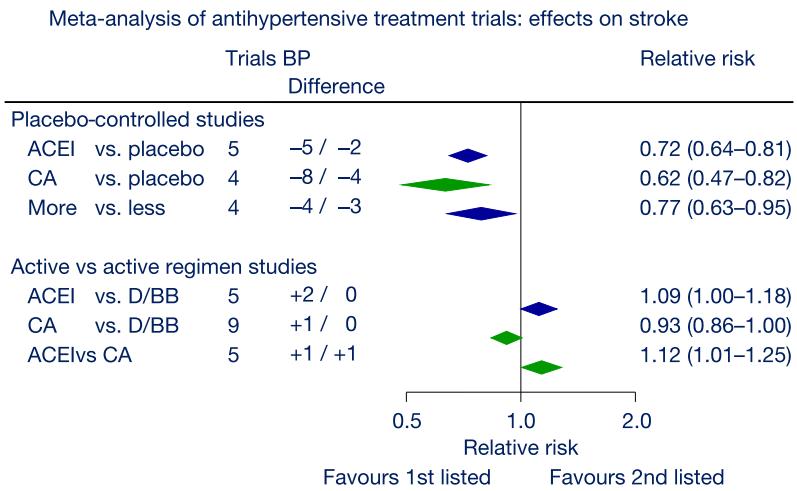

Fig. 3 This meta-analysis shows that CCBs are superior to ACE-inhibitors or to the combination beta-blockers/diuretics in reducing the incidence of stroke. Adapted from Turnbull, F., Blood Pressure Lowering Treatment Trialists' Collaboration. (2003). Effects of different blood-pressure-lowering regimens on major cardiovascular events: Results of prospectively-designed overviews of randomised trials. *Lancet 362*, 1527–1535.

potency as compared to eplerenone (Dietz *et al.*, 2008) (**Fig. 4**). In particular, dihydropyridine CCBs block aldosterone-induced recruitment of coactivators, and inhibit aldosterone-induced gene expression. Among dihydropyridines, a complete inhibition is elicited by nimodipine, felodipine, and nitrendipine, while amlodipine reduced aldosterone activation by only 50%. Some earlier studies suggest also that some dihydropyridine CCBs, such as efonidipine and benidipine (Imagawa *et al.*, 2006), are able to inhibit aldosterone production in in human adrenocortical cell line through blockade of T-type voltage-dependent calcium channels. Radiolabeled aldosterone binding assay suggests that benidipine directly binds to the mineralocorticoid receptor and excludes aldosterone binding. Benidipine showed more potent activity than the other calcium channel blockers, efonidipine, amlodipine, or azelnidipine, but it is less effective than nimodipine (Kosaka *et al.*, 2010). MR antagonist activity of CCBs is restricted to the dihydropyridine class: the non-dihydropyridine CCBs have no effect on MR (Dietz *et al.*, 2008).

Furthermore, the MR antagonist activity of CCBs is not due to the indirect effect by inhibition of L-type calcium channels (Kosaka *et al.*, 2010). In this framework, some authors argue that the beneficial effect of nimodipine on cerebral ischemia and stroke might be related to MR inhibition in the brain rather that to the effect on calcium channels (Dietz *et al.*, 2008).

Genetic studies confirmed the interrelationship between T-type calcium channel receptors and aldosterone signaling. A recurrent gain-of-function mutation in a T-type calcium channel, CACNA1H(M1549V) was identified as the cause of a novel Mendelian disorder characterized by early-onset primary aldosteronism and hypertension. When this mutation is transfected in the aldosterone-producing adrenocortical cancer cell line H295R and its subclone HAC15, aldosterone synthesis raised by seven times and was abrogated by the T-channel blocker antagonist mibrefadil (Reimer *et al.*, 2016).

On this basis, in the last years a new class of dihydropyridine-derived non-steroidal mineralocorticoid antagonists (MRAs) has been discovered. Indeed, very recently new molecules have been patented in the dihydropyridines family with mineralocorticoid receptor antagonist properties and they are designated as third-generation MRAs (Arhancet *et al.*, 2010). The first potent and selective MR antagonist of this class that was investigated was BR-4628. BR-4628 is a nonsteroidal mineralocorticoid receptor

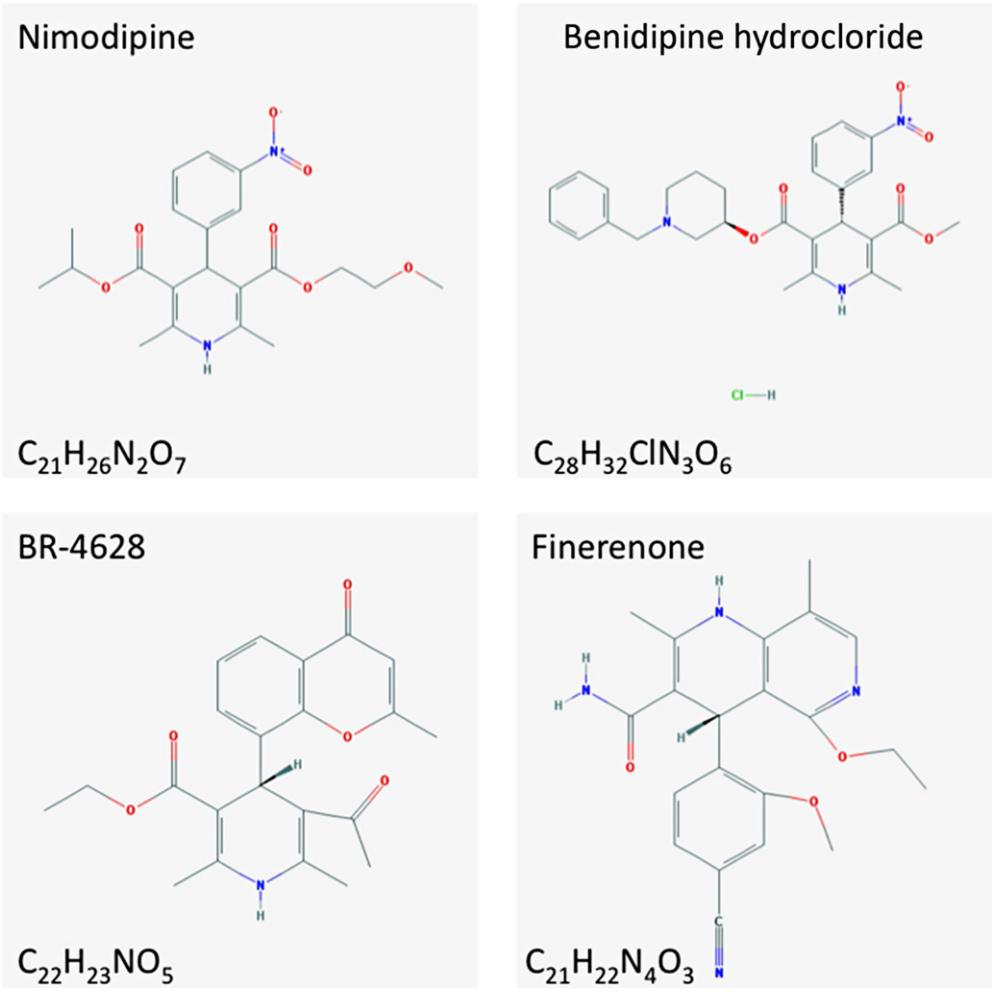

Fig. 4 Chemical structure of old (nimodipine, benidipine) and novel (BR-4628, finerenone) calcium channel blockers with mineralocorticoid receptor antagonist properties.

antagonist, which shares a similar efficacy with spironolactone as mineralocorticoid receptor inhibitor, but has no effect on the other steroidal receptors and on the L-type calcium channel (Fagart *et al.*, 2010).

Although BR-4628 has a strong binding activity to the MR, the MR-ligand complex is highly unstable. This precludes recruitment of transcriptional co-modulators, thereby disabling proper transcription and exerting a global inhibitor effect (Fagart *et al.*, 2010). In vitro studies showed that this compound has a 160-fold larger selectivity for the MR than for the androgen receptor, thus contrasting to an only 3-fold selectivity of spironolactone. Thus, this class is not expected to cause gynecomastia, a well-known adverse side effect of spironolactone. The potency to block the MR is similar to that of spironolactone, with a half-maximally inhibitory concentration (IC50) of 28 and 24 nM, respectively: therefore it is 40 times more potent than eplerenone (IC50: 990 nM). In contrast, this prototype of this class of MR antagonists has very weak calcium channel blocking activity, as compared to conventional dihydropyridine CCBs such as nitrendipine (Fagart *et al.*, 2010).

These seminal findings led to the synthesis of new molecules, such as finerenone (BAY 94-8662), which is substantially more potent and selective than spironolactone. For which data from randomized clinical trials are also available (Barfacker *et al.*, 2012). After several experimental animal studies, this drug has been tested in a randomized controlled trial for safety and efficacy (Pitt *et al.*, 2013). This trial recruited patients with heart failure with reduced EF and moderate chronic kidney disease randomized to: finerenone at different dosages, spironolactone or placebo. Finerenone decreased biomarkers of heart failure to a similar degree as spironolactone and was associated with less hyperkalemia and less renal function worsening than spironolactone.

These encouraging results have been tested in a number of larger phase 2 studies in patients with heart failure (ARTS-HF study) (Filippatos *et al.*, 2016) and patients with type 2 diabetes mellitus with diabetic nephropathy (ARTS-DN) (Bakris *et al.*, 2015).

The MinerAlocorticoid Receptor antagonist Tolerability Study-Heart Failure (ARTS-HF), enrolled 1066 patients with worsening heart failure and reduced ejection fraction and chronic kidney disease and/or diabetes mellitus, randomized to finerenone at different dosages or eplerenone. In this ARTS-HF, a reduction of $>30\%$ in baseline NT-proBNP (the primary endpoint, was achieved by finerenone at all dosages.

Cumulative event rates of the composite clinical endpoint (death from any cause, cardiovascular hospitalization, or emergency presentation for worsening chronic heart failure at 90 days) were significantly improved in the finerenone arms in comparison to eplerenone arm, when full doses were used. This trial also confirmed the neutral effect on BP and a similar incidence of hyperkalemia compared with eplerenone (Filippatos *et al.*, 2016).

In the ARTS-DN study, 823 patients with diabetic nephropathy treated with RAS-blockers and micro- or macroalbuminuria were randomized to finerenone from 1.25 to 20 mg/die or placebo. Finerenone treatment resulted in an improvement in the urinary albumin-creatinine ratio after 90 days (the primary outcome variable) in comparison to placebo, with a fairly good safety profile in terms of incidence of hyperkalemia (maximum 3.2% and GFR reduction (comparable to placebo).

None of the different doses tested induced a significant decrease in systolic BP in any of these studies. This different profile in comparison to classical MR antagonists might be attributed to the fact that Bay 94-8862 has a lower tissue distribution in the kidney as compared to the heart and constitutes an asset in patients with heart failure. An other possibility is the inability to cross the blood–brain barrier (at variance with steroidal MR antagonists) and act on cerebral MR, which are believed to play a major role in the control of blood pressure (Gomez-Sanchez and Gomez-Sanchez, 2012). On the other hand, for the same reason this drug is less suitable as an antihypertensive drug in the setting of essential hypertension or primary hyperaldosteronism. Indeed, no ongoing trials are present to date on clinicaltrials.gov entering as search terms “aldosteronism” and “finerenone” or “BAY 94–8862”.

Conclusions

CEBs can be considered a corner-stone of cardiovascular treatment. Especially in patients with hypertension these drugs are even underused in respect of their potential beneficial effect not only on blood pressure lowering but also on target organ damage and cardiovascular events, including stroke and coronary artery disease.

Concerning their activity on the endocrine system dihydropyridine CCBs possess a mineralocorticoid receptor antagonist activity as well a possible inhibitory effect on the aldosterone secretion which seems to be dependent on blockade of t-type calcium channels. This effect might be potential relevant in cardiovascular medicine and ongoing studies will tell us in the next future their possible application. In addition, these properties have disclosed a new line of research leading to the development of new molecules with should potentially act in a more specific and potent way on the mineralcorticoid system.

Pseudohypoaldosteronism Type 1

Fabio L Fernandes-Rosa, INSERM, Paris Cardiovascular Research Center, Paris, France; Paris Descartes University, Paris, France; and Assistance Publique-Hôpitaux de Paris, Hôpital Européen Georges Pompidou, Paris, France

Introduction

Pseudohypoaldosteronism type 1 (PHA1) is a rare pediatric disease characterized by a resistance to mineralocorticoid hormones. PHA1 is due to abnormalities of the mineralocorticoid receptor (MR) and the epithelial amiloride-sensitive sodium channel ENaC, molecules that play a crucial role in the regulation of water and electrolyte balance mediated by aldosterone. In neonates, the correct action of the mineralocorticoid axis is required as the immature tubular function in this period may impair the regulation of water and electrolyte balance by the kidneys. Moreover, prematurity, infections and, also, the physiological partial resistance to aldosterone in the newborn may contribute for the impaired regulation of electrolyte balance dependent of aldosterone.

The original case was reported by Cheek and Perry in 1958, who described an infant with severe salt wasting and failure to thrive without any renal or adrenal abnormalities. In general, patients exhibit severe salt wasting in the neonatal period, with hyponatremia, hyperkalemia and metabolic acidosis despite extremely high levels of plasma renin and aldosterone (Riepe, 2009). Classically, two different forms of PHA1 have been described, a renal mild form and a severe generalized form (Hanukoglu, 1991) with different genetic alterations described. Additionally, a secondary form of PHA1 associated with renal abnormalities was also described (Rodríguez-Soriano *et al.*, 1983). Moreover some studies have shown intermediate forms of PHA1 with an intermediary phenotype between the renal and the generalized forms.

Aldosterone Function in the Distal Nephron

The knowledge of the physiological role of aldosterone in the distal nephron, regulating volume and electrolyte homeostasis, is fundamental to understand the clinical consequences of the mineralocorticoid resistance. Aldosterone acts in a region of the nephron that includes the late distal convoluted tubule (DCT), the connecting tubule (CNT) and the collecting duct (CD), named aldosterone-sensitive distal nephron (ASDN). ASDN express the aldosterone receptor MR, the final effector of aldosterone in epithelial tissues (the sodium channel ENaC), and the 11-β hydroxysteroid dehydrogenase type 2, enzyme responsible for mineralocorticoid selectivity (Loffing and Kaissling, 2003; Farman and Rafestin-Oblin, 2001). Only 5%–10% of the filtered Na^+ load occur in ASDN, however, these nephron segments are responsible for the fine-tuning of the renal excretion of Na^+ (Campean *et al.*, 2001; Loffing *et al.*, 2001). In ASDN cells, sodium reabsorption is mediated at the apical cell membrane by ENaC (Biner *et al.*, 2002; Loffing and Kaissling, 2003; Reilly and Ellison, 2000). The sodium transport across the basolateral membrane to the interstitial fluid is mediated via the ubiquitous Na^+-K^+-ATPase, generating driving force for Na^+ transport. The sodium transport via the Na^+-K^+-ATPase generates large ion concentration gradients that drive potassium and hydrogen ion secretion (Reilly and Ellison, 2000). In the ASDN, apical K^+ channels as the renal outer medullary potassium channel (ROMK1 or Kir1.1) are involved in K^+ secretion (Wang *et al.*, 2010).

Aldosterone exerts its actions by binding to its receptor MR. After aldosterone binding MR will dilerize dimerization and translocate to the nuclei, where it will bind to regulatory regions of hormone responsive genes. This will increase the expression of aldosterone target genes, including the epithelial sodium channel ENaC, the Na^+–K^+-ATPase, and several genes involved in the transepithelial sodium transport. Aldosterone increases mRNA levels of the serum- and glucocorticoid regulated kinase 1 (sgk1), which phosphorylates Nedd4-2, protein responsible for ENaC ubiquitination. Phosphorylated Nedd4-2 is no more able to interact with ENaC, decreasing its retrieval and degradation, and increasing its localization to the apical membrane (Bhalla and Hallows, 2008). MR also increases ENaC expression in membrane surface and activity by regulating the transcription of the deubiquitylating enzyme Usp2-45 (Verrey *et al.*, 2008). An additional mechanism leading to increased ENaC expression on the cell membrane is the stimulation of glucocorticoid-induced leucine zipper protein (GILZ) expression by the MR, leading to the inhibition of the extracellular signal–regulated kinase (ERK) (Soundararajan *et al.*, 2005). MR seems also to play a role on K^+ secretion by stimulating sgk1 expression. Sgk1 could increase the export of ROMK channels from the endoplasmic reticulum, and suppress the inhibitory effect of serine/threonine protein kinase WNK4 on ROMK channels (Ring *et al.*, 2007; Vallon *et al.*, 2005; Wang *et al.*, 2010).

Renal PHA1

Clinical Features

Renal PHA1 (MIM#177735), also called autosomal dominant PHA1, is a mild and the most frequent form of PHA1, with a prevalence of $\sim$1 per 80,000 newborns (Zennaro and Fernandes-Rosa, 2017). Familial cases with an autosomal dominant inheritance and sporadic cases were described. The phenotypic expression is restricted to the kidney, with patients exhibiting a salt

 doi:10.1016/B978-0-12-801238-3.65188-7

losing syndrome in the neonatal period, with different degrees of weight loss, failure to thrive, vomiting and dehydration. Biological analysis is characterized by hyponatremia, hyperkalemia, metabolic acidosis, inappropriately high urinary sodium excretion, and low urinary potassium excretion. Despite the clinical and biological findings compatible with decreased aldosterone, affected neonates exhibit high plasma and urinary aldosterone and high plasma renin levels, confirming the mineralocorticoid resistance (Zennaro and Lombes, 2004). The symptoms usually improve in early childhood (18–24 months), with plasma aldosterone remaining high into adulthood (Zennaro *et al.*, 2012). The explanation for this clinical improvement includes kidney maturation, access to dietary salt and tubulo-glomerular feedback regulation. Phenotypic variability is observed within the PHA1 families, ranging from subjects with severe salt loss in the neonatal period to asymptomatic subjects. Interestingly, adult patients with renal PHA1 and MR mutations have no adverse cardiovascular outcome, but rather an improved diastolic left ventricular function, suggesting suggests that the cardiovascular consequences of aldosterone excess require full MR signaling (Escoubet *et al.*, 2013).

Pathophysiology

The genetic defect underlying the development of renal PHA1 was elucidated in 1998 by Geller *et al.* The authors identified heterozygous mutations in the *NR3C2* gene (coding for the MR) in four dominant and one sporadic cases of PHA1 (Geller *et al.*, 1998). Since this description, more than 70 heterozygous *NR3C2* mutations were described in patients with renal PHA1 (Zennaro and Fernandes-Rosa, 2017). Interestingly, in about 30% of cases, no MR mutations were identified.

NR3C2 spans over ~450 kB on chromosome 4p31.23 and is composed of 10 exons (Zennaro *et al.*, 1995). MR is a nuclear receptor and acts as a transcription factor, regulating the transcription by binding to specific hormone elements located in regulatory regions of target genes. The human MR is composed of 984 amino acids and possess three separate domains: N-terminal, DNA binding and ligand binding domains (Viengchareun *et al.*, 2007). The N-terminal domain (NTD), encoded by exon 2 of *NR3C2* contains an autonomous activation function (AF-1), supports recruitment of specific coregulators responsible for higher selectivity at the transcriptional level, and is a site of post-translational modifications that modulate its transcriptional activity (Pascual-Le Tallec and Lombes, 2005). The DNA binding domain (DBD), encoded by exons 3 and 4 of *NR3C2*, is composed of two zinc-finger involved in DNA binding and receptor dimerization (Luisi *et al.*, 1991). The ligand binding domain (LBD), encoded by exons 5–9 of *NR3C2* is involved in ligand binding and in the interaction with heat shock proteins and transcriptional coactivators (Couette *et al.*, 1996).

Mutations leading to renal PHA1 are always heterozygous and are located in all exons of the *NR3C2* gene. To date, no missense mutations were reported in exon 2, suggesting that missense mutations located in the N-terminal domain do not sufficiently affect MR function. *NR3C2* mutations occur at high frequency in patients with familial autosomal dominant and in sporadic PHA1 (Pujo *et al.*, 2007). The pathogenic mechanism of PHA1 in patients with heterozygous MR mutations is dependent on the type of mutation, comprising haploinsufficiency but also dominant negative effects on the wild type receptor (Riepe *et al.*, 2006; Sartorato *et al.*, 2003, 2004a). MR mutations differentially affect individual gene expression in a promoter-dependent manner (Fernandes-Rosa *et al.*, 2011; Sartorato *et al.*, 2004b). The same mutation may induce complete functional loss of transcriptional activity on one target promoter, while retaining a partial transcriptional activity on another gene. In this case, the phenotype of PHA1 may be modulated, in terms of target gene expression, not only by the quantitative extent of functional reduction but also by the specific qualitative impact of MR function over target genes (Fernandes-Rosa *et al.*, 2011). The clinical severity of renal PHA1, however, is not correlated with a particular MR genotype (Riepe, 2009). This could be explained by adaptive and compensatory mechanisms occurring in the distal part of the nephron.

Generalized PHA1

Generalized PHA1 (MIM #264350), is a severe, autosomal recessive, form of PHA1. It is characterized by salt wasting from multiple organs, including kidney, distal colon, and the salivary and sweat glands (Bosson *et al.*, 1986; Oberfield *et al.*, 1979; Savage *et al.*, 1982). Patients exhibit with severe dehydration, vomiting and failure to thrive in the neonatal period and the clinical course may be complicated by cardiac dysrhythmias, collapse, shock or cardiac arrest (Speiser *et al.*, 1986). Biological analysis is characterized by severe hyperkalemia, high plasma aldosterone and high plasma renin levels, confirming the mineralocorticoid resistance. The presence of elevated sweat and salivary Na^+ and Cl^- and absent nasal amiloride-sensitive Na^+ transport corroborate the systemic mineralocorticoid unresponsiveness (Hanukoglu, 1991; Thomas *et al.*, 2002). Signs of systemic salt loss may include a respiratory syndrome characterized by persistent rhinorrhea of clear liquid, congestion, tachypnea, wheezing, fever and recurrent pulmonary infections, due to their reduced capacity to absorb liquid from airway surfaces (Kerem *et al.*, 1999; Schaedel *et al.*, 1999). Cutaneous lesions similar to those appearing in miliaria rubra, associated to inflammation and damage in the eccrine structures, are due to high concentration of sweat salt (Martin *et al.*, 2005; Hanukoglu *et al.*, 2017). Cholelithiasis and salt loss from the Meibomian glands were also reported in children with PHA1 (Akkurt *et al.*, 1997; Kuhnle, 1997).

Early diagnosis is critical to survival in generalized PHA1 (Belot *et al.*, 2008). In contrast to renal PHA1, patients with generalized PHA1 suffer from recurrent life-threatening episodes of salt loss in childhood (Adachi *et al.*, 2001; Hanukoglu *et al.*, 2008). Interestingly, the evaluation of patients with systemic PHA1 throughout adolescence and early adulthood showed gradual normalization of urinary

Na/K ratios with age (Hanukoglu *et al.*, 2008). In the same way, the patients with near normal lives on a life-long high salt diet, and even PHA1 improvement with cessation of salt supplementation were described (Adachi *et al.*, 2010; Edelheit *et al.*, 2010).

Pathophysiology

Systemic PHA1 is caused by mutations in *SCNN1A*, *SCNN1B*, and *SCNN1G* genes coding for the ENaC subunits α, β and γ, respectively. *SCNN1A* is located on chromosome 12p13.3, whereas *SCNN1B* and *SCNN1G* are located within 400 kb on chromosome 16p12.2-p13.11. The three genes are comprised of 13 exons spanning over 17 kb. Parts of exons 2 and 13 encode the transmembrane regions, and exons 3–13 code for the extracellular loop (Saxena *et al.*, 1998; Thomas *et al.*, 1996; Ludwig *et al.*, 1998). After the association of the locus of ENaC subunits on chromosomes 12 and 16 with generalized PHA1 (Strautnieks *et al.*, 1996b), Chang *et al.* identified mutations in *SCNN1A* and *SCNN1B* in PHA1 patients from Arabian and Iranian Jewish ethnicity (Chang *et al.*, 1996). A mutation affecting *SCNN1G* was described in three families originating from the Indian subcontinent showing linkage to chromosome 16p (Strautnieks *et al.*, 1996a). Different homozygous or compound heterozygous inactivating mutations of ENaC subunits, as well as a large deletion in the promoter region of βENaC, were subsequently reported (Adachi *et al.*, 2001; Bonny *et al.*, 2002; Edelheit *et al.*, 2005; Kerem *et al.*, 1999; Riepe *et al.*, 2009; Saxena *et al.*, 2002; Schaedel *et al.*, 1999). ENaC mutations are in majority homozygous, mostly in consanguineous families, although compound heterozygous mutations can occur in non-consanguineous pedigrees. In contrast to the renal PHA1, ENaC mutations are identified in all subjects investigated.

ENaC constitutes the rate-limiting step for sodium reabsorption in ASDN of the kidney, the distal colon, salivary and sweat glands, and the lung (Canessa *et al.*, 1994). The three ENaC subunits act together to confer the channel's low Na^+ conductance, and its high selectivity for Na^+ and amiloride. While in animal models, the inactivation of one ENaC subunit is associated to specific phenotypes (Hummler *et al.*, 1996; McDonald *et al.*, 1999; Barker *et al.*, 1998), in humans the genotype–phenotype correlations are not well established. Hanukoglu *et al.* evaluated the reported distinct growth and puberty phenotypes in PHA1 patients depending on the degree of functional ENaC impairment (Hanukoglu *et al.*, 2008).

In the lungs, ENaC contributes for removal of fluid from the alveolar space by regulating the transepithelial alveolar sodium transport (Hummler and Planes, 2010). Accordingly, ENaC plays a role on the pathogenesis of pulmonary diseases such as cystic fibrosis and respiratory distress syndrome in preterm infants. In cystic fibrosis, ENaC activity is increased, contributing to airway mucus dehydration and decreased mucociliary transport (Boucher, 2007). In contrast, in systemic PHA1, the absence of ENaC activity results in increased airway surface liquid (Kerem *et al.*, 1999).

Secondary PHA1 and Intermediate Forms

Secondary PHA1 is characterized by transient mineralocorticoid resistance in infants with less than 7 months of age, associated with malformations in the urinary tract and/or urinary tract infections (Bulchmann *et al.*, 2001; Rodríguez-Soriano *et al.*, 1983; Watanabe, 2003). The phenotype is less severe in older infants than in neonates suggesting a pathophysiologic role for the tubular immaturity (Belot *et al.*, 2008). Other pathophysiological hypothesis is the increase in cytokines (mainly the transforming growth factor beta-1, -TGF-β1) in response to the urinary tract obstruction, resulting in the down regulation of MR (Klahr, 2000; Furness *et al.*, 1999; Kuhnle *et al.*, 1993; Bogdanovic *et al.*, 2009). Diagnosis of secondary PHA1 includes hyponatremia, hyperkalemia and metabolic acidosis in the presence of high levels of plasma aldosterone and renin, associated to abnormalities in urine culture and/or ultrasound examination, allowing the differentiation from genetic forms. Transient PHA1 was also observed secondary to congenital jejunal membrane (Nissen *et al.*, 2017), after resection of the ileum and colon in an adult patient (Vantyghem *et al.*, 1999), and in patients treated with immunosuppressants (Deppe *et al.*, 2002).

Recent studies challenged the classical classification of PHA1 in two distinct entities. These reports showed a continuum in the PHA1 phenotype between the severe generalized and the mild renal PHA1. While homozygote carriers of a αENaC mutation exhibit a generalized PHA1 phenotype, heterozygote carriers may exhibit a sub-clinical PHA1 phenotype only with increased sweat sodium and chloride concentrations (Riepe *et al.*, 2009). Moreover, cases of mild forms of PHA1 associated with homozygous ENaC mutations were also described (Dirlewanger *et al.*, 2011). Finally, a patient with a severe PHA1 phenotype was shown to carry two *NR3C2* mutations, each inherited from one parent (Hubert *et al.*, 2011). The gravity of the salt wasting syndrome was similar to the generalized PHA1 despite the MR mutation which is associated to the mild renal PHA1.

Differential Diagnosis

Differential diagnosis of PHA1 comprises diseases leading to renal salt wasting in the neonatal period, mainly congenital adrenal hyperplasia (CAH) and isolated deficiency in aldosterone synthase (**Table 1**). Classic CAH due to 21-hydroxylase (21OH) deficiency with salt loss is the main differential diagnosis of PHA1. Classic CAH-21OH is an autosomal recessive disease with an estimated prevalence of 1:10,000–1:20,000. Defective 21OH-hydroxylation results in decreased glucocorticoid and mineralocorticoid synthesis and elevated precursors, most notably 17-hydroxyprogesterone (17OHP), and concomitant ACTH-stimulated androgen production. It is characterized by hyponatremia and hyperkalemia in the neonatal period, with different degrees of

Table 1 Pseudohypoaldosteronism type 1 differential diagnosis

	Renal PHA1	*Generalized PHA1*	*Secondary PHA1*	*21-Hydroxylase CAH*	*3βHSD2 CAH*	*Isolated aldosterone deficiency*
Clinical phenotype	Different degrees of failure to thrive and dehydration. Improvement with age	Severe dehydration, failure to thrive, pulmonary and skin phenotype. Lifelong episodes of salt wasting	Failure to thrive and dehydration associated to urinary tract malformation and infection	Severe salt wasting syndrome in classic form. Ambiguous genitalia in females	Salt wasting associated with hypovirilization in males and virilization in females	Variant degrees of dehydration and vomiting
Inheritance	Autosomal dominant Sporadic	Autosomal recessive	Sporadic	Autosomal recessive	Autosomal recessive	Autosomal recessive Autosomal dominant with mixed penetrance
Genes	*NR3C2*	*SCNN1A*, *SCNN1B*, and *SCNN1G*		*CYP21A2*	*3βHSD2*	*CYP11B2*
Biochemical findings	Hyponatremia Hyperkalemia Metabolic acidosis Increased aldosterone Increased renin	Severe hyponatremia Hyperkalemia Metabolic acidosis Increased aldosterone Increased renin	Hyponatremia Hyperkalemia Metabolic acidosis Increased aldosterone Increased renin	Hyponatremia Hyperkalemia Hypoglycemia Metabolic acidosis Decreased aldosterone Decreased cortisol Increased ACTH Increased 17-OH Progesterone	Hyponatremia Hyperkalemia Hypoglycemia Metabolic acidosis Decreased aldosterone Decreased cortisol Increased ACTH Increased 17-OH Pregnenolone	Hyponatremia Hyperkalemia Metabolic acidosis Decreased aldosterone Increased renin
Treatment	Salt supplementation in early childhood	Lifelong salt supplementation, ion resins	Salt supplementation. Correction of urinary tract malformation and/or infection	Glucocorticoid and mineralocorticoid replacement. Salt supplementation	Glucocorticoid and mineralocorticoid replacement. Salt supplementation	Mineralocorticoid replacement

genitalia virilization in female neonates (DSD 46,XX) (New, 2003; Bizzarri *et al.*, 2016; El-Maouche *et al.*, 2017). Complete clinical examination to exclude the presence of ambiguous genitalia and measure of 17OHP are crucial for differentiate CAH-21OHD from PHA1. CAH due to 3β-hydroxysteroid dehydrogenase deficiency (3βHSD2) is a rare form of CAH responsible by salt wasting in the neonatal period. Abnormal 3βHSD2 activity leads to decreased in aldosterone, cortisol and androstenedione synthesis and an increase in DHEA production. Neonates affected exhibit hyponatremia and hyperkalemia associated to underdeveloped 46,XY genitalia (DSD 46, XY), and less frequent a virilization in 46,XX. The diagnosis is confirmed by high levels of the precursor 17-OH pregnenolone (New, 2003; El-Maouche *et al.*, 2017). Isolated aldosterone deficiency is a salt wasting disease due to a defect in the final steps of aldosterone biosynthesis caused by mutations in *CYP11B2* (coding for the aldosterone-synthase). Signs of aldosterone deficiency may appear at a few days or weeks of age but some patients are only diagnosed in the early childhood. Diagnosis is confirmed by presence of increased deoxycorticosterone, undetectable levels of aldosterone in the subtype I of the disease, and elevation of the ratio of 18-hydroxycorticosterone to aldosterone in patients with isolated aldosterone deficiency type II (Ulick *et al.*, 1992; White, 2004). Finally, patients with antenatal Bartter syndrome, an autosomal recessive disease caused by mutations in the potassium channel ROMK, may present with hyperkalemia in the first week of life associated with increased renin and aldosterone (Finer *et al.*, 2003). Usually, the hyperkalemia is transient and patients will develop hypokalemia and metabolic alkalosis.

Treatment

Treatment of PHA1 is based in the correction of water, electrolytes and acid–base disturbances. In the acute phase, salt supplementation, hydration and correction of hyperkalemia and acidosis hyperkalemia may be associated with the administration of fludrocortisone (mineralocorticoid) and hydrocortisone (glucocorticoid) while performing the differential diagnosis with CAH. Extracellular volume expansion and ion exchange resins may be required to normalize sodium and potassium levels. Recognize a salt wasting syndrome is important for all pediatricians and physicians in neonatal care and pediatric emergency services; adequate volume expansion, salt supplementation and steroid replacement are crucial in this death risk condition.

After the acute phase and confirmation of PHA1 diagnosis, salt supplementation is the basis of the treatment. In renal PHA1 the amount of salt supplementation depends on the severity of the phenotype, but usually 3–20 mEq/kg/d of Na^+ are able to

remediate the salt loss. Clinical and biochemical improvement are rapidly achieved, with catch-up on growth and development, and electrolytes normalization. Renal PHA1 improves with age and salt supplementation may be discontinued in the majority of patients after 18–24 months of age. Older children are asymptomatic, with normal growth and development, and electrolytes remaining in normal ranges. Some children, however, may exhibit growth on the lower percentiles of the growth curve (Loomba-Albrecht *et al.*, 2010). Symptoms and signs of secondary PHA1 usually improve with the surgical correction of the underlying urinary tract structural abnormalities and treatment of urinary tract infection. In the acute phase and before treatment of the urinary tract disease, patients with secondary PHA1 may need medical care similar to patients with renal PHA1.

Treatment of generalized PHA1 is specific for each patient and is usually based in high doses of sodium supplementation (20–50 mEq/kg/d), associated with ion resins and low K^+ diet to reduce potassium levels. The supplementation of high doses of sodium is difficult and requires tube feeding in some cases. So far, no specific drug has been described, but the use of glucocorticoid or indomethacin seems to be beneficial for some patients (Mathew *et al.*, 1993). Recent preliminary in vitro studies showed that tumor necrosis factor (TNF) activates ENaC current through its lectin-like (TIP) domain, and that peptides mimicking the TIP domain are capable to activate wild-type and mutant ENaC (Willam *et al.*, 2017). These data indicates that these peptides could represent a strategy to treat generalized PHA, however, further studies are necessary to evaluate in vivo efficacy and safety of these peptides. The treatment is needed throughout life but the sodium supplementation may decrease with age to 8–20 g NaCl/day. Specific symptomatic treatment is required for pulmonary and dermatological phenotype.

Hyporeninemic Hypoaldosteronism☆

Shrey Purohit, Duke University, Durham, NC, United States
Dalila B Corry and Michael L Tuck, David Geffen UCLA School of Medicine, Los Angeles, CA, United States

Introduction

Hyporeinemic hypoaldosteronism (HH), often used interchangeably with type IV renal tubular acidosis (RTA), is a syndrome of diminished renin secretion and resultant decreased aldosterone release. Basal levels of plasma renin activity (PRA) and aldosterone concentration are either low or normal but fail to respond to stimulatory testing (Soriano, 2002). Classically the syndrome is associated with renal dysfunction, most often secondary to long-standing diabetes, but can be present in any disorder that causes tubulointerstitial kidney injury and subsequent damage to the juxta-glomerular apparatus (JGA), the site of renin production.

The most prominent feature is a chronic mild or masked hyperkalemia that can become severe in or chronic kidney injury or when drugs antagonizing the renin–angiotensin–aldosterone system (RAAS) are added. Such medications include angiotensin converting enzyme inhibitors (ACEi), angiotensin receptor blockers (ARB), direct renin inhibitors (DRI), and aldosterone antagonists. Symptoms in HH, while rare, are usually due to hyperkalemia and include myopathic weakness, various tachyarrhythmias and bradyarrhythmias and, in severe cases, cardiac arrest and death (Medford-Davis and Rafique, 2014). The pathogenesis of HH and its relationship to hyperkalemia is complex and has multiple contributing factors including underlying diabetic nephropathy, diabetic autonomic neuropathy, hyperglycemia, and medications that act to inhibit the RAAS pathway (Sousa *et al.*, 2016). This last cause is most relevant as many of these drugs are indicated in patients with chronic kidney disease, diabetes and cardiovascular disease as these agents carry with them a significant morbidity and mortality benefit.

Pathogenesis of HH

The human adrenal cortex secretes several steroids including aldosterone which has predominantly mineralocorticoid properties. Aldosterone acts on the distal tubules and collecting duct of the kidney to promote sodium (Na^+) reabsorption and potassium (K^+) and hydrogen proton (H^+) excretion. Under most physiologic conditions, the RAAS is the main regulator of aldosterone secretion. Additionally, changes in the serum sodium content, the effective plasma volume, the sodium chloride concentration sensed by the macula densa, serum potassium levels and the autonomic nervous system can all play a role in aldosterone regulation (Sousa *et al.*, 2016).

Mechanisms of Hyporeninemia

Potential factors in the etiology of HH include inadequate renin and aldosterone production, failure of the autonomic nervous system or resistance to aldosterone action in the principal cells of the distal nephron. Although renin insufficiency plays the predominant role in HH, these other factors can also contribute to this syndrome (Sousa *et al.*, 2016). As HH occurs predominantly in diabetic patients with CKD, destruction of the JGA, in diabetic nephropathy likely via hyalinization of the afferent arteriole (Villoria *et al.*, 1988), reduces renin synthesis. High concentrations of the inactive renin precursor "big renin" (prorenin) have been reported in diabetic patients (Davis and Freeman, 1976) associated with low circulating PRA levels. These findings point to an impaired conversion of prorenin (big renin) to active renin in this disorder.

Sympathetic nerve terminals are found on the JGA and catecholamines, particularly epinephrine, can stimulate renin secretion (Sparks *et al.*, 2014). Loss of SNS activity, as in diabetic autonomic neuropathy, can contribute to the hyporeninemia in HH. Additionally, volume expansion due to sodium retention and chronic mild hyperkalemia as seen in CKD associated with diabetic nephropathy (DN) could further suppress renin release via tubuloglomerular feedback in the macula densa (Persson *et al.*, 2013). Some degree of prostaglandin deficiency or failure of the renal arteriole to respond to PGE in HH could also contribute to renin deficiency (Phelps *et al.*, 1980).

Regulation via Sodium

The secretion of pre-made renin from the JGA cells, located adjacent to the renal glomerulus and afferent arteriole, in response to decreased plasma volume results in angiotensin I synthesis, conversion to angiotensin II by angiotensin converting enzyme (ACE). Angiotensin II has a host of roles in the body including increasing vascular tone and release of aldosterone from the adrenal cortex

This chapter is an update of H Hatakeyama and T Watanabe, Hyporeninemic Hypoaldosteronism, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 672–674.

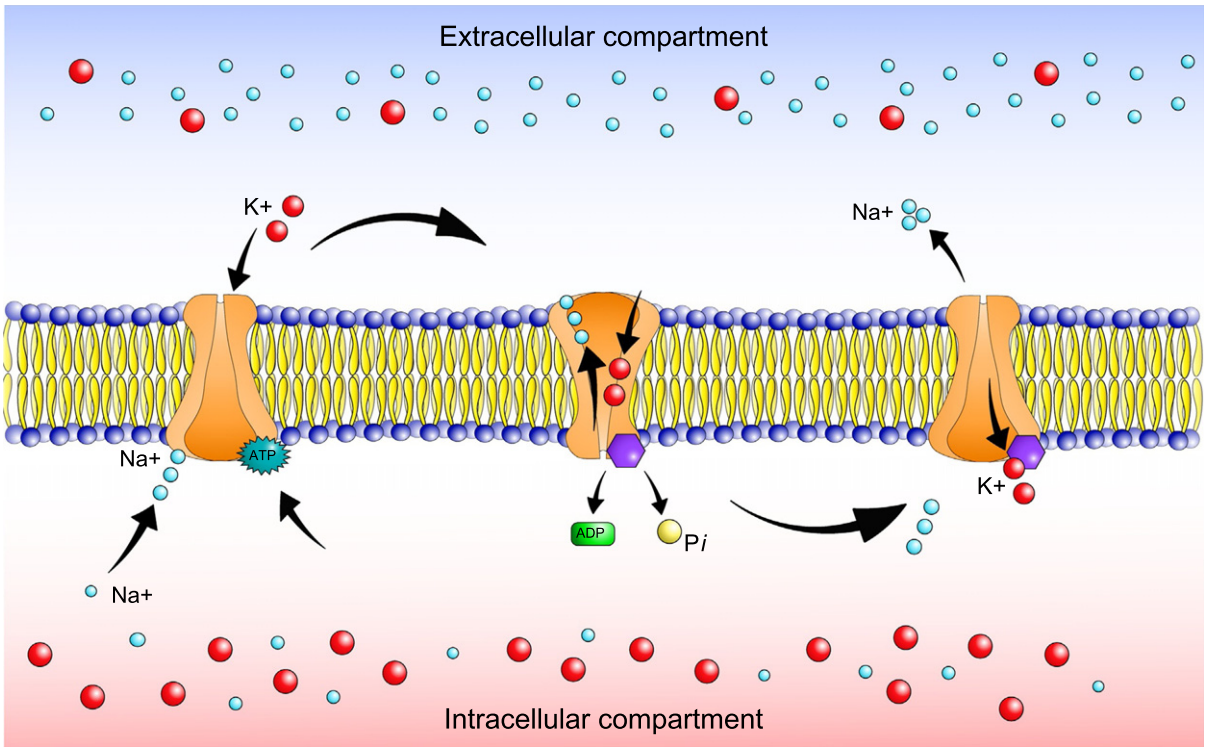

Fig. 1 The effects and regulatory mechanisms of the renin–angiotensin–aldosterone system.

resulting in retention of sodium from the kidney and restoration of circulating blood volume. (**Fig. 1** insert) This process occurs as a feedback loop; volume expansion has the opposite effect, resulting in suppression of renin and thus reduced aldosterone. A related mechanism is release of renin via the macula densa, an organ located near the distal tubule and collecting ducts of the kidney (Sparks *et al.*, 2014). In response to increased tubular sodium in the distal tubule, either due to increased filtration at the glomerulus, decreased resorption or both, the macula densa releases mediators to the JGA causing suppression of renin, constriction of afferent arterioles and dilation of efferent arterioles in the glomerulus of the kidney. This mechanism, termed tubuloglomerular feedback, effectively decreases glomerular filtration rate (GFR) and is thought to allow for rapid regulation of the GFR to prevent hyperfiltration injury (Fu *et al.*, 2012; Persson *et al.*, 2013).

Regulation via Serum Potassium

The other major contributor to aldosterone regulation is the potassium ion, which in the extracellular space, is tightly regulated (Palmer, 2004). Potassium stimulates aldosterone secretion directly at the adrenal gland; this regulation is independent of the RAAS or changes in effective circulating volume (Bollag, 2014). Even minute increases in plasma potassium stimulate aldosterone secretion to promote renal potassium excretion. Potassium depletion has the opposite effect, lowering aldosterone secretion to retain potassium ions and maintain cellular homeostasis.

In HH, potassium excretion via the renal tubules is deficient and subsequently a hyperchloremic metabolic acidosis is present due to multiple reasons including failure of hydrogen ion excretion due to deficient ammonium formation by the collecting duct, changes in the handling of ammonia in the renal medulla and transcellular shift of hydrogen protons out of cells to maintain normokalemia. Further contributing factors to the metabolic acidosis in HH can be acute kidney injury and chronic kidney disease. Because distal nephron acidification is still intact, urine pH is variable but often normal (Reddy, 2011).

Generally, patients with diabetes have higher serum potassium levels than nondiabetics due to a variety of reasons including transcellular shift of potassium, a higher potassium and lower sodium diets in diabetes, antihypertensive agents (beta-blockers, ACEi, ARBs, aldosterone, and renin antagonists) and underling diabetic nephropathy. Chronic hyperkalemia is associated with increased mortality in diabetes and chronic kidney disease (Collins *et al.*, 2017) and generally insulin resistance portends a higher serum potassium and worse diabetes control (Kim *et al.*, 2015). Potassium deficiency occurs less frequently in diabetes and is associated with low serum magnesium, insulin administration or chronic diarrhea states secondary to diabetic complications (Liamis, 2014). Hypokalemia impairs insulin secretion in the islet cells of the pancreas and induces further glucose intolerance perpetuating a vicious cycle of worsening insulin resistance and blood sugar control (Palmer and Clegg, 2015).

Potassium is tightly regulated in the body, with 98% located within the intracellular compartment and 2% in the extracellular space (see **Fig. 2**). Approximately 90% of potassium excretion occurs via the kidneys with gut excretion making up just 10%

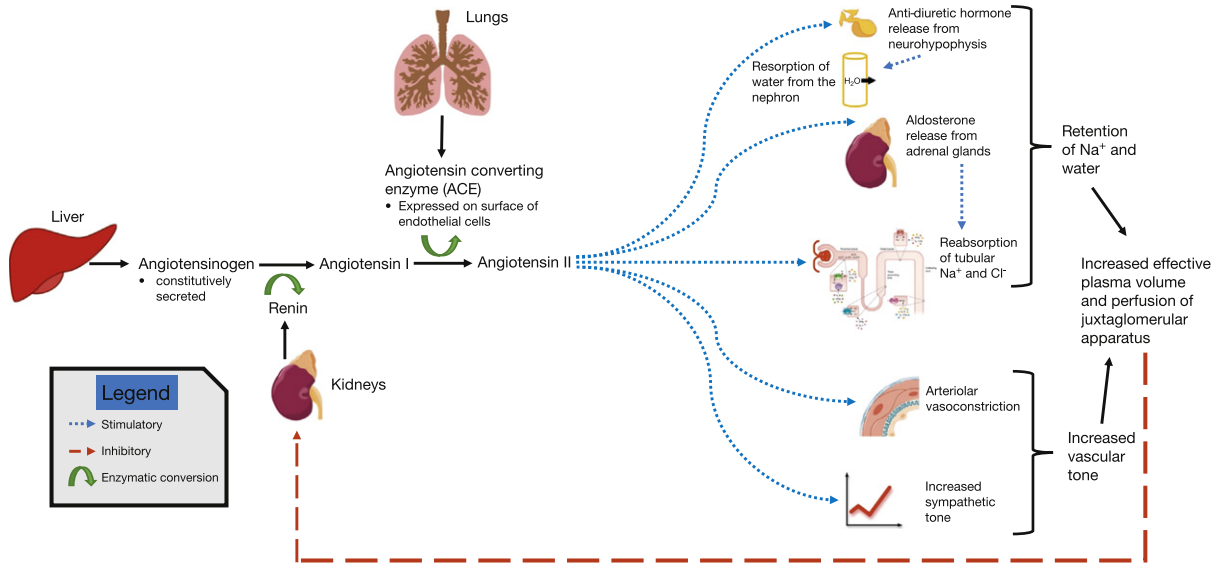

Fig. 2 Na^+–K^+ ATPase. The K^+ gradient in the intracellular space is maintained through active transport. 2 K^+ and 3 Na^+ are transported against their respective electrochemical gradient across cell membranes using energy generated by the cleavage of ATP into ADP and P_i.

however in chronic kidney disease and end-stage renal disease (ESRD) this gut mechanism can account for up to 25% of total potassium excretion (Tuck *et al.*, 1986). Cellular potassium shifts are mediated by Na–K ATPase pumps in response to a variety of endogenous and exogenous signals including, mineralocorticoids, ADH and catecholamines. Filtered potassium from the glomerulus is generally reabsorbed in the proximal tubule and the ascending limb of the loop of Henle. Potassium excretion into urine chiefly occurs in the distal convoluted tubule and cortical collecting duct (CCD) of the kidney. Aldosterone acts directly on the basolateral pumps on the CCD Na–K ATPases to move three sodium ions out in exchange for two potassium ions into the cell. Aldosterone also directly stimulates the Na–K ATPase increasing luminal membrane permeability to sodium and potassium and stimulates the opening of sodium channels in the principal cells of the CCD increasing sodium reabsorption. Sodium poor tubular fluid generates an electrochemical gradient that promotes excretion of potassium via channels on the luminal membrane side (Medford-Davis and Rafique, 2014).

Mechanisms of Metabolic Acidosis

In HH, decreased aldosterone synthesis and release results in impaired potassium excretion and hyperkalemia. Compounded with other mechanisms responsible for hyperkalemia in diabetes, this mineralocorticoid deficiency results in an elevated serum potassium. The chronic elevation of potassium is thought to play a pivotal role in the development of the mild non-anion gap metabolic acidosis that has historically been noted as part of the HH syndrome. The chief mechanism of hydrogen ion excretion and physiologic pH maintenance is renal ammoniagenesis at the proximal convoluted tubule (PCT) of the kidney. Ammonia (NH_3) is generated in the PCT from the amino acid glutamine, produced by the liver. Ammonia is then transferred in the thick ascending loop of Henle into the renal medullary interstitum and subsequently secreted into the CCD. Hydrogen protons generated by the daily acid load of metabolism are also excreted into the CCD by the intercalated cells in a process that is dependent on aldosterone. These protons combine with ammonia to generate ammonium (NH_4^+) which is excreted in the urine (Yaxley and Pirrone, 2016).

Chronic hyperkalemia impairs the generation of ammonia in the PCT though the exact cause is yet to be elucidated (Weiner and Verlander, 2013). Furthermore, elevated serum potassium induces H–K ATPases to exchange potassium ions for hydrogen protons to maintain normokalemia in the plasma. In this regulatory mechanism the body preferentially maintains normal serum potassium levels for a mild excess of hydrogen protons and hence acidemia. Finally, any underlying chronic kidney disease results in decreased ability to excrete generated ammonium and decreased excretion of phosphoric acids (Kraut and Madias, 2016). Thus numerous mechanisms in HH generate the classic findings of hyperkalemia and metabolic acidosis.

Additional Mechanisms in Aldosterone Regulation

Several other minor contributors to the control of aldosterone secretion are thought to be independent of the RAAS and serum potassium. These include baroreceptors in arterial walls of the carotid arteries and aorta, adrenocorticotrophic hormone (ACTH) secretion from the pituitary and innervation by the sympathetic nervous system (SNS). Baroreceptors sense mean arterial pressure and regulate aldosterone to maintain adequate blood volume (Bollag, 2014). The SNS similarly regulates aldosterone release in

response to a whole host of stimuli including emotional states, pain and posture. Prostaglandin E (PGE) is thought to regulate aldosterone by inducing variation of flow in the afferent arteriole and also directly inducing steroidogenesis in the zona glomerulosa (Tanaka and Kako, 1980). Additionally, PGE is also thought to directly stimulate renin release from the JGA (Adam and Wright, 2016). Finally ACTH, which predominantly is involved in cortisol release from the adrenal cortex, also plays a minor role in aldosterone release. ACTH deficiency can result in diminished aldosterone output which, in addition to cortisol deficiency, is thought to contribute to the hemodynamic instability in adrenal crises (Charmandari *et al.*, 2014).

Clinical

Hyperkalemia (serum $K^+ > 5.0$ mEq L^{-1}) is a common metabolic derangement noted in up to 3.3% of all hospitalized patients and is itself an ominous predictor of mortality and morbidity (Khanagavi *et al.*, 2014). When seen in the setting of CKD secondary to DN, it is often due to undiagnosed HH (Villoria *et al.*, 1988). The incidence of HH in diabetes is not certain, likely due to under recognition and subtle presentations however, in one small retrospective study, up to 42% of the patients admitted with diabetic nephropathy and hyperkalemia were noted to have some degree of hypoaldosteronism based on urine and serum potassium values (Haas *et al.*, 2013).

Clinical Presentations

There are two chief situations that strongly suggest HH in the context of diabetic nephropathy or any other chronic disease of the renal interstitum. The first, and likely most common, is asymptomatic hyperkalemia noted in a patient with comorbid diabetes and nephropathy; often the elevated potassium precludes initiation of medications such as ACEis and ARBs that can further worsen hyperkalemia. While most patients have only mild increases in serum potassium, some can present with life-threatening elevations and hemodynamic instability due to more profound mineralocorticoid deficiency (Palacio and Hsiao, 2012). The second common presentation is a dramatic elevation in serum potassium when using a medication that interferes with the RAAS (ACEi, ARB, DRI) or agents that perturb potassium homeostasis (beta-blockers, heparin, NSAIDs, bactrim). These situations often demand cessation of the medication to prevent life-threatening hyperkalemia.

Despite the low aldosterone levels in HH, handling of sodium and volume is retained, with most patients maintaining low-normal serum sodium levels and normal volume status. Indeed, patients can present with actual volume overload if kidney function is significantly compromised. These observations suggest that some degree of aldosterone release is still present in HH to maintain cardiovascular integrity. Other homeostatic mechanisms, including SNS, cortisol and anti-diuretic hormone (ADH) are also involved in preventing profound natriuresis and hemodynamic collapse in HH.

Hyperkalemia in Hyporeninemic Hypoaldosteronism

The clinical effects of hyperkalemia are manifold though, as noted, most often in HH patients with this condition present asymptomatically. The degree of potassium elevation is less a predictor of the severity of clinical response than the rapidity its increase; hence chronic hyperkalemia is much better tolerated than acute owing to numerous homeostatic mechanisms. The chief symptoms that patients report include muscle weakness (including ascending paralysis) and heart palpitations (Palmer and Clegg, 2015).

Skeletal muscle tissue is an enormous reservoir of intracellular potassium which is sensitive to changes in serum potassium. Decreases in the potential across the cell membrane results in muscle weakness (Viera, 2015). The muscle weakness generally resolves after correction of the hyperkalemia. Several classes of cardiac cells are affected by changes in serum potassium as well. As with skeletal muscle, hyperkalemia results in a decreased potential across the cardiac myocyte that generates areas of automaticity, most often in the ventricles and the atria. The electrocardiogram (ECG) findings show premature ventricular and atrial contractions.

The effect of elevated potassium on the conduction system of the heart can be dramatic and life-threatening. While there is no true serum potassium level that corresponds to ECG findings it is generally accepted that levels over 6 mEq L^{-1} cause changes in cardiac conduction. Patients with multiple comorbidities, particularly pre-existing cardiac conduction disease, can have changes at lower serum levels. The first finding on the ECG is peaked T-waves followed by P-wave flattening, PR-interval prolongation, widening of the QRS complex, and sine waves as the potassium progressively increases (Medford-Davis and Rafique, 2014). These changes are harbingers of inadequately perfusing rhythms and can lead to cardiovascular collapse and death. Bradycardia is an often underrecognized symptom of hyperkalemia, particularly among dialysis patients, and can present without any other classic ECG changes (Mohanlal *et al.*, 2013). Hyperkalemia can also exacerbate underlying congestive heart failure and unmask propensities for cardiac tachyarrhythmias including ventricular tachyarrhythmias and atrial fibrillation and flutter. It should be noted that the absolute serum potassium value itself is a poor predictor of clinical outcomes as patients with underlying heart or kidney dysfunction can have adverse outcomes at even mildly elevated potassium levels.

Metabolic Acidosis in Hyporeninemic Hypoaldosteronism

The metabolic acidosis in HH is generally chronic, mild (serum bicarbonate values between 15 and 20 mEq L^{-1}) and is compounded by underlying renal failure and hyperkalemia (Karet, 2009). The prevalence of acidosis in HH is not known however serum bicarbonate values are below 22 mEq L^{-1} in 2.3%–13% of stage III (GFR: 59–30 mL min^{-1}) and 19%–37% of stage IV (GFR: 30–15 mL min^{-1}) of CKD patients, suggesting multiple compounding etiologies for the acidosis. The metabolic acidosis in HH is generally non-anion gap while in CKD without HH there is generally a high-gap acidosis. Additionally, the degree of hyperkalemia is more severe than would be expected for the decrease in GFR (Arai and Chrousos, 2000). Patients are rarely symptomatic from the acidosis alone, however chronically acidosis can have several deleterious long-term health consequences including increased catabolism of muscle protein leading to muscle wasting and a negative nitrogen balance which both contribute to declining renal function (Chen and Abramowitz, 2014). The other significant consequence is metabolic bone disease, a protean entity that includes osteoporosis, osteomalacia and renal osteodystrophy. These factors contribute to increased debility and medical fragility, particularly in the elderly, and are both markers for increased morbidity and mortality (Kraut and Madias, 2016).

Differential Diagnosis

HH can be seen in disorders other than diabetic nephropathy though the exact incidence overall is difficult to determine. Conversely, conditions that affect aldosterone synthesis or prevent the effect of aldosterone without perturbing renin secretion can be indistinguishable clinically from HH. Finally, rare inherited disorders of the function of the aldosterone receptor or of aldosterone synthesis can present with HH-like features however tend to present only in very young and otherwise healthy children.

Disorders of the Renal Interstitium

HH has been described in patients with systemic lupus erythematosus (SLE) suffering from advanced nephritis (Porteous *et al.*, 2011) however this is rare, as most SLE patients present with a distal type I RTA. Patients suffering from human immunodeficiency virus (HIV) can also have hyperkalemia with metabolic acidosis, however the causes can be manifold including adrenalitis from viremia, type I RTA and HH. Generally, the virus has a predilection for the glomerulus and classically causes a "collapsing" focal segmental glomerulosclerosis pattern on pathology. Additionally, multiple HIV antiretroviral medications can induce acidosis and cause tubulointerstitial nephritis predisposing the patient to HH (Wyatt *et al.*, 2008). Trimethoprim, a component of the antibiotic bactrim, has been known to cause a reversible type IV RTA usually in the setting of a preexisting secondary insult to the synthesis of aldosterone such as sickle cell nephropathy (Nath and Hebbel, 2015).

Any condition that affects the JGA or upstream regulators of renin synthesis and excretion can give rise to HH. It has been noted in other cases of intraparenchymal renal injury including chronic tubulointerstitial disease (Quiroga and Garcia de Vinuesa, 2013), Sjogren's disease (Onozaki *et al.*, 2002), amyloidosis (Takemoto *et al.*, 2008), Alport syndrome (Tkacova *et al.*, 1993), venomous snake bites, (Karunarathne *et al.*, 2013), analgesic nephropathy (Perazella, 2005), calcineurin inhibitor nephropathy (Schmoyer *et al.*, 2017), and obstructive nephropathy (Pelleya *et al.*, 1983). (see **Table 1**).

Isolated Deficiencies of Aldosterone

Hypoaldosteronism without hyporeninemia suggests an underlying disorder of the adrenal gland. Primary adrenal insufficiency (PAI) can present with hyperkalemia and metabolic acidosis, however often other clinical and biochemical features are present including diffuse abdominal pain, nausea and vomiting, hyperpigmentation and cardiovascular collapse due to the concomitant lack of glucocorticoids. Furthermore, the causes of PAI are distinct and include autoimmune adrenalitis, inherited disorders, infiltrative diseases, metastatic cancers, granulomatous fungal infections and viremia with HIV and cytomegalovirus (CMV). Insufficiency adrenocorticotrophic hormone production from the pituitary or hypothalamus rarely results in clinical features of aldosterone deficiency due to other mechanisms stimulating aldosterone secretion. Critical illness due to any cause can suppress the hypothalamic–pituitary–adrenal (HPA) axis and cause what is termed "relative" adrenal insufficiency (Charmandari *et al.*, 2014). In these cases renin secretion is usually increased as part of the feedback look to induce aldosterone secretion.

Inherited Disorders of Aldosterone

Perturbation of aldosterone synthesis or resistance to aldosterone action are primarily inherited disorders in the synthesis of aldosterone or resistance to its action. A classic example is congenital hypoaldosteronism, known as the Visser–Cost syndrome, which is due to a mutation in aldosterone synthetase, the final enzyme for aldosterone synthesis in the adrenal gland. Afflicted children generally present at a very young age with salt-wasting, growth retardation and failure to thrive; renin levels are usually elevated (Peter and Sippell, 1996). Pseudohypoaldosteronism includes in its penumbra a heterogenous group of disorders that affect either the mineralocorticoid receptor or sodium channels in the distal tubule and collecting duct. These generally have a

Table 1 Causes of hyporeninemic hypoaldosteronism, hyperreinemic hypoaldosteronism and aldosterone resistance

Hyporeninemic hypoaldosteronism	*Hyperreninemic hypoaldosteronism*	*Aldosterone resistance*
Medications	Adrenal insufficiency	Pseudohypoaldosteronism (PHA) Type I
Cyclooxygenase inhibitors	Infectious adrenalitis	Renal PHA Type I
Heparinoids	*CMV, HIV*	Systemic PHA Type I
Renin antagonists	*Histoplasmosis*	Aldosterone antagonists
Antiretrovirals	*Waterhouse–Friderichsen*	Synthetic progestins
Calcineurin inhibitor	*Tuberculosis*	
Nephropathy		
β-Blockers	Primary adrenal insufficiency	
Paraproteinemia	*Isolated autoimmune adrenalitis*	
Amyloidosis	*Multiple autoimmune endocrinopathies*	
Myeloma	Secondary adrenal insufficiency (ACTH Deficiency)	
Sickle cell anemia	Infiltrative disease	
Analgesic neuropathy	*Sarcoidosis*	
Chronic tubulointerstitial Disease	*Hemochromatosis*	
Lupus nephritis	Medications	
Sjogren's disease	ACEi and ARBs	
Diabetic nephropathy	Trimethoprim	
Chronic urinary tract obstruction	Chronic steroid usage	
HIV nephropathy	Inherited disorders	
Diabetic autonomic neuropathy	Congenital adrenal hyperplasia	
	Congenital hyperreninemic	
Venomous snake bites	Hypoaldosteronism (Visser–Cost syndrome)	

more benign course and present at adolescence or later with unexplained hypertension, hyperkalemia and metabolic acidosis (Scheinman, 2009). Generally, in these inherited disorders renin levels are elevated as part of the feedback loop and as a group these are termed conditions of hyperreninemic hypoaldosteronism.

Iatrogenic Causes of Hypoaldosteronism

Medications that affect the RAAS can produce the signs and symptoms of HH. Most notable among these are the ACEi and ARBs, aldosterone and renin antagonists that directly interfere with some intermediate portion of the RAAS. Other notable medications include beta-blockers which disturb the SNS regulation of renin (Seifarth *et al.*, 2002), non-steroidal anti-inflammatory drugs (NSAIDs) which decrease renal prostaglandin via cyclooxygenase inhibition (Perazella, 2005) and heparin, which suppresses endogenous aldosterone production directly (Bengalorkar *et al.*, 2011). In clinical practice hyperkalemia with metabolic acidosis can develop when these medications are used, however, they can obfuscate the diagnosis of HH and, when used in individuals with an underlying propensity to HH, can cause the metabolic disturbances noted. Thus, HH has a great many imitators, both clinically and biochemically, and care should be taken when diagnosing the disorder as treatments are quite different for each of the disorders.

Diagnosis

As the name suggests hyporeninemic hypoaldosteronism is a disorder of insufficient renin and aldosterone release. The most salient biochemical features, hyperkalemia with or without a mild non-anion gap metabolic acidosis in the setting of mild renal insufficiency, is a common clinical scenario. HH should be considered when the serum potassium values are higher than expected for the decrease in GFR particularly in a patient with diabetic nephropathy.

Urine Studies

Urinalysis including pH and specific gravity, urine electrolyte values, microscopic examination and urine culture should be obtained. Underling tubulointerstitial disease can present with casts and active urine sediment suggests a glomerular lesion. Urine culture should be obtained to rule out an organism which would confound the results of urine indices because of its metabolic byproducts.

The urine pH is useful in differentiating HH from distal type I RTA as in the latter urine pH will be alkalotic (defined as pH $>$ 5.3) regardless of the degree of acidosis whereas in HH the urine pH can be variable but most often is normal (pH $<$ 5.3) (Reddy, 2011). An alkali load with sodium bicarbonate will increase the urine pH in HH transiently to $>$5.3 but not in type I RTA.

Caution should be taken in utilizing urine pH solely as the basis for diagnosis of RTA as volume depletion and urease-splitting organisms in the urine can dramatically alter this value (Yaxley and Pirrone, 2016).

Serum Aldosterone and Renin Values

Values of aldosterone concentration and plasma renin activity (PRA) should be measured to determine the underlying function of the adrenal glands and the JGA respectively. PRA is generally measured rather than renin concentration, though recent advances have suggested that the actual renin concentration is a more accurate measurement of whole body renin (Lonati *et al.*, 2014). Both values should be obtained from a midmorning, volume replete and upright patient as secretion of aldosterone appears to follow a circadian pattern and recumbent positioning can alter the renal perfusion and cause specious values.

Provocative Testing

In HH the ratio of the aldosterone concentration to the PRA is generally preserved but the values of both renin and aldosterone are low, though they can be normal (Villoria *et al.*, 1988). In contrast, in hypoaldosteronism without hyporeninemia, the JGA apparatus and feedback loop are preserved and the renin level is elevated while the aldosterone value will be low. (see **Table 2**) If clinical suspicion is high and laboratory values are non-diagnostic then stimulatory testing should be performed. A loop diuretic, most often furosemide, is administered to determine response to falling tubular sodium levels. Loop diuretics promote natriuresis, that is they increase tubular sodium values, and also block the sodium sensing receptors on the macula densa, effectively inducing activation of the RAAS. Aldosterone levels will not increase appropriately if HH is present (Reddy, 2011).

ACTH stimulation testing can also be used to determine whether hypoaldosteronism is present as the trophic hormone induces acute adrenal release of both cortisol and aldosterone. A blunted response to ACTH is indicative of aldosterone insufficiency (Dluhy, 1974). This latter test cannot distinguish between a primary adrenal defect in aldosterone (such as PAI) and low aldosterone levels due to hyporeninemia. Examination of the entire HPA axis should be considered if there is any suspicion of primary or secondary adrenal cortisol insufficiency.

Treatment

Treatment for HH is contingent on the long term deleterious consequences of chronic hyperkalemia and metabolic acidosis as the mineralocorticoid deficiency in HH rarely causes salt-wasting or cardiovascular collapse. Furthermore, many medications indicated for patients with diabetes, hypertension and chronic kidney disease, conditions commonly associated with HH, directly affect the RAAS and can worsen underlying hyperkalemia. This situation mandates either careful dose titration or discontinuation of these medications which is a dilemma as they have significant morbidity and mortality benefit in this population (Palmer, 2004).

Acute Treatment

In those few patients who do develop signs and symptoms of severe mineralocorticoid deficiency such as syncope, orthostatic hypotension or severe hyperkalemia, acute treatment is necessary. The most pressing issue is the patient's cardiovascular status and the elevated potassium and an isotonic crystalloid fluid, ideally normal saline, should be administered in boluses repeatedly until blood pressure is restored. Isotonic fluids that contain potassium, such as lactated Ringer's solution and colloids should not be used. Empiric so called “stress dose steroids” should be administered; generally, hydrocortisone is used as it has both mineralocorticoid and glucocorticoid activity. An ECG should be performed to evaluate for changes in the electrical architecture of the heart and empiric calcium gluconate or calcium chloride should be administered intravenously (IV) if ECG changes are present. The cardiac rate and rhythm should be continuously monitored during treatment.

The two methods of lowering the serum potassium are promoting excretion from the body and inducing transcellular shift into the cell; the latter method is employed first as it is rapid. Insulin and glucose and a nebulized beta-agonist, such as albuterol, are

Table 2 Expected changes in plasma renin activity, aldosterone concentration, presence of metabolic acidosis, serum potassium values and response to stimulatory testing in each category of aldosterone derangement

	Plasma renin activity (PRA)	*Aldosterone concentration*	*Metabolic acidosis*	*Serum potassium*	*Response to ACTH stimulation*	*Response to furosemide load*
Hyporeninemic hypoaldosteronism	↓ or –	↓ or –	≈	Mildly ↑	– PAC – PRA	– PAC – PRA
Hyperreninemic hypoaldosteronism	↑	↓	~	Mildly ↑ or –	– PAC ↑ PRA	– PAC ↑ PRA
Aldosterone resistance	↑	↑	~	Mildly ↑ or –	↑ PAC ↑ PRA	↑ PAC ↑ PRA

↑, elevated; ↓, lowered; –, normal; ~, variable; ≈, variable (present in approximately 50%).

given to stimulate uptake of potassium into cells. Potassium excretion is promoted by use of oral cation exchange resins, such as polystyrene sulfonate, via the stool. Kaliuresis is induced with a loop diuretic. In cases where potassium is severely elevated and the above methods cannot be employed due to comorbid conditions, acute dialysis is employed. Intravenous bicarbonate therapy has fallen out of favor as a method to shift potassium into cells because of concerns over its efficacy however in cases of metabolic acidosis associated with hyperkalemia, it is still a consideration (Viera, 2015).

If a patient who is symptomatic from HH but does not have life-threatening metabolic disturbances, as with postural syncope or with hyperkalemia, mineralocorticoid replacement such as fludrocortisone can be used. Indeed, patients have been described with asymptomatic severe hyperkalemia or orthostasis who respond well to this treatment (Lee *et al.*, 2009; Polsky *et al.*, 1993; Pelleya *et al.*, 1983). Caution should be used as most patients with HH have some degree of renal impairment and use of a mineralocorticoid agent could exacerbate sodium retention, worsening hypertension and volume overload.

RAAS Medications in HH

While the hyperkalemia in HH is generally mild use of a medication that affects the RAAS can cause rapid and life-threatening increases in serum potassium values. Furthermore, up to 10% of patients must discontinue an ACEi or ARB because of subsequent hyperkalemia (Palmer, 2004). Withholding these medications or discontinuing them brings up a dilemma for clinicians as these medications have a proven mortality benefit in CKD, with or out without diabetes. Furthermore, patients with comorbid coronary artery disease and congestive heart failure, common attendants to both CKD and diabetes, also benefit enormously from ACEi and ARBs (Molnar *et al.*, 2014). These medications improve the degree of proteinuria, decrease GFR preventing hyperfiltration injury and help prevent adverse cardiac remodeling after myocardial ischemia (Mcmurray *et al.*, 2003; Molnar *et al.*, 2014). Addition of an aldosterone antagonist to this regimen further provides a mortality benefit, particularly in heart failure after myocardial infarction (Hostetter, 2003).

When evaluating a patient with HH at risk for hyperkalemia who would benefit from addition of these medications it is useful to eliminate dietary sources of potassium including any herbal supplements. Elimination of other drugs that could affect renin secretion or induce hyperkalemia should be undertaken. NSAIDs are a frequent, often overlooked, cause of hyperkalemia (Zimran *et al.*, 1985). Consideration should be given to adding a loop diuretic which has potent kaliuretic properties and would be a counterweight to the hyperkalemia associated with ACEi, ARBs and aldosterone antagonists.

In HH RAAS inhibitors should be initiated at very low doses and only up titrated gradually to allow maximal therapeutic doses to be reached (Palmer, 2004). Frequent monitoring of all electrolytes and renal function during dose adjustments has been associated with decreased frequency of hyperkalemia (Eschmann *et al.*, 2013). The use of cation resins such as polystyrene sulfonate should be discouraged as they promote osmotic diarrhea and can cause intestinal injury and ischemia (Mcgowan *et al.*, 2009).

Treatment of Metabolic Acidosis

If the metabolic acidosis in HH is of concern then addition of sodium bicarbonate to treat both the acidosis and help lower serum potassium levels can be successful. No official values cutoff values are established for when to start treatment of acidosis in HH or for goal serum bicarbonate levels to attain. The guidelines established for CKD (Kraut and Madias, 2016) recommend initiating treatment at a serum bicarbonate level $< 23\ \mathrm{mg\,dL^{-1}}$. Care should be taken as sodium bicarbonate can provide a significant sodium load to the patient and, in the setting of underlying CKD, can provoke or worsen hypervolemia.

Bartter and Gitelman Syndromes

Lorenzo A Calò and Verdiana Ravarotto, University of Padua, Padua, Italy

Nomenclature

AT1R Angiotensin II type 1 receptor
BP Blood pressure
MLC Myosin light chain
MYPT-1 Myosin phosphatase target protein-1
p63RhoGEF p63 Rho guanine nucleotide exchange factor
PLCβ1 Phospholipase C β1
RGS-2 Regulator of G protein signaling-2

Introduction

In 1962 Frederic C. Bartter and then in 1966 Hillel J. Gitelman described two instances of salt-losing tubulopathy characterized by hypokalemia, metabolic alkalosis, and activation of the renin–angiotensin–aldosterone system (RAAS) notwithstanding normotension or hypotension (Bartter et al., 1962; Gitelman *et al.*, 1966). Further clinical investigations allowed the detection of some subtypes of these familial congenital diseases with different manifestations and severity (Simon *et al.*, 1996a, 1997; Gamba, 2005).

Bartter syndrome (BS) and Gitelman syndrome (GS) have specific symptoms onset timing: however, classic BS reveals in childhood or early adolescence can also have a neonatal form, while GS has a less severe clinical presentation and appears in adolescence or adulthood.

BS typical clinical features are muscle weakness, anorexia, polydipsia, polyuria, failure to thrive, and growth retardation. Hallmarks of this syndrome are salt-wasting, high plasma level of prostaglandins, and hyperprostaglandinuria. The electrolyte abnormalities of BS are similar to those induced by treatment with furosemide or other drugs that inhibit the Na–K–2Cl cotransporter of the thick ascending limb (TAL) of Henle's loop. GS, on the other hand, is shown through salt-craving, muscle weakness, fatigue, and cramps with electrolyte imbalance associated with the side effects of thiazide diuretics treatment acting on the distal convoluted tubule (DCT) (Naesens *et al.*, 2004; Favero *et al.*, 2011) (see **Fig. 1**).

Both syndromes are cataloged in the registry of inherited rare Mendelian diseases (Online Mendelian Inherited In Man®), with respective codes identifying the subtypes. The exact prevalence of these disorders is unknown, although for BS it is estimated to be 1 patient affected in 1 million people worldwide, and for GS 1 subject affected in 40,000, making it one of the most frequently inherited renal tubular disorders (Blanchard *et al.*, 2017).

BS and GS have, as common etiology, mutations in genes that encode for cotransporters or channels involved in the trafficking of electrolyte in the nephrons. The effects of these mutations are nonfunctional proteins, with ensuing salt-wasting and activation of counterbalancing systems as the RAAS.

Notwithstanding elevated plasma levels of renin, aldosterone, and angiotensin II, BS and GS subjects present with normotension or hypotension. This has prompted a great deal of interest in the research of the molecular mechanisms involved in blood pressure (BP) regulation (Calò *et al.*, 2014a).

Molecular Basis

Bartter Syndrome

It was found that electrolyte abnormalities of BS are similar to those induced by the treatment with furosemide or other drugs that inhibit the Na–K–2Cl cotransporter (NKCC2) of the TAL, and this prompted investigations on the gene SLC12A1 that encodes for the NKCC2 (Simon *et al.*, 1996a). Indeed, in affected patients, as a consequence of the mutations there is a loss of cotransporter function, which induces Na^+ and K^+ wasting in the TAL. NKCC2 mutation classifies BS type I (OMIM® #601678). In particular, the consequences of nonfunctional NKCC2 involve systemic alterations from fetal gestation onwards, with severe salt-wasting hypokalemic metabolic alkalosis, hypercalciuria, and hyperprostaglandinuria. Prostaglandin E2 excess is associated with fever, severe dehydration, hypocalcemia, hyponatremia, and subsequent development of nephrocalcinosis and osteopenia in infants.

Other mutations were found in genes involved in the regulation of NKCC2 activity. In particular, alterations in the KCNJ1 (Kir1.1) encoding for the apical ATP-sensitive K channel (renal outer medullary potassium channel, ROMK) identify BS type II (OMIM® #241200). The ROMK is an ATP-sensitive channel which recycles K^+ from the cell back into the lumen; as a consequence, the falling luminal K^+ shuts down NKCC2 activity and results in salt-wasting (Simon *et al.*, 1996b). A nonfunctional ROMK gives a pseudohypoaldosteronism type I phenotype-like for the transient hyperkalemia in the antenatal form. Mutations affecting the KCNJ1 gene cause the production of erroneous proteins which compromise

 doi:10.1016/B978-0-12-801238-3.65335-7

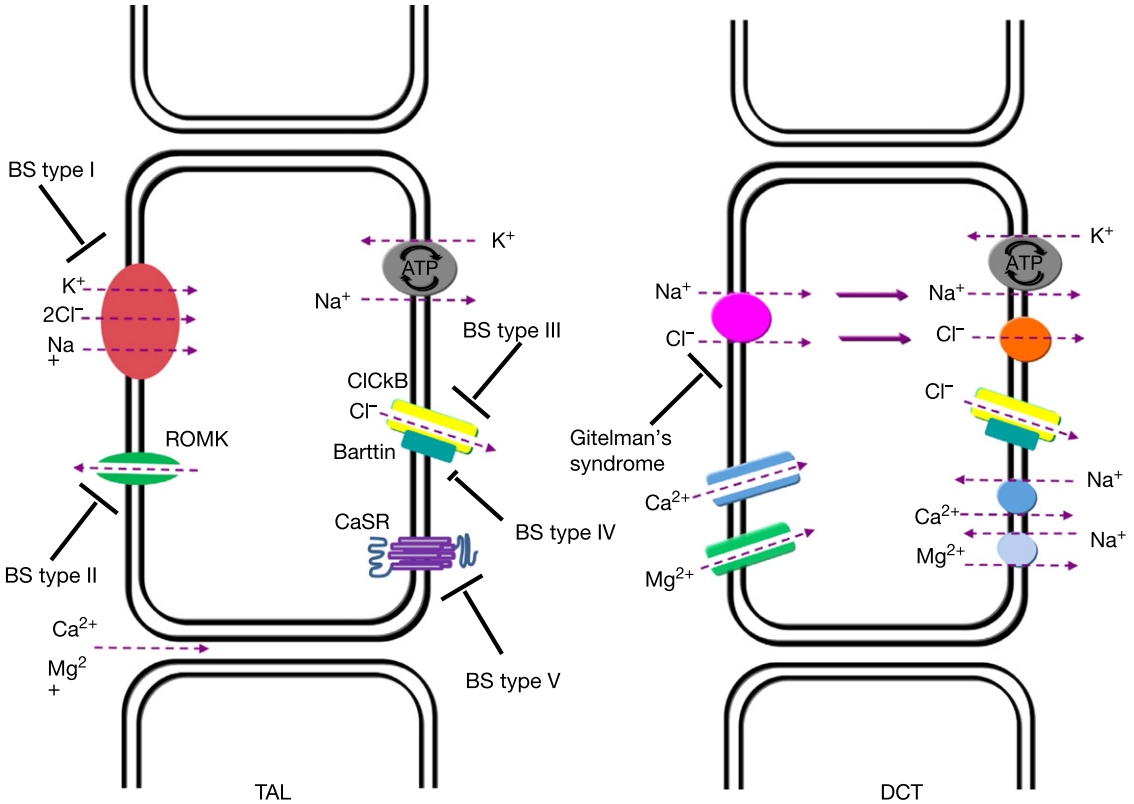

Fig. 1 Sites of genetic defects of BS type I–V and GS. *TAL*: Thick ascending limb of Henle's loop; *DCT*: distal convoluted tubule.

endoplasmic reticulum (ER) folding and are targeted to the ER-associated degradation (Finer *et al.*, 2003; O'Donnell *et al.*, 2017).

Alterations of the chloride channel CLCNKb (which mediates Cl^- reabsorption) might induce intracellular chloride accumulation, thus inhibiting NKCC2 activity. As a clinical outcome, mutations in CLCNKb in affected patients result in salt-wasting and hypovolemia, identifying BS type III (OMIM® #607364) (Simon *et al.*, 1997). CLCNKb requires an essential β-subunit barttin encoded by the BSND gene to function properly. Some mutations affecting the barttin interacting motifs led to significantly impaired protein, as well as causing mutations in the dimerization sites and in the selectivity filter, resulting in a severe phenotype of the disease. Other mutations in the alpha-helices display a milder form which can go undetected until adulthood. (Cheng *et al.*, 2017).

The protein barttin (BSND) is required for the location not only of the basolateral membrane CLCNKb but also for the isoform CLCNKa. As in BS type III, the consequence of mutations in this protein is an accumulation of chloride, which affects NCCK2 activity once more with salt-wasting (Naesens *et al.*, 2004). The characteristic BS type IVa (OMIM® #602522) phenotype appears in an antenatal form causing polyhydramnios, premature birth, and all other BS typical features, as well as sensorineural deafness in infants. In addition to mutations affecting the barttin protein, BS type IVb (OMIM® #613090) is characterized by digenic mutations (CLCKa and CLCKb) that inactivate all the 4 alleles of the 2 genes. In the inner ear, the highly expressed CLCKa contributes to maintaining the high K^+ ion concentration in the endolymph, which is necessary for normal hearing. As a result, an ion imbalance induces nerve deafness and a defect in the sensory-neural transduction of sounds (Miyamura *et al.*, 2003).

The functional characterization of barttin mutations established different mechanisms for impaired function, including: decreased number of coupled CLCNKb/barttin; decreased insertion of CLCNKb/barttin in the basolateral membrane and in the apical membrane; and impaired anion currents and CLCNKb being prevented from activating. An overview on the functional effects of the different mutations demonstrates that the deleterious effects on barttin impact the diversity of phenotypes (Janssen *et al.*, 2009). Indeed, notwithstanding the early manifestations of the disease, with premature birth and severe salt and water loss in the perinatal period, few cases have been reported of late diagnosis of BS type IV. This is probably due to a less severe phenotype with hidden or mild symptoms which led to the condition being unrecognized (Heilberg *et al.*, 2015).

Another phenotype described, BS type V (OMIM® #300971), is due to mutations in the Ca^{2+}-sensing receptor (CaSR). In the parathyroid, CaSR controls the response of the gland to the extracellular Ca^{2+} levels and thus hormone release; in the kidney, in the basolateral membrane of the TAL, it acts as an inhibitor for the reabsorption of Ca^{2+}. CaSR is a pleiotropic receptor regulating

several intracellular signaling pathways, including calcium mobilization and intracellular calcium oscillation. The structure of this receptor comprises an N-terminal domain and a long (~600 aa) extracellular domain, seven transmembrane domains, and a C-terminal intracellular domain. The long extracellular portion is fundamental not only for the binding of the receptor with its agonists, but also for its activation via dimerization. The binding of Ca^{2+} to the extracellular loops promotes a conformational change, which reflects on the transmembrane portions with ensuing modification of the intracellular C-terminus. The latter triggers different downstream pathways including activation of th phospholipase C pathway, extracellular signal-regulated kinases 1/2 (ERK1/2), and Rho kinase pathway, cyclic adenosine monophosphate (cAMP), essentially via regulation of four G proteins ($G_{q/11}$, $G_{i/o}$, G_s, and $G_{12/13}$) (Zhang *et al.*, 2016). Mutations in specific portions of the protein induce either loss or gain of function of the receptor. Experimental studies in rats showed that the activation of CaSR by high concentrations of extracellular calcium ions inhibits the activity of ROMK, which is fundamental to preserve positive luminal potential in TAL driving paracellular reabsorption of calcium and magnesium. Its inhibition by calcium via CaSR is expected to increase urinary excretion of these cations; therefore, gain-of-function mutations induce hypocalcemia that could develop into BS type V and autosomal dominant hypocalcemia (Brown and MacLeod, 2001; Pearce *et al.*, 1996).

Gitelman Syndrome

GS (OMIM® #263800) is the hypocalciuric variant of BS. Indeed, GS is characterized by the co-existence of not only hypokalemia, hypomagnesaemia, and activation of RAAS, but specifically hypocalciuria. Marked symptoms are muscle weakness, cramps, joint pain, polydipsia, polyuria, hypotension, salt craving, dizziness, and a prolongation of QT interval on electrocardiogram (which represents the depolarization and repolarization of the ventricles and causes arrhythmia) (Bettinelli *et al.*, 2002; Scognamiglio *et al.*, 2008). Calcium pyrophosphate (CPP) crystal deposition or chondrocalcinosis associated with arthropathy can also be observed (Favero *et al.*, 2011). In GS the electrolyte imbalance is associated with the side effects of thiazide diuretics. The target of this type of diuretics is the sodium-chloride cotransporter (NCC) present in the DCT. The cloning and characterization of the gene encoding this cotransporter, the SLC12A3 gene, in GS indicated that several mutations affect the NCC causing loss of function of the cotransporter with renal sodium wasting and triggering adaptive mechanisms in the kidney, including aldosterone-driven increased excretion of K+ in exchange for Na^+.

NCC is a member of the big class of solute carrier proteins (SLC) family, comprising 12 of the electroneutral cation-chloride cotransporters, and it is encoded by the gene SLC12A3 (Hediger *et al.*, 2004). SLC12A3 shares a highly conserved amino acid sequence with other members of the family, which features 12 transmembrane portions harboring a central hydrophobic domain and 2 cytosolic terminal ends (NH_2 and COOH) (Wang *et al.*, 2015). The central region seems to be highly specific for ion translocation and for thiazide binding, particularly the 7th and 8th domains, which entail the external loops fundamental for glycosylation sites (Wang *et al.*, 2015; Moreno *et al.*, 2006). Approximately 400 mutations are described that affect the cotransporter and cause GS. Most of them (~250) are missense mutations (see the human gene mutation database at www.hgmd.cf.ac.uk) and are spread along the whole protein. >50 mutations have been reported only in Asian populations (Wang *et al.*, 2015). The Na^+ transport in the early portion of the DCT is electroneutral considering the cotransport of Na^+ and Cl^- through NCC, while in the late portion of DCT, the epithelial sodium channel (ENaC) gives rise to a negative charge in the tubular lumen for its electrogenic transport of Na^+. As a counterpart, to restore a neutral charge in the lumen, potassium secretion is enhanced through ROMK channels or intercalated cells (Loffing and Kaissling, 2003). NCC loss-of-function mutations lead to Na^+ dissipation, which in turn stimulates a gradient for water to exit, whereas ENaC over-activates to restore the Na^+ intake. Finally, to replace the ionic imbalance in the tubular lumen, ROMK drives K^+ out, leading to hypokalemia.

Clinical Characteristics and Diagnosis

BS presents early in childhood with severe failure to thrive and mental or growth retardation. The antenatal form is severe and characterized by mother polyhydramnios, leading to premature delivery. Occasionally, recurrent episodes of severe dehydration and electrolyte imbalance can lead to a fatal outcome. These manifestations may be misleading in premature babies, thus hiding the renal dysfunction and making it difficult to identify the syndrome.

Polyuria and nicturia are a result of the tubule defect and the inefficiency to reabsorb sodium with increased urine volume. If not recognized, this can lead to dehydration with ensuing vomiting, fever, and failure to thrive. The loss of high volume of fluids should lead to low BP, nevertheless, BS patients usually have normal to low BP values. Indeed, there is a compensatory activation of the RAAS, which maintains the vascular resistance and the fluid balance. Typically, biochemical levels of aldosterone and angiotensin II are high; indeed, pseudohypoaldosteronism type I (PHA1) could be misconceived in BS type 2, especially for hyponatremia, transient hyperkalemia, and muscle weakness, but the high plasma renin should be a discriminating factor for its low level in PHA1 conversely to BS and GS.

Hypokalemia resulting from both ROMK mutations and as a compensatory effect of Na and Cl reabsorption drives the metabolic alkalosis. K^+ depletion itself increases bicarbonate reabsorption in the proximal tubule and stimulates ammonia production, which in turn increases urinary acid excretion.

K^+ is also important for the muscle function and contraction for its potential regulation of the cell, along with Mg. When Mg is attached to ATP, actin is released from myosin and therefore the muscle relaxes. In the absence of Mg, the binding of Ca to ATP extends the contraction, causing cramps and tetany.

Nephrocalcinosis is also a clinical feature of the syndrome, and presents with calcification in the renal parenchyma, especially in the tubular epithelium, due to high calcium excreted in the urine.

Calcium imbalance is present in GS as arthropathy associated with CPP crystal deposition or chondrocalcinosis (CC). In addition, GS shares with BS muscle weakness, cramps, limited sport endurance, paresthesia, abdominal pain, and in young patients growth retardation, pubertal delay, and short stature. In adults are reported dizziness, vertigo, polyuria, nocturia, joint pain, and palpitations with long QT interval. Nevertheless, GS is mostly asymptomatic in youth and is less severe when detected in early adulthood. Biochemical criteria for a suspected diagnosis of GS include: documented chronic hypokalemia (<3.5 mmoL/L) concomitant with inappropriate renal potassium wasting (spot urine, potassium creatinine ratio >2.0 mmol/mmol (>18 mmol/g)), in the absence of potassium-lowering drugs; metabolic alkalosis; hypomagnesemia (<0.7 mmoL/L (<1.70 mg/dL); inappropriate renal magnesium wasting (fractional excretion of magnesium >4%); hypocalciuria (spot urine, calcium-creatinine ratio <0.2 mmol/mmol (<0.07 mg/mg) in adults, with normal ranges of calcium-creatinine ratio being different in children with high renin (activity or plasma levels); fractional excretion of chloride >0.5%; normal or low BP; and normal renal ultrasound with an absence of nephrocalcinosis or renal abnormalities. If plasma electrolyte levels are normal or close to normal in a patient taking either or both of potassium or magnesium supplements, these supplements should be stopped for at least 48 h in order to attempt to unmask the abnormalities. Plasma and urine samples should be obtained concomitantly (Blanchard *et al.*, 2017).

A mixed BS-GS phenotype has also been reported, in which BS type III, caused by a mutation in the CLCNKB gene, has clinical and biochemical features common to GS as the co-existence of hypomagnesemia and hypocalciuria. This probably reflects the wide distribution of CLCNKb in the DCT and a possibly involvement of NCC for the physiologic electrolyte balance (Jeck *et al.*, 2000).

Both BS (type 1–4) and GS are autosomal recessive diseases, except for BS type V, which is autosomal dominant. The genetic test should therefore be performed to obtain specific diagnosis and to screen healthy carriers. Indeed, from heterozygous asymptomatic carriers, the risk of producing offspring with the full-blown disease is 25%. The condition to display BS or GS is to have both alleles affected by a mutation or affected by two different mutations.

Treatment

The current therapy for both syndromes is the correction and improvement of electrolyte abnormalities, which is effective in ameliorating the quality of life for patients. Different opinions exist with regard to the dietary salt intake. On the one hand it may enhance the K waste, thus inducing severe hypokalemia; on the other hand, since BS and GS are sodium wasting diseases, this suggests that it would be obvious to consume more NaCl.

In the antenatal form of BS, nonsteroidal antiinflammatory drugs can be used to counteract the excess of prostaglandin E.

In the presence of hypomagnesemia, magnesium supplementation should be considered first, because magnesium repletion will facilitate potassium repletion and reduce the risk of tetany and other complications.

In cases of persistent, symptomatic hypokalemia when supplements are not sufficient despite adherence or when side effects are unacceptable or both, the use of potassium-sparing diuretics, renin angiotensin system blockers, or nonsteroidal antiinflammatory drugs (such as indomethacin), or a combination of these have been proposed. The potassium-sparing diuretics amiloride, spironolactone, potassium canrenoate, and eplerenone can be useful, both to increase serum potassium levels in patients resistant to supplements and to treat magnesium depletion that is worsened by elevated aldosterone levels. The use of renin angiotensin system inhibitors (angiotensin-converting-enzyme inhibitors and angiotensin receptor blockers) has been reported occasionally in the treatment of GS. These drugs also aggravate renal sodium wasting and increase the risk of symptomatic hypovolemia; they should be stopped in cases of acute, salt-losing complications, such as vomiting or diarrhea. Prostaglandin synthase inhibitors such as indomethacin are rarely used in GS, because urinary prostaglandin E2 levels in GS are usually normal. (Blanchard *et al.*, 2017).

Vascular Tone Control: The Angiotensin II Signaling

Peculiar characteristics in the pathophysiology of BS and GS may provide useful insights to understand the mechanisms involved in the control and regulation of vascular tone and BP in humans.

Mostly through the hormone Ang II pathway, RAAS signaling drives increased peripheral resistance and hypertension in healthy individuals (Ravarotto *et al.*, 2015).

Extensive studies from our laboratory provided compelling evidences that in BS and GS Ang II signaling is blunted despite higher level of the hormone and a normal Ang II receptor number and affinity (Calò et al., 2014a). This suggests an interruption of Ang II signaling at postreceptor level or very close to the central switch controlling Ang II signals. The activation of mechanisms involved in the reduction of the BP, despite stimulation of the RAAS, makes BS and GS a "mirror image" of hypertension and a human model of an endogenous antagonism of Ang II signaling via its receptor AT1R.

Understanding the mechanisms involved upon Ang II receptors' stimulation could help to identify novel potential targets of therapy in diseases such as hypertension in which treatments consist in the direct inhibition of Ang II synthesis or activity. Indeed, current treatment of hypertension entails ACE inhibitors, Ang II AT1R blockers, and direct renin inhibitors. Of note, these treatments have the potential to go far beyond BP reduction: evidence from the most important trials on these drugs (EUTOPIA, VIOS, MORE, OLIVUS) demonstrated a reduction of markers of inflammation and improvement of cardiovascular risks, alongside the slowed progression of kidney diseases. This evidence correlates with a complex Ang II activity, which has a clearly pleiotropic nature confirmed by the presence of numerous enzymes, peptides, and receptors involved in its downstream pathways (Nguyen Dinh Cat and Touyz, 2011; Crowley and Coffman, 2012).

Short-Term Ang II Signaling

The multi-effects function of Ang II is exerted through its short- and long-term signaling. The specific intracellular pathways of the short-term signaling are mediated by monomeric and heterotrimeric G proteins and phospholipase Cβ (PLCβ), leading to the release of intracellular messengers inositol trisphosphate (IP3) and Ca^{2+}, the generation of superoxide (O_2^-), and the activation of protein kinase C (PKC) with ensuing vascular smooth muscle contraction (Ravarotto *et al.*, 2015). Noteworthy is a counter-balancing process that is represented by the nitric oxide (NO) system, which has vasodilatory and antiproliferative activity. NO is released by endothelial NO synthase (eNOS) and is negatively regulated by PKC; therefore, the net effect of Ang II on vascular function and structure is the result of the balance of signaling molecules, oxidative stress, and gasomessengers as nitric oxide (Clementi, 1998; Dzau, 2001). Ang II promotes short-term effects by acting directly on its receptors on the cells' membranes (Touyz and Schiffrin, 2000). The binding of Ang II with its heterotrimeric G-protein coupled receptors promotes the increase of free intracellular Ca^{2+} concentration and the activation of the RhoA/Rho kinase pathway with subsequent vasoconstriction. The Ang II–AT1R complex couples with PLCβ via heterotrimeric Gq and Gi proteins and promotes activation of PKC and phosphorylation of the regulatory chain of myosin II. The Ang II–AT1R complex couples first to PLCβ1 via heterotrimeric Gαq/11$\beta\gamma$ and Gαq/12$\beta\gamma$, then to PLCγ via tyrosine kinase. The α subunit of Gi protein transduces the Ang II signal to blunt adenylyl cyclase activity with ensuing decreased formation of the vasodilatory cAMP. In addition, the activation of the monomeric G-protein RhoA and its effector Rho kinase modulates the phosphorylation state of the regulatory chain of myosin II, mainly through inhibition of the myosin phosphatase target protein-1 (MYPT-1). By this mechanism, Ang II induces smooth muscle contraction and increased peripheral resistance.

To elucidate further, this paradoxical picture present in BS and GS of elevated RAAS and low BP is fundamental to investigating the single proteins involved in this signaling. In fact, BS and GS have decreased gene and protein expression of the α subunit of Gq protein and blunted downstream intracellular events that promote Ca^{2+} release and PKC activation (Calò et al., 2001, 2002, 2014a). In addition, in these patients the evaluation of the NO system via the endothelial nitric oxide synthase mRNA levels, urinary excretion of NO metabolites, and NO mediated vasodilation showed a significant increase of eNOS expression (Calò, 2006; Calò *et al.*, 1999), an increased urinary excretion of NO metabolites, which positively correlated with urinary excretion of cyclic guanosine monophosphate (cGMP), the NO second messenger (Calò, 2006; Calò *et al.*, 1995, 1996), and an increased NO mediated vasodilation compared with hypertensive patients (Calò et al., 2008a). In addition to these characteristics, which also underlie an antioxidant potential in these patients, the augmented expression of heme oxygenase 1 (HO-1) (Calò *et al.*, 1998, 2003), establishes an antioxidant and antiinflammatory potential.

The activity of G protein-coupled receptors (GPCR) is regulated by a tool of proteins that control the integration of information and subsequent downstream signaling. Regulators of G protein signaling (RGS) proteins are deputed to this purpose (Heximer and Blumer, 2007). RGS proteins can regulate many different effector proteins acting as GTPase-activating proteins for Gα subunits and also competitively inhibit Gα binding to PLC (Zhong and Neubig, 2001). Both NO and its second messenger, cGMP, increase the RGS-2 guanosine triphosphatase activity of Gq protein, which leads to dephosphorylation of myosin light chain and induces vascular smooth muscle cell relaxation. Collectively, these findings suggest that RGS-2 is central for the vasorelaxing activity of NO (Tang *et al.*, 2003). The relevance of RGS proteins in hypertension has been demonstrated in RGS-2 knockout mice, which showed persistent vasoconstriction and hypertension (Tang *et al.*, 2003). The characteristic normotension or hypotension of BS and GS, upon Ang II stimulation, suggests that abnormalities in the GPCR complex and in its regulator RGS-2 might be involved (Mehta and Griendling, 2007). Patients with BS and GS have, in fact, an increased gene and protein expression of RGS-2 (Calò *et al.*, 2004), which is the opposite of the decrease seen in hypertensive patients (Semplicini *et al.*, 2006; Calò *et al.*, 2004). The increased RGS-2 expression in BS and GS patients may explain their downregulation of Gq protein signaling (Calò et al., 2001, 2002) and the reduced peripheral resistance, vascular hyporeactivity and normotension or hypotension that are typical of these syndromes. Silencing RGS-2 in Bartter's and Gitelman's patients' fibroblasts, in fact, produces effects (Calò *et al.*, 2008b) that coincide with the results in knockout mice and humans (Tang *et al.*, 2003; Semplicini *et al.*, 2006; Heximer *et al.*, 2003).

The Rho A activation induced after Ang II binding with AT1R is mediated by some guanine nucleotide exchange factors (GEF) as p63RhoGEF and p115RhoGEF essentially via binding of the a subunit of Gq protein to activate RhoA and its effector Rho kinase. This leads to vascular contraction, cell proliferation, and cardiovascular remodeling. The impaired Ang II-dependent contraction and proliferation of rat aortic smooth muscle cells after p63RhoGEF depletion and the

blunted endothelin-1-induced portal vein contractile force upon p63RhoGEF silencing support the view that abnormalities of these RhoGEFs contribute to increased activation of RhoA/Rho kinase pathway in hypertension. In BS and GS patients, RhoA/Rho kinase pathway downregulation is accompanied by reduced mRNA and protein expression not only of Ang-II-induced p115RhoGEF, but also of p63RhoGEF. Moreover, these patients have decreased phosphorylation of MYPT-1, a marker of Rho kinase activity (Loirand *et al.*, 2006), which conversely is increased in hypertensive patients (Calò *et al.*, 2014b).

Long-Term Ang II Signaling

Long-term Ang II signaling changes the cell oxidative states inducing cardiovascular and renal remodeling in hypertension, atherosclerosis, and heart and kidney failure (Mehta and Griendling, 2007; Touyz, 2003; Griendling and FitzGerald, 2003).

Oxidative stress is due to an imbalance between oxidant and antioxidant agents and the loss of redox homeostasis due to increased pro-oxidant and pro-thrombotic activities causes harmful effects, in terms of free radicals and nitroxidative stress. NAD(P)H oxidases, Xantine oxidases, P-450 monoxygenases, lipoxygenases, and cycloxygenases are all sources of reactive oxygen species. All these enzymes produce a superoxide anion (O_2^-), which is an intermediate product of oxygen reduction. It reacts rapidly with other groups of molecules to induce high reactive compounds as hydroxyl radical (OH^-) and peroxynitrite ($OONO^-$). The main oxidative stress inducer is NAD(P)H oxidase (Nox), which catalyzes the production of superoxide from oxygen and NAD(P)H (Griendling *et al.*, 2000). Noxs are characterized by a catalytic subunit and a little $p22^{phox}$ subunit that is able to form the heterodimeric cytochrome b_{558}. The association between $p22^{phox}$ and Nox induces phosphorylation cascades that involve cytosolic subunits translations to the membrane and conformational changes in both the enzyme and the cellular membrane (Griendling *et al.*, 2000). The generated O_2^- initiates the production of free radicals and reactive oxidants, which are involved in atherosclerotic lesions and cardiovascular and renal remodeling (Griendling and FitzGerald, 2003; Griendling *et al.*, 2000). In BS and GS patients, the response of the NAD(P)H oxidase to Ang II is reduced. Ang II stimulation produces in these patients a reduced oxidative state in terms of decreased $p22^{phox}$ gene expression (Calò *et al.*, 2003). The decrease of the oxidant potential was related to a decrease in the $OONO^-$ and to an increase in the HO-1 gene expression, as antioxidant enzyme (Calò *et al.*, 2003).

In addition, BS and GS show a reduced susceptibility of the low density lipoprotein (LDL) to oxidation. Oxidated LDL is deeply involved in the progression of the atherosclerotic lesions both in the cardiovascular and renal systems, and the increased NO production in these patients also has a role in the protection of LDL from oxidation (Calò *et al.*, 1998). Furthermore, the reduced production of O_2^- results, in these patients, in an increased bioavailability of NO. In BS and GS the atherothrombogenic factor plasminogen activator inhibitor-1 (PAI-1) is also reduced upon the Ang II challenge (Pagnin *et al.*, 2004). Ang II stimulation promotes long-term fibrotic outcomes particularly involving cytokines. The profibrotic cytokine transforming growth factor β (TGFβ) controls proliferation and cell differentiation, and in the kidney is a cause of fibrosis. Again, BS and GS exhibit a reduced gene expression of TGFβ (Calò *et al.*, 2003).

In addition, the downregulation of the RhoA/Rho kinase pathway alongside a short-term vasoconstriction is increasingly recognized as important in hypertension and cardiovascular remodeling (Calò and Pessina, 2007; Loirand *et al.*, 2006; Shimokawa and Takeshita, 2005; Budzyn *et al.*, 2006). Basal release of NO from the endothelium prevents the activation of RhoA/Rho kinase in smooth muscle through protein kinase G-dependent inhibitory phosphorylation of RhoA (Sauzeau *et al.*, 2003). Excessive production of reactive oxygen species inactivates NO with ensuing increased vascular tone, at least in part through elevated RhoA/Rho kinase activity (Takemoto *et al.*, 2002, Jin *et al.*, 2006). BS and GS patients were found to exhibit a parallel downregulation of RhoA/Rho kinase and upregulation of the nitric oxide system. In addition, the reduced p63RhoGEF and p115RhoGEF expression further delineates the major role of these proteins in the blunted activation of RhoA/Rho kinase pathway (Calò *et al.*, 2014a,b; Calò and Pessina, 2007; Pagnin *et al.*, 2004, 2005a). These features and the lack of endothelial dysfunction and cardiovascular remodeling (Calò *et al.*, 2008a, 2009) produce in BS and GS an opposite image of hypertension; this supports the involvement of RhoA/Rho kinase in the processes leading to cardiovascular remodeling and atherogenesis.

Insulin Sensitivity

BS and GS patients have a normal oral glucose tolerance test, a reduced baseline insulin level, and a markedly higher oral glucose insulin sensitivity compared with healthy normotensive individuals (Davis *et al.*, 2006).

In vitro, Ang II decreases the insulin receptor substrate-1 protein levels via Src, phosphoinositide-dependent kinase-1, and reactive'oxygen-species-mediated phosphorylation of Ser307 (Taniyama *et al.*, 2005), leading to impaired insulin signaling. Ang II is also thought to inhibit insulin signaling and reduce glucose transport via stimulation of RhoA/Rho kinase activity, inhibition of phosphoinositol 3 kinase, and its downstream Akt pathway (Sowers, 2004). Blocked ATR1 signaling in BS and GS results in Akt pathway activation, as shown by increased expression of HO-1 (Calò *et al.*, 2003, 2011), which is under Akt control (Martin *et al.*, 2004). In turn, Akt activates NOS (Wolfrum *et al.*, 2004; Mita *et al.*, 2005). These effects provide a mechanistic explanation for the higher insulin sensitivity found in these patients, as the parallel positive effects reported regarding insulin resistance in the presence

of Ang II AT1R blockers. In addition, in these patients there is an unaltered expression of p66shc, an adaptor protein with a major role in oxidative stress related responses, including those mediated by Ang II, which sensitizes the cells to apoptosis (Calò *et al.*, 1998, 2003, 2008c; Graiani *et al.*, 2005). All this is in marked contrast to type 2 diabetic patients who show the opposite (Avogaro *et al.*, 2003; Pagnin *et al.*, 2005b). These data confirm in humans the linkage of Ang II and glucose metabolism, and provide a molecular mechanism in a human model such as BS and GS for the positive effect of blocking the RAAS and RhoA/Rho kinase pathway on glucose tolerance, diabetes, and atherogenesis.

Angiogenesis☆

Lindsay S Cooley and Andreas Bikfalvi, University Bordeaux, Pessac, France

Glossary

Angiogenesis In a strict sense, the formation of vessels from preexisting vessels. Generally, the development of new vessels.
Angiopoietins Factors implicated in the recruitment of accessory cells to the vasculature and vessel remodeling.
Arteriogenesis Formation of larger blood vessels including arterioles.
Endothelial cells Major cell type that is targeted by angiogenesis factors or inhibitors. Endothelial cells are in close contact with the blood and organize into tubular structures.
Fibroblast growth factors Pleiotropic growth factors that also induce angiogenesis.
Hypoxia-inducible transcription factors (HIFs) There are two HIFs, HIF-1α and HIF-2α, that regulate genes involved in angiogenesis.
Integrins Heterodimeric cell surface receptors for matrix molecules.
Lymphangiogenesis Formation of lymphatic vessels.
Mural cells Cells lining the vessel wall in close contact with the subendothelial matrix and endothelial basement membranes. Pericytes are among the principal mural cells and are found in capillaries.
Platelet-derived growth factors Growth factors implicated in the recruitment of accessory cells (mainly pericytes) to the vasculature.
Proteolytic enzymes Enzymes that degrade proteins such as extracellular matrix molecules. The major proteolytic systems for the degradation of matrix molecules are the plasmin/plasminogen activator–inhibitor system and matrix metalloproteinases.
Pruning Process that yields a mature remodeled vascular network.
RIP-Tag mouse model Transgenic mouse model with targeted expression of large T antigen in pancreatic β cells. A model for multistage carcinogenesis.
Vascular endothelial growth factors (VEGFs) The major regulators of angiogenesis.
Vasculogenesis Formation of blood vessels from progenitor cells

The formation of vascular channels, angiogenesis is a fundamental process that takes place during embryonic life and also plays a crucial role in the adult organism. This review covers an overview of mechanisms of angiogenesis and lymphangiogensis and the impact of angiogenesis research on the pathology and therapy of disease.

Overview of the Vascular System

The mammalian vascular system is made up of two circulatory networks, the blood and lymphatic vascular systems. The blood vascular system transports gases, nutrients, liquids, cells and chemical signals such as hormones to the tissues, and removes waste products. The lymphatic vascular system has complementary functions to those carried out by the blood vasculature. The lymphatic system collects fluid and macromolecules from within tissues (forming protein-rich lymph) and returns the fluid to the blood circulation via the thoracic duct.

Initial development of the blood vasculature occurs in the embryo via the process of *vasculogenesis*. Further remodeling and new vessel growth in the adult occur via *angiogenesis*, defined as the process of new blood vessel formation from the existing vasculature. Lymphatic vessel development occurs via the related process of *lymphangiogenesis*.

Basic Structure of Vessels

The vascular system is made up of large (macrovascular) blood vessels such as arteries and veins and small (microvascular) vessels such as capillaries, post-capillary venules and arterioles (see **Fig. 1**). Large vessels have a common basic structure and consist of three different layers. The tunica intima is made up of a central layer of endothelial cells (EC) forming the lumen of the vessel, surrounded by and attached to the vascular basement membrane (BM). Outside this is the tunica media, comprised of multiple layers of perivascular cells (smooth muscle cells or pericytes), and the outer tunica adventitia, which forms the outermost coat of the vessel and is formed from loose fibrous connective tissue, often continuous with the surrounding connective tissue. Microvessels are smaller and narrower than macrovessels. They are formed from an endothelial cell layer and basement membrane and

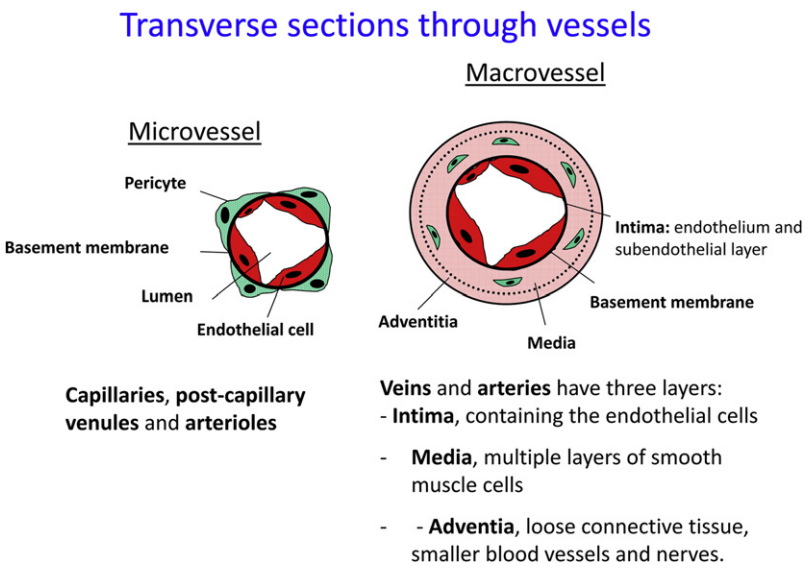

Fig. 1 Basic structure of blood vessels

are stabilized by pericytes. Within the vascular system, arteries carry afferent circulation away from the heart to the capillaries. They are thus exposed to the highest pressure and flow, and are surrounded by thick layers of smooth muscle cells (SMC). In contrast, veins carry efferent circulation back to the heart. Efferent circulation is less pressurized and veins typically have less surrounding smooth muscle and contain specialized valve structures to prevent backflow of blood. Capillaries form a branching and anastomosing network between small arterioles and venules, and are the sites for exchange of gases, nutrients and waste between the vasculature and organs. Capillaries show a remarkable heterogeneity and are uniquely adapted to suit the needs of a given tissue environment.

Structurally, lymphatic vessels show both similarities with and differences from blood vessels. Like blood vessels, the inner lining is made up of a single layer of endothelial cells (lymphatic endothelial cells, or LEC). Unlike blood vascular capillaries, lymphatic capillaries do not have a covering of perciytes, and very little basement membrane. Instead, LEC contact surrounding interstitial collagen directly via anchoring filaments composed of elastic fibers, which help to structurally support the vessel and prevent its collapse. Lymphatic vessels are generally larger in diameter than blood vessels, with loose junctions formed of layers of overlapping LEC. Larger vessels have a sparse covering of smooth muscle cells to aid unidirectional propulsion of lymph, as well as valves to prevent backflow.

Vasculature and Pathology

Angiogenesis plays roles in normal physiological processes such as wound healing, the female menstrual cycle and organ growth. It is a tightly regulated process in which new blood vessels form only as needed, with the vasculature remaining quiescent most of the time. Dysregulated angiogenesis leads to many pathological conditions. For example, vascular insufficiency is implicated in diseases including Alzheimer's, stroke, diabetes, atherosclerosis, Crohns disease, neonatal respiratory distress, nephropathy and osteoporosis. Conversely, excessive angiogenesis is involved in obesity, psoriasis, arthritis, diabetic retinopathy and many other diseases.

Arguably the most important aspect of excessive angiogenesis is that the growth and metastasis of solid tumors is angiogenesis-dependent. Like all cells, tumor cells require access to the blood vasculature in order to receive sufficient oxygen and nutrients to survive, and as a means of removing waste. A pre-vascular tumor grows until a critical size of 2–3 mm^2 is reached. At this point, insufficient oxygen and nutrients restrict the tumor growth, and it remains dormant, with cell proliferation balanced by apoptosis. In order for the tumor to grow any further, it must become vascularized via induction of blood vessel growth, a process described as the 'angiogenic switch' (see Fig. 2). Once this critical step occurs, the tumor is able to grow exponentially in size, and is also provided with a route to metastasize around the body. The vital importance of this critical step in the progression of cancer has led to major interest in the mechanisms and therapeutic control of blood vessel formation.

In recent years it has become clear that the lymphatic system plays a vital role in the spread of cancer around the body. The lymphatic vasculature is a primary route for metastatic tumor cells, presumably because the large diameter, lack of basement membrane and loose intercellular junctions of lymphatic vessels allow easier access than blood vessels. Tumor cells carried in the lymph gain access also gain access to the blood vascular system via the thoracic duct providing another route to distant tissues. Lymphatic vessel density of the primary tumor correlates with metastatic spread for a variety of tumors. However, some controversy remains as to whether tumor lymphatics are functional due to the high interstitial pressures within solid tumors.

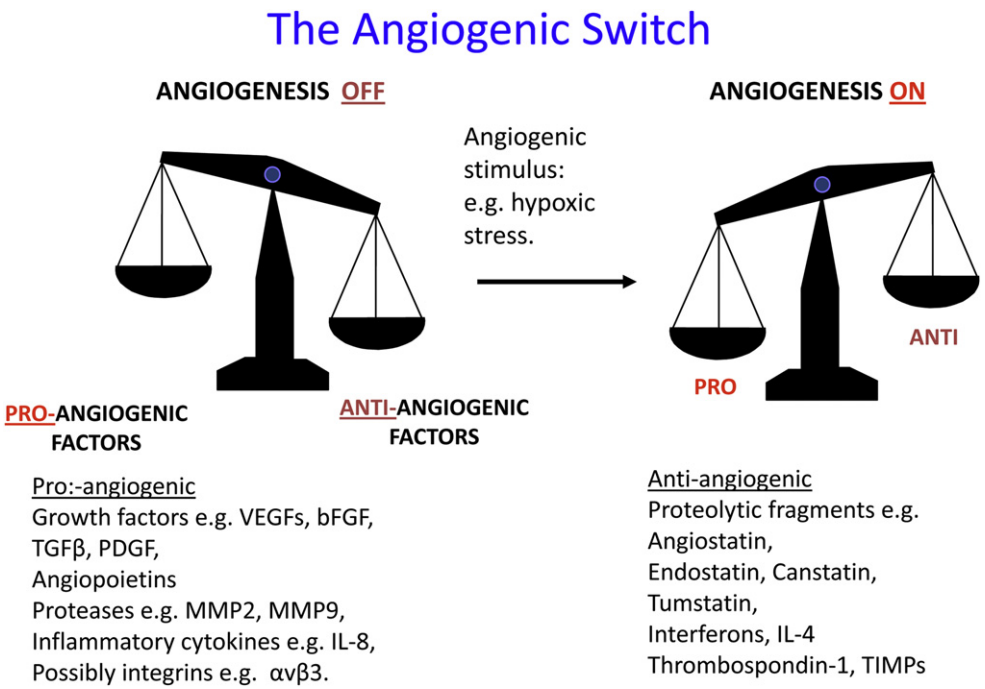

Fig. 2 A shift in the balance of pro- and anti-angiogenic factors leads to the 'angiogenic switch'. Following a known angiogenic stimulus such as hypoxic stress, pro-angiogenic factors begin to accumulate, and their effects eventually outweigh those of negative regulatory factors. The angiogenic switch is now 'on' and new vessel formation is induced.

Diabetic retinopathy remains the most common cause of acquired blindness among persons of working age in the industrialized world. The typical microangioathy changes include loss of pericytes and endothelial cells and thickening of the basilar membrane. Microaneurysms, that is, sites of outward ballooning of the capillary wall, are a common early feature of the disease. Occlusive microangioathy induces retinal ischemia and subsequent vitreoretinal neovascularization, whilst loss of hemato retinal barriers induces macular edema. Both complications threaten the patient's vision. Another diabetic condition where insufficient angiogenesis occurs is diabetic polyneuropathy seen in advanced-stage diabetes.

Another condition, where excessive angiogenesis occurs, is age-related macular degeneration. It was not until 1980 that macular degeneration was reported to be a significant cause of blindness in the United States. Since then, many studies have expanded upon the risks associated with new blood vessel growth in the aging retina, and have shown just how serious and widespread a public health issue AMD represents. Recently developed angiogenesis-therapies in this condition have yield to very significant results.

Basic Mechanisms of Vasoformation

Vasculogenesis

The blood vascular network is formed via two main processes, vasculogenesis and angiogenesis.

Vasculogenesis refers to the de novo formation of blood vessels, and is the mechanism of formation of a primitive blood vascular network in the embryo. Endothelial and hemtopoietic cells share a common progenitor, termed the hemangioblast. Aggregates of hemangioblasts (known as blood islands) form in the yolk sac, composed of inner cells which subsequently differentiate into hematopoietic cells, and outer cells which give rise to angioblasts (endothelial precursor cells). Angioblasts migrate and differentiate into mature endothelial cells, coalescing to form a vascular labyrinth, which is subsequently remodeled and extended by the related process of angiogenesis. For many years, it was thought that de novo blood vessel formation occurs only during embryonic development, and that all post-natal vascularization occurs via angiogenesis. However, in recent years it has become clear that endothelial precursor cells (EPC), which are defined as cells existing in differentiation stages between hemangioblasts and mature EC, are present in the adult bone marrow, at low levels in the blood circulation, and possibly in tissues. EPC are mobilized and recruited from their resident sites, and differentiate to mature EC in response to various factors such as VEGF, bFGF and insulin-like growth factor-1 (IGF-1). Such cells have been shown to contribute to neovascularization in the adult in a variety of settings, such as ischemic conditions, tumor growth and wound healing. The magnitude of participation of EPC in neoangiogenesis is still matter of debate. It has been argued that EPC contribute to new vessel formation by differentiating into mature EC, but a more likely explanation is by contributing to a pro-angiogenic environment via the release of cytokines such

as VEGF. The discovery of EPC in adult tissue has led to great interest in the potential therapeutic implications of using progenitor cells derived from bone marrow to aid re-vascularization in clinical settings, such as in repair of damaged heart and ischemic limb disease.

Angiogenesis

Angiogenesis is the process of new blood vessel formation from the existing vasculature. It is thus distinct from vasculogenesis in that new blood vessels arise from and extend a pre-existing vascular network. A second key difference is that angiogenesis occurs by division of mature endothelial cells rather than by differentiation of precursor cells. During sprouting angiogenesis, new vessels arise by extension of or branching from their vessel of origin. This process is now well characterized and can be divided into a series of non-discrete, overlapping stages, described below, and depicted in **Fig. 3**.

Initiation

In the adult, the vasculature is normally in a quiescent state. New vessels form only as required, in response to an angiogenic stimulus. In quiescent vasculature, inter-endothelial cell contacts are tight, and the vessel is stabilized by pericytes, which help to maintain EC in a quiescent state. The vessel must be destabilized in order for endothelial cells to migrate away from the parent vessel to form a new sprout. Current thinking suggests that a shift in the balance of pro- and anti-angiogenic factors regulates the 'decision' to induce vessel formation. Following a known angiogenic stimulus, pro-angiogenic factors begin to accumulate and their effects eventually outweigh those of negative regulatory factors, and new vessel formation is induced. Hypoxic stress, when tissues grow beyond the limit of oxygen diffusion is one such angiogenic stimulus. Low oxygen tension leads to upregulation of hypoxia-inducible transcription factors (HIFs) which induce expression of genes involved in angiogenesis, including nitric oxide synthase.

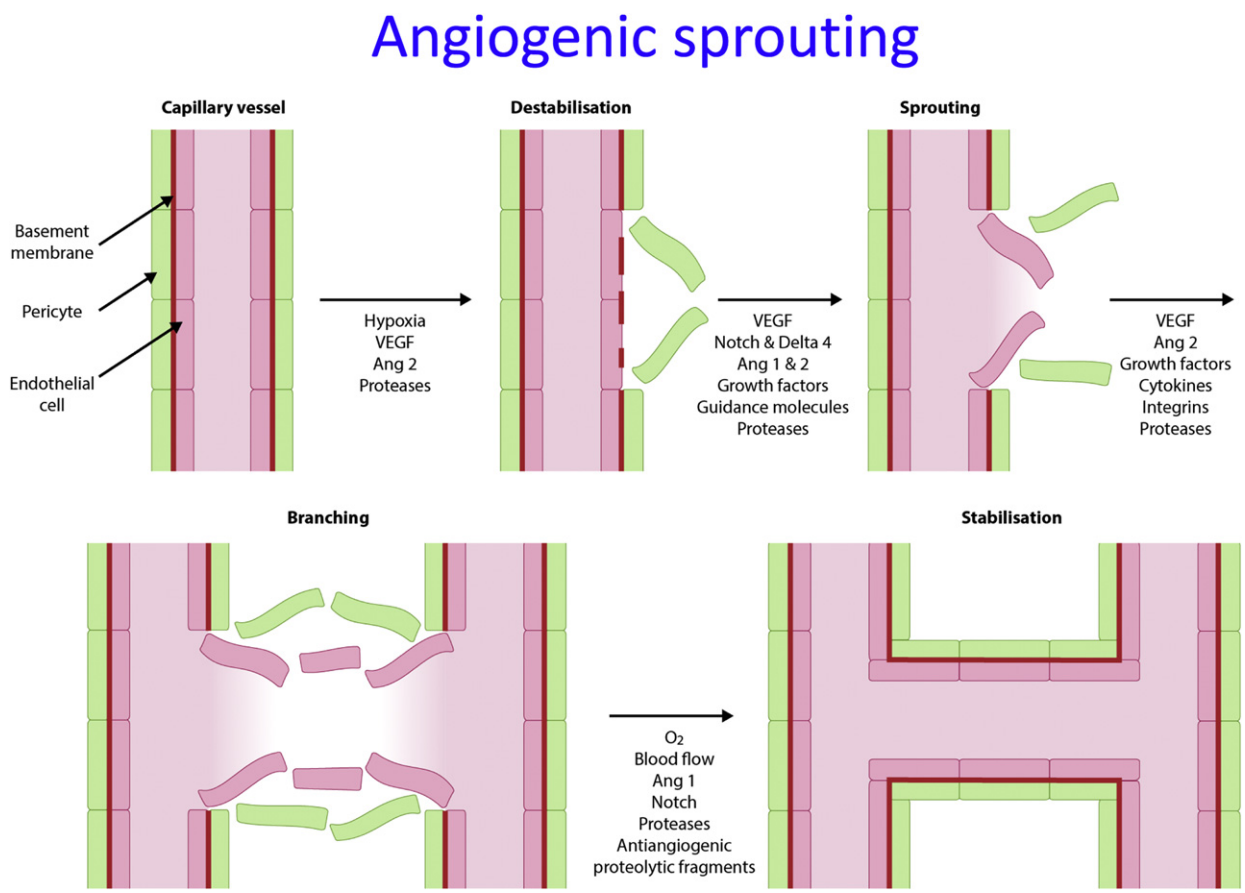

Fig. 3 Angiogenic sprouting. Resting vasculature is quiescent. In response to an angiogenic stimulus, endothelial cells are activated and the parent vessel is destabilised. Pericytes detach, and EC-EC contacts are loosened. Plasma proteins are extravasated and form a provisional scaffold. The basement membrane is degraded by the activity of proteases, and activated ECs proliferate and migrate towards the angiogenic stimulus, invading the ECM and forming a sprout. A new cord stucture is assembled, which is subsequently stabilised by the formation of new basement membrane and the attachment of pericytes.

Dilation and Destabilization of Parent Vessel

Induction of HIFs lead to expression of nitric oxide synthase and production of nitric oxide, which in concert with vascular endothelial growth factor (VEGF) leads to vasodilation. Inter-endothelial cell contacts are loosened via redistribution of inter-cellular adhesion molecules such as CD31 and vascular endothelial cadherin (VE-Cadherin) and pericytes detach from the basement membrane. Plasma proteins are extravasated from the dilated vessel, and form a provisional scaffold for migrating EC. Vessel destabilization must be tightly regulated to allow EC to leave the parent vessel, but without causing its collapse and regression. The process is regulated in a large part by the competing actions of angiopoietins in concert with the permeabalizing effect of VEGF.

Proliferation and Migration of Endothelial Cells

Endothelial cells in quiescent vasculature have a very low turnover. However, during new vessel formation, EC show a greatly increased rate of proliferation In order to migrate towards an angiogenic stimulus, EC produce proteases which are required for degradation of the vascular basement membrane, and to digest a path through the interstitial extracellular matrix. Endothelial cells migrate from the provisional scaffold, through the interstitial extracellular matrix (ECM) via the coordinated actions of proteases, integrins and endothelial mitogens such as VEGF. Each newly forming sprout has a single 'tip' cell which senses and responds to gradients of VEGF, guiding the nascent vessel. All other EC in the developing vessel, known as 'stalk' cells, proliferate and migrate after the tip cell without forming new sprouts. This process is regulated by Notch signaling.

Lumen Formation

Migrating EC assemble as a solid cord structure, which subsequently acquires a lumen. Studies have suggested that lumen formation occurs via an integrin-dependent pinocytotic mechanism. Vesicles form within individual EC, and fuse together to form vacuoles. Vacuoles form adjacent migrating chains of EC then merge to form the lumen. The diameter of the forming lumen is tightly regulated by VEGF isoforms and angiopoietins, as well as endogenous inhibitors of lumen formation such as thrombospondin-1 (TSP-1). An alternative explanation is that lumen formation occurs by cord hollowing. In this mechanism, two endothelial cells are brought in close contact by VE-cadherin. This contact is then partially broken by a de-adhesive process involving CD34-sialomucins, such as CD34 and podocalyxin. This is followed by recruitment of actin at the interface between two EC, which is under the control of ERM proteins, which are phosphorylated.

Vessel Stabilization

Maturation of newly formed vessels involves stabilization of the vessel structure by generation of a vascular basement membrane, and by the attachment of pericytes. Contact with the basement membrane induces EC quiescence, and promotes survival. The interaction of perivascular cells with nascent capillaries is vital for vessel stabilization, since vessels without a pericyte covering eventually regress. Endothelial-pericyte interactions are mediated in large part by platelet derived growth-factor –BB (PDFB-BB) signaling through the PDGF receptor β (PDGFRβ). Perivascular cells expressing PDGFβ are stimulated to differentiate and migrate towards PDGF-BB expressed by endothelial cells. Pericyte-endothelial cell contact requires EC proliferation, survival, migration and differentiation. Lack of pericyte coverage is believed to be responsible for the capillary fragility and impaired perfusion in diabetic retinopathy. Transforming growth factor-β (TGFβ) signaling contributes to vessel maturation by regulating differentiation of mural cells, and stimulating ECM production, and the action of angiopoietins is also required.

Remodeling and Maturation of the Vascular Network

After an initial burst of new vessel formation in response to an angiogenic signal such as hypoxia, formation of an ordered functional network occurs via vascular remodeling and 'pruning' of unnecessary vessels. This is a normal physiological mechanism to match perfusion with metabolic demand. Regression of immature vessels is induced on removal of angiogenic stimuli, but once vessels are stabilized by pericyte attachment, they become resistant to oxygen-induced regression. Thus, when the angiogenic switch is turned 'off' by accumulation of anti-angiogenic factors, or removal of pro-angiogenic stimuli, vessels must be actively maintained to avoid regression. Hemodynamic forces are also essential for vessel maintenance, via mechanisms which are still unclear, since vessels which are poorly perfused tend to regress. With maturation of the vascular network, EC also acquire the specialized characteristics required for vessel identity, including arterial, venous or lymphatic identity.

Detailed study of the lymphatic vasculature has only become possible in recent years with the discovery of lymphatic marker genes allowing discrimination of the (morphologically similar) lymphatic vessels from the blood vasculature. Lymphangiogenic sprouting appears essentially similar to angiogenic sprouting and is therefore thought to involve similar processes to those identified in angiogenesis. However, detailed knowledge of the precise mechanisms and molecules regulating the formation of new lymphatics is still lacking at this stage.

Key Factors Regulating Vascular Development/Therapeutic Targets

VEGF Family

The Vascular Endothelial Growth Factor (VEGF) family of secreted glycoproteins have long been recognized as prime regulators of angiogenesis. The VEGF family consists of five main members: VEGF-A (commonly known as VEGF), VEGF-B, VEGF-C, VEGF-D and placental growth factor (Plgf). The VEGFs interact with a family of receptor tyrosine kinases known as vascular endothelial growth factor receptors (VEGFR)-1, −2 and −3. Neuropilins (NP)-1 and −2 are also able to functionally interact with the VEGFRs (see Fig. 4). As a general rule, the VEGF family proteins are expressed in a wide range of cell types, with the receptors having a much more restricted cell-type expression. VEGFR1 and VEGFR2 are expressed predominantly by endothelial cells, while VEGFR3 is expressed mainly by lymphatic EC in the adult.

VEGF-A (also known as VEGF) was first identified as a vascular permeability factor secreted by tumor cells and is the best characterized of the VEGF proteins. It is the most potent pro-angiogenic protein described to date, and is the major hypoxia-inducible pro-angiogenic factor. It is a key regulator of angiogenesis, vasculogenesis and hematopoiesis. VEGF-null mice die early in development (E8-9) due to a block of hematopoietic and vascular development, and there is a dose-dependent requirement for VEGF protein since deletion of a single allele is also embryonic lethal. Endogenous expression of VEGF by EC is also required to maintain vascular function and stability. VEGF exists as at least 7 isoforms formed through alternative splicing, known as VEGF 121, 145, 148, 165, 183, 189 and 206 with VEGF 165 being the effector of VEGF function. VEGF binds both VEGFR1 and VEGFR2, and signals primarily through VEGFR2 to promote EC proliferation and survival, sprouting angiogenesis and increase migration and invasion.

VEGFR2 deletion is embryonic lethal in mice as a result of defects in hematopoietic and endothelial precursors. VEGF binds VEGFR1 with a higher affinity than VEGFR2, however VEGFR1 exerts less activation of intracellular signaling and has therefore been proposed to act as a negative regulator of VEGFR2 function. On the other hand, VEGFR1 has been reported to heterodimerise with VEGFR2 forming a complex with stronger signaling properties than either VEGFR1 or VEGFR2 homodimers. VEGFR2 has recently been proposed to play a role in lymphatic development.

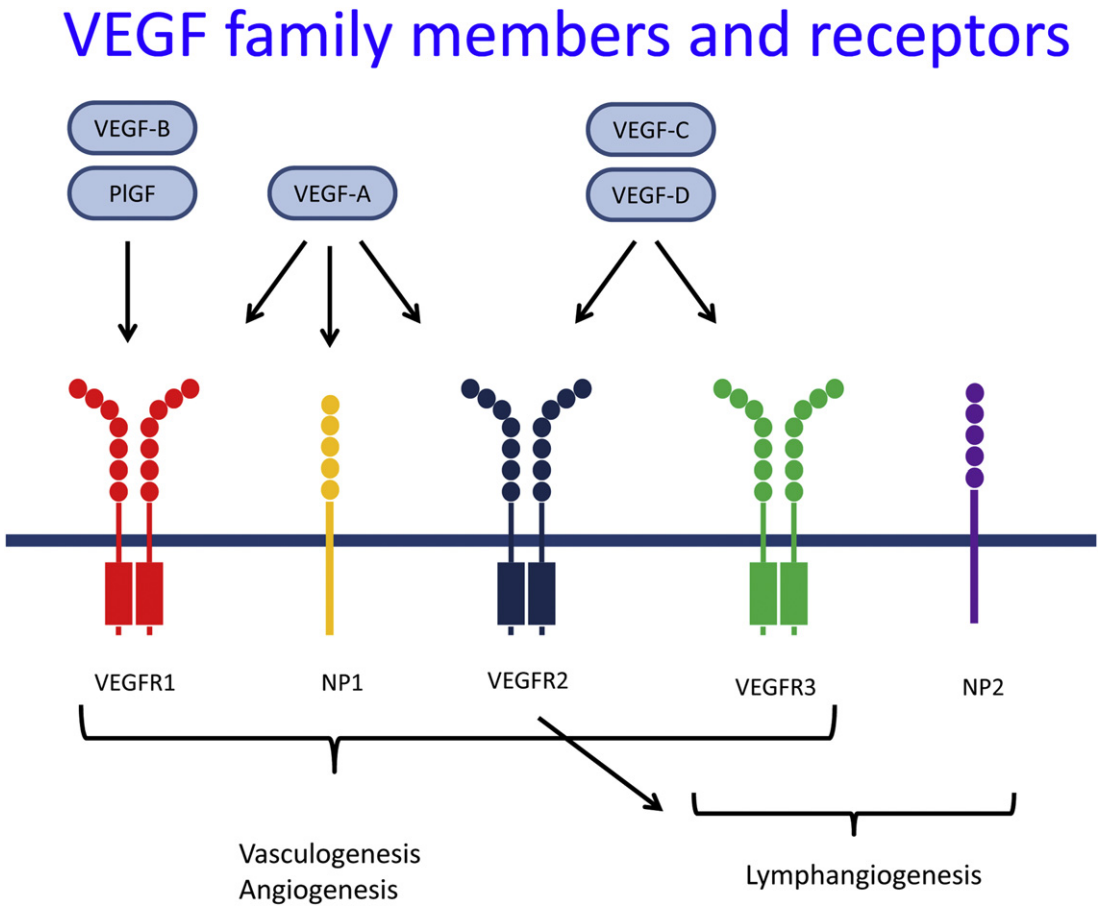

Fig. 4 VEGF family members and their receptors.

VEGFR3 plays a crucial role in embryonic blood vascular formation, however in later development its expression is restricted largely to the lymphatic endothelium. However, it has been shown to be re-expressed in the blood vasculature in certain pathological conditions such as on tumor vasculature, and blocking its function inhibits blood vascular endothelial cell tubulogenesis, suggesting that it can act in a pro-angiogenic role. VEGF-C is the critical growth factor regulating lymphangiogenesis, since the lymphatic vasculature fails to form in VEGF-C null mice. VEGF-C signals mainly through VEGFR3, although the proteolytically processed mature form can activate VEGFR2 in the blood vascular endothelium. Similarly, VEGF-D binds and activates VEGFR2 and VEGFR3.

Anti-angiogenic therapies currently in the clinic or in clinical trials focus largely on blocking VEGF signaling, either by sequestering VEGF or by inhibiting its receptors. The first FDA-approved anti-angiogenic therapy, Bevacizumab is a humanized monoclonal anti-VEGF antibody. It was first licensed in 2004 for the treatment of metastatic colon cancer in combination with standard chemotherapy, and is now licensed for used in a number of cancers including renal, ovarian, lung and glioblastoma multiforme. A derivative of Bevacizumab, Ranbizumab, has also been approved for the treatment of age related macular degeneration (AMD). Other approaches include the production of soluble decoy receptors, such as VEGF-Trap, a chimeric protein contains VEGF-binding domains of both VEGFR1 and VEGFR2. VEGF-Trap has also been licensed for the treatment of AMD, and is currently under investigation for therapeutic benefit in cancer treatment. Pegaptanib, an aptamer that selectively binds and neutrlises VEGF-165 has also been approved for AMD treatment.

A second approach to blocking VEGF signaling involves targeting the VEGFRs. Low molecular weight tyrosine kinase inhibitors such as Sorafenib, Sunitinib, Pazopanib and Everolimus are able to target multiple receptors including VEGFRs, PDGFRs and in some cases FGFRs. These drugs thus have the advantage of targeting multiple therapeutically relevant signaling pathways at once, and are used in the treatment of multiple cancers including renal cancer, liver cancer, and soft tissue sarcoma. A series of alternative receptor tyrosine kinase inhibitors are currently also in phase III clinical trials with the aim of treating a variety of cancers.

While anti-VEGF signaling therapy has a sound baiss, the clinical results of anti-angiogenic treatments to date have been perhaps less impressive than hoped for, largely due to the development of resistance in tumors treated with anti-angiogenic therapies. The reasons for resistance are manifold, but include the following:

- Upregulation of alternative pro-angiogenic signaling molecules, such as FGFs, Plgf, angiopoietins and ephrins in response to blockade of VEGF signaling.
- Upregulation of granulocyte colony stimulating factor (G-CSF) and stromal derived factor-1 (SDF-1), leading to recruitment of vascular progenitor cells from the bone marrow which can then participate in neovessel formation as described above. Existing blood vessels can also split (intusception) to form new vessels in the absence of sprouting angiogenesis. Co-option of existing blood vessels and vascular mimicry by tumor cells are also mechanisms to provide a tumor with a blood supply in the absence of sprouting angiogenesis.
- Increased perivascular cell coverage of tumor blood vessels. As discussed above, perivascular cell coverage stabilizes vessels and protects them from regression after withdrawal of VEGF stimulation.
- Selection of tumor cells harboring mutations rendering them relatively resistant to hypoxia, or lacking VEGF or VEGFRs.
- These have led to focus on the development of alternative therapies blocking other signaling pathways relevant to angiogenesis.

Angiopoietins

The Tie receptors Tie1 and Tie2 and their corresponding angiopoietin (Ang) ligands were identified as the second EC-specific tyrosine kinase receptor signaling system. The angiopoietin family consists of Ang-1, Ang-2, and Ang-4 (the mouse homologue of Ang-4 is known as Ang-3) as well as a set of angiopoietin-like proteins (Angptl1-7). Most studies have focused on Ang-1 and Ang-2 which bind the Tie2 receptor and have the best characterized roles in angiogenesis. The roles of Ang-1 and Ang-2 signaling are complex and context dependent. Ang-1 binds and directly activates the Tie2 receptor, and this can have pro-angiogenic roles, stimulating EC sprouting and vessel growth as well as being correlated with vessel density in a variety of tumors. However, contradictory anti-angiogenic roles have been proposed in pathological situations. Ang-1/Tie2 signaling can be broadly considered as promoting vascular stability. Ang-1 expressed by mural cells interacts with Tie2 expressed by EC, and it is involved in the induction of EC quiescence and stabilization of the vasculature via mediation of EC-perivascular cell interactions, antagonism of the permeability-inducing effects of VEGF, and promotion of EC survival via activation of the Akt signaling pathway.

Ang-2 deficient mice show defects in remodeling and maturation, with normal physiological vessel regression inhibited. Ang-2 binding to Tie2 does not result in receptor phosphorylation, and overexpression of Ang2 inhibits Tie2 signaling. This suggests that Ang-2 is a direct antagonist of Ang-1 and counteracts its effects on vessel stability. This has led to the concept of the balance between Ang-1 and Ang-2 acting as a switch between EC activation and vessel stability (see **Fig. 5**).Thus, constitutive Ang-1/Tie2 signaling would be expected to maintain the vasculature in a quiescent state, with Ang-2 signaling in response to pro-angiogenic signals allowing endothelial activation and sprouting. The removal of pro-angiogenic stimuli or accumulation of anti-angiogenic factors would reverse the balance, resulting in endothelial quiescence and stabilization of the newly-formed vasculature. Ang-2 is also required for lymphatic development. The role of Tie1 is unclear as it has no identified ligands but it is known to interact with Tie2, and its depletion from the endothelium of adult mice has been recently shown to inhibit tumor angiogenesis and growth by decreasing EC survival in tumor vessels without affecting normal vasculature.

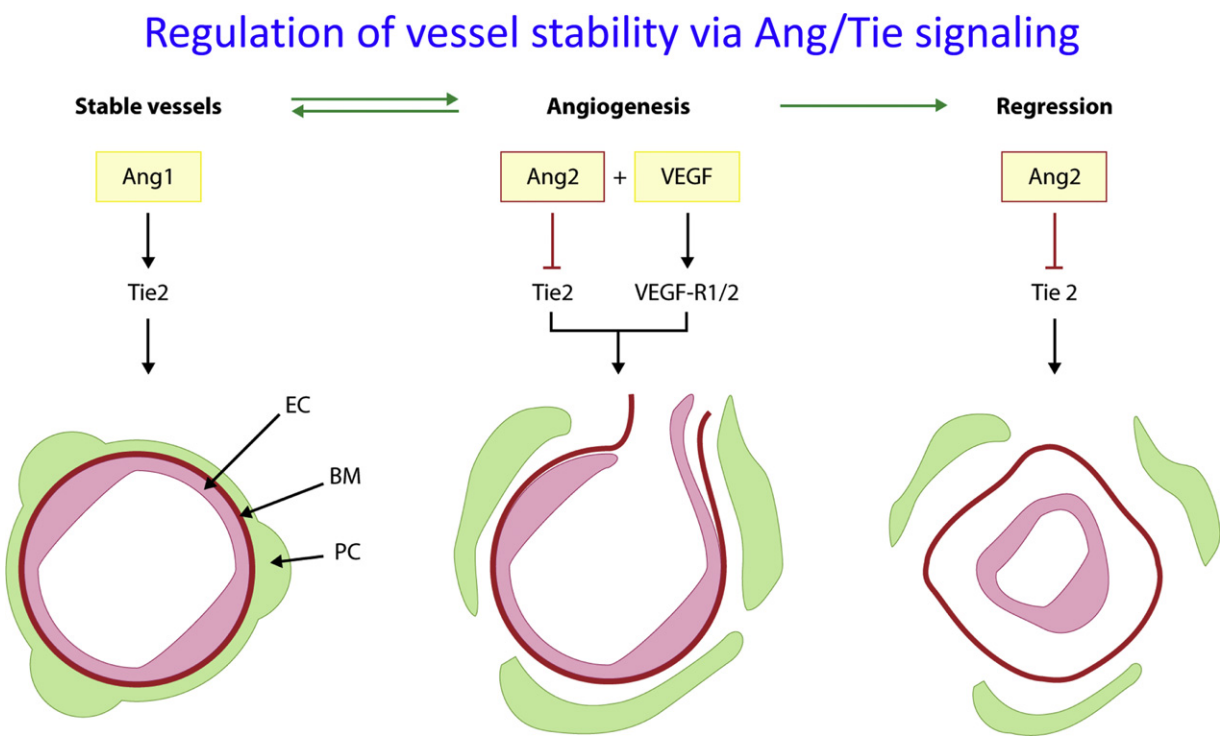

Fig. 5 Regulation of vessel stability by Ang/Tie signaling. In mature vessels Ang1 binds to Tie2 promoting recruitment and maintaining association of peri-endothelial support cells, thus stabilizing newly formed vessels. During initial stages of angiogenesis: Ang-2 binds Tie2 and blocks its activation, vessel structures become loosened, reducing EC contacts with matrix and peri-endothelial support cells, making the ECs more accessible and responsive to VEGF. VEGF binding to VEGF-R2 induces EC proliferation. Loosening of cell-matrix interactions via Ang-2/Tie2 binding in the absence of a growth or survival signals elicits endothelial cell death, likely by apoptosis, and therefore vessel regression.

The modulation of Ang/Tie signaling is of interest for therapeutic benefit. A number of drugs targeting Ang/Tie signaling, including monoclonal antibodies, peptibodies and aptamers against Ang1/Ang2 are currently in development or clinical trials, as well as tyrosine kinase inhibitors targeting Tie2.

Notch

The Delta/JaggedNotch signaling pathway is a conserved pathway regulating cell fate and differentiation, and includes four receptors (Notch 1–4), and five transmembrane ligands (Jagged1, Jagged2, Delta-like ligands (DLL) 1–4. The Receptor and ligands are tethered to the cell surface. Notch signaling enables cell-cell communication in multicellular organisms, and acts to influence cell proliferation, differentiation and apoptosis. In recent years, interest has focused particularly on the role of Dll4 interaction with Notch1 in angiogenesis. Dll4 expression is restricted to ECS and, similarly to VEGF, there is a dose-dependent requirement for Dll4 expression for vascular development. Expression of Dll4 is upregulated by VEGF, and strong in tumor vasculature compared to normal vessels. Surprisingly, despite its apparently clear pro-angiogenic role, a reduction in Dll4 signaling results in increased vessel density but shrinkage in tumor volume. Dll4-Notch1 signaling plays a role in specifying the phenotype of cells within growing sprouts, and therefore the number of branching sprouts formed. Dll4 is expressed on non-proliferative, highly motile 'tip' cells, and interacts with Notch1 on adjacent EC. This interaction results in repression of the 'tip' phenotype in these cells which take on a highly proliferative 'stalk' phenotype. Inhibition of Dll3 signaling therefore results in an expansion in the number of cells exhibiting the 'tip' phenotype, leading to increased sprout formation and the production of non-functional vasculature. The concept of 'abnormalization' of tumor vasculature is hoped to lead to the development of novel therapeutic agents to control pathological angiogenesis.

Pre-clinical data suggests that combining agents blocking VEGF and Dll4 is more effective than either drug used alone. Importantly, recent data also suggests that tumors which have become resistant to VEGF blockade remain sensitive to anti-DLL4 agents. A variety of antibodies targeting DLL4 are currently in clinical development.

Ephrins

The Ephs are a large family of receptor tyrosine kinases divided into classes A and B. They interact with their ligands, the ephrins, also divided into class A and B. Like Notch signaling, both Eph receptors and ephrin ligands are anchored to the cell surface,

requiring close proximity of cells for signaling to occur. A unique feature of ephrin signaling is that it is bi-directional, with both receptor and ligand activitiy signaling in the cells that bear them (known as 'forward' and 'reverse' signaling, respectively. The Eph/ephrin signaling mediates 'repulsive' roles, where receptor and ligand interaction results in repulsion of the receptor-bearing cell.

In the vasculature, Eph/ephrin signaling plays a variety of roles, including modulation of cell proliferation, migration, and cell-cell and cell-matrix interactions. Interest has focused on ephrin A2, which is overexpressed in multiple cancers, mediates VEGF-induced EC migration, and has been linked with vasculogenic mimicry. This is a process by which tumor cells form channels which 'mimic' blood vessels and is one means by which tumors become resistant to anti-angiogenic therapies. The monoclonal antibody EA5 targeting ephrin2A is in pre-clinical evaluation.

The interaction of EphB4 with its ligand ephrinB2 is also of interest, as both genes are essential for angiogenic remodeling and embryonic survival. EphB4/ephrinB2 interactions are important for the development of the vascular wall, since ephrinB2-defiicient pericytes fail to attach correctly to the nascent vessel. Furthermore, soluble ephrinB2 facilitates adhesion and migration of endothelial cells in culture, and blockade of EphB4 causes inhibition of angiogenesis in several pre-clinical models. EphB4/ephrinB3 are also linked to the development and patterning of the lymphatic vasculature. EphrinB2 is strongly expressed in the ECs of lymphatic collecting vessels, and mice engineered to express a mutant version of ephrinB2 showed disturbed maturation and patterning of the lymphatic vasculature. JI-101, a triple inhibitor of VEGFR2, PDGFRβ and EphB4 has entered early clinical evaluation.

Proteases

Several major classes of proteases have been identified as playing important roles in the processes that regulate angiogenesis. These include the Matrix Metalloproteases (MMPs), ADAMs (A Distintegrin And Metalloprotease domain), the related ADAMTSs (A Disintegrin And Metalloprotease with ThromboSpondin motifs), serine proteases, and some members of the cysteine cathepsins.

The primary role of proteases in angiogenesis is in remodeling of the extracellular matrix. For EC to exit the parent vessel, the vascular basement membrane must be degraded. Migration of activated EC into the interstitial ECM to form the new sprout also relies on the coordinated activity of proteases to digest the ECM, providing space for migration, as well as regulating adhesion and de-adhesion in the process of migration itself. While matrix remodeling is thus necessary for sprout formation to occur, this process must be tightly regulated. Insufficient proteolysis inhibits invasion of EC, however excessive matrix degradation results in collapse of the matrix scaffold, and prevents adhesion of EC, leading to EC death and vessel regression. The MMP family have distinct but overlapping substrate specificities, and collectively they can cleave virtually all components of the ECM. Furthermore, inhibition of MMP activity using broad spectrum inhibitors is able to completely block endothelial tube formation in *in vitro* and *ex vivo* angiogenesis models. This process is particularly dependent on a subset of cell-surface membrane-type (MT)-MMPs, particularly MT1-MMP. In vivo, proteolytic activity of MMPs, ADAMs and ADAMTSs is regulated by the Tissue Inhibitor of Metalloproteases (TIMPs).

Proteolysis contributes to angiogenesis via numerous mechanisms beyond simply providing spave for the new vessel to form. Partial proteolysis of native collagen during remodeling of the ECM results in exposure of cryptic sites, regulating processes such as adhesion and migration. Proteolytic activity also liberates growth factors such as VEGF, bFGF, tumor necrosis factor-α (TNFα), and insulin-like growth factor-1 (IGF-1) previously bound to the cell membrane or sequestered within the ECM. For example, MMP-9 was shown to activate the angiogenic switch in the Rip1Tag1 model of mouse carcinogenesis via the release of membrane-bound VEGF stores, in the absence of increased expression of either VEGF or its receptors.

Proteases and their inhibitors can also have anti-angiogenic activity. For example there is evidence that Plasminogen Activator Inhibitor-1 (PAI-1) is anti-angiogenic dependent on its local concentration. Certain ADAMTS including ADAMTS-1 and -8 also have anti-angiogenic roles, potentially by binding VEGF and also via the release of anti-angiogenic cleavage products of thrombospondins-1 and -2.

Integrins

Given their crucial role in communication between cells and their environment, it is unsurprising that several integrins are known to play roles in several aspects of vascular biology. A large body of evidence from both in vitro and in vivo studies has revealed roles for various integrins in angiogenesis including EC activation, survival and migration, ECM remodeling, vascular lumen formation, network remodeling via induction of cell death, vessel maturation and mediation of interactions between endothelial and perivascular cells.

Much attention has been focused on the role of $\alpha v\beta 3$ and $\alpha v\beta 5$, due to convincing evidence implicating both integrins in angiogenesis. Their inhibition blocks angiogenesis in a range of in vitro and in vivo angiogenesis models. However, generation of mice genetically engineered to lack either or both of these integrins show extensive developmental angiogenesis, suggesting that neither is required for vascular development. Furthermore, mice lacking $\alpha v\beta 3$ show enhanced tumor angiogenesis. These conflicting data suggest that $\alpha v\beta 3$ and $\alpha v\beta 5$ may have roles in negative regulation of angiogenesis. These may include binding of anti-angiogenic factors such as thrombospondin and angiostatin, mediating integrin-mediated cell death (IMD), in which presence of unligated $\alpha v\beta 3$ induces apoptosis in EC (even during an adherent state), or by negatively regulating activity of pro-angiogenic integrins or signaling cascades.

The role of integrins in the process of lymphangiogenesis is still a relatively unstudied area. Some integrins involved in angiogenesis are known to be expressed on lymphatic vasculature and some (e.g. $\alpha1\beta1$, $\alpha2\beta1$, $\alpha5\beta1$ and $\alpha4\beta1$) are known to be upregulated during pathological lymphangiogenesis. Possibly the most interesting data concerns $\alpha9\beta1$, which is expressed on lymphatic vasculature endothelium and absent from the blood vasculature. Mice deficient in $\alpha9$ survive until birth but die due to lymphatic defects 6–12 days later, suggesting an important role for this integrin in lymphangiogenesis.

Several integrin inhibitors are either in clinical use or are currently in clinical trials. These take the form of therapeutic antibodies, ligand mimetic peptides, or small molecule antagonists. Integrin inhibitors in the clinic target the integrin $\alpha4$ and platelet integrin $\alpha IIb\beta3$, with inhibitors in clinical trials targeting the RGD-binding integrins $\alpha v\beta1$, $\alpha v\beta3$, $\alpha v\beta5$ and $\alpha IIb\beta3$. Of these, the $\alpha v\beta3$/ $\alpha v\beta5$ inhibitor cilengitide, currently being tested in phase III clinical trials for glioblastoma, is the closest to approval.

Conclusion

Angiogenesis and lymphangiogenesis are fundamental mechanisms in embryonic and postnatal development which also play major roles in pathologies such as cancer, ocular neovascular disease, ischemic disease, and chronic inflammatory disease. Many molecules, receptors and intracellular signaling molecules have been implicated in vascular morphogenesis. These discoveries have offered novel opportunities for therapeutic intervention. There is an increasing repertoire of drugs with which to manipulate angiogenesis and new endothelial-specific genes with which to target the vasculature. Thus, angiogenesis research is at an exciting stage.

DEDICATION

Professor Luciano Martini, 1927–2017

The other Editor in Chief of the Encyclopedia, Professor Luciano Martini, passed away on July 13th, 2017. He was an internationally acclaimed authority in the field of endocrinology, in particular neuroendocrinology, a brilliant and imaginative scientist, and an impressive and erudite scholar.

Luciano achieved the venerable age of 90, and his long career was full of outstanding scientific achievements, leadership positions in academia and in scientific societies, academies, and committees.

Luciano received his MD degree from the University of Milan in 1950. He then rapidly progressed through junior academic ranks up to the position of Professor and Chairman of the Department of Pharmacology at the University of Perugia in 1968, and subsequently, in 1972, he returned to his *alma mater*, the University of Milan, as full Professor and Chairman of the Department of Endocrinology, a post he held until 2001. He served in Milan as director of the training and research program entitled Physiology of Reproduction for nearly 20 years and attracted to his team top-class Italian and foreign scientists to address his main research interests of neuroendocrine regulation of reproductive functions.

Scientific severity, ethical integrity, fine perception, and deep farsightedness describe best Luciano's character as a scientist. He created in his institute a scientific research group devoted to experimental endocrinology, which grew over the years in size and visibility and became widely recognized internationally. Luciano published more than 400 peer-reviewed and highly cited papers mainly in the fields of neuroendocrinology, endocrine oncology, physiology of reproduction, and steroid and energy metabolisms.

Luciano was a prolific editor of scientific books and journals, which include the two volumes of *Neuroendocrinology* and the nine biennial volumes of *Frontiers in Neuroendocrinology*. He was Editor in Chief of *Comprehensive Endocrinology* published in 12 volumes and the first Edition of *Encyclopedia of Endocrine Diseases*. He served as President in many national and international scientific societies including the International Society of Neuroendocrinology, the Italian Society of Endocrinology, the International Society of Endocrinology, and the European Federation of Endocrine Societies. For his scientific achievements Luciano received honorary doctorates in the universities of Liège, Santiago de Compostela, Pécs, and Milan, and he was the recipient of numerous scientific awards and invited academy memberships.

Luciano's portrait could not be complete if one forgets to mention his life-time passion for music. He was a well-trained and accomplished pianist, a passionate music listener, and an enthusiastic connoisseur of all types of music. He also was an amateur in visual arts and deeply interested in history.

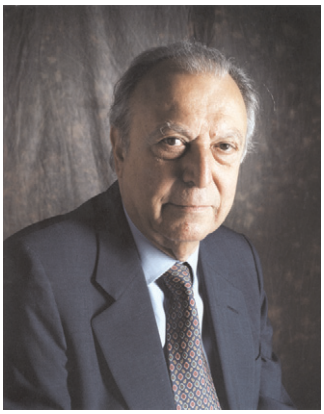
All of us who knew Professor Luciano Martini deeply mourn the loss of a great scientist and friend, the real "Il Maestro", teacher, colleague, and pioneer of modern neuroendocrinology. I trust Luciano would have been proud of this new edition of the Encyclopedia of Endocrine Diseases, and all of us having worked on its production would like to dedicate it to his memory.

Ilpo Huhtaniemi

Editor in Chief
Encyclopedia of Endocrine Diseases, 2nd edition

EDITORS IN CHIEF

Ilpo Huhtaniemi received his MD and PhD at University of Helsinki, Finland, did postdoctoral training in United States (UC San Francisco and NIH, Bethesda), and has been on sabbatical leave in Germany, United States and Scotland. In 1986–2002 he held the post of Professor and Chairman of Physiology at University of Turku, Finland. He moved in 2002 to UK to a Chair in Reproductive Endocrinology at Imperial College London, from which position he retired in 2015. He has received several national and international honors, amongst them a fellowship of The Academy of Medical Sciences, United Kingdom, and a Doctor Honoris Causa at the Medical University Łódź, Poland, and University of Szeged, Hungary. He was the Chief Managing Editor of *Molecular and Cellular Endocrinology* 1999-2017, has served in the Editorial Board of *Endocrinology and Endocrine Reviews* and is/has been the Editor or Editorial Board Member of several other scientific journals (e.g., *European Journal of Endocrinology*, *Clinical Endocrinology*, *Human Reproduction Update*, *Journal of Endocrinology*, *Molecular Human Reproduction*, *Reproduction*, *Asian Journal of Andrology*). He has extensive experience as Official of international scientific organizations (e.g., Past President of International Society of Andrology). His research interests include clinical and basic reproductive endocrinology, in particular the function of gonadotrophins and male reproductive endocrinology. He also has long-term interests in development of male contraception, hormone-dependent cancer, and the endocrinology of aging. He has authored about 700 peer-reviewed research articles and reviews, and his H-factor is 78.



Luciano Martini was born on May 14, 1927, in Milan, Italy. He obtained the degree of Medical Doctor "summa cum laude" on November 24, 1950, from the Faculty of Medicine of the University of Milan, Italy. He was Emeritus Professor of Pharmacology of the University of Perugia, Italy, and Emeritus Professor of Endocrinology of the University of Milan, Italy. He was Doctor Honoris Causa in Medicine of the Universities of Liège, Belgium, Santiago de Compostela, Spain, and Pécs, Hungary, and Doctor Honoris Causa in Biotechnological Sciences of the University of Milan, Italy. He was an author of more than 400 peer-reviewed scientific publications in the fields of endocrinology, neuroendocrinology, pharmacology, physiology of reproduction, steroid biochemistry, and basic oncology. He was elected member of the Accademia Nazionale dei Lincei (Italian National Academy) and of the American Academy of Arts and Sciences (Honorary Foreign Member).

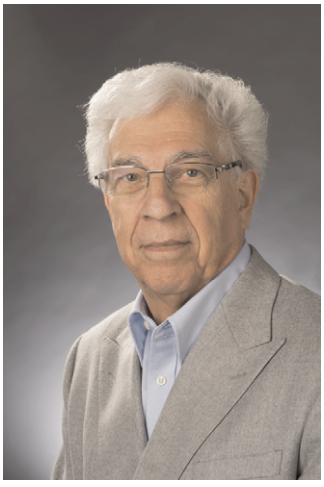
Luciano Martini acted as Editor in Chief of the journal *Frontiers in Neuroendocrinology* from 1990 to 2001, and was a Member of the Editorial Board of *Endocrinology* (Foreign Consulting Editor, 1961–65), as well as of several other speciality journals, such as *Experimental and Clinical Endocrinology*, *Biochemistry*, and *Steroids*. He has acted as Editor of several textbooks (e.g., *Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1966–67, and *Clinical Neuroendocrinology*, a textbook in 2 volumes, Academic Press, New York, 1977–82) as well of a series of books under the name *Comprehensive Endocrinology* (13 volumes), Raven Press, New York, 1979–84. He acted as Editor in Chief for the first edition of *Encyclopedia of Endocrine Diseases* (4 volumes), Academic Press-Elsevier, San Diego, 2004.

EDITORIAL BOARD

SECTION EDITORS

Professor **Jean-Jacques Body** has been trained as an endocrinologist and a medical oncologist. He was Head of the Department of Medicine at University Hospital Brugmann in Brussels and Full Professor of Medicine (Internal Medicine) at the Free University of Brussels, (ULB), Brussels, Belgium. He was previously Head of the Internal Medicine Clinic at Institute J. Bordet (Cancer Center of ULB). He has also developed the "Supportive Care Dept" at the same Institute. His particular research interests are osteoporosis and bone metastases. He has a long-standing interest for bone metabolism and turnover in osteoporosis and tumor bone diseases. He has authored or co-authored more than 250 international peer-reviewed papers and he counts more than 200 invited lectures for international meetings.

Felipe F. Casanueva is Professor of Medicine at University of Santiago de Compostela and Head of Department of Endocrinology and Nutrition at University Hospital Santiago. He has been President of the scientific societes, such as: European Federation of Endocrine Societies (EFES), The Pituitary Society, International Society of Endocrinology (ISE) and, Sociedad Española para el Estudio de la Obesidad (SEEDO). Has written more than 50 chapters in international books and published more than 700 papers in international journals. He has received several awards for research at national and international level, such as: Rey Jaime I to the Medical Research, Geoffrey Harris Prize in Neuroendocrinology, Fundación Lilly of Bio-medical Research Clinic, Fundacion Danone – Professional Career – Dr Carlos Martí Hennberg, European Hormone Medal by the European Society for Endocrinology (ESE); he has been named Honorary Doctorate in Medicine of the University of Łódź, Erciyes, and Belgrade, and Honorary Member of the European Society of Endocrinology.



Dr. **Jean-Louis Chiasson** is currently Full Professor of Medicine at the University of Montreal. He is Head of the Research Group on Diabetes and Metabolic Regulation at the Research Center of the Centre hospitalier de l'Université de Montréal (CRCHUM).

Dr. Chiasson obtained his MD at Laval University in Quebec City in 1967. He did his specialty training in Internal Medicine at Laval Univesity and in Endocrinology at McGill University. He then did a research Fellowship in Diabetes at Vanderbilt University in Nashville, Tennessee. In 1974–76 and 1978–80, he was appointed Assistant Professor in the Department of Medicine and Physiology respectively at Vanderbilt University. In 1980, he returned to Montreal as Assistant Professor in the Department of Medicine at the University of Montreal and as Endocrinologist at Hotel-Dieu Hospital, now merged into the Centre hospitalier de l'Université de Montréal.

Dr. Chiasson's research interests include the regulation of carbohydrate metabolism in health and diabetes, as well as the development and evaluation of new strategies for the treatment and prevention of diabetes and its vascular complications. He has contributed over 250 scientific publications and lectures nationally and internationally on various topics on diabetes mellitus, its pathogenesis, its treatment, and its prevention. His scientific contribution puts him in the prestigious club of the 100 most cited publications in the world in the field of diabetes.

Sophie Christin-Maitre received her MD at University of Paris XI and her PhD at University Paris VI, Pierre and Marie Curie, France. She did a postdoctoral training in United States (Massachusetts General Hospital, Harvard University, Boston); she specialized in reproductive medicine. She holds the post of Professor of Endocrinology at University of Sorbonne, Paris, France. She has been the head of the Adult Endocrine Unit, in Hôpital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, since 2011. She is a member of the INSERM research unit UMR S_933, specialized in identifying new genes in reproductive disorders. Her interests include clinical and basic reproductive endocrinology, in particular the management of patients with Turner syndrome, patients with primary ovarian insufficiency, patients with hypogonadisms, and patients with abnormalities of sex development. She has authored approximately 150 peer-reviewed research articles and reviews.

Ulla Feldt-Rasmussen is Professor at Copenhagen University and Chief of Medical Endocrinology, National University Hospital. Her research interests involve the thyroid gland and autoimmunity, as well as pituitary and adrenal dysfunction.

She has published more than 410 papers in peer-reviewed journals on e.g., thyroid hormones and body composition, thyroid autoimmunity and cancer, cytokines as regulators of endocrine cells, influence of thyroid disrupting chemicals on thyroid cells, growth hormone deficiency related to body composition, bone metabolism and other pituitary axes, and transition from adolescent to adult care, as well as several aspects of Fabry disease. In recent years her group has embarked on studies on pituitary function after traumatic brain injury in a nationwide setting, and focusing on diagnostic accuracy of pituitary testing procedures. She has further authored numerous proceedings, textbook chapters, and other publications; as well as organized numerous international meetings and postgraduate courses, and has led several European projects and other collaborations within many areas of endocrinology.

Professor Feldt-Rasmussen reviews for international journals, and is an editorial board member of several endocrine journals. She belongs to many international professional organizations, including the Endocrine Society, ETA, ATA, ENEA, and GRS; she has served as Secretary-Treasurer of ETA and as President of the ETA Cancer Research Network.

Professor Feldt-Rasmussen serves on the advisory boards of several ad hoc endocrine committees, and has received many prestigious prizes including the Mayo Clinic's Haynes Lecturer's Award and ETA's Pinchera Research Prize.

Wouter W. de Herder M.D. Ph.D. (1960) is Professor of Endocrine Oncology at the Erasmus MC in Rotterdam, the Netherlands. In this University Hospital he is chairman of a multidisciplinary group for endocrine oncology (tumorwerkgroep endocriene tumoren) and he is head of the ENETS centre of excellence for neuroendocrine tumors. His major research interests are neuroendocrine and endocrine tumors.

Professor de Herder received his M.D. in 1985 and his Ph.D. in 1990 from the Erasmus University in Rotterdam, the Netherlands.

He is a member of several international and Dutch national societies, such as the Dutch Society for Endocrinology (NVE), the Endocrine Society (USA), the European Society of Endocrinology (ESE), European Neuroendocrine Tumor Society (ENETS) and the North American Neuroendocrine Tumor Society (NANETS). He served as a board member of the Dutch Society for Endocrinology (NVE) (2009–14). He served as chairman (2006–08) and vice-chairman of ENETS (2008–10) (European Neuroendocrine Tumour Society). He is member of the advisory boards of ENETS and NANETS.

Professor de Herder has (co-)published over 400 peer-reviewed papers and book chapters and is a reviewer for many international journals.

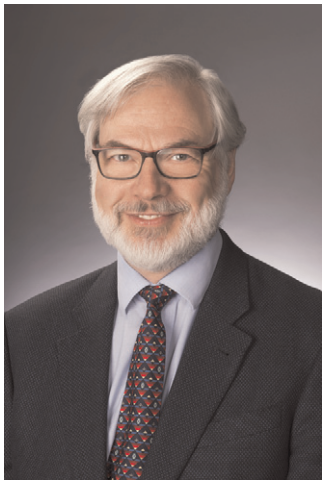
He is a member of the editorial boards of *Neuroendocrinology; Endocrinology, Diabetes & Metabolism Case Reports; Clinical Endocrinology*, and *Endocrine-Related Cancer*.

Professor de Herder has given over 200 invited presentations at Dutch national and international meetings.

Ieuan Hughes is currently Emeritus Professor of Pediatrics at the University of Cambridge and Honorary Consultant Pediatrician at Cambridge University Hospitals NHS Foundation Trust and Cambridge Biomedical Campus. He is the author of more than 300 papers and chapters across the whole range of paediatric endocrinology. His particular expertise is in disorders of sex development for which he coordinated the International Consensus on the approach to the investigation and management of this broad topic. Research interests focus on steroid enzyme deficiencies and molecular mechanisms of androgen action.
Professor Hughes has served on the editorial boards of several journals, including *Clinical Endocrinology*, *Journal of Clinical Endocrinology*, and *Metabolism* and *Archives of Disease in Childhood* where he was also the Associate Editor. He is Past-Secretary and President of the European Society for Pediatric Endocrinology and a recipient of the highest award of the Society, the Andrea Prader Prize. Professor Hughes is a James Spence Medallist of the Royal College of Pediatrics and Child Health for outstanding contributions to paediatric knowledge. He is a Fellow of the Academy of Medical Sciences, a Council Member of the Learned Society of Wales and a Trustee of two charities. The chapter on Disorders of Sex Development in *Williams Textbook of Endocrinology* (now in its 14e) by Hughes and co-authors is considered to be a definitive and up to date regular review of this topic, specific and key to pediatric endocrinology.

Dr. **Gregory Kaltsas** MD FRCP (Lon) is Professor in General Medicine and Endocrinology at the National and Kapodistrian University of Athens, Greece. He was trained in General Medicine in Athens, Greece and London, UK, and in Endocrinology at the Middlesex and St Bartholomew's Hospital, London, UK. He developed a particular interest in neuroendocrinology (pituitary and neuroendocrine tumors) and adrenal physiology and diseases. Upon returning to Greece he established a neuroendocrine network and he is currently running the European Neuroendocrine Tumor Society (ENETS) Center of Excellence at Laiko Hospital in Athens, Greece. He has served as a member of the advisory board of ENETS and of the Executive Committee of the European Neuroendocrine Association (ENEA) and he has been elected in the Executive Committee of the International Society of Endocrinology. He has recently been elected as a representative of the European Society of Endocrinology in the ExCo of the International Society of Endocrinology. He has published more than 300 original papers, reviews, and chapters and serves on editorial boards and as associate editor in several endocrine journals.

Jean-Marc Kaufman obtained his MD and PhD degrees at the Ghent University, Belgium. He was a Senior Postdoctoral Research Fellow (1982–84) in reproductive physiology at the University of Texas Medical School at Houston. He is board certified in Endocrinology and in Nuclear Medicine. In 1985 he joined the staff of the Ghent University Hospital; he headed the department of Endocrinology from 2003 to 2014 and the Laboratory for Hormonology from 1995 to 2014. He was appointed in 1993 Professor of Medicine at the Ghent University (1993) and is past Chair of the Department of Internal Medicine at the Ghent University (2010–14). From October 1st 2014 he is Professor Emeritus at the Ghent University where he is pursuing clinical and research activities. Main research interests are in the assessment, regulation, and action of sex steroids with focus on their role in health, disease, and aging in men, and in osteoporosis in men. He is (co)author of over 300 publications in international peer-reviewed journals.



André Lacroix, MD FCAHS is Professor of Medicine, Division of Endocrinology at Centre hospitalier de l'Université de Montréal (CHUM). His areas of interest include the mechanisms of adrenal Cushing syndrome, primary aldosteronism, adrenal tumorigenesis, the role of aberrant adrenal hormone receptors in adrenal overfunction, as well as new drugs in the therapy of Cushing disease, primary aldosteronism and adrenocortical cancer.
He was trained at the University of Montreal followed by fellowships in Endocrinology and research at Vanderebilt University and National Institutes of Health, USA. He was Chairman of Medicine and Director of Academic Affairs at CHUM. Former President of the Canadian Society of Endocrinology and Metabolism, he is currently chairperson of the International Society of Endocrinology (2016–20), Editor, Adrenal Section of UpToDate and *Encyclopedia of Endocrinology*, Senior Editor of the *European Journal of Endocrinology*. Fellow of the Canadian Academy of Health Sciences since 2008 and Foreign member of the National Academy of Medicine of France since 2016.

Franco Mantero received his MD at the University of Padua, Italy, did postdoctoral training in Switzerland (Clinique Medicale Therapeutique, Hopital Cantonal, University of Geneva) and in United States (University of California, San Francisco), and has been on sabbatical leave in United Kingdom, United States, and France. He held a post of Associate Professor in Medicine at the Institute of Semeiotica Medica, University of Padua (1981–86). In 1986 he moved to the University of Catania to the Chair of Andrology and Endocrinology, in 1992 to the University of Ancona, and in 2000 to the University of Padua to the Chair of Endocrinology and Chief of the Endocrinology Unit of the Department of Medicine. He has received national and international honors, including a Doctor Honoris Causa at the Semmelweis University, Budapest, Hungary.
He has been Editorial Board Member of several scientific journals (e.g., *Clinical Endocrinology*, *Endocrinology*, *Journal of Hypertension*, *Journal of Endocrinology Investigation Steroids*)
He has served as Member of the Council of several international scientific societies (including International Society of Endocrinology, International Aldosterone Conference, Journee Klotz d'Endocrinologie Clinique, ENS@T) and one of the founders of the European Network for the Study of Adrenal Tumors. His research interests include clinical and basic endocrinology of the adrenal gland and endocrinology of hypertension, in particular pathophysiology of mineralocorticoids and primary aldosteronism. He has authored approximately 500 peer–reviewed articles and edited several books and proceedings.

Jorma Toppari, MD, PhD, is Professor of Physiology at the University of Turku and Chief Physician of Pediatric Endocrinology at Turku University Hospital, Turku, Finland. He is also Adjunct Professor in the Department of Growth and Reproduction at the University of Copenhagen, Denmark. He has served as chief editor of International Journal of Andrology (2001–09), and has been on editorial boards of several endocrinological journals, including currently *Endocrinology* and *Journal of Clinical Endocrinology and Metabolism*. He is the past President of the European Academy of Andrology. He has made numerous contributions to the studies on endocrine disruption in the past 20 years. He has published approximately 400 articles on endocrinology.

Jacquetta Trasler is a James McGill Professor in the Departments of Pediatrics, Human Genetics, and Pharmacology and Therapeutics at McGill University and a Senior Scientist at the Research Institute of the McGill University Health Centre (RI-MUHC). She received her MD and PhD degrees from McGill University followed by postdoctoral training in reproductive molecular biology at Tufts University in Boston. She has served as Director of the McGill University MD-PhD Program, Scientific Director of the Montreal Children's Hospital Research Institute (and simultaneously as Deputy Director/CSO of the RI-MUHC), President of the Canadian Fertility and Andrology Society, Member of the Institute Advisory Board for the Canadian Institutes of Health Research (CIHR) Institute of Genetics and currently serves on the CIHR Stem Cell Oversight Committee and College of Reviewers. Her research focuses on epigenetics and epigenomics to better understand the molecular and cellular targets for drug effects on germ cells with implications for the resulting offspring. She has been involved in scientific program organization for numerous meetings in the field of reproductive biology and medicine and is collaborating with national and international colleagues in clinical studies to examine how assisted reproductive technologies, infertility, drug treatment, and folate deficiency and supplementation impact the human epigenome including that of future generations.

Christina Wang, MD is Professor of Medicine, Assistant Dean at the David Geffen School of Medicine at UCLA, and Associate Director for Clinical and Translational Science Institute and a faculty member of the Division of Endocrinology, Department of Medicine, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, California.

Dr. Wang has been involved in many funded basic and clinical research studies. Her current clinical research studies include androgen replacement therapy, hormonal male contraceptive development, late onset hypogonadism, accurate assessment of serum androgens, and diet and androgen metabolism. Her basic research studies focus on the regulation of spermatogenesis and mitochondrial derived peptides in spermatogenesis.

She has authored over 300 peer-reviewed publications, 67 chapters and reviews mainly on male reproductive biology including characterization of the pharmacokinetics and efficacy of androgens in men, trials of hormonal male contraceptive, regulation of germ cell apoptosis, and reproductive aging. Dr. Wang served on the Executive Council, several committees and was the President of the American Society of Andrology (2006–07). She also served the International Society of Andrology as Secretary (2001–05) and Chair of the Program Organizing Committee (2005–09). She was President of the International Society of Andrology (2009–13). She is a member of the Research Group on Methods for the Regulation of Male Fertility of the World Health Organization since 1984 and Chairperson (1991–2002).

She has mentored many physician and scientist and is an advocate of young investigators. Dr. Wang has been invited speaker and distinguished lecturer at many national and international endocrinology, reproductive endocrinology, and andrology conferences.

Sheffield Children's NHS FT and University of Sheffield, Sheffield, United Kingdom

Joanne C. Blair
Alder Hey Children's Hospital, Liverpool, United Kingdom

Sofie Bliddal
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Floyd E. Bloom
The Scripps Research Institute, La Jolla, CA, United States

Bruce Blumberg
University of California Irvine, Irvine, CA, United States

Fausto Bogazzi
University of Pisa, Pisa, Italy

Marco Bonomi
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Julia K. Bosdou
Aristotle University of Thessaloniki, Thessaloniki, Greece

Anja Bosy-Westphal
University of Kiel, Kiel, Germany

Philippe Bouchard
Sorbonne University, Paris, France

Roger Bouillon
Laboratory of Clinical and Experimental Endocrinology, KU Leuven, Leuven, Belgium; and University Hospitals, Leuven, Belgium

Isabelle Bourdeau
Centre hospitalier de l'Université de Montréal (CHUM), Montréal, QC, Canada

Jean-Pierre Bourguignon
University of Liège, Liège, Belgium; and CHU de Liège, Chênée, Belgium

Mary L. Bouxsein
Beth Israel Deaconess Medical Center, Boston, MA, United States; Harvard Medical School, Boston, MA, United States; and Massachusetts General Hospital, Boston, MA, United States

Elvira V. Bräuner
University of Copenhagen, Copenhagen, Denmark

S.D. Brain
King's College London, London, United Kingdom

Glenn D. Braunstein
Cedars-Sinai Medical Center, Los Angeles, CA, United States; and University of California Los Angeles, Los Angeles, CA, United States

Ralph Brecheisen
Maastricht University, Maastricht, The Netherlands

Claire Briet
University Hospital of Angers, Angers, France; and University of Angers, Angers, France

Janet Brown
University of Sheffield, Sheffield, United Kingdom

Thierry Brue
Reference Center for Rare Pituitary Diseases, Assistance Publique Hopitaux de Marseille, La Conception Hospital, Marseille Cedex 05, France; and INSERM UMR-U910, Aix Marseille University, Marseille Cedex 05, France

Antonio Bruni
University of Alberta, Edmonton, AB, Canada

Rosa Maria Bruno
University of Pisa, Pisa, Italy

Aude Bruyneel
Free University of Brussels, Brussels, Belgium

Michael Buchfelder
University Hospital Erlangen, Erlangen, Germany

Krupali Bulsari
Princess Alexandra Hospital, Brisbane, QLD, Australia; and University of Queensland, Brisbane, QLD, Australia

Peter Burckhardt
Hirslanden Clinic, Lausanne, Switzerland

Albert G. Burger
University of Bern, Bern, Switzerland; and University of Geneva, Geneva, Switzerland

Alexander S. Busch
University of Copenhagen, Copenhagen, Denmark

Luca Busetto
University of Padua, Padua, Italy

Gary Butler
University College London Hospital NHS Trust, London, United Kingdom; and UCL Great Ormond Street Institute of Child Health, London, United Kingdom

Véronique Cadoret
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France; and CHRU Bretonneau, Medicine and Biology of Reproduction, CECOS, Tours, France

Lorenzo A. Calò
University of Padua, Padua, Italy

Irene Campi
University of Milan, Milan, Italy

Biagio Cangiano
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Letizia Canu
University of Florence, Florence, Italy

Perrine Capmas
Bicetre Hospital, Le Kremlin Bicetre, France

Carlo Cappelli
University of Brescia, Brescia, Italy; and Endocrine and Metabolic Medicine Unit, ASST Spedali Civili di Brescia, Brescia, Italy

Marta Caretto
University of Pisa, Pisa, Italy

Robert M. Carey
University of Virginia Health System, Charlottesville, VA, United States

Rafael Carmena
University of Valencia, Valencia, Spain

Nancy Carrasco
Yale School of Medicine, New Haven, CT, United States

Olivera Casar-Borota
Uppsala University, Uppsala, Sweden

Livio Casarini
University of Modena and Reggio Emilia, Modena, Italy

James Casella-Mariolo
Sapienza University of Rome, Rome, Italy

C. Casellini
Eastern Virginia Medical School, Norfolk, VA, United States

Lidia Castagneto-Gissey
Sapienza University of Rome, Rome, Italy

Maurizio Castellano
University of Brescia, Brescia, Italy; and Endocrine and Metabolic Medicine Unit, ASST Spedali Civili di Brescia, Brescia, Italy

Frederic Castinetti
Reference Center for Rare Pituitary Diseases, Assistance Publique Hopitaux de Marseille, La Conception Hospital, Marseille Cedex 05, France; and INSERM UMR-U910, Aix Marseille University, Marseille Cedex 05, France

Frederic Castinetti
Aix Marseille University, Marseille, France

Victoria Catalán
University of Navarra, Pamplona, Spain; CIBEROBN, ISCIII, Pamplona, Spain; and IdiSNA, Pamplona, Spain

Victoria Catalán
Metabolic Research Laboratory, University of Navarra, Pamplona, Spain; CIBEROBN, Carlos III Health Institute, Pamplona, Spain; and Instituto de Investigación Sanitaria de Navarra (IdiSNA) Pamplona, Spain

Richard L. Cate
Boston University, Boston, MA, United States

Sophie Catteau-Jonard
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Anne Caufriez
Free University of Brussels, Brussels, Belgium

Isadora Pontes Cavalcante
University of São Paulo, São Paulo, Brazil

Etienne Cavalier
University of Liège, Liège, Belgium

Jonas Čeponis
Lithuanian University of Health Sciences, Kaunas, Lithuania

Filomena Cetani
University of Pisa, Pisa, Italy; and University Hospital of Pisa, Pisa, Italy

Nathalie Chabbert-Buffet
Sorbonne University, Paris, France

Alan Chait
University of Washington, Seattle, WA, United States

Peter T. Chan
McGill University Health Center, Royal Victoria Hospital, Montreal, QC, Canada

Philippe Chanson
Assistance Publique-Hôpitaux de Paris, Service d'Endocrinologie et des Maladies de la Reproduction and Centre de Référence des Maladies Hypophysaires Rares, Bicêtre Hospital, Le Kremlin-Bicêtre, France; Université Paris-Sud, Le Kremlin-Bicêtre, France; and Institut National de la Santé et de la Recherche Médicale (INSERM) U1185, Le Kremlin-Bicêtre, France

Karen E. Chapman
University of Edinburgh, Edinburgh, United Kingdom

Helaine Laiz Silva Charchar
University of São Paulo, São Paulo, Brazil

F. Charles Brunicardi
University of California Los Angeles, Los Angeles, CA, United States

Evangelia Charmandari
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Sumana Chatterjee
Barts and the London School of Medicine and Dentistry, London, United Kingdom

Eleftherios Chatzellis
251 Hellenic Air Force and VA Hospital, Athens, Greece

Tim Cheetham
Newcastle University, Newcastle-upon-Tyne, United Kingdom

Wassim Chemaitilly
St. Jude Children's Research Hospital, Memphis, TN, United States

H. Chen
University of Alabama at Birmingham, Birmingham, AL, United States

Sabrina Chiloiro
Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

Luca Chiovato
University of Pavia, Pavia, Italy

E.R. Christ
University of Bern, Bern, Switzerland; and University of Geneva, Geneva, Switzerland

Mirjam Christ-Crain
University Hospital Basel, Basel, Switzerland

Sophie Christin-Maitre
Hospital Saint-Antoine, Assistance-Publique Hôpitaux de Paris, Paris, France; and Sorbonne University, Paris, France

George P. Chrousos
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Janet S. Chuang
Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States

Maria Verena Cicala
South Tyrolian Academy of General Practice, Bolzano, Italy

Francesca Cioppi
University of Florence, Florence, Italy

Frédérique Clément
Project-team Mycenae, Inria Center of Paris, Paris, France

Philippe Clézardin
INSERM, Faculty of Medicine Lyon East, Lyon, France

Hedi L. Claahsen van de Grinten
Radboud University Medical Center, Nijmegen, the Netherlands

Mélanie Claps
University of Brescia, Brescia, Italy

Bart L. Clarke
Mayo Clinic, Rochester, MN, United States

Laurie E. Cohen
Harvard Medical School, Boston, MA, United States; and Dana-Farber/Boston Children's Hospital Cancer and Blood Disorders Center, Boston, MA, United States

Annamaria Colao
University of Naples Federico II, Naples, Italy

Annamaria Colao
Federico II University of Naples, Naples, Italy

Robert Coleman
University of Sheffield, Sheffield, United Kingdom

James J. Colt
Weill Cornell Medicine, New York, NY, United States

Oscar Coltell
Carlos III Health Institute, Madrid, Spain; and University Jaume I, Castellón, Spain

Robert V. Considine
Indiana University School of Medicine, Indianapolis, IN, United States

Lindsay S. Cooley
University of Bordeaux, Pessac, France

Martine Cools
Ghent University Hospital, Ghent, Belgium

Cyrus Cooper
MRC Lifecourse Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom

Cyrus Cooper
University of Southampton, Southampton, United Kingdom; University of Southampton and University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; WHO Collaborating Centre for Public Health Aspects of Musculoskeletal Health and Aging, Liège, Belgium; and University of Oxford, Oxford, United Kingdom

Georges Copinschi
Free University of Brussels, Brussels, Belgium

F. Coppedè
University of Pisa, Pisa, Italy

Claire Cordroch
University Hospital of Bordeaux, Bordeaux, France

Dolores Corella
University of Valencia, València, Spain; and Carlos III Institute of Health, Madrid, Spain

Isabel M. Cornejo-Pareja
Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Giovanni Corona
University of Florence, Florence, Italy; and Bologna Maggiore-Bellaria Hospital, Bologna, Italy

Dalila B. Corry
David Geffen UCLA School of Medicine, Los Angeles, CA, United States

Karen E. Cosgrove
University of Manchester, Manchester, United Kingdom

Maria Manuel Costa
Centro Hospitalar São João, Porto, Portugal; and Queen Mary University of London, London, United Kingdom

Luís Costa
Hospital of Santa Maria, Institute of Molecular Medicine, Faculty of Medicine, University of Lisbon, Lisbon, Portugal

Mariana Costanzo
Hospital de Pediatría Garrahan, Buenos Aires, Argentina

Carine Courtillot
Sorbonne University, Paris, France

Rafael Coveñas
University of Salamanca, Salamanca, Spain

Danila Covelli
University of Milan, Milan, Italy

Laura E. Cowen
Georgetown University Medical Center, Washington, DC, United States

Brittany Croft
Murdoch Children's Research Institute, Melbourne, VIC, Australia

William C. Cushman
University of Tennessee Health Science Center, Memphis, TN, United States

Daniele Cusi
Bio4Dreams, Milan, Italy

Lanfranco D'Elia
Federico II University of Naples, Naples, Italy

Stella D'Oronzo
University of Sheffield, Sheffield, United Kingdom

Catherine Dacou-Voutetakis
University of Athens, Athens, Greece

Rozenn Dalbies-Tran
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Adrian F. Daly
University Hospital Center of Liège, Liège, Belgium

A.H. Jan Danser
Erasmus MC, Rotterdam, The Netherlands

Jessica Daolio
Arcispedale Santa Maria Nuova of Reggio Emilia, Reggio Emilia, Italy

Emile Daraï
Sorbonne University, Paris, France

Mehul T. Dattani
Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom; and UCL Institute of Child Health, London, United Kingdom

Justin H. Davies
Southampton Children's Hospital, Southampton, United Kingdom

Stephen N. Davis
University of Maryland School of Medicine, Baltimore, MD, United States

Shanlee M. Davis
University of Colorado, Boulder, CO, United States

Adolfo J. de Bold
University of Ottawa, Ottawa, ON, Canada

Giuseppina De Filpo
University of Florence, Florence, Italy

K. De Gendt
Catholic University of Leuven, Leuven, Belgium

Wouter W. de Herder
Department of Internal Medicine—Sector of Endocrinology, Erasmus MC - University Hospital Rotterdam, Rotterdam, The Netherlands

Frank H. de Jong
Erasmus University Medical Center, Rotterdam, The Netherlands

Frank H. de Jong
Erasmus University Medical Centre, Rotterdam, The Netherlands

Peter W. de Leeuw
Maastricht University Medical Center, Maastricht, The Netherlands

Laura De Marinis
Pituitary Unit, Catholic University of Sacred Heart, Rome, Italy

Maria Cristina De Martino
University of Naples Federico II, Naples, Italy

Sabine M.P.F. de Muinck Keizer-Schrama
Erasmus Medical Center – Sophia Children's Hospital, Rotterdam, The Netherlands

Beatriz Marinho de Paula Mariani
University of São Paulo, São Paulo, Brazil

Jean De Schepper
Free University of Brussels, Brussels, Belgium

Miguel Debono
The University of Sheffield, Sheffield, United Kingdom

Peter A. Deddish
University of Illinois College of Medicine, Chicago, IL, United States

Asma Deeb
Mafraq Hospital, Abu Dhabi, United Arab Emirates

Olaf M. Dekkers
Leiden University Medical Centre, Leiden, The Netherlands

Rita Del Pinto
University of L'Aquila, L'Aquila, Italy

Anne Delbaere
Free University of Brussels, Brussels, Belgium

Elaine M Dennison
MRC Lifecourse Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom

Didier Dewailly
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Nathalie di Clemente
Pierre and Marie Curie University, Paris, France

Guido Di Dalmazi
Alma Mater Studiorum University of Bologna, Bologna, Italy

N. Di Iorgi
University of Genoa, Genoa, Italy

Paola Di Mauro
INSERM, Faculty of Medicine Lyon East, Lyon, France

Chantal Diaz-Latoud
INSERM, Faculty of Medicine Lyon East, Lyon, France

Michael DiMattina
Dominion Fertility, Arlington, VA, United States

Georgios K. Dimitriadis
University of Warwick Medical School, Coventry, United Kingdom; and Imperial College London, London, United Kingdom

Na Ding
Anhui Medical University, Hefei, China

Maria R. Dionísio
Hospital of Santa Maria, Lisbon, Portugal

S. Dizon
Queen's University, Kingston, ON, Canada

Graham J. Dockray
University of Liverpool, Liverpool, United Kingdom

Marie-Madeleine Dolmans
Pôle de Recherche en Gynécologie, Institut de Recherche Expérimentale et Clinique (IREC), Catholic University of Leuven, Brussels, Belgium; and Cliniques Universitaires Saint Luc, Brussels, Belgium

G.A. Donnan
University of Melbourne, Melbourne, VIC, Australia

Jacques Donnez
Society for Research into Infertility (SRI, Société de Recherche pour l'Infertilité), Brussels, Belgium; and Catholic University of Leuven, Leuven, Belgium

Olivier Donnez
Institut du Sein et de Chirurgie Gynécologique d'Avignon (ICA), Polyclinique Urbain V, Avignon, France

Robert M. Dores
University of Denver, Denver, CO, United States

Maria Dracopoulou
University of Athens, Athens, Greece

A. Drexler
UCLA School of Medicine, Los Angeles, CA, United States

Stenvert L.S Drop
Erasmus Medical Center-Sophia Children's Hospital, Rotterdam, The Netherlands

Ludivine Drougat
Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, United States

Jérôme Dulon
Sorbonne University, Paris, France

Agathe Dumont
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Typhanie Dumontet
CNRS, INSERM, Clermont Auvergne University, Clermont-Ferrand, France

Leo Dunkel
Queen Mary University of London, London, United Kingdom

Mark J. Dunne
University of Manchester, Manchester, United Kingdom

Leonidas H. Duntas
University of Athens, Athens, Greece

Richard Eastell
University of Sheffield, Sheffield, United Kingdom

Camilla Eckert-Lind
University of Copenhagen, Copenhagen, Denmark

Grigoris Effraimidis
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Urs Eiholzer
Paediatric Endocrine Center Zurich (PEZZ), Zurich, Switzerland

Graeme Eisenhofer
Technical University Dresden, Dresden, Germany

Jean-Marie Ekoe
CHUM University of Montreal, Montreal, QC, Canada

Mustapha El Lakis
National Cancer Institute, Bethesda, MD, United States

Sébastien Elis
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Rossella Elisei
University of Pisa, Pisa, Italy

Gregory R. Emkey
Pennsylvania Regional Center for Arthritis & Osteoporosis Research, Wyomissing, PA, United States

Klaus Engelke
University of Erlangen-Nürnberg, Erlangen, Germany

T. Erbas
Hacettepe University, Ankara, Turkey

Ervin G. Erdös
University of Illinois College of Medicine, Chicago, IL, United States

Héctor F. Escobar-Morreale
University Hospital Ramón y Cajal, Madrid, Spain; University of Alcalá, Madrid, Spain; Ramón y Cajal Institute for Health Research IRYCIS, Madrid, Spain; and Biomedical Research Network Center in Diabetes and Related Metabolic Diseases CIBERDEM, Madrid, Spain

Marc Espié
Saint-Louis Hospital, Paris

Stéphanie Espiard
Claude Huriez Hospital, Lille University Hospital, Lille, France

Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Electron Kebebew
National Cancer Institute, Bethesda, MD, United States; and The George Washington University, Washington, DC, United States

Daniel M. Kemp
Massachusetts General Hospital, Boston, MA, United States; and Harvard University, Boston, MA, United States

Ivana Kholová
Tampere University, Tampere, Finland

Wieland Kiess
University of Leipzig, Leipzig, Germany

John Paul Kilday
Royal Manchester Children's Hospital, Manchester, United Kingdom

Andreas Kjær
Nuclear Medicine & PET, ENETS NET CoE, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Marianne Klose
Copenhagen University Hospital, Copenhagen, Denmark

Ulrich Knigge
ENETS NET Center of Excellence (CoE), Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

Christian A. Koch
Technical University of Dresden, Dresden, Germany; and Medicover MVZ Oldenburg, Oldenburg, Germany

X. Kodji
King's College London, London, United Kingdom

Kamila Kolanska
Sorbonne University, Paris, France

Efstratios M. Kolibianakis
Aristotle University of Thessaloniki, Thessaloniki, Greece

Anne-Sophie C.A.M. Koning
Leiden University Medical Center, Leiden, The Netherlands

George Kontogeorgos
``George Gennimatas'' General Hospital of Athens, Athens, Greece; National and Kapodistrian University of Athens, Athens, Greece; and University of Toronto, Toronto, ON, Canada

John J. Kopchick
Ohio University, Athens, OH, United States

Márta Korbonits
Queen Mary University of London, London, United Kingdom

Olympia Koulouri
University of Cambridge, Cambridge, United Kingdom; and National Institute for Health Research Cambridge Biomedical Research Centre, Cambridge, United Kingdom

Stavroula Kousteni
Columbia University, New York, NY, United States

Jolanta Krajewska
Maria Sklodowska-Curie Memorial Institute-Cancer Center, Gliwice, Poland

Csilla Krausz
University of Florence, Florence, Italy

Berit Kriström
Umeå University, Umeå, Sweden

Helen Kroening
University of Sheffield, Sheffield, United Kingdom

Abraham A Kroon
Maastricht University Medical Center, Maastricht, The Netherlands

Heiko Krude
Charité–Medicine University, Berlin, Germany; and Institute of Experimental Pediatric Endocrinology, Berlin, Germany

George A. Kuchel
University of Connecticut Health Center, Farmington, CT, United States

Alexandra Kulle
Christian-Albrechts University of Kiel (CAU), Kiel, Germany; and University Hospital of Schleswig-Holstein (UKSH), Kiel, Germany

Ioannis Kyrou
Harokopio University, Athens, Greece; Aston University, Birmingham, United Kingdom; University of Warwick, Coventry, United Kingdom; and University Hospitals Coventry and Warwickshire NHS Trust, Coventry, United Kingdom

André Lacroix
Endocrine Division and Research Center, Centre hospitalier de l'Université de Montréal (CHUM), Montreal, QC, Canada

Svetlana Lajic
Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

Elizabeth M. Lamos
University of Maryland School of Medicine, Baltimore, MD, United States

Fabio Lanfranco
University of Turin, Turin, Italy

Bente L. Langdahl
Aarhus University Hospital, Aarhus, Denmark

Seppo W. Langer
ENETS NET CoE, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

A. Lania
University of Milan, Milan, Italy

E. Laspa
University Hospital of Ioannina, Ioannina, Greece

Guido Lastra
University of Missouri, Columbia, MO, United States

Ana Claudia Latronico
University of São Paulo, São Paulo, Brazil

Vincent Laudet
Sorbonne University, Banyuls-sur-Mer, France

S. Lauhon
University of Michigan, Ann Arbor, MI, United States

Michaël R. Laurent
University Hospitals Leuven, Leuven, Belgium

Fabio Lauria
National Research Council of Italy, Avellino, Italy

John H. Lazarus
Institute of Molecular and Experimental Medicine, Cardiff University, Cardiff, United Kingdom; and University Hospital of Wales, Cardiff, United Kingdom

Albert Lecube
University Hospital Arnau de Vilanova, Lleida, Spain; Obesity, Diabetes and Metabolism Research Group (ODIM), Lleida Biomedical Research Institute (IRBLleida), Lleida, Spain; and University of Lleida, Lleida, Spain

Benjamin Z. Leder
Harvard Medical School, Boston, MA, United States

E.C.-H. Lee
University of Connecticut, Storrs, CT, United States

Peter Lee
Penn State Hershey Medical Center, Hershey, PA, United States

Christoph Lees
Queen Charlotte's and Chelsea Hospital, London, United Kingdom; and Imperial College London, London, United Kingdom

Pierre J. Lefèbvre
University of Liège, Liège, Belgium

Lisa-Marie Legault
University of Montreal, Montreal, QC, Canada

Jacques W.M. Lenders
Radboud University Medical Center, Nijmegen, The Netherlands; and Technical University Dresden, Dresden, Germany

Livia Lenzini
University of Padua, Padua, Italy

A.M. Leung
Division of Endocrinology, UCLA David Geffen School of Medicine, Los Angeles, CA United States

Stafford Lightman
University of Bristol, Bristol, United Kingdom

Padiporn Limumpornpetch
University of Leeds, Leeds, United Kingdom; and Prince of Songkla University, Songkhla, Thailand

M. Link
University of Utah, Salt Lake City, UT

Benjamin A. Lipsky
University of Washington, Seattle, WA, United States; and Veterans Affairs Puget Sound Health Care System, Seattle, WA, United States

Saúl Lira-Albarran
National Institute of Medical Sciences and Nutrition SZ (INCMNSZ), Mexico City, Mexico

Kirstie Lithgow
University of Calgary, Calgary, AB, Canada

Peter Y. Liu
Clinical and Translation Science Institute, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Sarantis Livadas
University of Athens, Athens, Greece

Clare H. Llewellyn
University College London, London, United Kingdom

V. Llorente-Cortés
Cardiovascular Research Center, CSIC-ICCC Hospital Santa Creu I Sant Pau, Barcelona, Spain

Jay S. Loeffler
Massachusetts General and Harvard Medical School, Boston, MA, United States

Marc Lombès
University Paris-Sud, University of Paris-Saclay, Le Kremlin-Bicêtre, France; and Bicêtre Hospital, Le Kremlin Bicêtre, France

Lindsey A. Loomba-Albrecht
University of California Davis, Davis, CA, United States

Miguel López
CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain; and University of Santiago de Compostela (USC), Santiago de Compostela, Spain

Carolina López-Cano
University Hospital Arnau de Vilanova, Lleida, Spain; Obesity, Diabetes and Metabolism Research Group (ODIM), Lleida Biomedical Research Institute (IRBLleida), Lleida, Spain; and University of Lleida, Lleida, Spain

Isabel Losano
University of Turin, Turin, Italy

David A. Lovejoy
University of Toronto, Toronto, ON, Canada

María Lozano-Madrid
Carlos III Health Institute, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Gertrud Lund
CINVESTAV Irapuato Unit, Irapuato, Gto, Mexico

Elena Lundberg
Umeå University, Umeå, Sweden

Aldons J. Lusis
University of California Los Angeles, Los Angeles, CA, United States

Lorenza Macrina
IRCCS San Raffaele Scientific Institute, Milan, Italy

Filippo Maffezzoni
University of Brescia, Brescia, Italy

Mario Maggi
University of Florence, Florence, Italy; and Istituto Nazionale Biostrutture e Biosistemi, Rome, Italy

M. Maghnie
University of Genova, Genova, Italy

Amita Mahajan
University of Calgary, Calgary, AB, Canada

Eamonn R. Maher
Cambridge Biomedical Campus, Cambridge, United Kingdom

Virginie Maillard
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Katharina M. Main
University of Copenhagen, Copenhagen, Denmark

Gabriel M. Makhlouf
Virginia Commonwealth University, Richmond, VA, United States

Konstantinos Makris
KAT General Hospital, Athens, Greece; and University of Athens, Athens, Greece

Willy J. Malaisse
Free University of Brussels, Brussels, Belgium

J. Maletkovic
UCLA School of Medicine, Los Angeles, CA, United States

Federico Mallo Ferrer
Biomedical Research Center (CINBIO), University of Vigo, Vigo, Spain

Núria Mallorquí-Bagué
Carlos III Health Institute, Madrid, Spain; and University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Meera Mallya
Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom

Giuseppe Mancia
University of Milan-Bicocca, Monza, Italy

Jacqueline Mandelbaum
Tenon Hospital, Paris, France; and Pierre and Marie Curie University, Paris, France

Massimo Mannelli
University of Florence, Florence, Italy

Franco Mantero
University of Padua, Padua, Italy

Paolo Manunta
University Vita-Salute San Raffaele, Milan, Italy

Claudio Marcocci
University of Pisa, Pisa, Italy; and University Hospital of Pisa, Pisa, Italy

Roxana Marino
Hospital de Pediatría Garrahan, Buenos Aires, Argentina

Gabriel V. Markov
Sorbonne University, Banyuls-sur-Mer, France

Laura Marroquí
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Gary R. Marshall
University of Pittsburgh School of Medicine, Pittsburgh, PA, United States

Ritzén E. Martin
Karolinska Institute, Stockholm, Sweden

Laetitia Martinerie
University Paris-Sud, University of Paris-Saclay, Le Kremlin-Bicêtre, France; Service d'Endocrinologie Pédiatrique, Hôpital Robert Debré, Paris, France; and Paris Diderot University, Paris, France

Antoine Martinez
CNRS, INSERM, Clermont Auvergne University, Clermont-Ferrand, France

Daniel B. Martinez-Arguelles
McGill University, Montreal, QC, Canada

Sergio Martinez-Hervas
University of Valencia, Valencia, Spain; and CIBERDEM-Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, ISCIII, Madrid, Spain

Enio Martino
University of Pisa, Pisa, Italy

Katia Maruca
IRCCS San Raffaele Scientific Institute, Milan, Italy

George Mastorakos
National and Kapodistrian University of Athens, Aretaieion Hospital, Athens, Greece

Yuji Matsuzawa
Sumitomo Hospital, Osaka, Japan

Gherardo Mazziotti
Carlo Poma Hospital, Mantova, Italy

Eugene V. McCloskey
MRC Arthritis Research UK Centre for Integrated Research in Musculoskeletal Aging, Metabolic Bone Center, Northern General Hospital, Sheffield, United Kingdom; University of Sheffield, Sheffield, United Kingdom; and University of Sheffield Medical School, Sheffield, United Kingdom

Timothy McClure
Lefrak Center for Robotic Surgery, Weill Cornell Medicine, New York, NY, United States

Ken McElreavey
Institut Pasteur, Paris, France

Bruce S. McEwen
Rockefeller University, New York, NY, United States

Serge McGraw
University of Montreal, Montreal, QC, Canada

Christian Meier
University Hospital Basel, Basel, Switzerland

Onno C. Meijer
Leiden University Medical Center, Leiden, The Netherlands

Berenice B. Mendonca
University of São Paulo, São Paulo, Brazil

Gabriele Mertes
Mülheim, Germany

Gemma Mestre-Bach
University Hospital of Bellvitge-IDIBELL, Barcelona, Spain

Boyd E. Metzger
Northwestern University Feinberg School of Medicine, Chicago, IL, United States

Ralph G. Meyer
Utah State University, Logan, UT, United States

Heino F.L. Meyer-Bahlburg
New York State Psychiatric Institute, New York, NY, United States; and College of Physicians & Surgeons of Columbia University, New York, NY, United States

Mirella L. Meyer-Ficca
Utah State University, Logan, UT, United States

Dragan Micic
University of Belgrade, Belgrade, Serbia

Jesús E. Millán Núñez-Cortes
Gregorio Marañon University General Hospital, Madrid, Spain; and Complutense University of Madrid, Madrid, Spain

Joaquín J. Millán Pérez
Complutense University of Madrid, Madrid, Spain

Paul D. Miller
University of Colorado Health Sciences Center, Denver, CO, United States

Geltrude Mingrone
Catholic University, Rome, Italy; and Guy's Campus, King's College London, London, United Kingdom

Katrina M. Mirabito Colafella
Erasmus MC, Rotterdam, The Netherlands; and Monash University, Melbourne, VIC, Australia

Alexander D. Miras
Imperial College London, London, United Kingdom

Philippe Monget
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Danielle Monniaux
PRC, CNRS, IFCE, INRA, University of Tours, Nouzilly, France

Silvia Monticone
University of Turin, Turin, Italy

Rebecca J. Moon
Southampton Children's Hospital, Southampton, United Kingdom

Stefano Mora
IRCCS San Raffaele Scientific Institute, Milan, Italy

G. Morana
University of Genoa, Genoa, Italy

Rachel C. Morgan
Indiana University School of Medicine, Indianapolis, IN, United States

Alberto Morganti
Centro Fisiologia Clinica e Ipertensione, Policlinico Hospital, Milan, Italy; and University of Milan, Milan, Italy

Luigi Mori
University of Brescia, Brescia, Italy

A. Ross Morton
Queen's University, Kingston, ON, Canada

Howard A. Morris
University of South Australia, Adelaide, SA, Australia

Giovanna Motta
University of Turin, Turin, Italy

Pierre Mouriquand
Hôpital Mère-Enfant – Claude-Bernard University, Lyon, France

Miguel Muñoz
Virgen del Rocío University Hospital, Sevilla, Spain

Maria Teresa Muñoz
University Hospital Niño Jesús, Institute of Investigation La Princesa, Madrid, Spain; and Center for Biomedical Research in Network on the Pathophysiology of Obesity and Nutrition (CIBEROBN), Carlos III Health Institute, Madrid, Spain

Araceli Muñoz-Garach
Virgen de la Victoria Universitary Hospital (IBIMA), Malaga, Spain

Maria Lorenza Muiesan
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Dick Mul
Diabeter, Center for Pediatric and Adolescent Diabetes Care and Research, Rotterdam, The Netherlands

Manfred J. Müller
University of Kiel, Kiel, Germany

Beat Müller
Medical University Clinic, Kantonsspital Aarau, Aarau, Switzerland; and University Hospital Basel, Basel, Switzerland

Paolo Mulatero
University of Turin, Turin, Italy

Tayane Muniz Fighera
Federal University of Rio Grande do Sul, Porto Alegre, Brazil

K.S. Murthy
Virginia Commonwealth University, Richmond, VA, United States

Marina Muzza
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Angel Nadal
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Y. Nagayama
Nagasaki University, Nagasaki, Japan

Bimota Nambam
Louisiana State University, Shreveport, LA, United States

Ruta Navardauskaite
Lithuanian University of Health Sciences, Kaunas, Lithuania

M.-L. Névoret
Impeto Medical, San Diego, CA, United States

Markella Nezi
National and Kapodistrian University of Athens, Aretaieion Hospital, Athens, Greece

Brian T. Nguyen
Keck School of Medicine of University of Southern California, Los Angeles, CA, United States; and Los Angeles Biomedical Research Institute and Harbor-UCLA Medical Center, Torrance, CA, United States

Atossas Niakan
University of Tennessee Health Science Center, Memphis, TN, United States

Nicolas C. Nicolaides
National and Kapodistrian University of Athens Medical School, Athens, Greece; and Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Claus H. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Henriette S. Nielsen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Lynnette K. Nieman
National Institutes of Health (NIH), Bethesda, MD, United States

Sarah M Nikkel
University of British Columbia, Vancouver, BC, Canada

Charlotte M. Niznik
Northwestern University Feinberg School of Medicine, Chicago, IL, United States

James D. Nobles
Leeds Beckett University, Leeds, United Kingdom

Pavel Nockel
National Cancer Institute, Bethesda, MD, United States

Ruben Nogueiras
CIMUS, USC, IDIS, Santiago de Compostela, Spain; and Carlos III Health Institute, Madrid, Spain

Ruben Nogueiras
CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain; and University of Santiago de Compostela (USC), Santiago de Compostela, Spain

Anna Nordenström
Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

M. Nowak
Medical University of Lublin, Lublin, Poland

Tsuneo Ogawa
University of Ottawa, Ottawa, ON, Canada

Onyebuchi Okosieme
Cardiff University, Cardiff, United Kingdom

Wilma Oostdijk
Leiden University Medical Center, Leiden, The Netherlands

Jacques Orgiazzi
Lyon 1-Claude Bernard University, Lyon, France

Andrés E. Ortiz-Flores
University Hospital Ramón y Cajal, Madrid, Spain; University of Alcalá, Madrid, Spain; Ramón y Cajal Institute for Health Research IRYCIS, Madrid, Spain; and Biomedical Research Network Center in Diabetes and Related Metabolic Diseases CIBERDEM, Madrid, Spain

Nantia Othonos
University of Oxford, Oxford, United Kingdom

Susan M. Ott
University of Washington, Seattle, WA, United States

Karel Pacak
University of Connecticut Health Center, Farmington, CT, United States; and National Institutes of Health, Bethesda, MD, United States

Stephanie T. Page
University of Washington, Seattle, WA, United States

Uberto Pagotto
Alma Mater Studiorum University of Bologna, Bologna, Italy

Anna Paini
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Stefano Palomba
Grande Ospedale Metropolitano of Reggio Calabria, Reggio Calabria, Italy

George Paltoglou
Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom

Alessandra Panarotto
University of Brescia, Brescia, Italy

Amit V. Pandey
University of Bern, Bern, Switzerland

Vassilios Papadopoulos
University of Southern California, Los Angeles, CA, United States

Ralph Papas
University of Balamand, Beirut, Lebanon

Theodora Pappa
National and Kapodistrian University, Athens, Greece

Anne-Simone Parent
University of Liège, Liège, Belgium; and CHU de Liège, Chênée, Belgium

Gabriele Parenti
Endocrine Unit, Careggi Hospital, Florence, Italy

Ralf Paschke
University of Calgary, Calgary, AB, Canada

Leena Patel
The University of Manchester, Manchester, United Kingdom; and Royal Manchester Children's Hospital, Manchester University Hospitals NHS Trust, Manchester Academic Health Science Centre, Manchester, United Kingdom

Heather B. Patisaul
North Carolina State University, Raleigh, NC, United States

G. Patti
University of Genova, Genova, Italy

Michael A. Patton
St Georges University of London, London, United Kingdom

L.J. Pelliniemi
University of Turku, Turku, Finland

Bas Penders
Maastricht University, Maastricht, The Netherlands

Alberto M. Pereira
Leiden University Medical Center, Leiden, The Netherlands

Paola Perotti
University of Turin, Turin, Italy

Luca Persani
University of Milan, Milan, Italy

Luca Persani
University of Milan, Milan, Italy; and IRCCS Italian Auxological Institute, Milan, Italy

Panagiota Pervanidou
National and Kapodistrian University of Athens Medical School, Athens, Greece

Felice Petraglia
University of Florence, Careggi University Hospital, Florence, Italy

Cindy Pham
Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA, United States

Eliana Piantanida
University of Insubria, Varese, Italy

Jean-Yves Picard
Pierre and Marie Curie University, Paris, France

Marie-Eve Piché
Quebec Heart and Lung Institute, Quebec City, QC, Canada; Laval University, Quebec City, QC, Canada;

and Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom

Axelle Pintiaux
Free University of Brussels (ULB), Brussels, Belgium

Rosario Pivonello
University of Naples Federico II, Naples, Italy

Rosario Pivonello
Federico II University of Naples, Naples, Italy

T.M. Plant
University of Pittsburgh School of Medicine, Pittsburgh, PA, United States; and Magee-Womens Research Institute, Pittsburgh, PA, United States

P-F. Plouin
Hôpital Européen Georges Pompidou, Paris, France; and Paris-Descartes University, Paris, France

Genevieve Plu-Bureau
Paris-Descartes University, Paris, France

Paul Poirier
Quebec Heart and Lung Institute, Quebec City, QC, Canada; and Laval University, Quebec City, QC, Canada

Snezana Polovina
University Business Academy, Novi Sad, Serbia

Constantin Polychronakos
Research Institute of the McGill University Health Centre, Montréal, QC, Canada

Maguelonne Pons
Hôpital Mère-Enfant – Claude-Bernard University, Lyon, France

Giulia M. Pontesilli
Alma Mater Studiorum University of Bologna, Bologna, Italy

Callum Potts
Inova Fairfax Hospital, Falls Church, VA, United States

Aleksander Prejbisz
Institute of Cardiology, Warsaw, Poland

Lakdasa D.K.E. Premawardhana
Cardiff University, Cardiff, United Kingdom; and University Hospital of Wales, Cardiff, United Kingdom

Morton P. Printz
University of California San Diego, San Diego, CA, United States

Tomas Prior
Queen Charlotte's and Chelsea Hospital, London, United Kingdom; and Imperial College London, London, United Kingdom

Soraya Puglisi
University of Turin, Turin, Italy

Shrey Purohit
Duke University, Durham, NC, United States

Lechosław T. Putowski
Medical University of Lublin, Lublin, Poland

Ivan Quesada
Miguel Hernández University of Elche and CIBERDEM, Alicante, Spain

Ingrid Quevedo Wanichi
University of São Paulo, São Paulo, Brazil

Rémi Rabasa-Lhoret
Montreal Clinical Research Institute, Montreal, QC, Canada; University of Montreal, Montréal, QC, Canada; and Montreal Diabetes Research Center, Montréal, QC, Canada

Naila Rabbani
University of Warwick, Coventry, United Kingdom

Jacob Rajfer
David Geffen School of Medicine, Los Angeles, CA, United States

Ewa Rajpert-De Meyts
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Stuart H. Ralston
University of Edinburgh, Edinburgh, United Kingdom

S. Ramaswamy
University of Pittsburgh School of Medicine, Pittsburgh, PA, United States; and Magee-Womens Research Institute, Pittsburgh, PA, United States

Amarnath Rambhatla
Wayne State University, Detroit, MI, United States

Oliver J. Rando
University of Massachusetts Medical School, Worcester, MA, United States

Elena Rapizzi
University of Florence, Florence, Italy

Åse Krogh Rasmussen
Copenhagen University Hospital (Rigshospitalet), Copenhagen, Denmark

Joanne Rasschaert
Free University of Brussels, Brussels, Belgium

Giulia Rastrelli
University of Florence, Florence, Italy

Verdiana Ravarotto
University of Padua, Padova, Italy

Gérald Raverot
Groupement Hospitalier Est, Bron, France

José T. Real
University of Valencia, Valencia, Spain; and CIBERDEM-Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, ISCIII, Madrid, Spain

Dafydd Aled Rees
University Hospital of Wales, Cardiff, United Kingdom; and Cardiff University, Cardiff, United Kingdom

Jean-Yves Reginster
WHO Collaborating Center for Public Health Aspects of Musculoskeletal Health and Aging, Liège, Belgium; and University of Liège, Liège, Belgium

Ian R. Reid
University of Auckland, Auckland, New Zealand

Giuseppe Reimondo
University of Turin, Turin, Italy

Martin Reincke
Ludwig Maximilian University of Munich, Munich, Germany

Rodolfo A. Rey
R. Gutierrez Children's Hospital, Buenos Aires, Argentina

Caroline Reynaud
INSERM, Faculty of Medicine Lyon East, Lyon, France

Luigi Ricciardiello
Alma Mater Studiorum University of Bologna, Bologna, Italy

Guido Rindi
Catholic University – IRCCS Fondazione Policlinico Universitario A. Gemelli, Roma, Italy

Scott A. Rivkees
University of Florida College of Medicine, Gainesville, FL, United States

William B. Rizzo
University of Nebraska Medical Center, Omaha, NE, United States

René Rizzoli
WHO Collaborating Center for Public Health Aspects of Musculoskeletal Health and Aging, Liège, Belgium; and Geneva University Hospitals and Faculty of Medicine, Geneva, Switzerland

Carolina De Ciuceis Damiano Rizzoni
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Bernard Robaire
McGill University, Montréal, QC, Canada

Vettor Roberto
Center for the Study and the Integrated Treatment of Obesity – Bariatric Unit, University of Padua, Padua, Italy

Gary. L. Robertson
Northwestern University, Chicago, IL, United States

Geoffroy Robin
Department of Endocrine Gynecology and Reproductive Medicine, Lille University Hospital, Lille, France

Elisa Roca
University of Brescia, Brescia, Italy

Roberto Rocchi
University of Pisa, Pisa, Italy

Patrice Rodien
University Hospital of Angers, Angers, France; and University of Angers, Angers, France

B. Rogina
University of Connecticut Health Center, Farmington, CT, United States

Alan D. Rogol
University of Virginia, Charlottesville, VA, United States

Russell D. Romeo
Rockefeller University, New York, NY, United States

Susan R. Rose
Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States

Claudia Agabiti Rosei
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Richard Ross
University of Sheffield, Sheffield, United Kingdom

Judith L. Ross
Thomas Jefferson University, Philadelphia, PA, United States

Marco Rossato
University of Padua, Padua, Italy

Gian Paolo Rossi
University of Padua, Padua, Italy

Ermanno Rossi
Department of Internal Medicine, IRCCS Santa Maria Nuova Hospital, Reggio Emilia, Italy

Giovanni Maria Rossi
Nephrology Unit, Department of Clinical and Experimental Medicine, Parma University Hospital, Parma, Italy

Liliya Rostomyan
University Hospital Center of Liège, Liège, Belgium

Katherine Rotker
University of Massachusetts Medical School, Worcester, MA, United States

Charlotte Rougier
University of Nice-Sophia-Antipolis, Nice, France

Phillip W. Round
Life Sciences Center, Vancouver, BC, Canada

Serge Rozenberg
Free University of Brussels, Brussels, Belgium; and Vrije Universiteit Brussel, Brussels, Belgium

Speranza Rubattu
Sapienza University, Rome, Italy; and IRCCS Neuromed, Pozzilli, Italy

Nadia Rucci
University of L'Aquila, L'Aquila, Italy

Paola Russo
National Research Council of Italy, Avellino, Italy

A.S. Ryan
University of Maryland School of Medicine, Baltimore, MD, United States

Fiona J. Ryan
Oxford University Hospitals NHS Foundation Trust, Oxford, England

Lars Sävendahl
Karolinska Institutet, Stockholm, Sweden

Chiara Sabbadin
University of Padua, Padua, Italy

Azeez Salawu
University of Sheffield, Sheffield, United Kingdom

Salem A. Salem
University of Tennessee Health Science Center, Memphis, TN, United States

Nicola Salituro
Alma Mater Studiorum University of Bologna, Bologna, Italy

Maria Salomon Estebanez
Royal Manchester Children's Hospital, Manchester, United Kingdom; and University of Manchester, Manchester, United Kingdom

Katerina Saltiki
National and Kapodistrian University of Athens, Athens, Greece

Massimo Salvetti
Department of Clinical and Experimental Sciences, University of Brescia, ASST Spedali Civili di Brescia and Società Italiana dell'Ipertensione, Brescia, Italy

Mario Salvi
Graves' Orbitopathy Center, Fondazione IRCCS Cà Granda, Milan, Italy; and University of Milan, Milan, Italy

Susan L. Samson
Baylor College of Medicine, Houston, TX, United States

Jaspreet S. Sandhu
Memorial Sloan Kettering Cancer Center, New York, NY, United States

Darleen A. Sandoval
University of Michigan, Ann Arbor, MI, United States; and University of Cincinnati School of Medicine, Cincinnati, OH, United States

Daniele Santi
University of Modena and Reggio Emilia, Modena, Italy

Nora Saraco
Hospital de Pediatría Garrahan, Buenos Aires, Argentina; and Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina

Robert M. Sargis
University of Illinois at Chicago, Chicago, IL, United States

Theo C.J. Sas
Erasmus Medical Center – Sophia Children's Hospital and Diabeter, Rotterdam, The Netherlands

Martin O. Savage
Barts and the London School of Medicine and Dentistry, London, United Kingdom

Mesut Savas
Erasmus MC, University Medical Center Rotterdam, Rotterdam, The Netherlands

Camilla Schalin-Jäntti
Endocrinology, Helsinki University and Helsinki University Hospital, Helsinki, Finland

Desmond Schatz
University of Florida, Gainesville, FL, United States

André J. Scheen
University of Liège, Liège, Belgium

Jens M. Scherpe
University of Cambridge, Cambridge, United Kingdom

Stefan Schlatt
Institute of Reproductive and Regenerative Biology, Münster, Germany

Peter N. Schlegel
Weill Cornell Medicine, New York, NY, United States

Nadia Schoenmakers
University of Cambridge Metabolic Research Laboratories, Cambridge, United Kingdom

Anna Scholz
University Hospital of Wales, Cardiff, United Kingdom

R.K. Semple
University of Cambridge Metabolic Research Laboratories, Cambridge, United Kingdom

Luisa M. Seoane
Complejo Hospitalario Universitario de Santiago de Compostela (CHUS/SERGAS), A Coruña, Spain; and CIBER Fisiopatología Obesidad y Nutrición, Carlos III Health Institute, Madrid, Spain

Medical University Hospital Tübingen, Tübingen, Germany

PREFACE

The first Edition of the *Encyclopedia of Endocrine Diseases* was published in 2004. Because of the enormous development in the field it was found important to produce a completely revised and updated Second Edition of the Encyclopedia. The new Edition is a must-have one-stop reference covering every aspect of the physiological background, pathogenesis, clinical diagnostics, and therapeutic aspects of the wide array of endocrine and related metabolic diseases.

The functional balance of the body (homeostasis) is maintained by two regulatory circuits, i.e., the nervous and the endocrine systems. Among the most complex constructs in the body, the endocrine system comprises a group of glands that secrete hormones directly into the bloodstream, where they reach their specific receptors in other parts of the body, evoking specific intracellular signaling pathways leading to their biological effect. Many classically non-endocrine organs (e.g., the heart) have also turned out to have endocrine functions. The endocrine system maintains and regulates the body's homeostasis by using hormones to control metabolism, temperature, biological cycles, internal fluid volume, reproduction, growth, body composition, and development. The system is a marvel when functioning optimally, i.e., maintaining the body homeostasis. Unfortunately, there is a myriad of ways these processes, actions, and functions can go awry, resulting in various endocrine and metabolic diseases, which form the over-arching theme of the Encyclopedia.

The Encyclopedia is not meant as a primer on the subject of endocrinology, but instead intended to provide a comprehensive reference work on the extensive spectrum of diseases and disorders that can occur within the endocrine and metabolic system. The updated version of this groundbreaking encyclopedia is especially timely, as it covers the dramatic discoveries in the field of endocrinology and metabolism over the past 10 years, particularly with respect to novel diagnostic techniques and treatment approaches. In particular, there have been tremendous advancements in our understanding of the molecular basis of endocrine and metabolic diseases (mutations, epigenetics, signaling), as well as pathogenesis and therapy of the common forms of these diseases (e.g., diabetes, obesity, and endocrine malignancies).

The Encyclopedia offers a unique source of up-to-date information for the physicians and basic scientists working in the field. It is an essential resource for every clinician diagnosing and treating endocrine patients. The Encyclopedia also offers the prime source of information for students of medicine and science around the world, as well as basic research workers in academia, the pharma industry, and in other areas in need of information on endocrinology and metabolism. It also offers useful information for the lay public about normal and abnormal functions of hormones.

The Encyclopedia is intended to serve as a useful and comprehensive source of information spanning the many and varied aspects of the endocrine and metabolic system. The chapters have been written to be accessible to both clinical and nonclinical readers. The articles have been formatted in similar fashion and each is intended as a stand-alone presentation. Each article begins with a glossary list defining key terms that may be unfamiliar to the reader and are important for understanding the article. The body of the article begins with a brief introduction to the subject under discussion, bold headings lead the reader through the text, and figures and tables explain and illuminate most articles. The main text is followed by referenced citations to provide the reader with access to additional information on the topic, and cross-references lead the reader to related entries in the encyclopedia. The relatively short stand-alone articles have allowed us to recruit the best experts available for each topic.

Unlike the first Edition, where the articles were arranged in alphabetical order, the 2nd Edition is arranged in organ-based thematic order, where each organ-based group of diseases is presented as cluster of articles in the first four volumes. The fifth volume is a stand-alone compilation of all articles on pediatric endocrinology. The thematic organization gives the reader a better general view of the coverage of articles on a specific endocrine organ or disease type.

The Second Edition of the Encyclopedia builds of the first edition. Nevertheless, to bring a major reference work with such a broad scope from initial conception to final publication involved a great deal of planning and organization, together with the efforts of innumerable individuals. The authors of the first edition were invited to update their earlier texts. If this was not possible, the Section Editors invited another expert in the topic either to update the previous text or to write a de novo text; the latter happened in most of these cases. Hence, the Second Edition contains to a large extent totally new information, or at least the fluency of all texts has been scrutinized. Furthermore, all manuscripts have undergone peer-review arranged by the Section Editors.

Assembling a large volume of articles with the purpose to cover all essential topics of endocrine diseases posed multiple challenges. Coverage was a significant problem: on one hand some redundancy of the topics was almost impossible to avoid in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these gaps in future editions. We also note that as can be expected for a large multi-author compilation the individual articles do differ in detail and approach. We considered it more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines.

Most of the editing work of the Encyclopedia has been carried out by a highly competent board of 16 Section Editors, each of them internationally renowned experts in their respective field within clinical endocrinology. First, the broadest possible list of topics was compiled, aiming at the best possible coverage. Throughout the editorial process, the Section Editors supervised their subject area of expertise, recommended and corresponded with fellow editors and article contributors, reviewed the manuscripts, and continuously helped to refine the final list of topics. This has made the task of the Editor in Chief easy, mainly entailing the supervision of smooth progress of the project.

The Section Editors and their fields deserve being listed here: *Jean-Jacques Body* (Belgium, bone endocrinology), *Felipe F. Casanueva* (Spain, metabolism and obesity), *Richard N. Clayton* (United Kingdom, pituitary gland), *Jean-Louis Chiasson* (Canada, diabetes), *Sophie Christin-Maitre* (France, female reproduction), *Wouter W. de Herder* (The Netherlands, neuroendocrinology), *Ulla Feldt-Rasmussen* (Denmark, thyroid gland), *Ieuan Hughes* (United Kingdom, pediatric endocrinology), *Gregory Kaltsas*, Greece, and *Martin O. Weickert*, United Kingdom, (gastrointestinal hormones), *Jean-Marc Kaufman* (Belgium, endocrinology of aging), *André Lacroix* (Canada, adrenal cortex), *Franco Mantero* (Italy, adrenal medulla and endocrine hypertension), *Jorma Toppari* (Finland, endocrine disruptors), *Jacquetta Trasler* (Canada, endocrine epigenetics) and *Christina Wang* (United Kingdom, male reproduction).

The Elsevier editorial staff, *Will Smaldon*, *Laura Escalante Santos*, and *Kate Miklaszewska-Gorczyca*, have been of enormous help to the editors at every step during this long project. I admire the professionalism of everyone and am deeply indebted to all for their dedication and hard work to make the Encyclopedia the leading reference book of clinical endocrinology.

The authors of the individual chapters, more than 450 in total, were specifically selected by the Section Editors to represent the best available knowledge on the topic available. They all should be thanked for their dedication and the excellent quality of their contributions.

Ilpo T. Huhtaniemi
Editor in Chief

VOLUME 1 – General Principles of Hormone Production and Action, Diabetes, Lipid Metabolism and Atherosclerosis, Obesity, Gastrointestinal Hormones, Multi-Organ Endocrine Diseases, Endocrinology of Aging, and Endocrine toxicology and EDCs

General Principles of Hormone Production and Action

History of Endocrinology *Wouter W de Herder* 1
Statistics in Endocrinology: Meta-Analysis Advantages and Pitfalls *Olaf M Dekkers* 11
Evolution of Hormonal Mechanisms *Vincent Laudet and Gabriel V Markov* 16
General Principles of Endocrine Genetics *Constantin Polychronakos* 23
Endocrine Epigenetics, Epigenetic Profiling and Biomarker Identification *Virginie Bertrand-Lehouillier, Lisa-Marie Legault, and Serge McGraw* 31
Protein and Peptide Hormone Synthesis *Johannes Hofland and Frank H de Jong* 36
Protein and Peptide Hormone Action *Frank H de Jong and Johannes Hofland* 43
Roles of Plasma Binding Proteins in Modulation of Hormone Action and Metabolism *Geoffrey L Hammond, Lesley A Hill, and Phillip W Round* 51
Dynamic Endocrine Rhythms *Thomas J Upton and Stafford Lightman* 61
Growth Factors *Uxía Fernandez, Luisa M Seoane, and Ruben Nogueiras* 69

Diabetes

Normal Glucose Physiology *Mazen Alsahli and John E Gerich* 72
Glucose Metabolism and Hormonal Regulation *Keith Tornheim* 87
Insulin Secretion: Functional Biochemical Aspects *Willy J Malaisse* 95
Insulin Action; Post-Receptor Mechanisms *Ashok K Srivastava, Preeti Bajpai, and Ashish Jain* 100
Diagnosis and Classification of Diabetes Mellitus *Jean-Marie Ekoé* 105
Type 1 Diabetes *Bimota Nambam, William Winter, and Desmond Schatz* 110
Type 2 Diabetes *Susan L Samson and Alan J Garber* 116
Diabetes Mellitus and Pregnancy *Emily D Szmuilowicz, Charlotte M Niznik, and Boyd E Metzger* 122
Diabetes Mellitus; Diagnosis and Treatment in the Elderly *Odilia I Bermudez* 133

Carbohydrate Metabolism: Diabetes Mellitus, Genomic Aberrations *RK Semple* 141
Lifestyle Diabetes Prevention *Ahmad Alkhatib and Jaakko Tuomilehto* 148
Hyperglycemic Hyperosmolar State *J Maletkovic and A Drexler* 160
Hypoglycemia *Darleen A Sandoval, Elizabeth M Lamos, Lisa Younk, Maka S Hedrington, and Stephen N Davis* 163
Glycation- and/or Polyol Pathway-Inducing Complications *Naila Rabbani and Paul J Thornalley* 170
Hypertension and Diabetes *Atossas Niakan and William C Cushman* 180
Dyslipidemia in Diabetes *Savitha Subramanian and Alan Chait* 186
Ocular Manifestations Associated With Diabetes *S Lauhon, MS Stem, and PE Fort* 199
Kidney Disease in Diabetes *Stephanie Toth-Manikowski and Mohamed G Atta* 202
Diabetic Nerve Disease; Neuropathy *Jean-Marie Ekoe* 207
Neurological Disease and Diabetes, Autonomic *Aaron I Vinik, Tomris Erbas, M-L Névoret, and C Casellini* 210
Foot Disease in Diabetes *Jean-Marie Ekoé, Benjamin A Lipsky, and David G Armstrong* 216
Cardiovascular Disease in Diabetes *Marie-Eve Piché and Paul Poirier* 219
Treatment: Alpha Glucosidase Inhibitors *Markolf Hanefeld and Gabriele Mertes* 238
Insulin Pumps and Artificial Pancreas *Nadine Taleb, Véronique Gingras, and Rémi Rabasa-Lhoret* 245
Transplantation: Pancreatic and Islet Cells *Anissa Gamble, Antonio Bruni, and AM James Shapiro* 259
Hypoglycemic State, Nondiabetic *Pierre J Lefèbvre and André J Scheen* 270

Lipid Metabolism and Atherosclerosis

Classification of Hyperlipidemias and Dyslipidemias *Jesús E Millán Núñez-Cortes and Joaquín J Millán Pérez* 275
Atherosclerosis *Jesus A Araujo and Aldons J Lusis* 282
Atherogenesis *L Badimon and V Llorente-Cortés* 289
Epigenetics, the Vascular Wall, and Atherosclerosis *Gertrud Lund and Silvio Zaina* 303
Primary Mixed Dyslipidemias *Rafael Carmena* 314
Hypercholesterolemia *Sergio Martinez-Hervas and Juan F Ascaso* 320
Low HDL and High HDL Syndromes *Shizuya Yamashita and Yuji Matsuzawa* 327
Hypertriglyceridemias and Their Treatment *José T Real* 340

Obesity

Genetic Basis of Obesity *Dolores Corella and Oscar Coltell* 346
Gut Microbiota; Its Importance in Obesity *Araceli Muñoz-Garach, Isabel M Cornejo-Pareja, and Francisco J Tinahones* 353
Regulation of Food Intake *Albert Lecube and Carolina López-Cano* 363
Adipose Tissue *Xabier Unamuno, Gema Frühbeck, and Victoria Catalán* 370
Comorbidities of Obesity *Vettor Roberto and Di Vincenzo Angelo* 385
Hypothalamic Control of Food Intake and Energy Homeostasis *Luisa M Seoane, Miguel López, and Ruben Nogueiras* 393

Gastrointestinal Hormones and Their Regulation of Food Intake *Luca Busetto, Marco Rossato, and Roberto Vettor* 398

Body Composition *Manfred J Müller, Corinna Geisler, and Anja Bosy-Westphal* 406

Obesity and Food Addiction *Fernando Fernández-Aranda, Trevor Steward, Gemma Mestre-Bach, Susana Jiménez-Murcia, and Ashley Gearhardt* 414

Leptin *Rachel C Morgan and Robert V Considine* 420

Lifestyle and Nutrition *Dragan Micic and Snezana Polovina* 428

Physical Activity and Exercise *Federico Mallo Ferrer* 436

Treatment of Obesity with Bariatric Surgery *Maitane Izaguirre, Gema Frühbeck, and Victoria Catalán* 442

Metabolic Surgery; Indications and Outcomes *Lidia Castagneto-Gissey, James Casella-Mariolo, and Geltrude Mingrone* 459

Treatment: New Drugs *Silvia Garelli, Nicola Salituro, Giulia M Pontesilli, Luigi Ricciardiello, Valentina Vicennati, and Uberto Pagotto* 464

Binge-Eating, Bulimia, and Other Eating Disorders *Zaida Agüera, Núria Mallorquí-Bagué, María Lozano-Madrid, Andreas Stengel, Stephan Zipfel, and Fernando Fernández-Aranda* 473

Lipodystrophy *Marta Giralt, Francesc Villarroya, and David Araújo-Vilar* 482

Gastrointestinal Hormones

GI Hormone Development (Families and Phylogeny) *Anders H Johnsen* 496

GI Tract: General Anatomy (Cells) *George Kontogeorgos* 501

GI Hormones Outside the Gut: Central and Peripheral Nervous Systems *Graham J Dockray* 515

GI Tract: General Pathology of Neuroendocrine Growths *Guido Rindi, Frediano Inzani, and Enrico Solcia* 520

Gastrin *Graham J Dockray* 525

Cholecystokinin (CCK) *Nori Geary* 529

Pancreatic Polypeptide (PP) *Dana K Andersen and F Charles Brunicardi* 534

Peptide YY (PYY) *Peter Holzer and Aitak Farzi* 546

Glucagon and Glucagon-Like Peptides *Daniel M Kemp and Joel F Habener* 555

Glucagon Like Peptide 2 (GLP-2) *Georgios K Dimitriadis and Alexander D Miras* 561

Enterochromaffin-Like Cells *Apostolos V Tsolakis* 565

Substance P *Miguel Muñoz and Rafael Coveñas* 571

Gastrointestinal Hormones in Cancer *Inbal Uri, Kristallenia Alexandraki, and Simona Grozinsky-Glasberg* 579

Somatostatin Receptor Expression in Gastrointestinal Tumors *Eleftherios Chatzellis and Gregory Kaltsas* 587

Gastrointestinal Neuroendocrine Tumor Syndromes (GI NETS) *Robert T Jensen* 597

Gastrinomas *Robert T Jensen* 617

Pancreatic Islet Cell Tumors *Ulrich Knigge, Mikkel Andreassen, Birgitte Federspiel, Carsten Palnæs Hansen, Andreas Kjær, and Seppo W Langer* 626

Peptide Neurotransmitters and Smooth Muscle in the Gut *JR Grider, KS Murthy, and GM Makhlouf* 635

Multi-Organ Endocrine Diseases

Pituitary Tumors Associated With Multiple Endocrine Neoplasia Syndromes *Liliya Rostomyan, Adrian F Daly, and Albert Beckers* 642

Endocrinology of Aging

Aging and Longevity of Human Populations *Diana van Heemst* 648

Animal Models for Aging *EC-H Lee, B Rogina, L Haynes, and GA Kuchel* 653

Oxidative Stress and Aging *Arthur K Balin and RG Allen* 659

Immunology and Aging *Victor Appay* 664

Premature Aging Syndromes *Fabio Coppedè* 669

Hormonal Circadian Rhythms and Sleep in Aging *Georges Copinschi and Anne Caufriez* 675

Circadian Clock, Epigenetic Regulators (Sirtuins), and Metabolism *Mirella L Meyer-Ficca and Ralph G Meyer* 690

Somatotropic Axis in Human Aging *Sabrina Chiloiro, Antonio Bianchi, Antonella Giampietro, and Laura De Marinis* 700

Abnormalities in Water Homeostasis in the Elderly *Laura E Cowen and Joseph G Verbalis* 708

Body Weight, Body Composition, and Aging *Odessa R Addison and Alice S Ryan* 713

Lipid Disorders in the Elderly *Wilbert Aronow* 719

Gonadotropins and Testicular Function in Aging *Fiona Yuen, Peter Y Liu, Ronald Swerdloff, and Christina Wang* 723

Hypogonadism and Testosterone Therapy in Elderly Men *Bu B Yeap* 729

Sexual Function in Aging Men *Giulia Rastrelli, Giovanni Corona, and Mario Maggi* 739

Osteoporosis in the Oldest Old *Evelien Gielen* 748

Aging and the Thyroid Gland *Leonidas H Duntas* 758

Endocrine toxicology and EDCs

Introduction to Endocrine Toxicology and Endocrine Disruption *Jorma Toppari* 762

Toxic Effects of Common Environmental Pollutants in Pancreatic β-Cells and the Onset of Diabetes Mellitus *Paloma Alonso-Magdalena, Eva Tudurí, Laura Marroquí, Ivan Quesada, Robert M Sargis, and Angel Nadal* 764

Endocrine Disruptors and Obesity *Sigal A Willner and Bruce Blumberg* 776

Endocrine Disruptors and Thyroid Function *Josef Köhrle* 787

Neuroendocrine Disruption of Reproduction *Julie Fudvoye, Jean-Pierre Bourguignon, and Anne-Simone Parent* 793

Association of Endocrine Disrupting Chemicals With Male Reproductive Health *Helena E Virtanen, Katharina M Main, and Jorma Toppari* 802

Endocrine Disrupting Chemicals and Behavior *Sheryl E Arambula and Heather B Patisaul* 812

VOLUME 2 – Neuroendocrinology, Pituitary Gland and Diseases, Female Reproduction, and Male Reproduction

Neuroendocrinology

Corticotropin-Releasing Hormone (CRH) *Nicolas C Nicolaides and George P Chrousos* 1

Neurotensin *Arthur Shulkes* 10

Carcinoid Syndrome *Marina Tsoli and Gregory Kaltsas* 13

Catecholamines *Graeme Eisenhofer and Jacques WM Lenders* 21

Pineal Tumors *María-José Barahona and Susan M Webb* 25

Vasopressin *Aoife Garrahy and Christopher J Thompson* 29

Effects of Steroid Hormones on Brain *Anne-Sophie CAM Koning, Russell D Romeo, Bruce S McEwen, and Onno C Meijer* 36

Memory and Epigenetics: Role of Estrogen *Jennifer J Tuscher, Ashley M Fortress, and Karyn M Frick* 42

VIPoma, Glucagonoma, and Somatostatinoma *Wouter T Zandee and Wouter W de Herder* 52

Insulinoma *Wouter T Zandee and Wouter W de Herder* 58

Melatonin *J Arendt* 63

Overview of Neurotransmitters *Floyd E Bloom* 75

Pituitary Gland and Diseases

Anatomy of Hypothalamus *Béla Halász* 81

Pituitary Gland Anatomy and Embryology *Béla Halász* 90

Hypothalamic Disease *Sylvia L Asa and Shereen Ezzat* 97

Diabetes Insipidus *Gary L Robertson* 107

Growth Hormone (GH) *Rikke Hjortebjerg, Gerhard Baumann, and John J Kopchick* 116

Natural and Synthetic Growth Hormone Secretagogues *Giovanna Motta, Stefano Allasia, Marco Zavattaro, Ezio Ghigo, and Fabio Lanfranco* 127

Luteinizing Hormone (LH) *Livio Casarini, Daniele Santi, Gary R Marshall, and Manuela Simoni* 142

Follicle-Stimulating Hormone (FSH) *Daniele Santi, Livio Casarini, Gary R Marshall, and Manuela Simoni* 149

Prolactin: Regulation of Secretion and Action *Filippo Maffezzoni, Gherardo Mazziotti, and Andrea Giustina* 157

Molecular Pathogenesis of Pituitary Tumors *Shereen Ezzat and Sylvia L Asa* 165

Classification of Pituitary Neuroendocrine Tumors (PitNets) *Jacqueline Trouillas, Alexandre Vasiljevic, Emmanuel Jouanneau, and Gérald Raverot* 176

Genetic Causes of Familial Pituitary Tumors *Maria Manuel Costa and Márta Korbonits* 185

Clinical Features of Acromegaly *I Ilie and M Korbonits* 212

Diagnosis of Acromegaly *I Ilie and M Korbonits* 223

Therapy for Acromegaly *Philippe Chanson* 230

ACTH-Secreting Pituitary Tumors *Rosario Pivonello, Maria Cristina De Martino, Davide Iacuaniello, Chiara Simeoli, and Annamaria Colao* 248

TSH-Secreting Pituitary Adenomas *Olympia Koulouri and Mark Gurnell* 261

Surgery for Pituitary Tumors *Pamela Jones and Brooke Swearingen* 267

Clinical Features, Diagnosis, and Management of Nonfunctioning Tumors of Pituitary *Athanasios Fountas and Niki Karavitaki* 271

Surgical Treatment of Nonfunctioning Pituitary Tumors *Michael Buchfelder and Yining Zhao* 281

Pituitary Radiotherapy *Frederic Castinetti and Thierry Brue* 289

Diagnosis and Clinical Management of Aggressive Pituitary Tumors *Gerald Raverot, Emmanuel Jouanneau, and Jacqueline Trouillas* 294

Hypopituitarism, Causes, Diagnosis, Management and Mortality *Athanasios Fountas and Niki Karavitaki* 301

Diagnosis of Prolactinoma and Causes of Hyperprolactinemia *James Ahlquist* 314

Prolactinomas: Clinical Manifestations and Therapy *Anna Scholz and Dafydd Aled Rees* 319

Hypophysitis *Federica Guaraldi, Olivera Casar-Borota, and Marie-Lise Jaffrain-Rea* 325

Radiology of the Pituitary *Jane Evanson* 339

Hyponatraemia *Aoife Garrahy and Christopher J Thompson* 349

Pituitary Disorders Following Traumatic Brain Injury *Anne Marie Hannon and Christopher J Thompson* 365

Female Reproduction

Folliculogenesis *Danielle Monniaux, Véronique Cadoret, Frédérique Clément, Rozenn Dalbies-Tran, Sébastien Elis, Stéphane Fabre, Virginie Maillard, Philippe Monget, and Svetlana Uzbekova* 377

Human Menstrual Cycle *Sophie Christin-Maitre* 399

Implantation *Lechosław T Putowski and M Nowak* 404

Pregnancy Endocrinology *Stefano Palomba and Jessica Daolio* 408

Placental Epigenetics and Outcomes in Children *Patricia Fauque* 418

Endocrinology of Delivery *Silvia Vannuccini and Felice Petraglia* 425

Premenstrual Syndrome (PMS) *M Link* 432

Amenorrhea *Sophie Christin-Maitre* 436

Congenital Hypogonadotropic Hypogonadism in Females *Jacques Young* 439

Functional Hypothalamic Amenorrhea *Sarah L Berga* 444

Polycystic Ovary Syndrome *Stephen Franks* 451

Polycystic Ovary Syndrome: Implications for Cardiovascular, Endometrial, and Breast Disease *HF Escobar-Morreale* 456

Ovarian Androgen-Producing Tumors *Michael DiMattina and Callum Potts* 458

Sport and Menses *Angelica Lindén Hirschberg* 461

Primary Ovarian Insufficiency *Luca Persani* 471

Adult Care of Turner Syndrome *Claus H Gravholt, Mette Viuff, Kirstine Stochholm, and Niels H Andersen* 482

Initial Evaluation of the Infertile Couple *Jean-Marie Antoine and Jacqueline Mandelbaum* 490

Endometriosis *Alain Audebert* 498

Epigenetics of Endometriosis *Daniel Vaiman* 506

Uterine Fibroids and Infertility *Jacques Donnez, Olivier Donnez, Pablo Arriagada, and Marie-Madeleine Dolmans* 513

Environmental Factors and Female Reproduction *Patrick Fénichel and Charlotte Rougier* 525

Miscarriages *Hervé Fernandez and Perrine Capmas* 538

Obesity and Reproduction *Andrés E Ortiz-Flores and Héctor F Escobar-Morreale* 543

Developmental Epigenetics and the Contribution of Parental Diet to Offspring Outcomes *Oliver J Rando and Rebecca A Simmons* 553

Anti-Müllerian Hormone (AMH) in Adults *Agathe Dumont, Geoffroy Robin, Sophie Catteau-Jonard, and Didier Dewailly* 556

Ovarian Stimulation with Clomiphene Citrate *J Gianfortoni* 567

Ovulation Induction With Gonadotropins *Aude Bruyneel, Ralph Papas, and Anne Delbaere* 570

Ovarian Hyperstimulation Syndrome *Basil C Tarlatzis, Julia K Bosdou, and Efstratios M Kolibianakis* 581

Fertility and Pregnancy in Patients With 21-Hydroxylase Deficiency *Virginie Grouthier, Carine Courtillot, Jérôme Dulon, Philippe Touraine, and Anne Bachelot* 588

In Vitro Fertilization (IVF) *Renato Fanchin* 595

Ovarian Failure Treatment Strategies: Egg Donation *Pedro N Barri* 599

Fertility Preservation in Women *Julie Benard, Alexandra Benoit, Charlotte Sonigo, and Michael Grynberg* 603

Female Hormonal Contraception *Genevieve Plu-Bureau* 615

Progesterone Receptor Modulators: Current Applications and Perspectives *Kamila Kolanska, Axelle Pintiaux, Philippe Bouchard, Emile Daraï, and Nathalie Chabbert-Buffet* 622

Diagnosis of Menopause *Tommaso Simoncini, Marta Caretto, Andrea Giannini, and Andrea R Genazzani* 628

Menopausal Treatment *Anne Gompel* 634

Hormonal Treatment of Breast Cancer *Stéphanie Bécourt and Marc Espié* 646

Hormonal Treatment of Male to Female Transgender *Alessandra D Fisher and Louis Gooren* 656

Male Reproduction

Testes Embryology: Cellular Molecular Changes *T Svingen and LJ Pelliniemi* 664

Spermatogonial Physiology and Regulation of the Niche *Stefan Schlatt and Swati Sharma* 670

Male Germ Cell Differentiation *My-Thanh Beedle and Michael D Griswold* 678

Endocrine Control of Spermatogenesis *TM Plant, S Ramaswamy, and Karel De Gendt* 684

Gonadotropin-Releasing Hormone (GnRH) Development and Actions *Margaret E Wierman* 692

Genes and Gene Defects Affecting Gonadal Development and Sex Determination *Dagmar Wilhelm and Stefan Bagheri-Fam* 695

Mutations of the Gonadotropin-Releasing Hormone Receptor Gene *Alfredo Ulloa-Aguirre, Teresa Zariñán, and Saúl Lira-Albarran* 704

Androgen Biosynthesis and Gene Defects *Adina F Turcu and Richard J Auchus* 713

Reproductive and Nonreproductive Actions of Testosterone *Shalender Bhasin and Ravi Jasuja* 721

Hormone Replacement Therapy in Men *Cindy Pham, Christina Wang, and Ronald S Swerdloff* 735

Male Hormonal Contraception *Brian T Nguyen, Ronald S Swerdloff, Frederick CW Wu, and Christina Wang* 741
Estrogen and the Male *Agnė Kadusauskienė and Jonas Čeponis* 751
Gynecomastia *Glenn D Braunstein* 763
Male Sexual Dysfunction *Amarnath Rambhatla and Jacob Rajfer* 767
Androgens and Benign Prostatic Hyperplasia *Maritza Farrant and Stephanie T Page* 775
Prostate Cancer *Timothy McClure, Spyridon P Basourakos, Jaspreet S Sandhu, Peter N Schlegel, and James J Colt* 784
Insulin-Like Peptide 3 (INSL3) *Ravinder Anand-Ivell and Richard Ivell* 793
Epididymis *Maria Christina W Avellar and Barry T Hinton* 807
Fertility in Men With Spermatogenesis Abnormalities *Katherine Rotker and Mark Sigman* 814
Genetics of Male Infertility *Csilla Krausz and Francesca Cioppi* 821
Testicular Tumors *Ewa Rajpert-De Meyts* 831
Male Oncoinfertility *Bernard Robaire and Peter T Chan* 840

VOLUME 3 – Adrenal Glands and Hypertension

Adrenal Glands and Hypertension

Adrenal Cortex; Physiology *Fady Hannah-Shmouni and Christian A Koch* 1
Adrenal Cortex; Development *Typhanie Dumontet and Antoine Martinez* 8
Corticotropin-Releasing Hormone Peptide Family *David W Hogg, Mia Husic, and David A Lovejoy* 16
Regulation of POMC and ACTH Secretion *Dongyun Zhang and Anthony P Heaney* 27
ACTH, Melanocortin Receptors, and MRAP Accessory Proteins *Robert M Dores* 38
Adrenocorticotropic Hormone (ACTH): Physiology and Its Involvement in Pathophysiology *George Mastorakos and Athanasios Antoniou-Tsigkos* 48
Adrenal Steroidogenesis *Daniel B Martinez-Arguelles and Vassilios Papadopoulos* 56
Overview of Glucocorticoids *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 64
Stress and Endocrine Physiology *Nicolas C Nicolaides, Panagiota Pervanidou, and George P Chrousos* 72
Hypothalamic–Pituitary–Adrenal Suppression *Nicolas C Nicolaides and George P Chrousos* 83
Glucocorticoid Metabolism and Activation *Nantia Othonos and Jeremy Tomlinson* 90
Glucocorticoid Receptor *Nicolas C Nicolaides, Evangelia Charmandari, and George P Chrousos* 104
Glucocorticoids and Immunity *Karen E Chapman* 112
Corticotropin-Releasing Hormone and Inflammation *Markella Nezi, Evangelia Zapanti, and George Mastorakos* 121
Adrenal Insufficiency: Etiology and Diagnosis *Nicolas C Nicolaides and Evangelia Charmandari* 131
Primary Adrenal Hypoplasia and ACTH Resistance Syndromes *Ioannis Kyrou and Constantine Tsigos* 139
Impact of Glucocorticoid Receptor Polymorphisms on Glucocorticoid Action *Mesut Savas and Elisabeth FC van Rossum* 147

Glucocorticoid Resistance Syndromes and States *Nicolas C Nicolaides and George P Chrousos* 157

X-Linked Adrenoleukodystrophy/Adrenomyeloneuropathy *William B Rizzo* 166

Steroid Replacement in Adrenal Insufficiency *Joanne C Blair, Miguel Debono, and Richard Ross* 172

Management of Adult Patients With Congenital Adrenal Hyperplasia Due to 21-Hydroxylase Deficiency *Virginie Grouthier, Jérôme Dulon, Anne Bachelot, and Philippe Touraine* 185

Cushing Syndrome; Screening and Differential Diagnosis *André Lacroix and Lynnette K Nieman* 193

Molecular Genetics of Cushing Disease *Martin Reincke, Marily Theodoropoulou, and Adriana Albani* 205

Pituitary Surgery for Cushing Disease *Pamela Jones and Brooke Swearingen* 215

Evaluation and Follow-Up of Patients With Cushing Disease After Pituitary Surgery *Amandine Ferriere, Claire Cordroch, and Antoine Tabarin* 223

Medical Therapy of Hypercortisolism *Richard A Feelders* 232

Radiation Therapy in Patients With Cushing Disease *Nicholas A Tritos, Jay S Loeffler, and Beverly MK Biller* 237

Bilateral Adrenalectomy for Cushing Disease *Frederic Castinetti* 243

Cushing Syndrome—Unilateral Adrenal Adenoma *Guido Di Dalmazi* 249

Somatic β-Catenin Gene Mutations and WNT Signaling in Adrenal Tumors *Isabelle Bourdeau* 259

Adrenocortical Tumors and *gsp* Mutations *Maria Candida Barisson Villares Fragoso, Isadora Pontes Cavalcante, Leonardo Tadeu Araujo, Helaine Laiz Silva Charchar, Ingrid Quevedo Wanichi, Vania Balderrama, Amanda Meneses Ferreira, and Beatriz Marinho de Paula Mariani* 266

PPNAD, Carney Complex, and Other Micronodular Adrenal Hyperplasia *Stéphanie Espiard and Jérôme Bertherat* 271

Genetics of Familial Forms of Cortisol-Secreting Adrenal Tumors and Hyperplasias *Ludivine Drougat and Constantine A Stratakis* 283

Primary Bilateral Macronodular Adrenal Hyperplasia *André Lacroix* 293

Adrenal Incidentalomas *Massimo Terzolo, Soraya Puglisi, and Giuseppe Reimondo* 303

Adrenocortical Carcinoma: Diagnosis and Therapy *Massimo Terzolo, Soraya Puglisi, Paola Perotti, Mélanie Claps, Elisa Roca, and Alfredo Berruti* 308

Adrenocortical Carcinoma: Genetics and Molecular Markers *Anne Jouinot and Guillaume Assié* 317

Adrenal Surgery *Pavel Nockel, Mustapha El Lakis, and Electron Kebebew* 323

Long-Term Complications of Hypercortisolism *Rosario Pivonello, Davide Iacuaniello, Chiara Simeoli, Maria Cristina De Martino, and Annamaria Colao* 341

Effects of Glucocorticoids on the Brain *Alberto M Pereira, Susan M Webb, and Onno C Meijer* 360

Hypertension; Overview *Morton P Printz and Rebecca L Jaworski* 369

Neurogenic Hypertension *Gino Seravalle, Guido Grassi, and Giuseppe Mancia* 381

Renal Hypertension *Daniele Cusi* 383

Endocrine Hypertension *Inga Harbuz-Miller, Ryan Woodman, and Guido Lastra* 390

Resistant Hypertension *Robert M Carey* 402

Hypertension and Target Organ Damage *Maria Lorenza Muiesan, Anna Paini, Claudia Agabiti Rosei, Fabio Bertacchini, Carlo Aggiusti, Carolina De Ciuceis Damiano Rizzoni, and Massimo Salvetti* 406

Stroke *PCAJ Vroomen and GA Donnan* 415

Normetanephrine and Metanephrine *Jacques WM Lenders and Graeme Eisenhofer* 420

Adrenergic Mechanisms *Peter W de Leeuw and Abraham A Kroon* 425

Novel Insights in β-Adrenergic Receptor Signaling *Guido Iaccarino and Daniela Sorriento* 432

Baroreceptor Responses *AF Sved, EM Stricker, and SD Stocker* 440

Antiadrenergic Agents *Enrico Agabiti-Rosei* 443

Pheochromocytoma and Paraganglioma Syndromes *Vitaly Kantorovich and Karel Pacak* 449

Pheochromocytoma/Paraganglioma: Diagnosis and Treatment *Maurizio Castellano, Mara Giacchè, Luigi Mori, Alessandra Panarotto, and Carlo Cappelli* 455

Malignant Pheochromocytoma *Massimo Mannelli, Gabriele Parenti, Letizia Canu, Giuseppina De Filpo, and Elena Rapizzi* 460

Pheochromocytoma/Paraganglioma: Management, Genetics, and Follow-up *Anne-Paule Gimenez-Roqueplo and Laurence Amar* 469

Renin and Prorenin *Alberto Morganti* 478

Angiotensinogen and Angiotensins *Massimo Volpe and Speranza Rubattu* 483

Kininases *Randal A Skidgel, Ervin G Erdös, and Peter A Deddish* 490

Tissue Ace–Angiotensin–AT_1 Receptor Axis and Repair in the Heart *Yao Sun and Karl T Weber* 497

Hypertension and the Renin–Angiotensin–Aldosterone System *Elena Kaschina, Ulrike M Steckelings, and Thomas Unger* 505

Hyperreninemia *Pierre-François Plouin, Laurence Amar, and Michel Azizi* 511

Renal Vein Renin Measurement as a Diagnostic Tool *Gian Paolo Rossi* 516

Interference With the Renin–Angiotensin System (RAS): Classical Inhibitors and Novel Approaches *Katrina M Mirabito Colafella, Estrellita Uijl, and AH Jan Danser* 523

Aldosterone; Synthesis and Metabolism *John W Honour* 531

Aldosterone; Action and Function *Peter J Fuller and Morag J Young* 540

Aldosterone Receptors *Say Viengchareun, Marc Lombès, and Laetitia Martinerie* 546

Regulation of Potassium Homeostasis *Paola Russo, Fabio Lauria, and Alfonso Siani* 552

Salt-Sensitivity of Blood Pressure *Pasquale Strazzullo, Ferruccio Galletti, and Lanfranco D'Elia* 558

Endogenous Ouabain *Paolo Manunta and Marco Simonini* 564

Atrial Natriuretic Factor and the Family of Natriuretic Peptides *Tsuneo Ogawa and Adolfo J de Bold* 569

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Pathophysiology *John W Funder* 581

Mineralocorticoids and Mineralocorticoid Excess Syndromes: Clinical Aspects *Ellen Marie Freel* 586

Primary Aldosteronism; Epidemiology and Screening *Michael Stowasser* 598

Primary Aldosteronism; Diagnosis and Treatment *Franco Mantero and Maria Verena Cicala* 607

Adrenal Venous Sampling for Primary Aldosteronism *Gian Paolo Rossi* 613

Genetics of Familial Hyperaldosteronism *Silvia Monticone, Martina Tetti, Isabel Losano, Franco Veglio, and Paolo Mulatero* 623

Aldosterone-Producing Adenomas; Genetics *Livia Lenzini, Sofia Zanin, and Gian Paolo Rossi* 631

Apparent Mineralocorticoid Excess *Padiporn Limumpornpetch and Paul M Stewart* 638

Licorice and 11β-Hydroxysteroid Dehydrogenase *Decio Armanini and Chiara Sabbadin* 644

Liddle Syndrome *Ermanno Rossi and Giovanni Maria Rossi* 652

Secondary Hyperaldosteronism *Aleksander Prejbisz and Andrzej Januszewicz* 664

Aldosteronism in Congestive Heart Failure *Yenal I Harper, Oluwaseun A Akinseye, Salem A Salem, Muhammad Shahreyar, and Karl T Weber* 668
Mineralocorticoid Receptor Antagonists *John W Funder* 674
Diuretics *Claudio Ferri and Rita Del Pinto* 681
Calcium Channel Blockers *Stefano Taddei and Rosa Maria Bruno* 689
Pseudohypoaldosteronism Type 1 *Fabio L Fernandes-Rosa* 696
Hyporeninemic Hypoaldosteronism *Shrey Purohit, Dalila B Corry, and Michael L Tuck* 703
Bartter and Gitelman Syndromes *Lorenzo A Calò and Verdiana Ravarotto* 714
Angiogenesis *Lindsay S Cooley and Andreas Bikfalvi* 722

VOLUME 4 – Calcium and Bone, and Thyroid Gland

Calcium and Bone

Bone Cells: Osteoblast/Osteoclast/Osteocyte *Nadia Rucci and Anna Teti* 1
Bone Remodeling *Susan M Ott* 10
Bone Structure and Biomechanics *Fjola Johannesdottir and Mary L Bouxsein* 19
Bone and Bone Marrow; Interactions *Delphine Spruyt, Céline Gillet, and Joanne Rasschaert* 31
Bone Muscle Interactions and Exercise *Jenny E Gunton* 40
Bone as an Endocrine Organ *Gerard Karsenty and Stavroula Kousteni* 47
Calcium Homeostasis in Humans *Roger Bouillon* 52
Calcium-Sensing Receptor *Giuseppe Vezzoli, Teresa Arcidiacono, Lorenza Macrina, Katia Maruca, and Stefano Mora* 58
Phosphate Metabolism, Hyperphosphatemia, and Hypophosphatemia *Seiji Fukumoto* 68
Vitamin D *Ian R Reid* 75
Nutrition and Bone *Peter Burckhardt* 82
Bone Development During Childhood and Adolescence: Peak Bone Mass *Jean De Schepper* 89
Bone Mass Measurement *Paul D Miller and Pierre JM Bergmann* 94
X-Ray Based Imaging Methods to Assess Bone Quality *Klaus Engelke* 102
Bone Turnover Markers *Etienne Cavalier, Richard Eastell, Niklas Rye Jørgensen, Konstantinos Makris, Samuel Vasikaran, and Howard A Morris* 116
Primary Hyperparathyroidism *Claudio Marcocci and Filomena Cetani* 128
Parathyroid Cancer *D Fink and Elizabeth Shane* 139
Parathyroid Surgery *EF Garner and H Chen* 151
Hypercalcemia: Other Causes than Primary Hyperparathyroidism *René Rizzoli* 160
Parathyroid Hormone Related Protein (PTHrP) *Archana Kamalakar, Charity L Washam, and Larry J Suva* 168
Physiology of Calcitonin and Its Therapeutic Uses *Sunil J Wimalawansa* 178
Hypoparathyroidism and Other Causes of Hypocalcemia *Bart L Clarke* 192
Calcitonin Gene-Related Peptide (CGRP) *AA Aubdool, X Kodji, and SD Brain* 204

Epidemiology of Fractures *Nicholas R Fuggle, Elaine M Dennison, and Cyrus Cooper* 213
Pathogenesis of Osteoporosis *Emma O Billington and Ian R Reid* 222
Role of Estrogens and Androgens in Osteoporosis *Michaël R Laurent* 233
Osteoporosis in Premenopausal Women *Serge Rozenberg* 246
Secondary Osteoporosis *Gregory R Emkey* 253
Osteoporosis; Prevention and Ca–Vitamin D Treatment *Bo Abrahamsen* 270
Osteoporosis Treatment: Bone-Forming Agents *Bente L Langdahl* 275
Osteoporosis Treatment: Sequential and Combination Therapy *Benjamin Z Leder and Joy N Tsai* 281
Osteoporosis: Treatment Gaps and Health Economics *Nicholas CW Harvey, Eugene V McCloskey, René Rizzoli, John A Kanis, Cyrus Cooper, and Jean-Yves Reginster* 288
Cancer Treatment-Induced Bone Loss (CTIBL) *Catarina Abreu, Maria R Dionísio, Joana C Silva, and Luís Costa* 296
Bone Metastases; Basic Aspects *Margaux Bernard, Paola Di Mauro, Caroline Reynaud, Chantal Diaz-Latoud, and Philippe Clézardin* 304
Bone Metastases; Clinical Aspects *Steven Wood, Azeez Salawu, Helen Kroening, Stella D'Oronzo, and Janet Brown* 310
Bone Metastases; Medical Treatment *Robert Coleman* 320
Multiple Myeloma Bone Disease *Evangelos Terpos and Maria Gavriatopoulou* 329
Diabetes and Bone *Peter Vestergaard* 341
Paget Disease of Bone *Stuart H Ralston* 350
Heterotopic Ossification and Calcification *Chen Kan, Na Ding, and Lixin Kan* 356
Kidney Stones *S Dizon, EA Iliescu, and A Ross Morton* 365
Pseudohypoparathyroid States *A Tsatsoulis, A Fountas, and E Laspa* 372

Thyroid Gland

Thyroid Gland: Anatomy and Physiology *Salvatore Benvenga, Giovanni Tuccari, Antonio Ieni, and Roberto Vita* 382
Thyroid Gland Development, Molecular Biology *Marina Muzza and Laura Fugazzola* 391
Hypothalamus–Pituitary–Thyroid Axis *Marco Bonomi, Biagio Cangiano, and Luca Persani* 398
Thyroid-Stimulating Hormone (TSH; Thyroptopin) *Leonidas H Duntas* 403
TSH Function and Secretion *Susan R Rose and Janet S Chuang* 408
TSH (Thyrotropin) Receptor *Yuji Nagayama* 416
Thyroid Hormone Metabolism *Josef Köhrle* 420
Sodium/Iodide Symporter (NIS) *Nancy Carrasco and Rachel R Kaspari* 429
Thyroid Peroxidase *Salvatore Benvenga and Roberto Vita* 433
Thyroglobulin *Marina Muzza and Laura Fugazzola* 439
Serum Thyroid Hormone-Binding Proteins *Luigi Bartalena and Eliana Piantanida* 442
Thyroid Hormone Receptors *Claire Briet, Frédéric Illouz, and Patrice Rodien* 448
Thyroid Hormone Action *Yui Watanabe and Roy E Weiss* 452
Resistance to Thyroid Hormone *Gisah Amaral de Carvalho, Tayane Muniz Fighera, and Roy E Weiss* 463

TSH-Producing Adenomas and Resistance to Thyroid Hormones *P Beck-Peccoz, L Persani, and A Lania* 473
Thyroid Function Tests *ER Christ and Albert G Burger* 477
Epidemiology of Thyroid Disease *Mark PJ Vanderpump* 486
Genetic Factors in Thyroid Disease *Marina Muzza and Laura Fugazzola* 496
Environmental Goitrogens *Veena Agrawal, Sana A Ghaznavi, and Ralf Paschke* 506
Iodine Deficiency *Peter Taylor, Onyebuchi Okosieme, Lakdasa Premawardhana, and John H Lazarus* 512
Nontoxic Goiter *Sana Ghaznavi, Kirstie Lithgow, Veena Agrawal, and Ralf Paschke* 524
Thyroid Nodule *Laszlo Hegedüs* 529
Thyroid and Irradiation *Barbara Jarzab, Daria Handkiewicz-Junak, and Jolanta Krajewska* 539
Thyroid Imaging *Luca Giovanella, Giorgio Treglia, and Pierpaolo Trimboli* 545
Thyroid Fine Needle Aspiration Cytology *Ivana Kholová and Camilla Schalin-Jäntti* 565
Thyroid Carcinoma *Rossella Elisei* 573
Medullary Thyroid Carcinoma *Maria Alevizaki, Katerina Saltiki, and Theodora Pappa* 586
Causes of Hypothyroidism *Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen* 600
Diagnosis of Hypothyroidism *Ulla Feldt-Rasmussen, Marianne Klose, and Åse Krogh Rasmussen* 604
Central Hypothyroidism *Luca Persani and Marco Bonomi* 608
Hashimoto's Thyroiditis *Grigoris Effraimidis and Ulla Feldt-Rasmussen* 613
Systemic Manifestations of Hypothyroidism *Massimo Tonacchera and Luca Chiovato* 616
Treatment of Hypothyroidism *Bernadette Biondi* 624
Myxedema Coma *Leonard Wartofsky* 627
Hypothyroidism, Subclinical *Bettina F Winzeler, Mirjam Christ-Crain, Beat Müller, and Christian Meier* 630
Thyroid Autoimmunity *Ulla Feldt-Rasmussen, Sofie Bliddal, and Claus H Nielsen* 636
Thyrotoxicosis; Overview of Causes *Claudio Marcocci and Roberto Rocchi* 651
Thyrotoxicosis; Diagnosis *Claudio Marcocci and Roberto Rocchi* 657
Thyrotoxicosis; Systemic Manifestations *Claudio Marcocci and Filomena Cetani* 665
Thyrotoxicosis; Treatment *Claudio Marcocci and Filomena Cetani* 673
Subclinical Hyperthyroidism *Bernadette Biondi* 680
Antithyroid Drugs *Jacques Orgiazzi* 683
Radioactive Iodine *Barbara Jarzab and Jolanta Krajewska* 688
Thyrotoxicosis Factitia *Fausto Bogazzi and Enio Martino* 693
Thyrotoxic Storm *Leonard Wartofsky* 695
Graves' Disease *Irene Campi and Mario Salvi* 698
Hyperthyroidism in Graves' Disease *Danila Covelli and Mario Salvi* 702
Pretibial Myxedema *Guia Vannucchi and Mario Salvi* 707
Graves' Orbitopathy *Mario Salvi* 711
Smoking and the Thyroid *Luigi Bartalena and Maria L Tanda* 719

Toxic Adenoma *Kirstie Lithgow, Sana A Ghaznavi, Alexandra Stephenson, Amita Mahajan, and Ralf Paschke* 723
Toxic Multinodular Goiter *Amita Mahajan, Sana A Ghaznavi, Kirstie Lithgow, and Ralf Paschke* 730
Thyroiditis, Infectious and Subacute *Grigoris Effraimidis and Ulla Feldt-Rasmussen* 737
Postpartum Thyroid Dysfunction *Lakdasa DKE Premawardhana and John H Lazarus* 746
Thyroid and Infertility *Sofie Bliddal, Henriette S Nielsen, and Ulla Feldt-Rasmussen* 752
Thyroid Disease and Pregnancy *AM Leung and Jerome M Hershman* 762
Thyroid Disorders in the Elderly *Vafa Tabatabaie and Martin I Surks* 768
Drug Effects and Thyroid Function *Ulla Feldt-Rasmussen and Åse K Rasmussen* 772
Lithium *John H Lazarus* 780
Amiodarone and Thyroid *Fausto Bogazzi and Enio Martino* 782
Thyroid Disease and Bone *Bente L Langdahl* 787
Thyroid Function and Depression *Martin B Jørgensen and Ulla Feldt-Rasmussen* 792
Measuring Impact of Benign Thyroid Diseases on Quality of Life *Torquil Watt* 802

VOLUME 5 – Pediatric Endocrinology

Pediatric Endocrinology

Control and Monitoring of Fetal Growth *Tomas Prior and Christoph Lees* 1
Physiology of Growth Hormone in Fetus and Child *Vijayarangan G Kannian and Fiona J Ryan* 10
Infant, Childhood, and Adolescent Auxology *Gary Butler* 19
Body Proportions *Willem JM Gerver, Bas Penders, and Ralph Brecheisen* 31
Genetic and Hormonal Control of Growth *George Paltoglou, Harshini Katugampola, and Mehul T Dattani* 38
Abnormal Growth: Small for Gestational Age *Kathryn Beardsall, Meera Mallya, and Ajay Thankamony* 55
Growth Hormone Deficiency in Children *Berit Kriström and Elena Lundberg* 66
Growth Hormone Insensitivity *Martin O Savage, Sumana Chatterjee, Vivian Hwa, and Helen L Storr* 81
Tall Stature *Sabine E Hannema and Lars Sävendahl* 94
Growth in Childhood Chronic Conditions *Kung-Ting Kao, Syed Faisal Ahmed, and Sze Choong Wong* 102
Normal Puberty: Somatic Characteristics *Dipesalema Joel and Ieuan Hughes* 118
Genetic and Epigenetic Control of Puberty *Ana Claudia Latronico and Leticia F Silveira* 126
Hormonal Control of Puberty *Lindsey A Loomba-Albrecht and Dennis M Styne* 137
Secular Changes in Puberty *Camilla Eckert-Lind, Alexander S Busch, Elvira V Bräuner, and Anders Juul* 144
Delayed Puberty; Male *Alan D Rogol* 153
Delayed Puberty and Hypogonadism; Female *Sasha Howard and Leo Dunkel* 157

Gonadotropin-Dependent Precocious Puberty; Female and Male *Dick Mul, Wilma Oostdijk, and Stenvert LS Drop* 166

Gonadotrophin-Independent Precocious Puberty; Female and Male *Stenvert LS Drop and Hedi L Claahsen van de Grinten* 175

Organ-Specific Pediatric Endocrine Disorders, Pituitary: Craniopharyngioma *Timothy Shao Ern Tan, John Paul Kilday, and Leena Patel* 186

Hamartoma, Pituitary *G Patti, G Morana, N Di Iorgi, and M Maghnie* 196

Anorexia Nervosa *Maria Teresa Muñoz, Monserrat Graell, and Jesús Argente* 205

Endocrine Late Effects in Childhood Cancer Survivors *Wassim Chemaitilly and Laurie E Cohen* 216

Disturbances of Sodium and Water. Diabetes Insipidus in Children *Rasa Verkauskiene and Ruta Navardauskaite* 235

Obesity, Childhood, and Adolescence *Wieland Kiess* 247

Appetite and Weight *Clare H Llewellyn and Alison Fildes* 260

Management of Obesity in Children and Adolescents: Lifestyle and Exercise Options *James D Nobles and Paul J Gately* 269

Congenital Hypothyroidism: Screening, Early Management, and Outcome *Tim Cheetham* 280

Genetic Causes of Congenital Hypothyroidism *Nadia Schoenmakers* 291

Congenital Hypothyroidism: A Historical Perspective on Cognitive Outcome *Heiko Krude* 308

Hyperthyroidism, Childhood and Adolescence *Scott A Rivkees* 312

Thyroid Tumors in Children *Ari J Wassner* 322

Physiology of Fetal and Neonatal Calcium Metabolism *Jeremy Allgrove* 330

Rickets and Osteomalacia *Suma Uday and Wolfgang Högler* 334

Osteogenesis Imperfecta *Nick Bishop* 350

Hypercalcemia *Justin H Davies and Rebecca J Moon* 361

A Review of Skeletal Dysplasias for the Pediatric Endocrinologist *Sarah M Nikkel and Leanne Ward* 373

Premature Adrenarche *Antonis Voutetakis, Catherine Dacou-Voutetakis, Maria Dracopoulou, and Sarantis Livadas* 380

21-Hydroxylase Deficiency: Clinical and Biochemical Aspects *Anna Nordenström and Svetlana Lajic* 388

Prenatal Diagnosis and Treatment of Congenital Adrenal Hyperplasia *Svetlana Lajic and Anna Nordenström* 401

Steroidogenic Factor 1 (SF-1; NR5A1) *Ken McElreavey and Anu Bashamboo* 410

11β-Hydroxylase Deficiency *Krupali Bulsari and Henrik Falhammar* 416

Human P450 Oxidoreductase Deficiency *Christa E Flück and Amit V Pandey* 426

Pediatric Cushing Disease *Ingrid CE Wilkinson, Martin O Savage, and Helen L Storr* 439

Genetic Control of Fetal Sex Development *Rajini Sreenivasan, Brittany Croft, and Andrew Sinclair* 449

Hormonal Control of Fetal Sex Development *Nadine Hornig, Alexandra Kulle, and Paul-Martin Holterhus* 463

Classification and Presentation of Disorders of Sexual Development (DSD) *Kanthi Bangalore Krishna, Selma F Witchel, Christopher Houk, and Peter Lee* 471

Androgen Biosynthetic Defects: 17β-Hydroxysteroid Dehydrogenadse Type 3 and 5α-Reductase Type 2 Deficiencies *Nathalia L Gomes, Rafael L Batista, and Berenice B Mendonca* 481

Androgen Insensitivity Syndrome (AIS): Complete AIS (CAIS) *Jarmo Jääskeläinen* 487

Androgen Insensitivity: Partial AIS *Rieko Tadokoro-Cuccaro and Ieuan A Hughes* 496

Anti-Müllerian Hormone Deficiency and Resistance *Rodolfo A Rey, Jean-Yves Picard, Nathalie di Clemente, Richard L Cate, and Nathalie Josso* 501

Hypospadiac Genital Tubercle (GT) *Maguelonne Pons, Daniela-Brindusa Gorduza, and Pierre Mouriquand* 513

Undescended Testes *Ritzén E Martin* 521

Human Aromatase Deficiency *Gabriela Guercio, Nora Saraco, Mariana Costanzo, Roxana Marino, and Alicia Belgorosky* 527

Turner Syndrome *Theo CJ Sas, Janielle AEM van Alfen-van der Velden, and Sabine MPF de Muinck Keizer-Schrama* 545

Klinefelter Syndrome *Shanlee M Davis and Judith L Ross* 556

45,X/46,XY Gonadal Dysgenesis, 46,XX/46,XY Chimerism (and Variants), and 46,XX Testicular and Ovotesticular DSD *Martine Cools* 563

Intersexuality: Gender Assignment and Psychosocial Care *Heino FL Meyer-Bahlburg* 570

Ethical and Legal Aspects of DSD/Intersex *Jens M Scherpe and Jameson Garland* 581

Neonatal Diabetes Mellitus *Abdelhadi Habeb and Asma Deeb* 591

Congenital Hyperinsulinism *Indraneel Banerjee, Maria Salomon Estebanez, Karen E Cosgrove, and Mark J Dunne* 602

Beckwith–Wiedemann Spectrum *Eamonn R Maher* 618

McCune–Albright Syndrome *Erica A Eugster* 629

Noonan Syndrome *Michael A Patton and Alistair P Patton* 635

Prader–Willi Syndrome *Urs Eiholzer, Claudia Katschnig, and Annik Hauri-Hohl* 639

Bone Cells: Osteoblast/Osteoclast/Osteocyte

Nadia Rucci and Anna Teti, University of L'Aquila, L'Aquila, Italy

Glossary

Bone marrow mesenchymal stem cells (BMMSCs) Pluripotent cells isolated from the bone marrow, which are able to proliferate and self-renew, as well as to give rise to progeny of the osteogenic, chondrogenic, and adipogenic lineages.

Bone remodeling Physiological process by which bone maintains a dynamic steady state through sequential resorption and formation of bone at the same site by osteoclasts and osteoblasts.

Cleidocranial dysplasia (CCD) (*Alias* cleidocranial dysostosis) rare autosomal dominant disease characterized by hypoplastic or absent clavicles, dental anomalies, and delayed skeletal development. It is caused by a mutation of the 6p21gene coding for runt-related transcription factor (Runx)2.

Endosteal niche (*Alias* osteoblast niche) niche present in the endosteal part of the bone marrow. It includes osteoblast-like cells, called spindle-shaped N-cadherin$^+$/CD45$^-$ osteoblasts (SNOs) through which it regulates quiescence of long-term (LT)-hematopoietic stem cells (HSCs).

Hematopoietic stem cells (HSCs) Multipotent, self-renewing progenitor cells which give rise to all differentiated blood cells. HSCs can be found in bone marrow, peripheral blood, and umbilical cord blood.

High bone mass disease Rare genetic disease characterized by mandible enlargement and increased bone mass. It is caused by dominant missense mutations of the gene coding for the low density lipoprotein (LDL) receptor-related protein 5 (LRP5).

Matrix vesicles Membrane-enclosed vesicles secreted by odontoblasts, osteoblasts, and chondrocytes which serve as nucleation centers for the mineralization of calcified cartilage, bone, and dentin.

Osteoporosis pseudoglioma syndrome Autosomal recessive disease characterized by severe thinning of the bones (osteoporosis) and eye abnormalities that lead to vision loss. It is caused by an inactivating mutation of the gene coding for the low density lipoprotein (LDL) receptor-related protein 5 (LRP5).

Sclerosteosis Autosomal recessive disease characterized by bone overgrowth, sometimes associated with syndactyly. It is caused by inactivating mutation in the sclerostin (Sost) gene.

van Buchem disease Autosomal recessive bone dysplasia characterized by otosclerosis and thickening of skull, face, and trunk bones, also associated to facial paralysis and sight or hearing loss. It is caused by inactivating mutation in the sclerostin (Sost) gene.

Osteoblasts: Not Just Bone Building Cells

Osteoblastogenesis

Bone marrow mesenchymal stem cells are spindle-shaped nonhematopoietic stem cells accounting for 0.001%–0.01% of the nucleated fraction in the bone marrow (Pittenger *et al.*, 1999) and representing a reservoir of many progenitors of connective tissue cells, among them the osteoblasts.

One of the earliest steps in osteoblast differentiation is the commitment of MSCs toward an osteo/chondroprogenitor, which is expected to express the following markers: Runt-related transcription factor 2 (Runx2) and its downstream regulated genes Osterix (Osx) and Distal-less homeobox 5 (Dlx5). The role of Runx2 (*alias* core binding factor alpha 1, cbfa1, and osteoblast specific factor 2, Osf2) in osteogenesis is undisputed, since this transcription factor drives the expression of the principal osteoblast-specific genes (Ducy *et al.*, 1997). Consistently, missense mutations in the Runx2 gene cause cleidocranial dysplasia, an autosomal dominant disease characterized by hypoplastic or absent clavicles, dental anomalies, and delayed skeletal development (Lee *et al.*, 1997).

Runx2 is a direct target of Wnt/β-catenin pathway and, in turn, promotes the transcriptional expression of the osteoblast marker ALP and collagen I (Col1A1), bone sialoprotein (BSP) and BGLAP, that is the gene coding for osteocalcin (OCN). Another gene whose transcription is driven by Runx2 is Osx, also known as Sp7, which further pushes the osteo/chondroprogenitor toward the osteoblast lineage by promoting the expression of SATB2 (Tang *et al.*, 2011). This is a transcription factor belonging to the family of special AT-rich binding (Satb), whose haploinsufficiency causes craniofacial defects in humans (Britanova *et al.*, 2006). SATB2 interacts with both Runx2 and activating transcription factor 4, another crucial transcription factor as demonstrated by the fact that its knock down significantly impairs bone formation (Yang *et al.*, 2004). All these three factors cooperate to drive osteoblastogenesis.

Once formed, osteoprogenitors undergo a phase of proliferation; then they become preosteoblasts, expressing high amounts of ALP, which eventually differentiate into mature osteoblasts. These are very active cells producing bone matrix proteins, among which OCN is considered a late marker of osteoblast differentiation, while at this stage ALP expression progressively decreases (**Fig. 1**). In histological

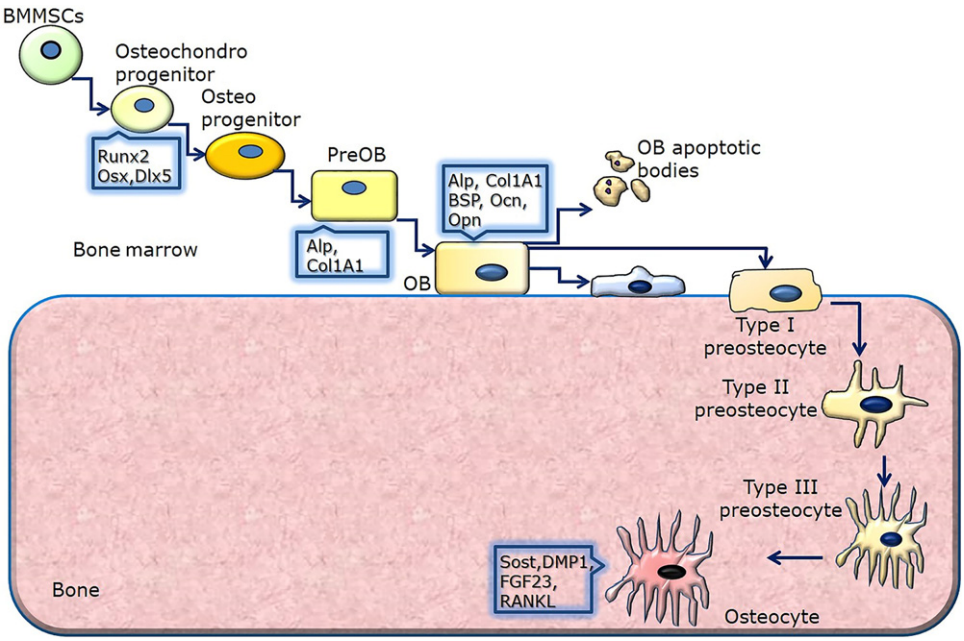

Fig. 1 Schematic representation of the multistep process of osteoblast (OB) and osteocyte differentiation. *BMMSCs*, bone marrow mesenchymal stem cells.

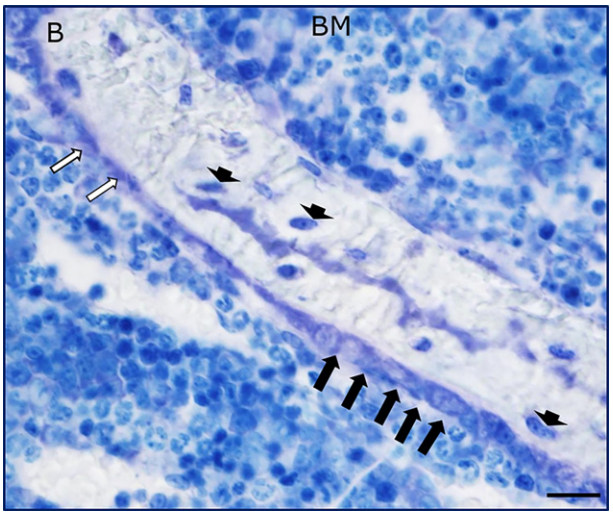

Fig. 2 Histological section of a mouse tibia, stained with toluidine blue. *Black arrows* indicate a row of osteoblasts on a bone trabecula, *white arrows* indicate bone-lining cells, *arrowheads* show the osteocytes. *B*, bone; *BM*, bone marrow; bar = 15 μm.

sections, active osteoblasts usually appear as large cuboidal cells arranged in single layer along the bone surface (**Fig. 2**, black arrows). They also present with cytoplasmic processes toward the bone matrix, which allow the contact with osteocytes.

We now have quite a complete picture of the main pathways driving osteoblastogenesis, which include Wnt and bone morphogenetic proteins (BMPs). The former is a family of at least 19 glycoproteins, which accounts for a broad range of functions in development, cell growth, and differentiation, while an aberrant activation of the Wnt pathway is causative of many cancers. In bone, the importance of the Wnt pathway came to light by studying two bone diseases, opposite in their phenotype, but both caused by a dysregulation of Wnt signaling: the osteoporosis pseudoglioma syndrome, due to an inactivating mutation of the Wnt co-receptor Lrp5, and the high bone mass syndrome, characterized by a gain-of-function mutation of the same gene (Gong *et al.*, 2001; Boyden *et al.*, 2002).

To transduce the signal, Wnt proteins interact with seven different G-coupled receptors belonging to the frizzled (Fzd) family and the Lrp5/Lrp6 coreceptors. Interaction of Wnt ligands with the tyrosine kinases Ryk and Ror as coreceptors has also been observed (Lu *et al.*, 2004). Two main intracellular pathways are triggered by Wnt, known as canonical or noncanonical. The former

relies on the stabilization of the β-catenin, which in turn translocates into the nucleus and activates the lymphoid-enhancing factor/T cell factor (Lef/Tcf) transcription factor. In particular, when Lrp5/6 and Fzd are not engaged by Wnt, the glycogen synthase kinase 3 (GSK3)-β and Ck1 serine kinases form the β-catenin destruction complex along with axin and the adenomatous polyposis of colon (APC) oncosuppressor protein. In this way, GSK3-β phosphorylates the β-catenin creating a docking site for the F-box-containing protein E3 ubiquitin ligase b-TrCP, eventually leading to its ubiquitination and subsequent proteasomal degradation (Aberle *et al.*, 1997). The interaction of Wnt with its receptor Fzd induces phosphorylation of the LRP5/6 receptor, which allows the destruction complex to be sequestered into multivesicular endosomes, thus allowing stabilization and accumulation of the β-catenin (Taelman *et al.*, 2010).

The alternative signaling pathway of Wnt, not involving β-catenin, depends on the G-protein-coupled function of the Fzd receptor, which in turn activates Rho and Rac GTPase and the downstream effectors JNK and p38 (Tu *et al.*, 2007). In osteoblasts, this pathway promotes their differentiation and is triggered by Wnt3a (Tu *et al.*, 2007). A Wnt/Ca^{2+}-dependent pathway has also been described, which requires phospholipase C (PLC) engagement, eventually leading to increased intracellular Ca^{2+} and activation of protein kinase C and calcium calmodulin-dependent kinase 2 (Sheldahl *et al.*, 1999).

Commitment of MSCs toward an osteoblast progenitor is driven by Wnt3a and Wnt10b which at the same time also inhibit adipogenic differentiation (Bennett *et al.*, 2007). The role of Wnt10b in osteogenesis has also been confirmed in transgenic mouse models overexpressing or knocked down for this protein (Bennett *et al.*, 2007; Stevens *et al.*, 2010).

Several Wnt antagonists affecting bone homeostasis have been identified, such as sclerostin (Sost), a molecule mainly produced by osteocytes, which inhibits Wnt/β-catenin pathway by binding to Lrp5 (van Bezooijen *et al.*, 2004). Two pathologies characterized by bone overgrowth, van Buchem syndrome and sclerosteosis, are due to inactivating mutations in the SOST gene (Brunkow *et al.*, 2001; Balemans *et al.*, 2002). Moreover, intermittent treatment with PTH inhibits Mef2c activity, eventually leading to a reduced expression of Sost (Koeller and Kneissel, 2005).

Other molecules counteracting the Wnt action are the Groucho/TLE family members, which are transcriptional corepressors that inhibit Wnt target gene transcription by competing with β-catenin for TCF/LEF binding (Daniels and Weis, 2005).

The second pivotal pathway for osteoblast differentiation belongs to the transforming growth factor beta-bone morphogenetic proteins (TGFβ-BMPs) family, which includes at least 30 members involved in several functions, such as embryonic development, cell proliferation, and differentiation. BMPs are mainly involved in the earliest phases of osteoblast differentiation, favoring the commitment of bone marrow MSCs toward an osteo/chondroprogenitor (Chen *et al.*, 2012). Osteoblast conditional knockout for BMP-2 and BMP-4 significantly affects osteogenesis (Bandyopadhyay *et al.*, 2006). Another BMP involved in osteoblast differentiation is the -7 isoform, which increases ALP activity in MSCs and nodule formation (Shen *et al.*, 2010).

Osteoblast differentiation is also regulated by fibroblast growth factors (FGFs), a family of 23 members, which are also involved in adipogenic differentiation. FGF-2, -4 and -8 increase Runx2 expression in MSCs. FGF-2, -9, and -18 also promote ALP activity and bone mineralization (Woei *et al.*, 2007).

Recent findings point out a role for microRNAs (miRNAs) in osteoblast homeostasis (van der Eerden, 2014). Indeed, a proadipogenic effect at the expense of osteoblastogenesis has been observed for miR-204 and miR-637, by targeting Runx2 and osterix, respectively (Huang *et al.*, 2010; Zhang *et al.*, 2011). With regard to miRNAs stimulating osteoblast differentiation, worth mentioning are miR194, miR216a, targeting c-Cbl, and miR26-a, targeting GSK3-β (Jeong *et al.*, 2014; Huang *et al.*, 2017; Li *et al.*, 2013). However, findings in this field are increasing more and more, broadening the picture of the regulation of osteoblast differentiation.

Osteoblast Functions

Bone matrix deposition and mineralization are the well-known functions of osteoblasts, which secrete collagen type I and noncollagenous proteins. The latter include osteopontin (OPN), osteonectin, BSP, dentin sialoprotein, and dentin matrix protein 1 (DMP1), all belonging to the small integrin binding ligand N-linked glycoproteins family (Fisher and Fedarko, 2003) and OCN.

The organic matrix, called osteoid, is destined to undergo mineralization, a process starting when local Ca^{2+} and phosphate (PO_4^{3-}) ions reach levels high enough to precipitate, leading to the formation of hydroxyapatite crystals. The process of bone mineralization occurs by means of the matrix vesicles. These are extracellular membrane-layered vesicles enriched in alkaline phosphatases and acidic phospholipids, which are secreted by chondrocytes and osteoblasts to shuttle hydroxyapatite crystals (Bonucci and Dearden, 1976; Anderson, 2003). The latter are then released into the extracellular space where they grow in clusters and fill the gaps within and between the collagen fibrils.

An intense crosstalk exists between osteoblasts and osteoclasts, with a reciprocal regulation, eventually leading to a coupling of their functions. From the side of osteoblasts, they regulate osteoclast life by producing macrophage-colony stimulating factor (M-CSF), receptor activator of NFkappaB ligand (RANKL), and osteoprotegerin (OPG) (Felix *et al.*, 1990; Lacey *et al.*, 1998; Simonet *et al.*, 1997), as will be described in more detail in the next paragraph. RANKL is mainly produced as a membrane-bound factor, thus requiring a cell–cell contact, and at low level as a soluble molecule. Mechanisms of cleavage of membrane bound RANKL by metalloproteinases (MMPs), such as MMP-14, allow the release of the soluble form (sRANKL). Other paracrine factors released by osteoblasts that regulate osteoclastogenesis are tumor necrosis factor (TNF)-α, interleukin (IL)-1β and IL-6.

Quite interesting is the recently emerged "endocrine" role of the osteoblasts, through the release of OCN, now considered a real hormone (Karsenty and Ferron, 2012). In its undercarboxylated form, this glycoprotein is able to regulate glycaemia by

stimulating pancreatic islets to produce more insulin, which in turn also affects osteoblast function by reducing OPG production (Lee *et al.*, 2007). Osteoblast-derived OCN also influences adipose tissue and male gonadal functions, by stimulating adiponectin and testosterone production, respectively (Ferron *et al.*, 2008; Oury *et al.*, 2011). Finally, a role for OCN in the regulation of learning and memory skills and in the prevention of anxiety and depression in mouse models has been recently ascertained (Oury *et al.*, 2013).

Bone and bone marrow are two tissues linked not only anatomically but also functionally. It is therefore conceivable that these organs can affect each other. Interestingly, some years ago, Zhang and colleagues identified a subpopulation of osteoblasts named, as suggested by their morphology, spindle-shaped N-cadherin^{+}/CD45^{-} osteoblasts (SNOs), which regulate hematopoietic stem cell (HSC) life (Zhang *et al.*, 2003). Consistent with their function, another peculiarity of the SNOs is their location close to the endosteal surface. This finding led to the identification in the bone marrow of the endosteal (i.e., osteoblast) niche, where SNOs are the nurse cells for the long-term (LT)-HSCs, guaranteeing their quiescent *status*. The SNOs-LT-HSCs interaction is likely determined by the Notch signaling, where Notch1 is expressed by HSCs and binds to its ligand Jagged1 expressed by SNOs, thus inhibiting HSC mobilization and differentiation (Varnum-Finney *et al.*, 2000). Another putative signaling pathway regulating HSC quiescence by SNOs is the angiopoietin-1 (Ang-1)/Tie2 (Arai *et al.*, 2004). Coherently with the role of osteoblasts in HSCs regulation, conditional ablation of osteoblasts results in depletion of LT-HSCs (Visnjic *et al.*, 2004), while PTH treatment increases the number of HSCs (Calvi *et al.*, 2003). Among the pathways involved in the regulation of this function, a regulatory role has been established for the SNOs, which also secrete the stromal cell-derived factor (SDF)-1, *alias* CXCL12, whose receptor, CXCR4, is expressed by HSCs. It has been demonstrated that high levels of SDF-1 on the surface of osteoblasts favor HSCs to return to the osteoblast niche (Varnum-Finney *et al.*, 2000).

In line with these findings, a recent paper from Kousteni's group points out a role for osteoblasts in the pathophysiology of the hematopoietic system, where they demonstrated that constitutive activation of beta catenin in osteoblasts induces acute myeloid leukemia, together with genome instability and chromosome mutations in the LT-HSCs (Kode *et al.*, 2014).

Osteocytes: Not Just Buried Alive Cells

Osteocyte Formation

Among the pool of mature osteoblasts, a small fraction (i.e., 15%) remains embedded in the bone matrix, giving rise to the osteocyte population, the most abundant and long lived cell type in the bone, while the remaining osteoblasts will become inactive flat osteoblasts, named lining cells, or will undergo apoptosis (**Fig. 1**). The peculiar spider-like morphology of osteocytes is due to several cytoplasmic processes located in canaliculi arranged in a complex network, which participate in an intracellular and an extracellular communication system. The intracellular communication system occurs between osteocytes or osteocytes and osteoblasts by means of gap junctions, mainly formed by connexin 43, through which they exchange signals, while the extracellular communication system occurs through the pericanalicular space and provides nutrients and oxygen to the osteocytes (Komori, 2016).

Osteocyte formation follows different phases, during which the osteoblast goes through the phases of type I preosteocyte stage, a type II preosteocyte, which is encased in the osteoid, type III preosteocyte, young osteocyte and old osteocyte, the latter embedded in a fully mineralized matrix (Franz-Odendaal *et al.*, 2006). This gradual evolution toward a mature osteocyte reflects molecular and morphological changes, which finally culminate in the formation of a stellate-shaped cell, encased in lacunae and expressing specific markers, such as Sost and DMP1 (**Fig. 1**).

Osteocyte Functions

Thanks to the tri-dimensional network of their cytoplasmic processes, osteocytes are classically considered mechanosensing cells, with the job of converting a mechanical stimulus into a biological signal. This requires the involvement of a protein complex, including the cilia-associated proteins PolyCystin (PC) 1 and PC2 (Xiao *et al.*, 2006), and of the cytoskeleton, by means of the focal adhesion protein complex. The latter includes multiple actin-associated proteins like vinculin, talin, and paxillin, and is activated by fluid flow, eventually leading to the stabilization of β-catenin (Santos *et al.*, 2010).

Besides their mechanosensing function, osteocytes are crucial regulators of bone remodeling. Indeed, it has been demonstrated that osteocyte apoptosis, occurring after menopause or by microfracture, primes bone resorption. This is accomplished by the secretion of factors stimulating osteoclast formation, including IL-1, IL-6, and, last but not least, RANKL (Kogianni *et al.*, 2008; Al-Dujaili *et al.*, 2011). Indeed, one recent finding identified osteocytes as the main source of RANKL in the bone, and the specific knockout of RANKL in osteocytes leads to an increased bone mass in adult mice (Nakashima *et al.*, 2011). Consistently, RANKL produced by osteocytes is required to induce bone loss caused by glucocorticoids (Piemontese *et al.*, 2016). Osteocytes also release OPG under the control of the Wnt/β-catenin pathway (Kramer *et al.*, 2010).

Other factors produced by osteocytes are interferon (INF)-β and TGF-β, which inhibit osteoclastogenesis (Hayashida *et al.*, 2014; Heino *et al.*, 2002), insulin-like growth factor (IGF)-1, whose deletion in osteocytes abolishes the loading-induced activation of the Wnt signaling (Lau *et al.*, 2013) and vascular endothelial growth factor, which is produced by apoptotic osteocytes thus promoting angiogenesis (Cheung *et al.*, 2011).

Going to the side of osteoblast regulation, the production by osteocytes of Sost and Dickkopf-related protein 1 (DKK-1) is well ascertained. These two inhibitors of the Wnt pathway are regulated by mechanical stimuli in osteocytes, with their expression significantly reduced in loading and increased in unloading conditions, respectively (Robling *et al.*, 2008). Taken together, all these findings point to the osteocytes as important determinants of bone remodeling.

Other unexpected functions for osteocytes have been identified over the years, such as the removal of the perilacunar matrix. Indeed, electron microscopy studies of tibiae from rats immobilized for 10 days showed periosteocytic osteolysis, characterized by fragmentation of collagen fibers and loss of mineral crystals (Krempien *et al.*, 1976). This perilacunar reabsorption seems to be exacerbated during lactation, as recently demonstrated by Qing *et al.* (2012). Moreover, a gene array of osteocytes from lactating animals showed an increase of tartrate-resistant acid phosphatase (TRAcP) and cathepsin K mRNA expression, which returned to basal levels after weaning (Qing *et al.*, 2012). Concurrent with the ability to regulate calcium homeostasis, osteocytic osteoplastic activity has also been described in lying hens previously fed with a low calcium diet and then subjected to calcium replacement (Zambonin-Zallone *et al.*, 1983).

Finally, osteocytes participate in the regulation of phosphate homeostasis in the kidney by producing FGF-23, a hormone that induces renal phosphate wasting, thus impairing mineralization (Liu *et al.*, 2006).

Osteoclasts: Not Just Any Bone Destroying Cells

Osteoclast Differentiation

Osteoclasts are multinucleated giant cells (from 4 to 20 nuclei) arising from the monocyte–macrophage lineage. The identification of the origin of these cells came after a key experiment by Walker, who showed the ability of osteopetrotic mice to recover bone resorption after bone marrow transplant from healthy mice (Walker, 1975). Ontogenesis of osteoclasts follows different steps and is triggered by two transcription factors: PU-1 and microphthalmia transcription factor, both promoting the commitment of HSCs toward a common macrophage/osteoclast progenitor expressing c-fms, the receptor for M-CSF (Tondravi *et al.*, 1997; Kawaguchi and Noda, 2000). The latter cytokine positively acts on the macrophage/osteoclast progenitor pool by stimulating their proliferation and survival through the activation of ERK and Akt (Biskobing *et al.*, 1995). Moreover, it increases the expression of RANK in osteoclast precursors, which is a key event that allows commitment toward an osteoclast (Arai *et al.*, 1999). At this point, the RANKL/RANK/OPG signaling takes place as the "king of the game." In particular, RANKL, which in bone is mainly produced by osteocytes, osteoblasts, and stromal cells, binds to its receptor RANK that in turn interacts with the TNF-receptor-associated factor (TRAF)-6 adaptor protein, thus triggering osteoclast differentiation by means of the nuclear factor κ-light-chain-enhancer of activated B cells (NF-κB). This is a dimeric transcription factor, whose knockout induces an osteopetrotic phenotype, thus demonstrating its importance in osteoclast differentiation (Franzoso *et al.*, 1997). NF-κB, along with c-Fos, stimulates the expression of another important transcription factor, the nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent (NFATc1) (Asagiri *et al.*, 2005). In parallel, RANKL interaction with TRAF6 also leads to Src engagement, which in turn influences osteoclastogenesis through the activation of the PI3K/Akt pathway (Wong *et al.*, 1999).

The RANKL/RANK pathway is essential for osteoclastogenesis; however it has to rely on a parallel signal triggered by two immune coreceptors, expressed on the surface of preosteoclasts, displaying the immunoreceptor tyrosine-based activation motif: Fc receptor common γ signaling chain (Fc$R\gamma$) and DNAX activating protein of 12 kDa (DAP12). It is known that in osteoclasts Fc$R\gamma$ interacts with osteoclast associated receptor (OSCAR) and paired immunoglobulin-like receptor-A, while DAP12 interacts with triggering receptor expressed in myeloid cells 2 and signal regulator protein β1. Engagement of these immunoreceptors results in the activation of PLCγ, which increases intracellular Ca^{2+}, thus promoting the calcineurin-dependent auto-activation of NFATc1 (Nakashima *et al.*, 2012).

The final event downstream of these RANKL pathways is the promotion of transcriptional expression of osteoclast-specific genes, such as TRAcP, calcitonin receptor, cathepsin K, matrix metalloproteinase (MMP)-9, OSCAR, and genes involved in osteoclast fusion, like CD44, macrophage fusion receptor, and dendritic cell-specific transmembrane protein (Cappariello *et al.*, 2014).

Coherently with the osteogenic role of Wnts, recent reports demonstrated that these molecules also participate in the regulation of osteoclast formation. Wnt3a inhibits 1,25-dihydroxyvitamin D_3-induced osteoclastogenesis in cocultures of bone marrow cells and osteoblasts (Yamane *et al.*, 2001), while osteoblast-derived Wnt16 inhibits RANKL-induced pathway and Nfatc1 expression by the noncanonical signaling (Movérare-Skrtic *et al.*, 2014). Similar effects were also observed for Wnt4 (Yu *et al.*, 2014). In contrast, a pro-osteoclastogenic effect has been demonstrated for Wnt5a, which increases osteoclastogenesis by a Ror2-mediated mechanism (Maeda *et al.*, 2012).

Osteoclast Functions

A mature osteoclast can be easily visualized in bone sections by the histochemical detection of TRAcP activity (**Fig. 3**A). To fulfill its principal function, that is bone resorption, the osteoclast must be polarized. Its plasma membrane is organized in different domains with distinct functions. The portion of the plasma membrane facing the vascular compartment is called the "basolateral membrane." Here, ion channels, sodium/potassium pumps, and the HCO_3^-/Cl^- anion exchanger 2 are localized (Lindsey

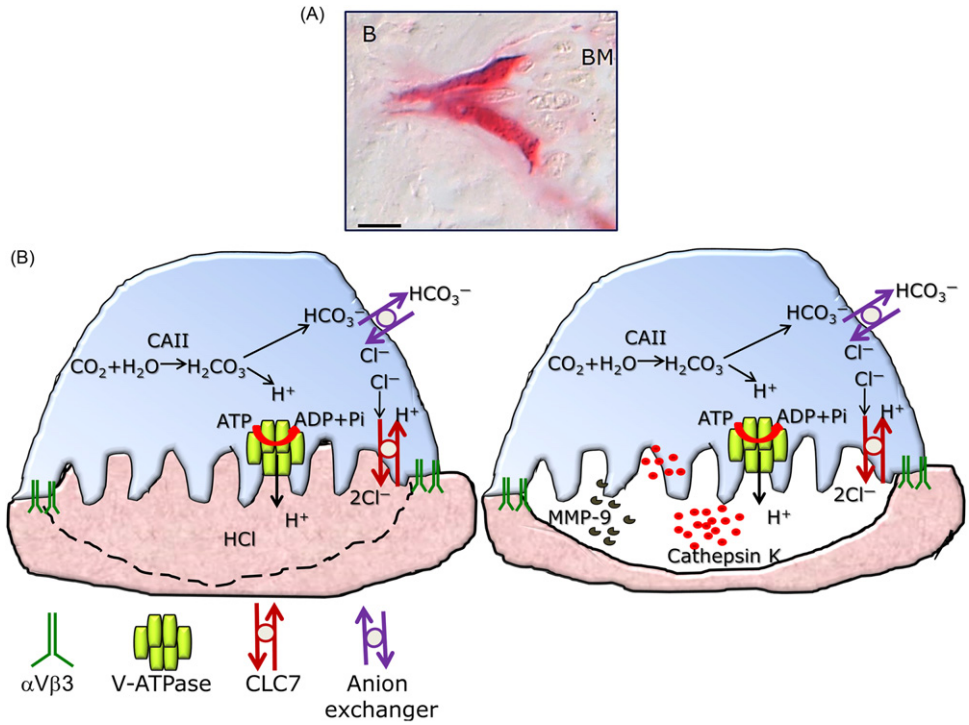

Fig. 3 (A) Histological section of a mouse tibia stained for the tartrate resistant acid phosphatase (TRAcP) activity to visualize the osteoclasts (purple spots, bar = 25 μm). (B) Cartoon showing the acidification process (left), which allows dissolution of the hydroxyapatite crystals, followed by the enzymatic digestion of the organic matrix (right).

et al., 1990). On the opposite side, the plasma membrane of the osteoclast facing the bone matrix is organized in several deep folds and constitutes the so called "ruffled border." Nearby it is possible to identify the "sealing zone" which allows the osteoclast to circumscribe the surface of the bone that will be reabsorbed. This is a circular outer domain containing characteristic adhesion structures, called podosomes (Marchisio *et al.*, 1984). They are very dynamic dot-like membrane protrusions with a core of actin filaments associated with a number of actin binding, adhesion, signaling, and regulatory proteins, including fimbrin, α-actinin, vinculin, talin, paxillin, gelsolin, tyrosine kinases, Wiskott–Aldrich syndrome protein, and Arp2/3. Before starting bone resorption, osteoclasts arrange podosomes in hook-like structures called actin rings, whose correct organization is pivotal to seal the resorption lacuna and allow the process of bone matrix degradation.

The dynamic nature of podosomes is guaranteed by a relatively fast polymerization/depolymerization of F-actins, resulting in a half-life turnover every 2–12 min. Integrin receptors, mainly $\alpha V\beta 3$ and to a lesser part $\alpha 2\beta 1$, contribute to osteoclast adhesion by forming a transmembrane bridge between the microfilaments and the adhesion proteins of the extracellular matrix. The $\alpha V\beta 3$-mediated signaling pathway involves PYK2 (belonging to the focal adhesion kinase family), Src, and Cbl, which are necessary for osteoclast polarization and bone resorption (Sanjay *et al.*, 2001). Interestingly, while $\alpha V\beta 3$ dominates in differentiated osteoclasts, $\alpha V\beta 5$ is the major integrin expressed by osteoclast precursors and the switch from $\alpha V\beta 5$ to $\alpha V\beta 3$ is a step required for osteoclast maturation (Inoue *et al.*, 1998).

Bone resorption can now start, with a phase of acidification that dissolves the hydroxyapatite crystals, followed by the enzymatic digestion of the organic components of the matrix (**Fig. 3**B). Briefly, carbonic anhydrase II catalyzes the chemical reaction of hydration of carbon dioxide (CO_2) to form carbonic acid (H_2CO_3) which gives rise to bicarbonate (HCO_3^-) and hydrogen (H^+) ions. The latter are pumped outside the osteoclasts into the resorption lacuna by means of a V-H^+-ATPase located in the ruffled border. To avoid the alkalinization of the cytosol, the HCO_3^-/Cl^- anion exchanger 2 allows the efflux of HCO_3^- and the influx of chloride ions (Cl^-) (Teti *et al.*, 1989), which is then released into the resorption lacuna by the $2Cl^-/1H^+$ antiporter (CLC7, chloride channel type 7) (Leisle *et al.*, 2011). In the resorption lacuna there is now HCl, which dissolves the hydroxyapatite crystals (**Fig. 3**B, left). This exposes the bone matrix that can be digested by cathepsin K and MMP-9 (**Fig. 3**B, right), while the debris is mainly removed by transcytosis and released at the basolateral domain (Salo *et al.*, 1997; Stenbeck and Horton, 2004).

Bone digestion releases growth factors stored in the matrix, such as BMPs, IGF-1, and TGF-β, which fuel the bone remodeling process because they attract the osteoblasts, thus inducing new bone formation. Interestingly, osteoclasts can also directly influence osteoblast behavior by producing the so-called clastokines (Drissi and Sanjay, 2016). Sphingosine-1-phosphatase is one of them along with TRAcP and complement factor C3a, the latter isolated from the conditioned medium of osteoclasts. Most clastokines have pro-osteoblastogenic effects (Pederson *et al.*, 2008; Hayman and Cox 2003; Matsuoka *et al.*, 2014; Teti, 2013), although others are antiosteoblastic, revealing the need of a balance between these two types of stimuli for physiological osteoblast activity.

As osteoblasts do, osteoclasts also contribute to hematopoiesis. This is supported by the evidence that treatment with anti-resorptive agents, which affect osteoclast behavior, such as bisphosphonates, increased the number of peripheral HSCs after mobilization induced by G-CSF (Takamatsu *et al.*, 1998). A similar effect was observed in osteopetrotic mice characterized by the lack of osteoclasts, while in OPG knock out mice, which instead present with a higher number of osteoclast, an opposite effect on HSC mobilization was noticed (Miyamoto, 2013).

Bone Remodeling☆

Susan M Ott, University of Washington, Seattle, WA, United States

Glossary

Activation frequency The frequency at which a particular point on the bone surface will be reached by a basic multicellular unit.

Basic multicellular unit (BMU) A group of osteoblasts and osteoclasts that resorb a volume of bone and replace it with new bone.

Bone mineral density The weight of mineral per volume of bone tissue.

Bone tissue The total material found within a bone, including the bone marrow, fat, mineralized bone, and unmineralized osteoid.

Bone turnover An ambiguous term that is either the bone formation rate or the bone resorption rate and is meaningful only when these rates are equal.

Bone volume The bone material, including mineralized bone and unmineralized osteoid.

Mineral apposition rate The rate at which mineral is deposited at a discrete point on the bone surface; expressed in micrometers per day.

Mineralization density The weight of mineral per bone volume.

Osteoid Newly formed bone, composed primarily of lamellar collagen with small amounts of other bone proteins and glycoproteins, that forms a matrix that can accept deposition of hydroxyapatite crystals and that will become mineralized bone.

RANK A receptor on preosteoclasts and osteoclasts, which increases maturation or activity of the cells.

Runx2 A transcription factor that promotes osteoblast activity and is necessary for maturation and proliferation of osteoblasts.

Sclerostin A protein secreted by osteocytes that inhibits osteoblasts by blocking the wnt-signaling pathway.

Wall thickness The thickness (in three-dimensions) of a completed volume of new bone, measured perpendicularly from the interface with the bone marrow.

Introduction

Bone is such a solid substance that an orthopedic operating room resembles a carpenter's workshop, with its saws, drills, screws, and hammers used to repair broken and damaged furniture. This reinforces the concept that bones are mechanical structures; indeed, one of the major functions of the skeleton is to provide support to the rest of the body. The dynamic properties of the bone, however, are seldom considered, except to acknowledge that living bone, unlike the leg of a table, can repair a fracture. Actually, the skeleton is continually remodeling, responding to external forces and internal signals.

During childhood bones are formed at the growth plates and shaped by resorbing the outer surfaces. Once the growth plates have fused, the shape of a bone changes very slowly during life by formation at the periosteal surfaces. The diameters of the long bones gradually expand. The process of forming bone and changing the shape is termed modeling. There may also be some modeling on the trabecular surfaces of bone, where new bone is formed over a quiescent surface of older bone.

The newly formed bone is not permanent. Throughout life, quantities of bone are dissolved and then refilled with new bone. This process is termed remodeling, and it keeps the bone strong by removing old or damaged regions and replacing them with new bone. Overall, the cancellous bone in the entire skeleton is refreshed about every 5 years and the cortical bone every 12 years (Parfitt, 2002).

Bone remodeling always follows the same sequence. First there are signals to start remodeling a volume of bone. Then a cavity of bone is resorbed, and finally filled in with new bone.

Basic Multicellular Unit

The bone remodeling process involves a group of different kinds of cells, termed the basic multicellular unit (BMU) (Frost, 1969). The major bone cells are the osteoclasts and the osteoblasts.

☆*Change History*: January 2018. SM Ott made edits through-out the chapter to bring topics up to date. Larger sections were added about signaling pathways, canopies, and osteoporosis treatments.

This article is an update of SM Ott, Bone Remodeling, Dynamics of, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 386–391

 doi:10.1016/B978-0-12-801238-3.95755-6

Osteoclasts

The osteoclasts are derived from the same hematopoietic stem cells that produce macrophages. These stem cells differentiate into preosteoclasts which circulate in the bloodstream. They express RANK (receptor receptor activator of NF-kappaB), a membrane receptor. When these cells encounter the RANK-ligand, they become active, fuse and form multinucleated cells which can resorb the bone.

Osteoblasts

The osteoblasts are derived from stromal stem cells that reside in the bone marrow. These cells can produce either adipocytes or preosteoblasts, depending on the condition. Situations that increase PPARγ (peroxisome proliferator-activated receptor gamma) will direct the stem cells to produce adipocytes. VEGF (vascular endothelial growth factor A) instead promotes preosteoblast formation.

The transcription factor Runx2 is a master switch for osteoblast differentiation. The second important transcription factor is Osterix. These transcription factors regulate expression of most of the osteoblast-specific genes. Several signaling pathways will increase expression of Runx2 and promote osteoblast maturation and proliferation. One of the most important is the wnt-signaling pathway. Other signaling pathways include BMP (bone morphogenic protein), TGF-β (transforming growth factor beta), PTH (parathyroid hormone), IGF-1 (insulin-like growth factor), FGF (fibroblastic growth factor), Notch, and Hedgehog. Not only are there multiple pathways, they also can interact with each other in a complex system of cell regulation (de Gorter and ten Dijky, 2013).

Some of the ligands for these pathways are in the general circulation, others from cells in the bone marrow. Some represent cell–cell communication between the osteoblasts and the osteoclasts. For example, the osteoblasts express RANK-ligand which signals maturation of osteoclasts, and also secrete osteoprotegerin, a decoy receptor that will prevent RANK signaling. Another example is even more complex: the mature osteoblasts secrete TGFß into the bone matrix, where it remains until the bone is resorbed in a subsequent bone remodeling cycle. Then, during bone resorption, the TGFß is released from the bone and activates receptors on the osteoclasts, which leads to secretion of the wnt ligand that will increase the wnt-signaling pathway in the osteoblasts (Weivoda *et al.*, 2016).

The mature osteoblasts form the bone matrix. They then either undergo apoptosis or further differentiate into osteocytes or lining cells. The osteocytes remain in the bone matrix and the lining cells form a boundary between the bone and the marrow.

Each BMU has a blood vessel. Other cells, including bone marrow stromal cells, bone marrow adipocytes, nerve cells, T-lymphocytes, and vascular endothelial cells, can influence the BMU but are not actively resorbing or forming bone.

Sequence of Bone Remodeling

A fundamental property of bone remodeling is that it occurs in discrete locations. In cancellous bone, the BMUs travel along the bone surface, spreading over an area. In the cortical bone, they tunnel through the bone, with the osteoclasts at the cutting edge and newly formed bone in the wake.

Each BMU performs its functions in the same sequence: origination and organization of the BMU, activation of osteoclasts and beginning of recruitment of osteoblasts, resorption of old bone, then a reversal phase, then formation of new bone matrix, then a quiescent period where there are no new cells but during this time mineralization continues (**Fig. 1**). Many of the details of this sequence have been elucidated by Parfitt (2001), and measurements of the timing of each phase were done by Eriksen *et al.* (1984). At one spot along the surface, the cycle takes about 170 days. The lifespan of a BMU is limited, it spreads along a surface and then ends, after most cells have died from apoptosis. Cortical BMUs can wander for months, usually in a straight line. Parfitt (1994) estimates the duration is 2–8 months. This is harder to measure in cancellous bone because the two-dimensional sections do not capture the entire serpentine course of the BMU (**Fig. 2**).

Origination

The osteocytes form a network within the bone, and these cells direct the bone remodeling (Dallas *et al.*, 2013). They are able to sense mechanical loading as well as hormonal signals. Small cracks caused by microdamage will initiate a BMU. Signals from osteocytes or lining cells that have detected mechanical stress, local cytokines from marrow cells, or systemic hormones that regulate mineral metabolism may also be involved in BMU origination. Possibly, some BMUs commence at random.

Mori and Burr demonstrated an association between fatigue damage and intracortical remodeling. They anesthetized mature dogs and applied a cyclic load to the radius, which caused asymptomatic microscopic cracks. Eight days later, an identical load was applied to the opposite radius. Histologic sections showed an equal number of cracks on each side. However, at the site with the earlier load, there was a significant increase in resorption cavities that were adjacent to the cracks. The temporal design of the study demonstrated that the resorption occurred after the fatigue damage (Mori and Burr, 1993).

Origination occurs only once for each BMU at a quiescent surface of the cancellous bone or on a surface nearest a crack in the cortical bone. Lining cells change their shape from that of flat, epithelial-like cells to rounded cells, thereby exposing some of the

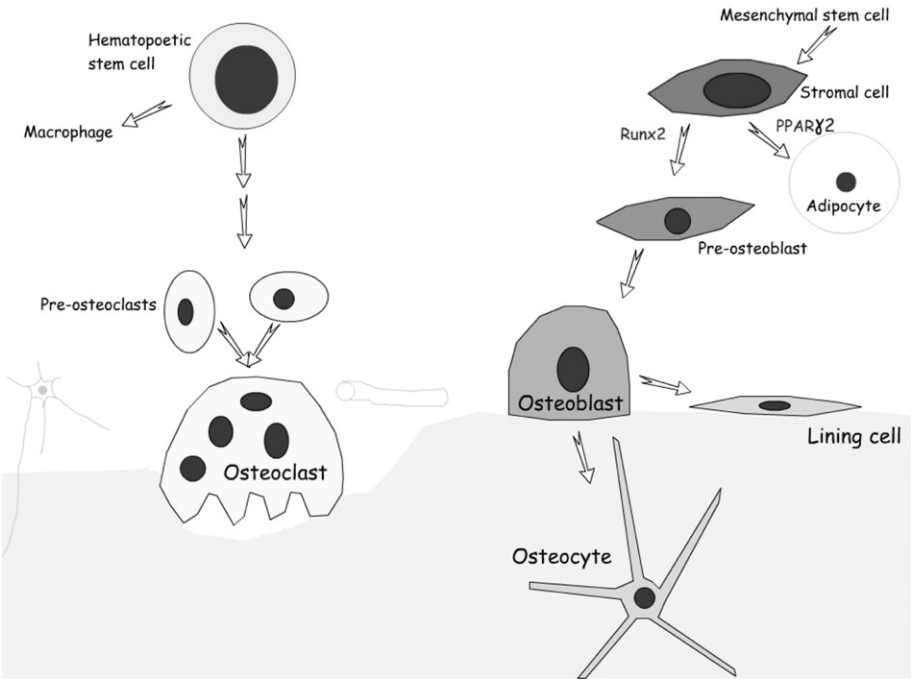

Fig. 1 Cells involved in bone remodeling. The osteoclasts resorb the bone and the osteoblasts form new bone. Osteocytes and lining cells remain after the BMU has finished remodeling a volume of bone.

collagen matrix. They also secrete collagenase to expose the bone mineral. The lining cells then fuse with endothelial cells to form a canopy above the bone surface that is connected with the vasculature (Jensen *et al.*, 2015). Within this canopy, osteocytes, and osteoclasts expressing RANK-ligand on their surface will attract the preosteoclasts which express the RANK receptor. The pre-osteoclasts fuse and become mature multinucleated osteoclasts.

Activation

Activation is a process that occurs at the cutting edge of the BMU, and as the BMU spreads, new surfaces undergo activation. The BMU "front" travels at a rate of approximately 10 μm/day and is followed by osteoblasts and new blood vessels. The original osteoclasts undergo apoptosis while the BMU is still progressing; thus, new cells must replenish the dying ones. Systemic hormones, growth factors, and interleukins may enlarge the precursor pool, but systemic factors cannot localize the preosteoclasts to the cutting edge.

Resorption

Preosteoclasts fuse when the RANK receptor encounters RANK-ligand on the surface of osteocytes or osteoblasts. At a given spot on the bone surface, resorption is rapid for the first 10 days, and continues for about a month. Once activated, the osteoclast becomes polarized and undergoes cytoskeletal changes that allow it to attach to bone (Teitelbaum, 2007). Small GTP-ases are necessary for these changes. The side of the osteoclast near the bone surface forms a "ruffled border" that will attach to integrins that were imbedded within mineralized bone matrix. The osteoclast seals off a circular surface of bone, creating a space between the bone and the ruffled border which is separated from the bone marrow (**Fig. 3**).

The integrins convey signals from the bone matrix to the osteoclast interior. The osteoclast then pumps hydrogen ions into the resorbing space by a hydrogen ATP-ase (the same pump is used by renal tubular cells to secrete acid into the urine). These ions are generated from water and carbon dioxide by carbonic anhydrase, and the bicarbonate is secreted into the bone marrow. Chloride flows through a chloride channel to maintain electrical neutrality. The acid environment will then dissolve the mineral from the bone. Also, the osteoclast secretes cathepsin K into the resorbing space; this degrades the collagen. The osteoclasts can also engulf debris through endocytosis, similar to macrophages, which are closely related cells.

During resorption, bone-derived growth factors are released, including TGF-β, insulin-like growth factor (IGF), and fibroblast growth factor (FGF), which were deposited into the matrix by the previous generation of osteoblasts. TGF-β is activated by the acid environment caused by osteoclastic proton secretion. These growth factors (delayed autocrine factors) account for the coupling between resorption and formation that is seen in normal situations (Weivoda *et al.*, 2016).

The osteoclasts eventually undergo apoptosis; the lifespan and activity of the osteoclasts determine the depth of the resorption cavity. The apoptosis may be promoted by TGFß and estrogen (Janssens *et al.*, 2005).

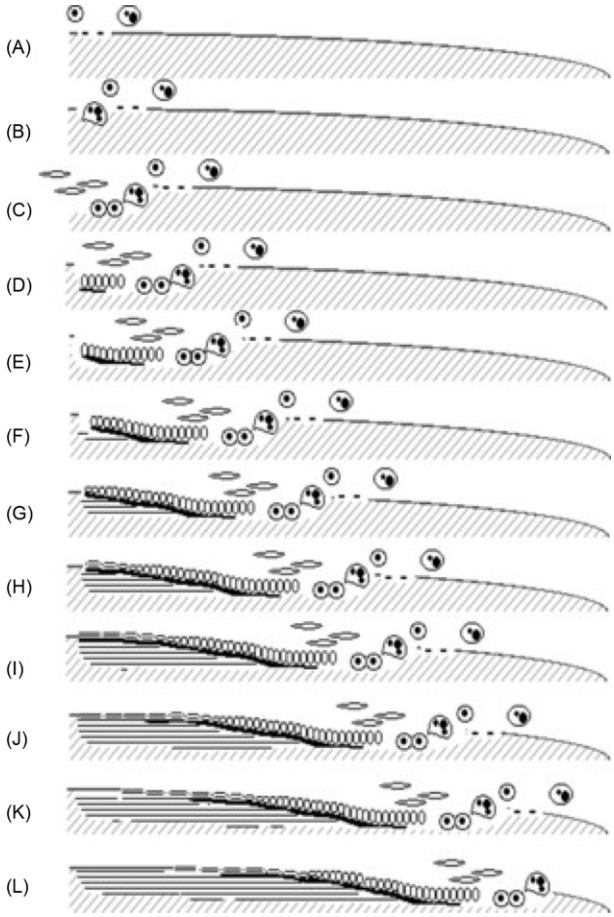

Fig. 2 The basic multicellular unit (BMU), moving along a cancellous surface. Each step represents approximately 10 days, and the BMU moves approximately 10 μm each day. (A) Origination of BMU: lining cells contract to expose collagen and fuse with endothelial cells to form a canopy over the bone. Osteocytes secrete factors that control osteoblast and osteoclast differentiation. (B) Preosteoclasts respond to RANK, fuse into multinucleated cells, and resorb a cavity. The resorbed bone contains growth factors which stimulate osteoblast formation, and the osteoclasts also secrete signals to the new osteoblasts to proliferate. (C) Mononuclear cells continue resorption. (D) Osteoblast team forms at the bottom of the cavity and starts forming osteoid. (E) Osteoblasts continue forming osteoid (shown as *black line*) and previous osteoid starts to mineralize (*horizontal lines*). (F–H) Osteoblasts continue formation and mineralization. (I and J) Osteoblasts begin to flatten; many undergo apoptosis, some differentiate into osteocytes and remain in the bone matrix. (K and L) Osteoblasts turn into lining cells; bone remodeling at initial surface (left of drawing) is now complete and that surface will be quiescent for years, but BMU is still advancing (to the *right*).

Formation

After the maximum eroded depth has been achieved, there is a reversal phase that lasts ~9 days. Reversal cells express Runx2 and other gene markers that are in the osteoblast family (Abdelgawad *et al.*, 2016). These cells, which are especially located between the osteoclastic bone resorption surface and the osteoblast formation surface, may play an important role in coupling between the osteoclastic resorption and osteoblastic formation (Delaisse, 2014). During this phase, the osteoblasts converge at the bottom of the cavity. The osteoblasts derive from precursors in the marrow stromal cells, which can differentiate into either osteoblasts or adipocytes, depending on the transcription factor runx2 (previously known asCbfa1) as well as PPARγ. The team of osteoblasts then begins to form osteoid, which is mainly composed of collagen but includes other bone proteins, growth factors, and proteoglycans. After about 15 days, the osteoid begins to mineralize. The osteoblasts continue to form and to mineralize osteoid until the cavity is filled or nearly filled, which takes about 120 days at any point on the surface.

At the bottom of the cavity, the new osteoblasts are plump and vigorous, have tall nuclei, and make a thick layer of osteoid. The cells then gradually flatten as they slow production, and finally they undergo apoptosis or mature into quiescent lining cells. Some of the osteoblasts differentiate into osteocytes and remain in the matrix. The osteocytes may secrete inhibitory factors, such as sclerostin, that slow the rate of bone formation as the resorbed cavity is nearly filled. As the BMU progresses, new osteoblasts are added, but only at the edge behind the osteoclasts.

The density of the osteoblasts at the formation site may vary. When the cells are more crowded, they are taller and narrower, and they collectively can make more osteoid than when there are fewer cells. Osteoporotic patients have the same rate of osteoid production per cell, but overall the wall thickness is decreased and the amount of newly formed bone is inadequate to fill the

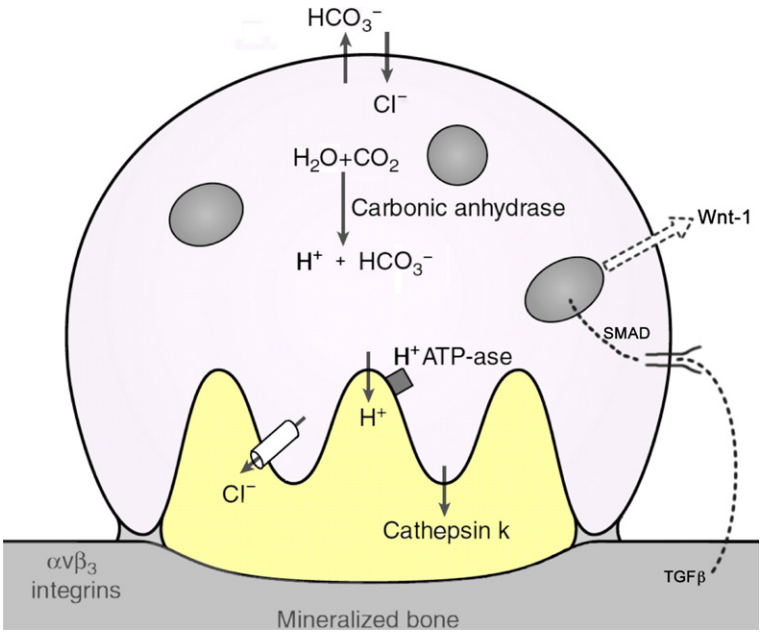

Fig. 3 Mature osteoclast resorbing bone. Integrins bind to the bone collagen, creating a space beneath the ruffled border. Carbonic anhydrase converts water and carbon dioxide to hydrogen and bicarbonate. The bicarbonate is exchanged for chloride, and the hydrogen is secreted into the resorbing space, dissolving bone. The chloride exits through a channel. Cathepsin K is secreted to break down collagen. Then TGFß from the bone is released and activated by the acidic environment, it activates receptors on the cell surface, signaling through SMADs to target expression of wnt-1, which is secreted and activates the osteoblast wnt-signaling pathway.

resorbed cavity. Some investigators think that bone formation is discontinuous (on and off), but studies with tetracycline labeling suggest that the osteoblast team does not take vacations (Ott, 1993).

Mineralization

Mineralization begins ~ 15 days after osteoid has been formed. In most situations (except in the case of osteomalacia), the average rate of osteoid formation and the rate of mineralization are the same and are measured by tetracycline labels.

After the BMU has completely restored the bone volume, the mineralization density continues to increase as the crystals become more densely packed. It is not known how long it takes to reach the maximum mineralization density, but indirect evidence suggests this takes approximately 3 years (**Fig. 4**).

The mineralization density is related to the bone formation rate. When the bone formation rate is high, mineralization density is low. When the bone formation rate is low, more of the bone is older and more highly mineralized (Boivin *et al.*, 2009).

Other Tissues That Are Within Bone

Vasculature

Each BMU is associated with a capillary. In cortical bone, the capillary grows along the excavated tunnel. On trabecular surfaces, small capillary-like structures are frequently seen adjacent to the osteoblasts. The cells that form these structures have characteristics that are unlike endothelial cells and resemble lining cells. In addition to supplying nutrients and a source of precursor cells, the vasculature may help direct the localization of the BMU.

Nerves

Anatomic studies have documented a dense and intimate innervation of bone tissue. The fibers contain markers for neural tissue, both sensory fibers and sympathetic fibers. Nerve endings are seen in contact with bone cells. Glutamate is expressed in the fibers that are in proximity to bone cells, suggesting a potential role of glutamatergic innervation in the bone remodeling process.

Adipocytes

Adipocytes and osteoblasts derive from the same precursors, and factors such as lipid levels can favor differentiation into adipocytes, which will reduce the number of available osteoblasts. The adipocytes also secrete leptin, but the ability of leptin to either stimulate or inhibit bone formation is still debated (Gimble, 2011).

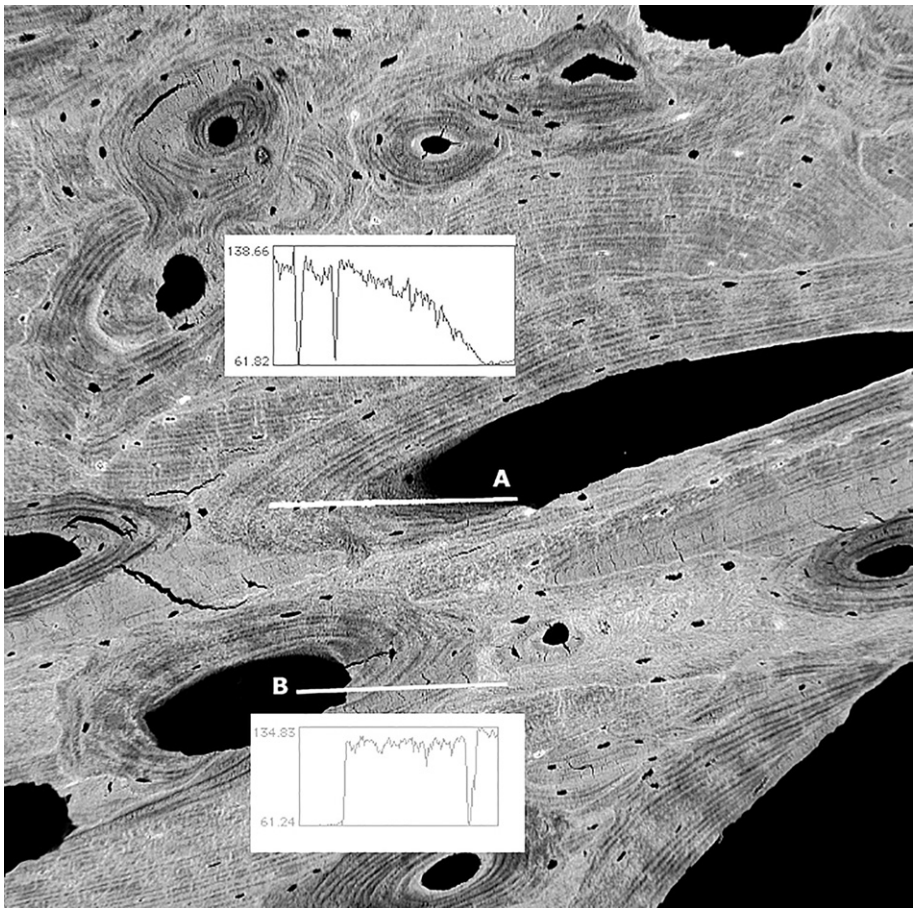

Fig. 4 Electron backscattered image of iliac cortical bone showing two new osteons, with plot profiles taken along the *white lines*. The line A profile shows that density is low in the newly formed osteoid (*dark gray*) and gradually increases as the bone becomes older (toward the left). The line B profile shows an abrupt change from the Haversian canal space to the bone; this line crosses a surface of bone resorption. The downward spikes in the plot profiles represent the osteocyte lacunae. Near the end of line B (right), there is higher mineralization after line B crosses the cement line into an area of older bone, which appears whiter on the image.

Control of Bone Remodeling

Mechanical Stress

The osteocytes, once thought to be trapped in the bone mineral, are actually active within their lacunae and canaliculae (Atkins and Findlay, 2012). They have multiple long cell processes that extend within the bone and form junctions with other osteocytes. The resulting network resembles a neuronal network, and the osteocytes are considered the brains of the bones A special cell process, like a cilia, can be found on these extensions, which is firmly attached to the mineral of the canalicular wall (McNamara *et al.*, 2009). When mechanical loads are applied to the bone, the cilia can detect fluid movement (Santos *et al.*, 2009), and thus the osteocytes can sense mechanical strains. They then stop secreting sclerostin (Robling *et al.*, 2008), which releases inhibition of the osteoblasts. The osteocytes also secrete stimulatory factors into the marrow, including prostaglandins, nitric oxide, and IGF. Where there is microdamage, the osteocytes undergo apoptosis, and as they lay dying they express RANK-ligand to signal osteoclasts to come and start the repair process.

Hormones That Regulate Mineral Metabolism

Parathyroid Hormone

Parathyroid hormone (PTH) and PTH-related protein can activate lining cells to secrete RANK ligand and originate a BMU. PTH may also affect osteoblast proliferation. When given as intermittent injections, it can bypass the bone remodeling system and stimulate bone formation directly on quiescent surfaces. PTH-related protein causes increased bone resorption and loss of bone during lactation.

Vitamin D

Vitamin D can also activate lining cells to secrete RANK ligand. It increases the proliferation of preosteoclasts and may play a role in osteoblast recruitment. Indirectly, it is important in the maintenance of serum mineral levels.

Calcitonin

Calcitonin receptors are present on osteoclasts, and when activated, the cells stop resorbing bone. The calcitonin gene-related protein appears to increase bone formation, but the mechanism is not clear.

Estrogen

Estrogen exerts a major effect on bone remodeling, possibly through different mechanisms. Several mechanisms are involved: (1) estrogen increases osteoclast apoptosis; (2) by suppressing interleukins and proinflammatory cytokine expression in bone marrow cells, estrogen decreases the number of osteoclasts; (3) by inhibiting the production of RANK-ligand, estrogen reduces the number and activity of osteoclasts; and (4) by increasing stromal cell/osteoblast cell expression of TGFß, estrogen inhibits osteoclast activity. Estrogen also has some positive effects on bone formation by acting as a mitogen to cells early in the osteoblast line, reducing apoptosis of osteoblasts, and increasing expression of TGFβ, bone morphogenetic proteins, and IGF-I (Modder *et al.*, 2011).

Bone Remodeling in Osteoporosis

When the bone resorption rate is higher than the bone formation rate, the bone volume will decrease, resulting in osteoporosis. The most common is postmenopausal osteoporosis with an increased bone resorption rate and a bone formation rate that is increased but not enough to match the increased resorption. Bone loss also occurs with normal resorption but low bone formation, as in some cases of renal osteodystrophy with adynamic bone. The most rapid bone loss is seen in diseases such as multiple myeloma where there is both increased bone resorption and decreased bone formation.

Aging Bone Loss

With aging, the osteoblasts lose their ability to fill the resorbed spaces. This is shown by age-related decreases in the wall thickness. When bone porosity increases, the remaining bone accumulates microdamage at an exponential rate. A vicious cycle is begun: bone mass decreases, so the remaining bone is subject to more fatigue damage that increases bone resorption, which may further weaken the bone and disrupt the osteocyte network.

Mechanisms of Action of Osteoporosis Medications

Understanding bone remodeling is important for predicting the response to therapeutic agents used for osteoporosis. Antiresorptive agents (estrogen, estrogen-receptor modulators, bisphosphonates, calcitonin, denosumab, and strontium ranelate) all decrease bone resorption, but they also decrease bone formation.

Bisphosphonates

The more potent nitrogen-containing bisphosphonates decrease the tetracycline-labeled bone formation rate by $\sim$95%. Small increases in bone volume occur while the BMUs that were forming bone continue to fill in the eroded cavities. Eventually, a new steady-state bone volume is reached, after which there is no further gain in bone volume because bone remodeling has been inhibited. Bone density will increase even after bone volume has reached a steady state because the mineralization density continues to increase. Women taking bisphosphonates have increasing bone density at the hip for $\sim$3 years; thereafter, the bone density does not increase further. The long-term ($>$7 years) consequences of prolonged suppression of bone formation rates are not known, but potentially fatigue damage and microcracks could accumulate. A bone biopsy study from patients who had taken bisphosphonates longer than 7 years showed increasing prevalence of microdamage (Ward *et al.*, 2016).

PTH and PTHrp

Intermittent parathyroid hormone and parathyroid hormone-related protein are anabolic agents that increases both bone formation and resorption, but the balance is positive, with large increases of bone density. Mineralization density decreases because a greater proportion of the bone is newly formed and incompletely mineralized. Therefore, anabolic agents have completely different mechanism of action from that of antiresorbing agents.

Sclerosin inhibitors

The newest category of medications studied in osteoporosis is sclerostin-inhibitors. By inhibiting sclerostin, wnt-signaling is increased and more osteoblasts are formed. The bone formation rate increases dramatically. The wnt-signaling also results in secretion of osteoprotegerin, which inhibits formation of mature osteoclasts, so that bone resorption is inhibited. The combination of decreased resorption and increased formation results in greater increases in the bone mass than the other medications (Cosman *et al.*, 2016).

Fluoride and the importance of bone quality

It is important to recognize that increasing the bone volume is not sufficient to improve the bone strength. Fluoride was a popular drug used to treat osteoporosis in the 1980s, and in 1990 a 4-year clinical trial found a 32% median increase of bone density in the spine (greater than any of the drugs mentioned above). The fracture rate, however, was not different than placebo in the spine and there were significantly more nonvertebral fractures (Riggs *et al.*, 1990). Bone biopsies from fluoride-treated patients show disorganized bone, high mineralization, abnormal crystals, and the bone strength was weaker (Kleerekoper and Balena, 1991). In growing children, bisphosphonates increase the bone volume and density, causing osteopetrosis, but these bones are more likely to fracture (Whyte *et al.*, 2003).

Other Mechanisms of Altering Bone Structure

Microcallus Formation

When trabeculae fracture, a microcallus can form that resembles the familiar "macrocallus" of a fractured bone. These microcallus formations in the spine increase after age 50, mostly in the lower thoracic and lumbar spine near the endplates. There are more in females than in males and even more in osteoporotic persons. These formations can account for up to 10% of the trabecular bone volume. Microcallus formations can allow creation of new trabeculae by forming bridges between existing trabeculae. They undergo resorption and modeling, eventually becoming mineralized and indistinguishable from trabecular bone. This mechanism of altering trabecular structure could be relatively important in patients with osteoporosis (Hahn *et al.*, 1995).

Direct Activation

In some situations, bone formation can also occur along surfaces in the absence of previous resorption. With fluoride therapy, bone formation surfaces increase markedly, but the bone is woven and not normal lamellar bone. Beagles treated with aluminum show new bone formation in some, but not all, experimental conditions, but this phenomenon is not seen in humans, who develop osteomalacia when exposed to parenteral aluminum. Intermittent PTH causes increases in the bone formation rate that occur too soon to be explained by the bone remodeling cycle. Measurements of the distance from new bone edges to cement lines also suggest that previously quiescent surfaces start to form bone. This is also seen with sclerostin antibody administration (Kim *et al.*, 2017).

Bone Arising From the Marrow Space

Patients with metastatic prostate cancer can develop osteoblastic lesions within the marrow spaces. First, spindle-shaped cells with characteristics of osteoblasts appear in the marrow spaces adjacent to the cancer cells, and then these calcify and become woven bone. The bone eventually becomes osteosclerotic (Roudier *et al.*, 2008).

Periosteal Bone Formation

The periosteal surfaces of cortical bone gradually expand throughout adult life. This compensates for loss of bone tissue because bone with a larger diameter has greater bending strength. Periosteal expansion occurs without prior bone resorption. In some cases, when there have been repetitive stresses on the bone, woven bone will form at the periosteal surface. This has been noted, for example, in young military recruits during basic training. The woven bone can be formed more rapidly than the lamellar bone formed during usual bone remodeling.

Introduction

The skeletal system is made up of specialized connective tissues, namely bone and cartilage. Bone is the main part of the system and the structure of bone can be usefully considered in several different ways that reflect its variety of functions and constituents. Its precise form and composition vary with location, nature having selected optimal designs for different roles. The purpose of bones are (1) to allow for locomotion by providing rigid support and sites for muscle action; (2) to provide a shield for vital internal organs and bone marrow; (3) to serve as a reservoir of ions, particularly calcium and phosphate, for maintenance of serum mineral homeostasis; and (4) to serve as an endocrine organ, modulating metabolism. In addition, the bone marrow serves as a source of precursor cells of the hematopoietic and mesenchymal lineage. Bone is a composite material with tough, resilient protein fibers embedded in a hard and rigid mineral matrix (Fig. 1). Its great advantage over sophisticated human-designed composite materials is its ability to repair itself and adapt by biological remodeling and turnover, by altering its mass, shape and properties, to meet the mechanical loads placed on it. Within a single skeletal element there are dramatically different forms of bone, some designed for load bearing, such as the cortical shaft, and some, such as trabecular bone in the metaphysis, providing both a supporting network and a large surface area for metabolic responses to the requirements of mineral homeostasis. Both of these types of bone are evident in the longitudinal section of the human tibia in Fig. 2.

Given its obvious structural role, bone is not always appreciated as one of the more complex and dynamic, living tissues in the body. Its cellular constituents include not only the bone-forming osteoblasts and the bone-resorbing osteoclasts, but also the matrix-embedded osteocytes which maintain communication with one another and with the bone surface from deep within the solid bone matrix through a dense, interconnected network of submicrometer-sized canaliculi. Interactions between bone cells and those of cartilage, blood vessels, teeth, and cells that degrade and/or remodel the extracellular matrix during growth are regulated in part locally, in part systemically, and in part by mechanisms still under intensive investigation.

Bone also contains pools of hematopoietic and mesenchymal stem cells. The osteoblast/osteocyte lineage originates from mesenchymal stem cells, which can also differentiate into other connective tissue cell types, including cartilage or fat. Osteoclasts differentiate from hematopoietic stem cells, primarily under the influence of the growth factor, receptor activator of NF-κB ligand (RANKL). Besides the obvious protection bones provide for brain, spinal cord, and thoracic organs, they also enclose the soft and vulnerable hematopoietic marrow, providing homing signals for colonization by hematopoietic and stromal stem cells. In addition, bone plays host to nerves, arteries, veins, and venous sinuses.

Macroscopic Structural Features

Types of Bone

There are two major types of bones in the skeleton: flat bones located in the axial skeleton (i.e., skull, scapula, mandible, and ilium) and long bones found in the appendicular skeleton (i.e., radius, tibia, femur, humerus, etc.). These two types of bone are distinguished not only by their overall anatomy, but also by their primary mechanism of development. In general, flat bones are formed by a developmental process in which bone-forming cells differentiate directly from the surrounding mesenchyme, a process called intramembranous ossification. Whereas long bones undergo endochondral ossification, in which a cartilage model, or anlagen, is replaced by bone during development and growth, in a sense recapitulating the evolutionary path from a non-mineralized to a mineralized endoskeleton.

Anatomy of Bone and Bone Compartments

The overall structure of a typical long bone is shown in Fig. 2, a longitudinal section of an adult human tibia. The shaft of the bone, called the diaphysis, consists of a hollow cylinder of dense, or compact, bone (C) surrounding a marrow space (Ma).

This article is an update of Paul R. Odgren, Alison Gartland, April Mason-Savas, Sandy C. Marks, Bone Structure, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 392-400.

Fig. 1 Composition of bone. Human fibula before (left) and after (right) extraction with ethylenediaminetetraacetic acid (EDTA). EDTA removes the mineral by chelation, and what remains is the tough, fibrous protein matrix, 90% type I collagen. The demineralized bone matrix has very high tensile strength, greater than steel on a weight basis. It has, however, little resistance to compressive or bending forces, enabling it to be tied in a knot. The calcium phosphate crystalline form (hydroxyapatite) that comprises the mineral component has high compressive strength, but alone is brittle and has little resistance to tensile forces. Together they make the hard, somewhat flexible, composite material known as bone.

The bone at this location is also called cortical bone. The external surface of bone is covered by the periosteum and the internal surface (i.e., facing the marrow space) by the endosteum. These are fibro-cellular layers not present on the dried bone specimen in **Fig. 2**. At the end of the bone one sees the widened region called the epiphysis (E) which supports the articular cartilage that forms the cushioned interface of the joint. The region where the bone narrows, or flares, from epiphysis to diaphysis is called the metaphysis (Me). The metaphysis is a key structural and metabolic region that plays a crucial role in endochondral ossification and in mineral homeostasis. The metaphysis is occupied by cancellous, or trabecular, bone, organized in an open network of interconnecting rods and plates of bone (trabeculae) that transmits forces between the joint and the shaft of the bone. The trabeculae are oriented along stress lines and the surface covered with endosteum. As each delicate trabecular arch joins the bone shaft, the cortical bone thickens to bear the additional load being transferred (see **Fig. 2** inset). The crossing arches of bone trabeculae are reminiscent of human architectural solutions to the problem of transmitting the weight of a heavy roof to building's walls while leaving open interior spaces.

Due to its structure, trabecular bone has a much larger surface area exposed to marrow than cortical bone, and because bone resorption and formation occur on bone surfaces, trabecular bone is more metabolically active than cortical bone. As a result, changes in bone due to age, diet, disease or pharmacologic intervention occur sooner and are more pronounced in trabecular compared to cortical bone. Functionally, cortical bone fulfills more of a structural function (mechanical and protective) whereas trabecular bone serves to maintain serum mineral homeostasis, although trabecular bone is essential for transmitting loads from the joint surface to the cortex. In older individuals, cortical bone with high porosity (and therefore high surface area) may also have very high remodeling rates.

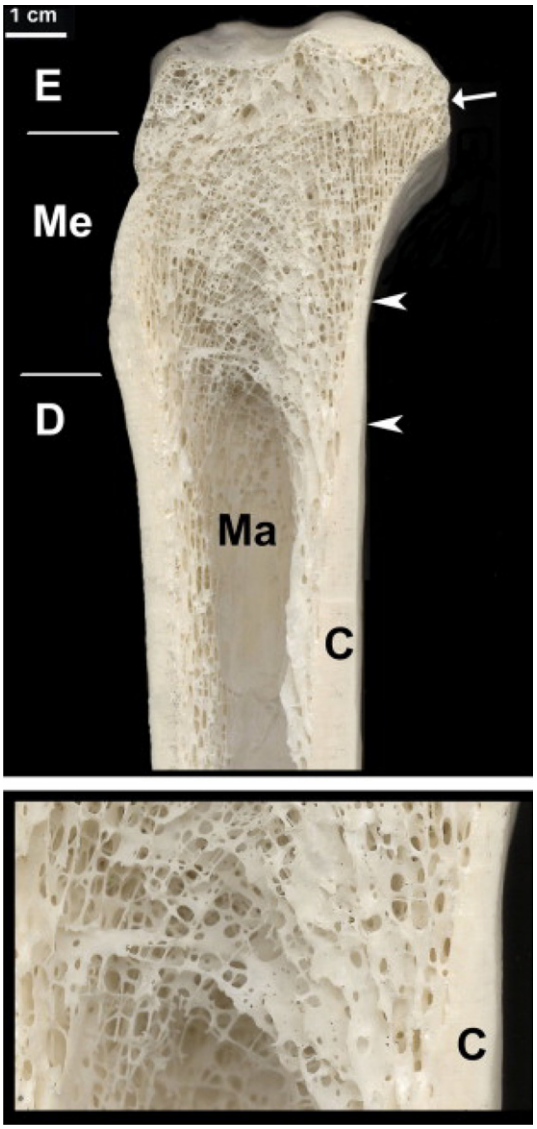

Fig. 2 Structure of a typical long bone. Longitudinal section of adult human tibia with all cellular material removed. Typically, a long bone can be divided into three regions. The epiphysis (E) of the tibia is the widened "knob" that articulates at the knee joint (the joint cartilage is removed in this specimen). The central shaft, or diaphysis (D), is a hollow cylinder of dense, high-strength cortical bone (C) which surrounds a marrow cavity (Ma). Between these two regions, the metaphysis (Me) is filled with a highly anastomosing network of bony trabeculae, that both distributes mechanical load between the joint and the bone shaft and provides an extraordinarily high surface area for metabolic activity. Between the epiphysis and the metaphysis, one can see the epiphyseal line (*arrow*), which is the mineralized remnant of the physis, the cartilage growth plate. In this adult, the growth plate has all turned to bone. The *arrowheads* indicate the area shown at higher magnification in the lower panel, which gives greater detail of the meshwork of metaphyseal trabeculae. Note that as more trabeculae join the cortical bone shaft, thereby transferring higher mechanical load from the joint, there is a corresponding thickening of the cortex (C) to bear the extra weight.

Of equal importance, the metaphysis provides signals and cell types required for the replacement of cartilage by bone during endochondral ossification in growing bones. When bones reach their adult size in humans and other large mammals, the layer of growth cartilage, called the physis or the epiphyseal growth plate, ceases its growth activity and becomes fully mineralized. The ossified remnant of the growth plate is visible as a boundary, called the epiphyseal line, between the epiphysis and metaphysis in Fig. 2 (*arrow*).

At higher magnification in Fig. 2, the inset shows in detail the enormous surface area achieved by the metaphyseal bone spicules. Bone being the body's chief reservoir of calcium and phosphorous, the metaphysis is a site of constant metabolic activity. Upon microscopic examination, during the process of bone remodeling it is common to find both bone formation (by osteoblasts) and bone resorption (by osteoclasts) occurring side-by-side on the same trabecular surface. This demonstrates that bone building and resorption are controlled not only by systemic signals such as hormones or circulating levels of minerals, but also by

local signals reflecting mechanical loading, genetic patterning, and/or microdamage. This dynamic state achieves an active balance that is poised to respond to environmental demands, maintaining mineral homeostasis over the long-term without compromising mechanical needs.

Bone Composition and Microscopic Structural Features

The basic composition of bone consists of cells and an extracellular matrix. The extracellular matrix itself is comprised of water, collagen, other noncollagenous proteins, and mineral. The specific composition of bone varies depending on skeletal sites (i.e., its function), age, diet, and disease. In general, however, the mineral (or inorganic phase) accounts for 60%–70% of the tissue, water accounts for 5%–10% and the organic components comprise the remainder. The calcified bone matrix is not inert, as cells (osteocytes) are embedded in the matrix, and are thought to play a critical role in local activation of bone remodeling.

Bone Cells

There are four principal bone cell types. Bone lining cells are a pool of quiescent, fibroblast-like cells that cover all bone surfaces (**Figs. 4**A and **5**). At least some bone lining cells are derived from previously active osteoblasts that have entered a quiescent phase. When called upon, they may differentiate into osteoblasts (**Fig. 3**B) that secrete the proteinaceous bone matrix called osteoid and subsequently matrix vesicles that deliver the mineral component and initiate the precipitation of hydroxyapatite crystals in the matrix. Note that unlike the nomenclature used for some other cell systems, osteoblasts are fully differentiated and functioning cells. As the layer of bone matrix deposited by osteoblasts thickens, a subset of the osteoblasts becomes fully surrounded by the matrix. Once encased in bone, the cell is called an osteocyte (**Fig. 3**C and **4**D). Each osteocyte inhabits a lacuna within the matrix and maintains contact with other cells, with circulating blood, and with the bone surface via a dense network of cytoplasmic processes that thoroughly permeate the bone matrix (see also section "The Haversian System—Metabolic Lifeline"). Osteocytes are

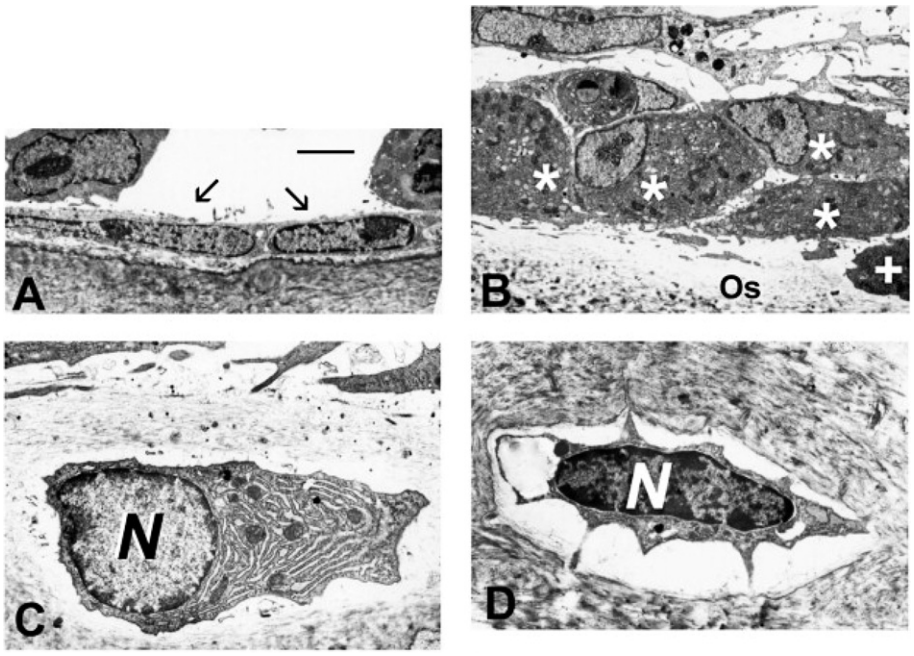

Fig. 3 Life cycle of bone-forming cells. (A) Quiescent, flat bone lining cells (*arrows*) cover the surface of bone. Above is marrow space with marrow cells at the right and left edges. Bone lining cells can differentiate into active osteoblasts when stimulated by parathyroid hormone or other osteogenic signals. (B) Osteoblasts (*asterisks*, *) actively secreting bone matrix. They are roughly cuboidal and contain well-developed organelles needed to synthesize and secrete bone matrix. They lie upon the layer of osteoid (Os) they have just secreted. Part of one osteoblast (+) at the right hand edge of the image can be seen in the process of being entrapped within the bone matrix, so becoming an osteocyte. (C) An osteogenic osteocyte is newly entrapped in bone and is still actively synthesizing matrix components: note the well-developed rough endoplasmic reticulum that fills the cytoplasm. Young osteocytes completely fill the lacuna that they inhabit. The lower margins of osteoblasts on the bone surface can be seen at the top of the image. (D) An osteolytic osteocyte. Late in their life cycle, osteocytes contract and also begin to degrade the surrounding bone matrix, creating unoccupied space within the lacuna. Some of the cytoplasmic projections that permeate the bone matrix can be seen around the cell's margin. Transmission electron micrographs of rat tibia; bar = 3.2 μm in A, 4.1 μm in B, 1.5 μm in C, and 1.7 μm in D. N in C and D = nucleus.

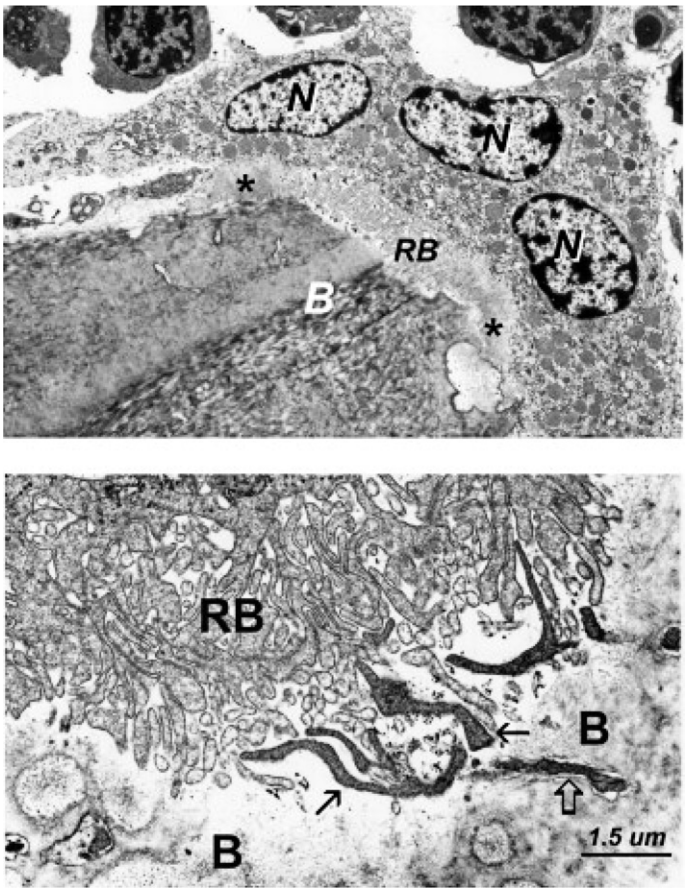

Fig. 4 The osteoclast. Upper panel: Three nuclei (N) are visible in this bone-resorbing osteoclast. It is firmly attached to the bone (B) by the so-called clear zone (*asterisks*), a dense ring of actin filaments that seals off the compartment under the cell where bone resorption occurs, the resorption lacuna. The ruffled border (RB) is a specialized region of highly invaginated plasma membrane where active secretion and resorption take place. Proton pumps in the ruffled border membrane acidify the extracellular compartment to dissolve the mineral, and proteolytic enzymes degrade the proteinaceous matrix. The dissolved bone is engulfed and transported through the osteoclast and released from another specialized domain on the free surface, the facultative secretory domain. Transit time through the cell is on the order of 20 min. Several marrow cells are visible along the top of the image. Lower panel: Higher magnification of a ruffled border reveals details of the elaborate ruffling that occurs over the area of bone (B) being resorbed. Several cytoplasmic processes of osteocytes can be seen in the process of being broken down (*arrows*), with one (*open arrow*) still inside its surrounding canaliculus. Transmission electron micrographs of rat tibia.

by far the most numerous bone cells, comprising 90%–95% of the total number of cells, with osteoblasts second at about 4%–6%, and osteoclasts third at about 1%–2% of cells.

The fourth cell type is the osteoclast (Fig. 4), which differentiates via fusion of mononuclear hematopoietic cells of the monocyte/macrophage lineage. This process occurs on the bone surface and results in very large, highly polarized, multinucleated cells. Osteoclasts form a tight seal against the bone surface, acidify the subcellular compartment (the resorption lacuna) to dissolve the mineral, and secrete proteolytic enzymes, especially cathepsin K and matrix metalloproteinase 9, to dissolve the proteinaceous bone matrix. The solubilized bone is endocytosed by the osteoclast, broken down further, transported through the cell and released from the free surface. The calcium and phosphate thus liberated are important in overall cell and tissue physiology.

Bone Matrix

The extracellular matrix of bone consists of crystalline precipitates of mineral (the hydroxyapatite form of calcium phosphate; see below) that permeate a dense protein substrate. Type I collagen fibrils comprise 90%–95% of the proteinaceous material in bone and provide very high tensile strength, which gram for gram is greater than that of steel. Also present are dozens of other glycoproteins, proteoglycans, integrin-binding proteins, other low-abundance collagens, growth factors, and water. Bone is first laid down as immature, "woven" bone, in which collagen fibrils are oriented randomly (Fig. 5). This bone is later resorbed by osteoclasts and replaced by osteoblasts as mature, lamellar bone, in which the collagen fibrils are ordered. Lamellar bone contains highly oriented type I collagen fibrils that are layered in alternating directions, much as the grain in individual layers of plywood, supplying maximal strength with minimal mass (Fig. 6).

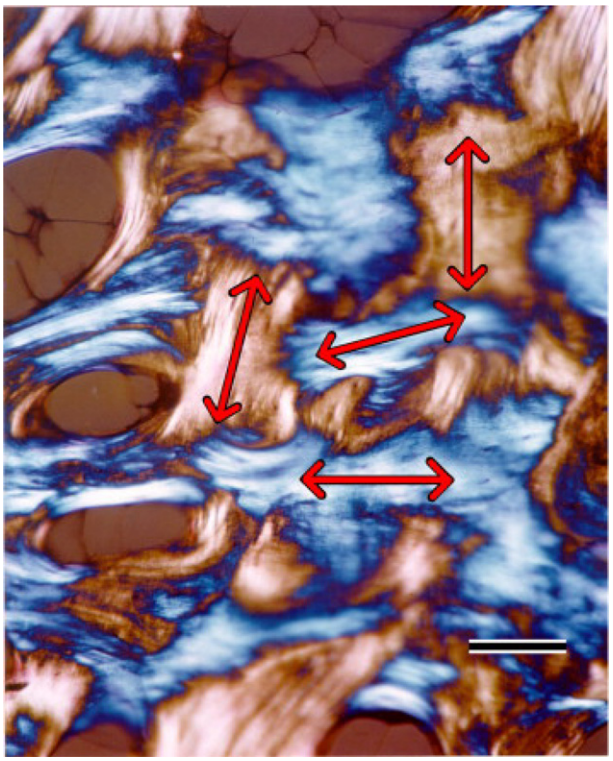

Fig. 5 Woven bone in polarized light (dog mandible). Collagen fibril orientation is visible in light micrographs with polarized illumination. *Double-headed arrows* indicate the orientations of several domains. This "first-generation" bone matrix is brittle and weak, and needs to be resorbed by osteoclasts and replaced by osteoblasts as mature, lamellar bone to attain full strength and resilience. Bar = 75 μm.

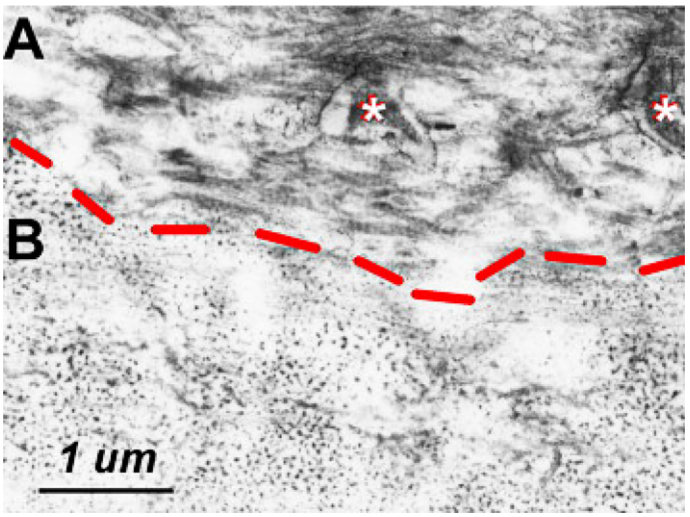

Fig. 6 Collagen fibrils in lamellar bone. Mature lamellar bone is so-called because of the layered, highly oriented collagen fibrils that comprise it, as seen in this electron micrograph. In the upper layer of matrix (A, above the *dashed line*), the cartilage fibrils travel in the plane of the image. In the lower layer (B), they project straight into the plane of the image and are seen end-on as small dots. As a result of this alternating orientation of the collagen fibrils, lamellar bone has much greater strength and resilience than woven bone. Small portions of osteocyte cytoplasmic projections are marked with *asterisks* (*). Transmission electron micrograph, rat tibia.

The processing of collagen needed to assemble this ordered extracellular matrix is complex, beginning within the osteoblast and continuing after secretion. Collagen molecules are assembled in the endoplasmic reticulum (ER) of osteoblasts into right-handed triple helices of highly posttranslationally modified monomers, designated α chains. Type I collagen consists of two α1[I]

chains and one α2[I] chain, each 1050 amino acids long and encoded by different genes, with a middle region rich in glycine, lysine, and proline. At both the amino (N-)- and carboxy (C-)-termini there are registration peptides that are not a part of the triple helix, but are required to align the monomers in proper registration. Within the ER, signal peptides are cleaved off and hydroxyl groups are added to the side chains of proline and lysine residues in hydroxyltransferase-mediated reactions that are vitamin C-dependent. The failure of this pathway in the absence of vitamin C is a major contributor to the pathogenesis of scurvy. Disulfide bonds form between the carboxy-terminal registration peptides of adjacent chains, aligning the monomers. Thus modified and registered, three monomers readily form right-handed, triple helical bundles 300 nm long and 1.5 nm in diameter wound in a C-to-N direction. O-linked sugars are added to some hydroxylysines and N-linked sugars to the terminal regions. The assembled trimers, or "procollagen" molecules, move to the Golgi, where they are packaged into secretory vesicles and secreted.

Once outside the cell, the terminal peptides are cleaved off and the resulting triple-helical molecules are called "tropocollagen." Tropocollagen then polymerizes in aligned bundles, with covalent bonds forming between C- and N-termini of adjacent trimers to form highly ordered collagen fibrils. The periodicity of the overlapping collagen molecules within the fibrils is seen at very high magnification as a banding pattern 67 nm in length (**Fig. 7**). The alternating orientation of the fibrils in successive layers of bone collagen fibrils that is crucial to the mechanical resilience and strength of bone can be seen in electron micrographs (**Fig. 6**). The surface of bone is generally covered by a "capsule" of collagen fibers arranged parallel to the surface, called the circumferential lamella. The exception to this occurs at the points of attachment of tendons and ligaments, whose collagen fibers penetrate the bone surface at an angle and become continuous with the bone collagen fibers. These are called Sharpey's fibers.

In addition to its high collagen content, the proteinaceous bone matrix secreted by osteoblasts (called "osteoid") contains many noncollagenous proteins, about 5%–10% of protein weight. Osteoid provides the microenvironment where mineral precipitates in a controlled way, and it is thought to mediate a wide range of other biological processes (Boskey and Robey, 2013). Among the bone matrix proteins are many growth factors, including the bone morphogenetic proteins (BMPs), members of the TGF-β gene family, some of which are used clinically to induce bone growth and repair. Other growth factors include platelet-derived growth factor, fibroblast growth factor a and b, and connective tissue growth factor. There is vitronectin, critical for integrin binding during osteoclast bone resorption, and a host of proteins having roles in regulating hydroxyapatite crystallization and facilitating remodeling by osteoclasts, such as osteopontin, osteonectin, osteocalcin, and matrix Gla proteins. There is also an assortment of highly glycosylated proteoglycans and glycosaminoglycans, among them aggrecan, perlecan, and hyaluronan, all of which assist in microstructure and water retention, and some of which may "mark" tissue destined to be bone rather than cartilage. Although many of these proteins are synthesized by osteoblasts, some may be absorbed from other sources, bone being a highly absorbent tissue. With such an array of cell regulatory molecules embedded within the bone matrix, it is clear that bone provides an information-rich environment that helps direct and integrate diverse cellular activities such as cell attachment, bone synthesis, collagen assembly, mineral deposition, and bone resorption, as well as responses to environmental cues such as mechanical loading or dietary status. Presumably some of these noncollagenous bone matrix proteins are also essential for the remarkable ability of osteocytes to survive while inhabiting lacunae deep within the matrix, interconnected via cytoplasmic processes that inhabit the profuse networks of cannaliculi, and for the formation and maintenance of the capillary network that thoroughly permeates the entire Haversian system (see below). Identifying specific biological functions for the many noncollagenous bone matrix proteins is an important area of ongoing research.

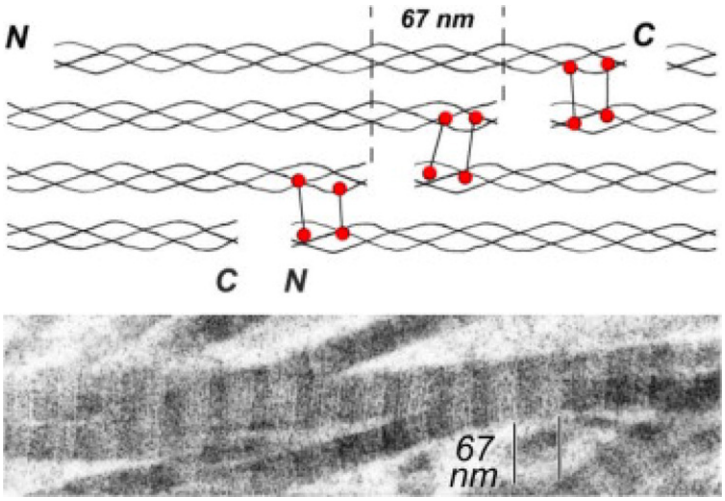

Fig. 7 Type I collagen fibrils in bone. The ends of adjacent tropocollagen trimers are staggered by 67 nm, as diagramed in the upper illustration. The N-terminal region of one trimer forms covalent disulfide bonds (represented as *ball-and-sticks*) with the C-terminal region of adjoining trimers. The spacing between the overlapped ends is seen as a banding pattern in high magnification electron micrographs, as in the lower panel, a transmission electron micrograph of rat tibia. The crosslinked trimers form collagen fibrils that constitute 90%–95% of the proteinaceous component of bone matrix.

Bone mineral is composed mainly of calcium and phosphate in the form of hydroxyapatite, $Ca_4(PO_4)_6(OH)_3$ (**Fig. 8**), which is secreted in matrix vesicles by osteoblasts. Thus, even though mineral deposition takes place outside the cells, it is a cell-regulated process. Matrix vesicles are seen near osteoblasts that supply mineral to the matrix and are roughly 100 nm in diameter. They contain alkaline phosphatase and other enzymes needed to produce high concentrations of calcium and phosphorous. The vesicles rupture, releasing their contents and permitting the precipitation of hydroxyapatite crystals—under the local control of components of the osteoid—that eventually permeate the osteoid completely to form the composite material we call bone. The mineral adds great rigidity and resistance to compressive and bending forces to the skeletal elements (**Fig. 1**). Bone mineralization is not completed immediately after the osteoid is secreted. Mineral accumulates over time, and can take 60 days or longer to be completed.

The crystal structure of bone mineral resembles pyrophosphate (Combes and Rey, 2010, p. 7), a fact which enables an important class of drugs called bisphosphonates—which mimic pyrophosphate in structure and charge—to bind to bone. These drugs are used clinically to block osteoclast bone resorption in osteoporosis and other conditions involving bone loss.

The Haversian System—Metabolic Lifeline

In large mammals, including humans, compact bone such as that found in the shafts of the limb bones, is too thick to permit adequate nutrient, signal, and waste exchange from the surface to sustain the embedded osteocytes. The evolutionary solution to this problem is the Haversian system, in which concentric cylinders of bone surround a nutrient artery and vein located within a central Haversian canal oriented parallel to the long axis of the bone (**Figs. 9** and **10**). The canals are typically about 50 μm in diameter and contain capillaries, and sometimes nerve fibers. The concentric rings of bone surrounding the canals are arranged much like growth rings in trees. One Haversian canal and its accompanying concentric lamellae is called an "osteon." Adjacent Haversian systems are interconnected at frequent intervals by blood vessels that travel in transverse passages called Volkmann's canals. Together, the Haversian and Volkmann's canals penetrate the entire bone substance and maintain communication among all the osteocytes embedded within the cortex. Note that small mammals such as rats and mice do not possess Haversian systems, their bones being small enough to permit survival of osteocytes without intraosseous circulatory elements.

Osteons, like other bony structures, are subject to remodeling. Successive waves of resorption by osteoclasts and formation by osteoblasts leave telltale structural evidence. The osteons most recently formed are generally the least densely mineralized and, more noticeably, have the most complete sets of rings. As new osteons form, they construct new bone in the territory cleared of older osteons by osteoclasts, sometimes overlapping more than one osteon's territory. This phenomenon is shown diagrammatically in **Fig. 9**B. This remodeling is essential to maintain the bones and to repair microdamage that accumulates over time. Metabolic studies have revealed that in the adult human, roughly 10% of the skeleton is remodeled per year. This implies that a complete skeletal replacement occurs about once a decade.

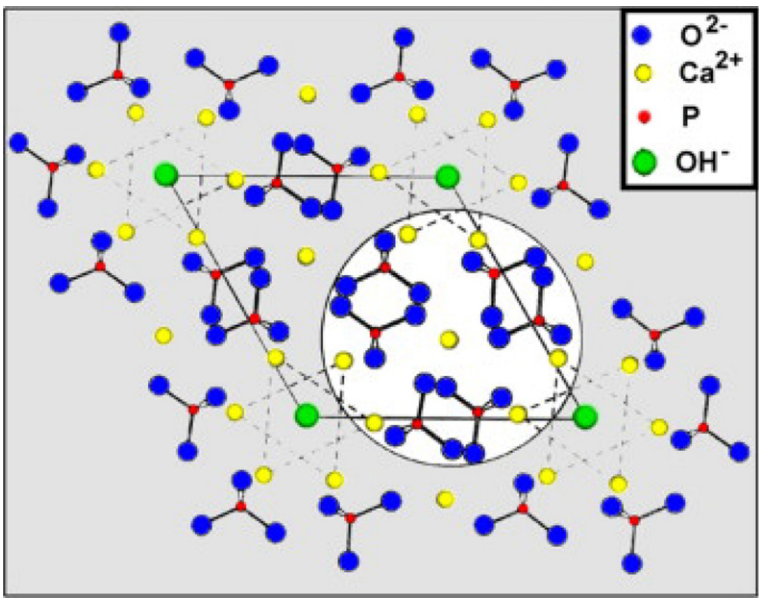

Fig. 8 Hydroxyapatite ($Ca_4(PO_4)_6(OH)_3$). The mineral crystals in bone are complex, with the so-called Posner cluster, having sixfold symmetry, highlighted near the center, and coordinated with the larger crystal structure around four hydroxyl groups marked by the *rhombus*. After Combes, C. and Rey, C. (2010). Amorphous calcium phosphates: Synthesis, properties and uses in biomaterials. *Acta Biomaterialia* **6**, 3362–3378.

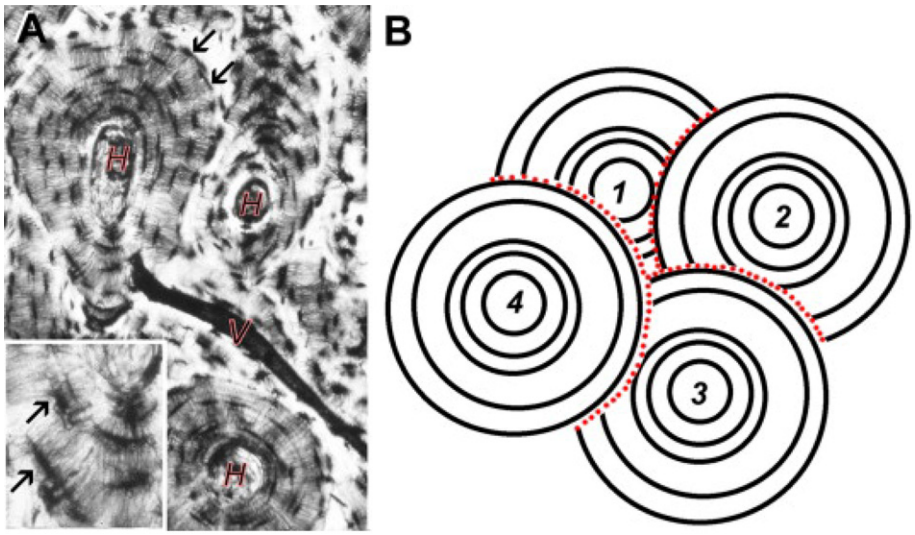

Fig. 9 Haversian systems and osteon remodeling sequence. Panel (A) is a transverse section of human cortical bone, polished and stained with India ink, without any cellular material. Three Haversian canals (H) and their associated structures are visible in the micrograph. A transverse Volkmann's canal (V) is also seen. These canals contain blood vessels that nourish the bone, and some also carry nerves. The concentric ring-shaped patterns, similar to tree rings, are produced by the osteocytes arranged around the central canals. Osteocytes occupy lacunae within the bone, several of which are indicated by *arrows* in the main panel and the inset. The collagen fibrils in successive rings are in alternating orientations. Each Haversian canal and its accompanying concentric rings (Haversian system) is called an osteon. The inset shows the dense meshwork of canaliculi that interconnect the osteocytes to permit transport of nutrients and signaling molecules from the blood vessels that occupy the canals throughout the entire bone volume. The diagram in (B) shows the succession of osteons due to remodeling over time. Osteons are not replaced on a one-to-one basis, but are resorbed and remodeled as controlled by local signals of microdamage, mechanical loading, and other factors. The oldest osteons (in this diagram, osteon #1) has been invaded by osteons 2, 3, and 4. Osteon #4 is the most recently formed, its territory impinging on the others. The intersecting boundaries are indicated by the *red dotted* lines.

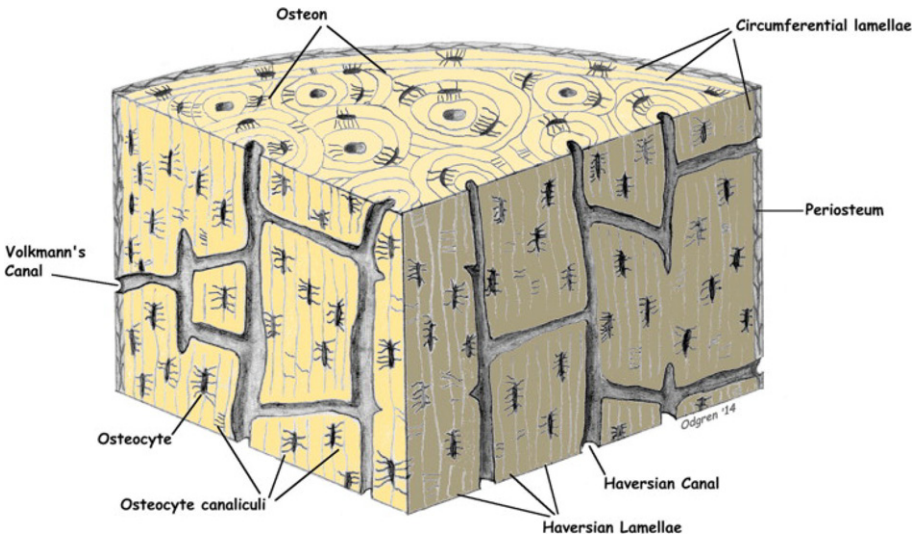

Fig. 10 Illustration showing Haversian bone (also called compact, or cortical, bone). Haversian and Volkmann's canals penetrate the bone, providing contact with the osteocytes that inhabit the bone. Cytoplasmic processes of the osteocytes occupy the canaliculi and permit responses to environmental stimuli such as mechanical loading and circulating levels of hormones, minerals, and other factors. At the inner (not shown) and outer surfaces, bone forms circumferential lamellae, in which the cells are sufficiently near the surface not to require Haversian organization to retain metabolic contact. In each layer of an osteon, the collagen fibrils are in different orientations to maximize tensile strength and flexibility.

Bone Biomechanics and Determinants Bone Strength

Bone is a unique material that has the ability to repair itself and adapt through modeling and remodeling which mediates changes in the traits that influence bone strength. Thus, diseases and drugs that impact bone remodeling will influence bone's resistance to fracture. Bone requires mechanical stress in order to grow and strengthen therefore physical activity is important to develop and

maintain bone strength. A fracture results from a structural failure of the bone, that is likely initiated at the material level, when the loads applied to the bone exceed its load-bearing capacity. Bone is a complex and heterogeneous material that is a consequence of its varied composition and microstructure that differ across anatomic sites and are dependent of age. The ability of a bone to resist fracture (or "whole bone strength") depends on the amount of bone (i.e., mass), the spatial distribution of the bone mass (i.e., shape and microarchitecture), and the intrinsic properties of the materials that comprise the bone (**Fig. 11**). Thus, properties at the cellular, matrix, microarchitectural, and macroarchitectural levels may all contribute to bone strength. Effects on the microscopic level are clinically relevant if they affect mechanical performance at more macroscopic levels.

In any discussion of bone strength, it is important to distinguish between the mechanical behavior of a whole bone as a structure (structural behavior) and the mechanical behavior of the bone tissue (material behavior). During any activity, a complex distribution of forces is applied to the skeleton. With the imposition of these forces, bones undergo deformations. This relationship between the forces applied to the bone and the resulting deformations characterize the structural behavior, or structural properties, of the whole bone. Thus, the size and shape of the bone, as well as the properties of the bone tissue influence structural properties. In contrast to the structural behavior, the material behavior, or material properties, of bone tissue is independent of the specimen geometry. Thus, the material properties reflect the intrinsic biomechanical characteristics of cortical and trabecular bone. Although the biomechanical properties of the whole bone are functionally the most important outcome, assessing bone material properties is critical for understanding the mechanisms that underlie changes in whole bone properties. The factors that are most likely to influence the structural and material behavior of bone will be presented in the sections that follow.

Role of Bone Geometry

The size of bone and its shape (i.e., distribution of mass) have an effect on overall fragility with larger bones being less susceptible to fracture (Bouxsein and Karasik, 2006; Bouxsein and Seeman, 2009; Crabtree *et al.*, 2001; Silva and Gibson, 1997). For example, decreased cross-sectional area of the radius is a risk factor for wrist fracture among both young girls (Skaggs *et al.*, 2001) and postmenopausal women (Ahlborg *et al.*, 2003), and individuals with smaller vertebral bodies have an increased risk of vertebral fracture (Gilsanz *et al.*, 1994, 1995; Duan *et al.*, 2001).

The loads applied to the skeleton generally are a combination of compression or tension forces with bending or torsional moments. The resistance to bending and torsional loading is particularly important because the highest stresses in the appendicular skeletal are due to these loading modes (Martin, 1993). The most efficient design for resisting bending and torsional loads involves distributing the bone mass far from the neutral axis of bending or torsion. The diameter and thickness of cortical bone varies in the skeleton, depending on the types of stresses that are applied to it in each location. For example, the mid-femoral neck adjacent to the shaft is elliptical, with the longer diameter in the superior–inferior direction and with greater cortical thickness inferiorly to minimize bending. On the other hand near the femoral head, stresses are mainly compressive and the geometry reflects this with the femoral neck being more circular and largely trabecular bone, with cortical bone of uniform thickness around its perimeter.

Role of Microarchitecture

The microarchitecture of bone is an important structural property and that is supported by experimental and clinical studies showing altered trabecular and cortical microarchitecture in subjects with fragility fractures compared to controls without fractures (Aaron *et al.*, 2000; Bell *et al.*, 2000; Ciarelli *et al.*, 2000; Crabtree *et al.*, 2001; Fields *et al.*, 2009; Legrand *et al.*, 2000; Thomas *et al.*, 2009).

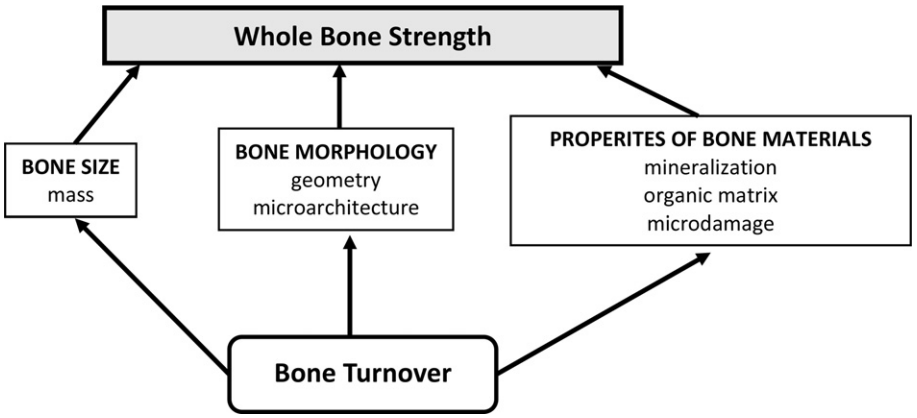

Fig. 11 Determinants of whole bone strength. Bone size, morphology, and bone tissue material properties contribute to whole bone strength. Bone turnover, or remodeling, is a crucial factor in controlling the quality and the quantity of bone.

Although bone density is among the strongest predictors of the mechanical behavior of trabecular bone, both empirical observations and theoretical analyses show that aspects of the trabecular microarchitecture influence trabecular bone strength as well (Gibson, 1985; Keaveny *et al.*, 2001; Rice *et al.*, 1988; Ulrich *et al.*, 1997, 1999). Trabecular bone microarchitecture can be described in terms of the number of trabeculae in a given volume, their average thickness, the average distance between adjacent trabeculae, the degree to which trabeculae are connected to each other, and their orientation relative to a given loading direction. The trabeculae are arranged in vertical and horizontal direction, the latter elements being critical to the bone's strength. Trabecular tissue can be modeled as a network of interconnected beams (horizontal trabeculae) and columns (vertical trabeculae) whereas the horizontal elements have the function of connecting and supporting the structure. A decrease in number of trabeculae reduces strength whereas loss of horizontal trabecular elements leads to more reduction in strength because it will markedly decrease the structure's buckling strength. Reduced strength due to the thinning of the trabeculae can be reversed with the appropriate treatment. Whereas, if the disconnectivity between the trabeculae (horizontal trabeculae disappear) increases the loss of resistance becomes irreversible and reduces the strength of the structure to a greater degree than accounted for by the loss of bone mass alone (**Fig. 12**). There is an association between the risk of fracture and the anisotropy (that is its mechanical properties are dependent upon direction of loading) of trabecular bone tissue. For example, after controlling for bone volume, trabecular bone architecture of specimens from the femoral head of individuals who had suffered a hip fracture was more oriented in a single direction than bone from unfractured individuals (Ciarelli *et al.*, 2000).

Cortical bone microarchitecture, such as cortical thickness and porosity, also play important roles in bone strength and skeletal fragility. Several studies, both in vitro (Bell *et al.*, 2000; Bousson *et al.*, 2001, 2004; Norman *et al.*, 2008; Zebaze *et al.*, 2010), and more recently with high resolution in vivo imaging (Burghardt *et al.*, 2010a,b; Macdonald *et al.*, 2011; Nishiyama *et al.*, 2010; Zebaze *et al.*, 2010), found marked increases in cortical porosity with aging due to accelerated remodeling (Zebaze *et al.*, 2010).

Role of Bone Matrix Properties

The features of the bone matrix itself influence bone mechanical properties. Thus, characteristic that affect bone mechanical properties include (but are not limited to) the composition of the matrix, the relative ratio of inorganic (i.e., mineral) to organic (i.e., water, collagen, and noncollagenous proteins); the degree of matrix mineralization; mineral crystal size, and maturation; the extent and nature of collagen cross-links; and the amount and nature of matrix microdamage (Burr, 2003; Follet *et al.*, 2004; Ottani *et al.*, 2001). The stiffness and strength of bone are positively related to the degree of matrix mineralization (Follet *et al.*, 2004), while collagen provides bone ductility and toughness.

Role of Bone Turnover

Bone is a complex living tissue that undergoes constant renewal to repair damage and adapt to mechanical loading in a healthy individual. The function of bone modeling and remodeling then influences the factors that determine whole bone strength, that is, bone size and shape, microarchitecture, and material properties. Bone turnover, or remodeling, is a crucial factor in controlling the quality and the quantity of bone. An imbalance between bone resorption and bone formation will either results in a net loss or gain of bone tissue. The onset of menopause is associated with increased bone turnover rate which leads to bone loss and an abnormal bone microarchitecture because of the cessation of estrogen production. Estrogen deficiency increases the lifespan of osteoclasts so that more bone is resorbed than is formed. This leads to increased porosity, bone thinning, and disconnection of trabeculae, ultimately resulting in a decrease in bone strength.

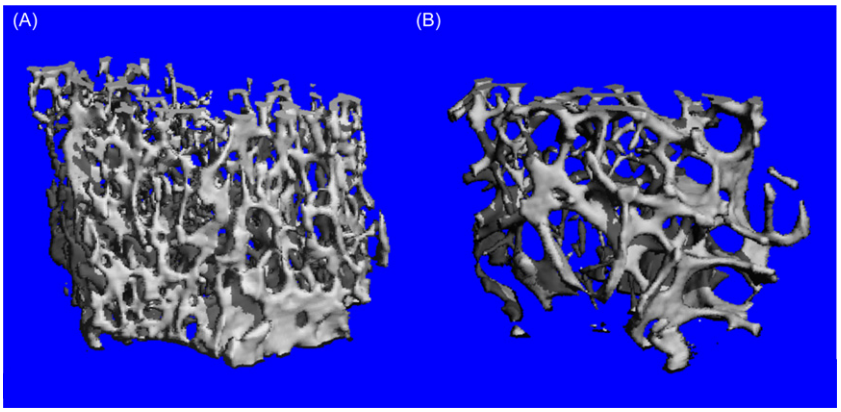

Fig. 12 Age-related changes in tibial trabecular architecture. 3D models of mouse tibial trabecular bone made from high resolution micro-CT. (A) 8 weeks old mouse (B) 52 weeks old mouse. Note the progressive loss of trabeculae, leading to a wider separation of trabecular elements, and unsupported vertical trabeculae.

Abbreviations

BM	Bone marrow
C/EBPα	CCAAT/enhancer binding protein α
CEBPδ	CCAAT/enhancer binding protein δ
CSF	Colony-stimulating factor 3
CXCL12	C–X–C motif chemokine 12
Dex	Dexamethasone
DHA	Docosahexaenoïc acid
ECM	Extracellular matrix
EPO	Erythropoietin
FA	Fatty acid
GM-CSF	Granulocyte-macrophage colony-stimulating factor
HSC	Hematopoietic stem cells
IBMX	Isobutylmethylxanthine
IGF-1	Insulin growth factor-1
IL	Interleukin
LIF	Leukemia inhibitory factor
M-CSF	Macrophage-colony stimulating factor
MUFA	Mono-unsaturated fatty acid
NF-κB	Nuclear factor-kappa B
Osx	Osterix
PPARγ	Peroxisome proliferator-activated receptor γ
PUFA	Polyunsaturated fatty acid
RANKL	Receptor activator of NFκB ligand
Runx2	Runt-related transcription factor 2
SFA	Saturated fatty acids
sFRP-1	Frizzled-related protein 1
SSC	Skeletal stem cells
TGF-β	Transforming growth factor-β
TNF-α	Tumor necrosis factor-α

Introduction

Bone and bone marrow (BM) function closely together as a single entity, exhibiting functional, and structural interdependences. They form a unique system implicating cooperation and interactions of different cell types that are critical for the equilibrium of hematopoiesis and the maintenance of skeletal health.

Bone and Bone Remodeling

Bone is a mineralized connective tissue that constitutes the skeleton, together with the cartilage. In adult humans, the skeleton is composed of 80% cortical bone and 20% trabecular bone and, despite its inert appearance, it is completely renewed every 10 years (Bartl and Frisch, 2009; Clarke, 2008).

Cortical bone is a 90% calcified dense and compact tissue, with an annual remodeling rate of approximately 2.5%. By contrast, trabecular bone presents a spongy, honeycomb-like network that provides the structural support for BM, filling the intertrabecular spaces. Its renewal rate is elevated, reaching 25% per year.

The ratio of cortical to trabecular bone is not constant throughout the skeleton and any decrease in bone mass is therefore firstly manifest in bones containing a large fraction of trabeculae, as the vertebral column and the intertrochanteric region of the proximal femur which present a cortical to trabecular bone ratio of 25:75 and 50:50, respectively (Bonnick, 2010; Hunter and Sambrook, 2000).

Bone exhibits four programmed cell types (i.e., osteoblasts, bone lining cells, osteocytes, and osteoclasts) which cumulate their activities to assure a well-balanced system. Bone formation and bone resorption are indeed highly regulated processes involving complex interactions between osteoblasts, the bone forming cells, and osteoclasts, the bone resorbing cells. These intercellular communications are crucial for the maintenance of skeletal integrity as their disturbance has been shown to result in abnormal bone mass and/or density and to lead to well-known bone diseases such as osteonecrosis, osteoporosis, and osteopetrosis.

Osteoclasts are highly specialized cells originated from a mononuclear hematopoietic precursor of the monocyte-macrophage lineage. Once activated, the osteoclastic precursors fuse to form a multinucleated osteoclast, which attaches to the endosteal bone surface and starts the bone resorption process (Baron, 2008).

Osteoblasts originate from a particular subset of BM stromal cells, the skeletal stem cells (SSCs), pluripotent cells that are both skeletal precursor cells and paracrine regulators of the BM microenvironment (Sacchetti *et al.*, 2016; Sworder *et al.*, 2015; van der Eerden and van Wijnen, 2017). SSCs are capable to differentiate into various cells of the mesenchymal lineages such as osteoblasts, adipocytes, and chondrocytes, depending on the presence of multiple environmental factors (Owen and Friedenstein, 1988; Prockop, 1997; Pittenger, 1999). Of note, although SSCs are a limited cell population, representing 0.001%–0.01% of the BM cell types (Pittenger, 1999), they remain one of the most promising types of stem cells used for cell-based therapies, already serving as therapeutic agents in a variety of diseases (Prockop, 2007; Wei *et al.*, 2013).

The principal function of osteoblasts is to synthesize the extracellular bone matrix and to further promote its mineralization. To fulfill their physiological role, osteoblasts do not function individually but are in contact with each other through gap junctions assuring intercellular communications.

Once the process of bone formation is achieved, most osteoblasts become gradually enclosed in the bone matrix and differentiate into osteocytes, the bone cells acting as mechanosensors and controlling the activity of bone forming and resorbing cells (Bonewald, 2011). Concomitantly, a small population of osteoblasts become flattened and die by apoptosis or remain as quiescent lining cells sited at the endosteal surface of bone (Florencio-Silva *et al.*, 2015). These bone lining cells are located on inactive bone surfaces, where neither formation nor resorption of bone occur (Miller *et al.*, 1989). Their physiological function is not completely understood, but they seem to play an important role in the process of bone remodeling since their activity was described as an essential prerequisite for subsequent bone formation. Indeed, by cleaning bone surface not adequately resorbed by osteoclasts and by depositing a thin collagenous matrix, bone lining cells prepare the surface where osteoblasts could start bone matrix production and mineralization (Everts *et al.*, 2002). Of note, during adulthood, quiescent bone lining cells may be activated by parathyroid hormone or nitric oxide and constitute a major source of osteoblasts (Matic *et al.*, 2016).

As osteoblasts and osteocytes, bone lining cells communicate via gap junctions (Prideaux *et al.*, 2016) allowing them to propagate a triggering signal that will initiate bone remodeling via recruitment of bone resorbing and forming cells.

Besides their principal role, osteoblasts regulate osteoclast maturation by the release of soluble factors (e.g., M-CSF, RANKL, IL-6, IL-1, TNF-α) that will create a microenvironment supporting osteoclastogenesis (Feng, 2009; Suda *et al.*, 1999). During the process of bone resorption, osteoclasts liberate factors (e.g., TGF-β, IGF-1) inhibiting their own activity and activating osteoblast function (Mohamed, 2008; Phan *et al.*, 2004).

The remodeling process is thus a coordinated series of events where osteoblasts and osteoclasts are coordinately regulated to assure an adequate coupling between bone formation and resorption.

Chondrocytes, originating also from SSCs, have a dual function as they regulate cartilage synthesis and degradation. The process of chondrogenesis requires aggregation and condensation of SSCs expressing specific extracellular matrix (ECM) and cell adhesion molecules. After proliferation, those particular SSCs differentiate into chondrocytes and start the production of cartilage-specific ECM molecules (e.g., aggrecan and type 2 collagen) that enlarge the cartilaginous shape (Goldring, 2012; Zuscik *et al.*, 2008). Chondrocytes are responsible for the turnover of the extracellular cartilaginous matrix in their surrounding area by regulating the synthesis of its major constituents and by producing cytokines and enzymes that will degrade it (e.g., IL-1β, TNF-α, IL-6, matrix metalloproteinases) (Goldring *et al.*, 2011; Tetlow *et al.*, 2001).

In case of joint disease, the equilibrium between cartilage synthesis and degradation is disrupted, supporting loss of ECM molecules and leading therefore to irreversible alteration of the cartilage, due to the limited replication potential of chondrocytes (Fox *et al.*, 2009). In such circumstances, cartilage turns into bone via the process of endochondral ossification. Chondrocytes proceed to terminal differentiation, increasing in size and leading to their hypertrophy. Subsequently, hypertrophic chondrocytes undergo apoptosis, generating cavities used by blood vessels to invade the remaining cartilaginous structure. Using the blood stream, SSCs enter the vascularized cartilage and invade the free spaces, where they differentiate into osteoblasts. The cartilage matrix serves then as a scaffold for endochondral bone formation (Goldring, 2012; Zuscik *et al.*, 2008).

Bone remodeling is therefore a complex process involving interconnected signaling between the four different types of bone cells, cooperating closely together to maintain a balanced bone mass (Sims and Martin, 2014). Moreover, since bone turnover occurs mainly at the endosteal surface where bone and bone marrow interact, commitment, proliferation, and differentiation of bone cells are also regulated by local signals and factors released by other BM surrounding cells (**Fig. 1**).

Bone Marrow and the Bone Marrow Niches

BM is one of the most dynamic and large tissues of the mammalian organism. It is a soft tissue located in the cavities of trabecular bones, presenting highly vascularized areas due to presence of a rich sinusoidal network of capillaries (Wang, 2012). BM is a complex organ, divided in arrays characterized by different cell populations that are interdependent (Heideveld and Van Den Akker, 2017). It contains two distinct lineages, the hematopoietic and the nonhematopoietic lineage, from which osteoclasts and osteoblasts originate, respectively. Therefore, BM exists in two appearances, varying in composition and function, the so-called red (hematopoietic) and yellow (nonhematopoietic) BM.

Red BM contains hematopoietic stem cells (HSC), the blood progenitor cells, and adipocytes; its red color is due to the presence of hemoglobin in erythroid cells. It is mainly devoted to hematopoiesis, contrary to yellow marrow, though to be made of 80% fat with few hematopoietic components (Małkiewicz and Dziedzic, 2012).

In mammalian fetus, BM is almost entirely red, since it is primarily composed of hematopoietic cells and does not contain fat. At birth, the conversion of red to yellow marrow starts, red marrow being subsequently replaced by yellow marrow following a well-defined pattern that evolves from the peripheral to the central skeleton (Gurevitch *et al.*, 2007). At the third decade of life, BM cavities are filled by 50%–70% yellow marrow (Moerman *et al.*, 2004; Rosen *et al.*, 2009).

In vertebrates, BM serves as the principal active site for hematopoiesis, allowing maintenance of homeostatic levels of circulating blood cells (Calvi and Link, 2014). HSC possess the ability to differentiate into mature blood cells and the capacity of self-renewal, a property essential to assure a permanent pool of stem cells, generating a continuous production of mature blood cells (Calvi and Link, 2014).

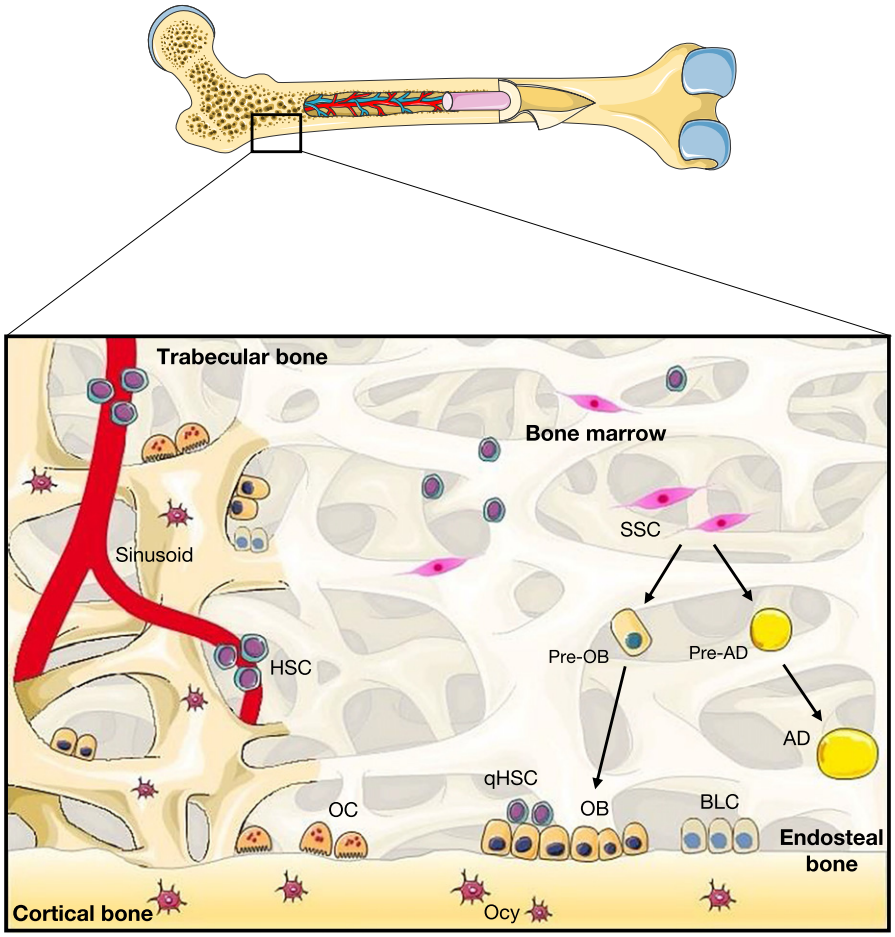

Fig. 1 Interactions in the bone marrow microenvironment. Bone marrow is the main place for hematopoiesis and for bone formation/resorption. Bone and bone marrow function closely together, as a single entity, exhibiting functional, and anatomical interdependences. Cells originated from different lineages communicate closely together to maintain a well-balanced microenvironment essential for normal hematopoiesis and osteogenesis. Bone marrow contains skeletal stem cells (SSC) that can differentiate into pre-osteoblasts (pre-OB) or pre-adipocytes (pre-AD), which mature to become fully functional (OB and AD). Endosteal bone surface principally includes bone-forming cells (OB) and bone-resorbing cells (OC), as well as osteocytes (Ocy), and bone lining cells (BLC). Quiescent hematopoietic stem cells (qHSC) are retained next the endosteum, in close contact with osteoblasts, whereas committed progenitors and differentiated hematopoietic cells (HSC) are localized near the perisinusoidal regions. Illustration realized thanks to Servier Medical Art (https://smart.servier.com/).

Mature HSC are located in a highly vascularized area of the BM due to the presence of a dense network of sinusoids and arterioles (Boulais and Frenette, 2015). Quiescent HSC are retained next to the endosteal bone surface, in close contact with osteoblasts that produce factors maintaining them in an undifferentiated state (**Fig. 1**). Physiological stress induces rapid mobilization of quiescent HSC and their migration into sinusoids. Once released into the vascular system, they home to particular organs and either restore their function or regenerate the stem cell pool (Heissig *et al.*, 2002). Therefore, the existence of two distinct HSC specialized microenvironments (also called "niche") generated by cell-dependent interactions has been proposed: the osteoblastic and the vascular niche (Del Fattore *et al.*, 2010; Yin and Li, 2006). The osteoblastic niche provides a quiescent microenvironment for HSC maintenance, while the vascular niche allows proliferation and differentiation of the blood cell precursors and their migration into blood vessels.

Bone and BM Cellular Interactions

Cellular Interactions Between Bone and Hematopoietic Cells

Cell populations sited in the BM are closely associated and communicate with each other. These reciprocal relationships are essential for maturation of both SSCs and HSC and, *in fine*, for maintenance of hemopoiesis and skeletal homeostasis. The cellular mechanisms involved in these interactions are not yet completely elucidated, but a large number of studies have already documented their close and intricate association.

Homeostasis of the hematopoietic system is maintained by highly regulated interactions among HSC and their microenvironment (Pontikoglou *et al.*, 2011). Numerous studies have already shown that SSCs as well as cells of the osteoblastic lineage, besides maintaining bone homeostasis, are fundamental regulators of hematopoiesis. They participate to the development of the HSC niche by releasing factors that support HSC migration, homing, self-renewal, proliferation and differentiation (Aqmasheh *et al.*, 2017). Clinical studies have shown that co-administration of SSCs and HSC promote hematological engraftment and prevent engraftment failure as well as poor graft function, making SSCs attractive candidates for cellular therapy in immune-based disorders, especially when HSC transplantation is needed (Koç *et al.*, 2000; Pontikoglou *et al.*, 2011; Zhao and Liu, 2016).

Likewise, a subset of specialized immature osteoblasts located in the endosteum is likely to play an important role in hematopoiesis by regulating function and maintenance of the hematopoietic progenitor cells. These particular osteoblasts support expansion of immature HSC and secrete factors (e.g., IL-6, IL-7, EPO or GM-CSF) regulating their activity (Calvi, 2006; Fazzi *et al.*, 2004; Zhang *et al.*, 2003; Rankin *et al.*, 2012; Taichman, 1994; Visnjic *et al.*, 2004). As well, HSC direct SSCs differentiation toward the osteoblastic lineage (Jung *et al.*, 2008). A cross-talk between HSC and osteoblastic cells seems thus to be essential for the optimal development of both populations.

Osteoclasts are also involved in the mobilization of hematopoietic progenitors. In a murine model, it was shown that inhibition of osteoclast differentiation severely affects the HSC pool and that functional recovery of the osteoclasts reestablishes the maintenance of the HSC niche, probably through an indirect effect on osteoblast turnover (Lymperi *et al.*, 2011).

The influence of BM adipocytes (BM-adipocytes) originating from SSCs, on the hematopoietic niches is still debated. On one hand, they produce factors (e.g., leptin and adiponectin) impairing expansion of the hematopoietic progenitors (Laharrague *et al.*, 2000; Yokota *et al.*, 2000). BM-adipocytes also negatively influence hematopoiesis by releasing growth factors inhibiting HSC proliferation such as neuropillin-1 and lipocalin 2 (Ambrosi *et al.*, 2017; Belaid-Choucair *et al.*, 2008; Miharada *et al.*, 2008; Naveiras *et al.*, 2009). On the other hand, the recent study of Mattiucci and coworkers proposes that BM-adipocytes support HSC survival and could play a role in their steady state maintenance by producing critical molecules such as C–X–C motif chemokine 12 (CXCL12), IL-8, colony-stimulating factor 3 (CSF3), and leukemia inhibitory factor (LIF) (Mattiucci *et al.*, 2017).

In physiological conditions, the various factors secreted by the different hematopoietic and nonhematopoietic cell types create a well-balanced BM microenvironment that is essential for optimal hematopoiesis and osteogenesis. An inadequate production of some of those factors, such as factors released by BM-adipocytes, could destabilize the system and disturb bone and red marrow interactions, leading to alteration of hemopoiesis and/or osteogenesis.

Cellular Interactions Between Bone and Nonhematopoietic Cells

In mammalians, BM is the only place where bone and fat (i.e., BM-adipocytes) are in close contact. Initially described as passive occupants and space fillers, BM-adipocytes are now recognized as an active organ that modulates the function and survival of neighboring cells by producing and secreting factors acting in paracrine and autocrine fashions.

In humans, adipocytes constitute the most abundant stromal cell population found in the BM at adult age. Like osteoblasts, BM-adipocytes originate from the pluripotent SSCs and a well-balanced differentiation of SSCs into the osteoblastic or adipocytic lineage is crucial for the maintenance of bone homeostasis (Muruganandan *et al.*, 2009).

In bone diseases such as osteonecrosis and osteoporosis, a shift toward a preferential differentiation of SSCs into adipocytes at the expense of the osteoblastic lineage is described, leading to excessive accumulation of BM-adipocytes in BM and decreased number of functional osteoblasts. The impact of abnormal BM-adipocytes accretion on skeletal integrity is currently under active investigation (Hardouin *et al.*, 2016; van der Eerden and van Wijnen, 2017) and it is proposed that adipocytes accumulated in the BM modulate bone remodeling through a paracrine action, influencing the physiology of osteoprogenitor and mature bone cells (Abdallah, 2017; Zhu *et al.*, 2015) as well as the activity of bone resorbing cells (Drosatos-Tampakaki *et al.*, 2014).

The impact of adipokines and cytokines secreted by BM-adipocytes on their surrounding cells is well documented (Kawai *et al.*, 2012; Lecka-Czernik, 2012; Rosen *et al.*, 2009).

Leptin, an adipokine secreted by BM-adipocytes, exerts complex effects on the skeleton (Ducy *et al.*, 2000; Hamrick *et al.*, 2005; Hamrick and Ferrari, 2008). Osteoblasts and osteoclasts express the leptin receptor, allowing a direct action of the adipokine on both cell types (Lecka-Czernik, 2012; Upadhyay *et al.*, 2015), in vitro studies having demonstrated that it promotes osteoblastic proliferation and differentiation and inhibits osteoclastogenesis (Cornish *et al.*, 2002). In vivo studies examining the impact of leptin administration or using leptin-deficient mice have highlighted its indirect inhibitory action on bone formation, that is, through the central nervous system via a hypothalamic relay (Ducy *et al.*, 2000; Takeda *et al.*, 2002).

As for leptin, the influence of adiponectin on bone cells is controversial. Most in vitro studies suggest that adiponectin has a positive action on bone formation, enhancing osteoblast proliferation and differentiation while inhibiting osteoclastogenesis. As such, mice treated with adiponectin show increased trabecular bone mass and mineralized osteoblasts, accompanied by a decreased number of functional osteoclasts (Oshima *et al.*, 2005). However, human clinical studies indicate an inverse relationship between circulating adiponectin levels and bone mass density (Chen *et al.*, 2017; Kajimura *et al.*, 2014; Kanazawa *et al.*, 2007, 2009; Luo *et al.*, 2005; Naot *et al.*, 2017).

Chemerin, a more recently identified adipokine, was shown to promote adipogenic differentiation while inhibiting osteoblastic differentiation (Muruganandan *et al.*, 2017).

BM-adipocytes also produce pro-inflammatory cytokines such as IL-1β, IL-6 or TNF-α which have been shown to increase osteoclast activity (Cao *et al.*, 2010; Suda *et al.*, 1999).

Moreover, they inhibit osteoblastic differentiation by blocking BMP2-induced osteoblastogenesis and by activating the proinflammatory NF-κB signaling pathway (Abdallah, 2017). BM-adipocytes secrete frizzled-related protein 1 (sFRP-1), an inhibitor of the Wnt signaling pathway, and co-culture experiments demonstrated that depletion of sFRP-1 abolishes this anti-osteoblastic effect (Taipaleenmäki *et al.*, 2011). Interestingly, in humans, BM-adipocytes display the particularity to express RANKL and OPG, and the RANKL/OPG ratio increases following dexamethasone treatment (Goto *et al.*, 2011; Hozumi *et al.*, 2009), a situation resembling that observed in mature osteoblasts. In mice, RANKL expression rises while OPG is reduced throughout adipogenesis and aging, an observation further supporting the link between adipogenesis and osteoclastogenesis (Takeshita *et al.*, 2014).

If the influence of cytokines and adipokines on skeletal health is documented by numerous studies, the impact of free fatty acids released by BM-adipocytes on bone cells was only deeply investigated during the last decade.

Maurin *et al.* were the first to demonstrate that co-culture of human osteoblasts and adipocytes isolated from mammary gland inhibits osteoblast proliferation via the release of arachidonic acid (C22:4) and docosahexaenoic acid (DHA; C22:6), two members of the omega-6 polyunsaturated fatty acid (PUFA) family (Maurin *et al.*, 2000, 2002). Later in vitro studies documented that human BM-adipocytes release large amounts of, palmitate (C16:0) and stearate (C18:0), two saturated fatty acids (SFA) disturbing the differentiation process and survival of SSCs and osteoblasts (Elbaz *et al.*, 2010; Lu *et al.*, 2012; Wang *et al.*, 2013).

Fatty acids serve as key sources of metabolic fuel in physiological conditions but it is recognized that a chronic exposure to high concentration of SFA favors their abnormal cellular accumulation and triggers cell dysfunction and organ injury through a process called lipotoxicity (Unger, 2002). As such, long-chain SFA are well known cytotoxic agents for several cell types including insulin secreting pancreatic β cells (Unger and Zhou, 2001), hepatocytes (Hetherington *et al.*, 2016), and cardiomyocytes (Kong and Rabkin, 2000).

We and others further characterized the molecular mechanisms responsible for the toxicity of palmitate in human SSCs and osteoblasts; furthermore, we demonstrated that the mono-unsaturated fatty acid (MUFA) oleate (C18:1) protects these bone cells from lipotoxicity (Fillmore *et al.*, 2015; Gillet *et al.*, 2015). Interestingly, unlike its well-known deleterious action in numerous cell types, palmitate is not cytotoxic for osteoclasts and enhances osteoclastogenesis while oleate counteracts palmitate-induced osteoclastogenesis (Drosatos-Tampakaki *et al.*, 2014).

SFA and MUFA have thus opposite actions on osteoblasts and osteoclasts and BM-adipocytes expansion could therefore create an imbalance between bone formation and bone resorption that may alter skeletal integrity, leading to bone loss, through the release of SFA.

In line with this proposal, an elevated SFA dietary intake has been reported to be associated with higher risk of bone loss in murine models (Chen *et al.*, 2016) as well as in humans (Corwin *et al.*, 2006) while investigations performed on Mediterranean population have shown a positive correlation between MUFA dietary intake and bone mass density (Pérez and Velasco, 2014; Savanelli *et al.*, 2017; Trichopoulou *et al.*, 1997). Human and animal studies have also highlighted the beneficial effect of an appropriate consumption of omega-3 PUFA on bone metabolism (Farina *et al.*, 2011; Li *et al.*, 2010; Sun *et al.*, 2003) while omega-6 PUFA appear to negatively impact bone remodeling (Casado-Díaz *et al.*, 2012; Kruger *et al.*, 2010; Orchard *et al.*, 2013). The clinical trial VITAL is currently investigating the effects of omega-3 fatty acid supplements on bone health and fracture risk (LeBoff *et al.*, 2015).

Disturbance of Bone and BM Interactions

Due to their particular secretory activity, disproportionate accumulation of BM-adipocytes could impair the concerted network signaling required to establish optimal bone remodeling or regeneration and, therefore, be implicated in the evolution of bone diseases characterized by BM fat accumulation such as osteoporosis and osteonecrosis.

BM-adipocytes and osteoblasts originate from SSCs. Accumulated evidence indicates that commitment of SSCs to the different lineages is directed by multiple cellular and molecular signals implicating critical transcriptional factors and that biological, chemical and physical factors regulate the balance between adipogenic and osteoblastic differentiation.

In vitro, the stemness of freshly isolated SSCs is therefore determined using well-established culture medium containing specific chemicals.

The couples PPARγ-C/EBPα and Runx2-osterix (Osx) are key transcriptional regulators of adipocyte and osteoblast differentiation, respectively (Zhang *et al.*, 2012).

To induce adipogenic differentiation, SSCs are usually cultured in medium supplemented with isobutylmethylxanthine (IBMX), indomethacin, dexamethasone (Dex), and insulin, factors that will, inter alia, stimulate genetic expression and activity of the transcriptional factors PPARγ and C/EBPα (Chen *et al.*, 2016; Pittenger, 1999).

Osteogenic medium contains Dex, L-ascorbic acid, and β-glycerophosphate (Pittenger, 1999), allowing cells to synthetize an extracellular matrix and further leading to upregulation of Runx2, Osx, alkaline phosphatase and osteocalcin expression, the major markers of osteoblast differentiation (Chen *et al.*, 2016; Huang *et al.*, 2007).

In vivo, SSCs physically interact with components of the BM microenvironment, for example, growth factors, adipokines, fatty acids and cytokines, released by surrounding cells as, notably, BM-adipocytes, that influence their differentiation (see previous

sections). More recently, it was demonstrated that human BM-adipocytes may also affect BM microenvironment through secretion of extracellular vesicles containing adipogenic mRNAs (i.e., PPARγ, CEBPα, and CEBPδ mRNA) (Martin *et al.*, 2015) that could be incorporated and translated by osteoblasts, further supporting the idea that BM-adipocytes modulate the osteoblastic phenotype (Morris and Edwards, 2016).

Moreover, SSCs cell–cell contact, physicochemical factors such as oxygen tension, ionic strength and pH, impact the fate of SSCs (McAdams *et al.*, 1997; Pattappa *et al.*, 2011; Zhang *et al.*, 2012). Pharmacological stress as glucocorticoid treatment or ethanol abuse also disturb the BM microenvironment and deregulate the maturation of bone precursor cells by favoring adipogenesis at the expense of osteoblastogenesis (Georgiou *et al.*, 2012).

The process of aging is a biological factor affecting bone mass and quality that may evolve to osteoporosis. It is characterized by decreased bone formation due to a decline of osteoblastogenesis associated with enhanced adipogenesis, leading to fat accumulation in the BM. SSCs isolated from aged subjects display a higher adipogenic potential concomitant to altered osteoblastic activity (Moerman *et al.*, 2004). Moreover, excessive degradation of the trabecular bone augments the trabecular space, which will be progressively infiltrated by marrow fat, generating a negative correlation between the amount of marrow fat and bone mass and density in old people (Griffith *et al.*, 2006; O'Neal *et al.*, 2011).

The loss of bone quality observed in aging and in pathological situations such as osteoporosis, diabetes, obesity and, puzzlingly, anorexia nervosa is currently definitely associated with an excessive expansion of BM-adipocytes (Devlin and Rosen, 2015). Likewise, clinical studies have highlighted accumulation of BM-adipocytes in the proximal femur of patients suffering from nontraumatic osteonecrosis of the femoral head (Mitchell *et al.*, 1986; Vande Berg *et al.*, 2006), a disease associated with low bone mineral density (Gangji *et al.*, 2018). Moreover, SSCs isolated from osteonecrotic patients are more susceptible to lipotoxicity and the fatty acid and cytokine composition of their BM-microenvironment is disturbed (Gillet *et al.*, 2017).

Having highlighted the impact of excessive BM-adipocyte accretion on skeletal health, the research is now focusing on the characterization of the qualitative aspects of BM adiposity.

Advanced imaging techniques allow for indirect evaluation of the BM lipid content and bone marrow aspiration permits the direct assessment of the BM environment lipid profile. Current studies reveal the dynamic lipid composition of BM, varying according to physiological and pathological situations. BM fat composition is enriched in SFA in patients with chronic diseases such as osteoporosis (Miranda *et al.*, 2016; Yeung *et al.*, 2005), osteonecrosis (Gillet *et al.*, 2017) or type-2 diabetes mellitus (Baum *et al.*, 2012; Patsch *et al.*, 2013).

Elucidation of the relationship between bone cells and BM-adipocytes could therefore help to get new insights on the pathophysiology of bone diseases characterized by marrow fat accumulation (Devlin and Rosen, 2015). In line with this proposal, studies could also be performed to clarify the influence of fatty acids on the survival and function of HSC and endothelial cells of the BM sinusoidal network.

Introduction

Bone and skeletal muscle are closely physically linked, with bone providing the scaffold for muscles to exert their force. With population aging, diseases of the musculoskeletal system are becoming more common. The increasing population obesity also has important effects on the skeleton and on muscle function. Sarcopenia, or loss of muscle mass and function and osteopenia or osteoporosis with associated fractures cause much of the disability in older life, with enormous societal and economic costs. The costs of these are estimated at $850 billion dollars a year in the USA (Connelly *et al.*, 2006).

Throughout life in people, muscle mass and bone mass are linked. This linkage requires direct mechanical interactions, and tissue cross-talk. Bones weaken with decreased muscle use in people and in animals. Congenital myotonic dystrophy and with other hereditary muscle disorders are examples of this effect. These patients are born with already thin long-bones, due to impaired and weaker fetal movements (Rodríguez *et al.*, 1988a,b). With weightlessness, astronauts lose bone and muscle mass rapidly. Bone mass and muscle strength is also rapidly lost with neurological injuries, for example, spinal cord lesions.

Bones release a number of osteokines, reviewed below. Growth hormone/insulin-like growth factor (IGF)-1, sex steroids and Wnt-signaling may help to coordinate the bone-muscle unit during fetal life and with adaptation to mechanical stimuli (Christoforidis *et al.*, 2005).

Development and Regulation of Bone and Muscle

Skeletal muscles and bones develop in close proximity to each other during early fetal life from the somatic mesoderm, and their development has been reviewed (Schweitzer *et al.*, 2010; DiGirolamo *et al.*, 2013).

Bone forms with a series of ordered steps. The first is condensation of mesenchymal precursors at future skeletal sites, followed by differentiation into chondrocytes to form the cartilage anlage (i.e., endochondral bone) or direct differentiation into osteoblasts (i.e., intramembranous bone) (DiGirolamo *et al.*, 2013) and mechanical cues are important during the process.

During life, bone continues to be remodeled. This occurs in response to loading, with an important role for sclerostin, and in order to repair microdamage. The cycle in the bone unit has been the subject of many reviews (Clarke, 2008). Bone is resorbed by osteoclasts, matrix is laid down, and then it is mineralized by osteoblasts. Mature bone cells (osteocytes) sense mechanical forces and may initiate both bone resorption and formation.

In fetal life, muscle development occurs next to skeletal development, at the same time. Pax3 is the master regulator in fetal life, and in adulthood this role is taken over by Pax7. Mesodermal precursors regulated by Pax3 commit to the myogenic lineage, and with external signals including Myf5 and MyoD fuse to multinucleated syncytia (Buckingham *et al.*, 2009). These syncytia ultimately form myotubes and then multinucleated muscle fibers. Some of the cells do not join with myotubes and instead remain on the edge of myofibres as a pool of Myf5/MyoD positive muscle precursors called satellite cells (Zammit *et al.*, 2002; Wang *et al.*, 2014; Hawke *et al.*, 2001; Sambasivan *et al.*, 2011; Seale *et al.*, 2000).

These developmental pathways for muscle and bone suggests the possibility that common signaling pathways could regulate their function and mass. To support this, mice with genetic defects in muscle development (MyoD knockout) display profound impairments in bone development and mineralization (Nowlan *et al.*, 2010). Signals thought to influence coordinated muscle/bone development include FGFs, transforming growth factors (TGFs), IGF-1 and other morphogens (Hamrick, 2012).

Exercise increases both muscle and bone mass, and disuse decreases both muscle and bone mass. There are obviously direct mechanical interactions, but evidence suggests that muscles may indirectly regulate bone repair via paracrine effects. After a fracture, covering the break with a muscle flap improves healing, even though the area is immobilized (Johnson *et al.*, 1996; Yoshizawa *et al.*, 1997). Conversely, injury to overlying muscle impairs fracture healing (Li *et al.*, 1997). Some of the secreted factor are shown in **Fig. 1** along with the effects of exercise and their effects on muscle and bone.

 doi:10.1016/B978-0-12-801238-3.65835-X

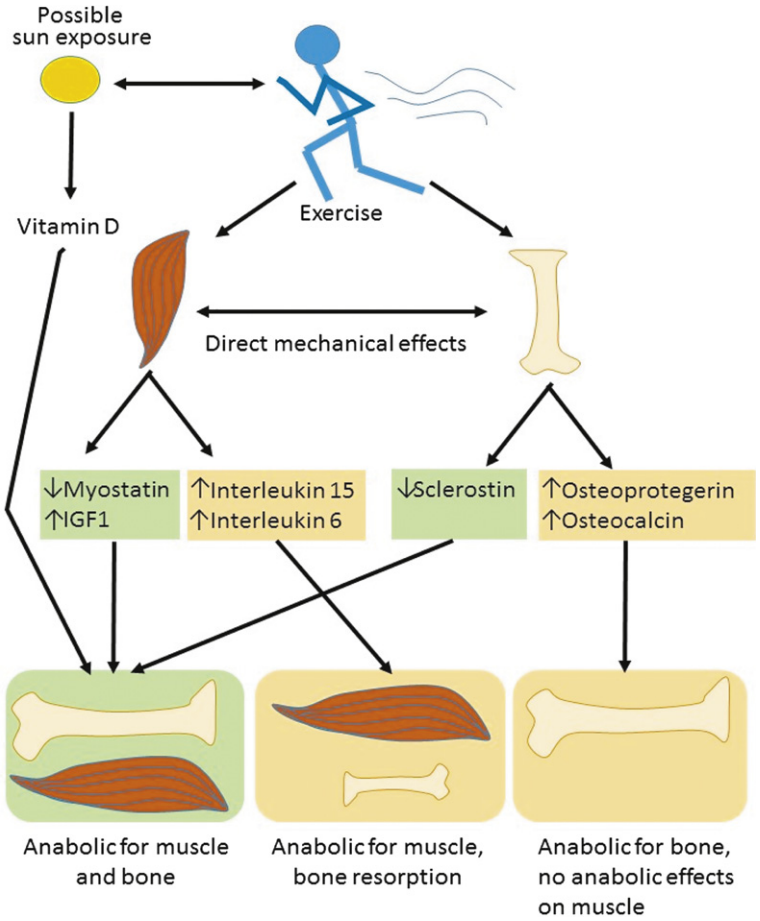

Fig. 1 Potential mechanisms underlying effects of exercise on bone and muscle. Exercise is often associated with sun exposure, generating increased vitamin D. Muscle decreases myostatin release and increases release of IGF1 (insulin like growth factor 1) and interleukins 6 and 16. Bone in response to exercise decreases sclerostin production, and increases osteoprotegerin (OPG) and osteocalcin. Osteocalcin increases muscle insulin sensitivity.

Vitamin D

Many kinds of exercise associate with sun exposure. Vitamin D is synthesized by conversion of 7-dehydrocholesterol in the skin with ultraviolet (UV) light exposure. Thus, vitamin D is not actually a true vitamin because humans can actually synthesize it, but it has retained the name for historical reasons.

Vitamin D is hydroxylated in the liver to form 25-hydroxyvitamin D (25D). This is the main circulating form and levels are used to assess vitamin D status. However, the active hormone is 1,25-dihydroxyvitaminD (1,25D). This is formed in kidney and a range of other cell types by 1α-hydroxylase. 1,25D binds to VDR, which is a member of the nuclear steroid hormone receptor superfamily. VDR usually heterodimerizes with RXR (the retinoid X receptor). It can, alternately, homodimerize with a second VDR. The VDR-dimer, when translocates to the nucleus, binds to vitamin D response elements (VDRE) in the DNA and regulates transcription (Lips, 2006).

There are hundreds of well-characterized gene regulation targets for activated VDR. Recent use of RNA-sequencing combined with chromatin immunoprecipitation (ChIP) has given new power to examine genes regulated by vitamin D in nonclassic target tissues such as liver (Ding *et al.*, 2013) and bone cells (Pike *et al.*, 2014) although this technology has not yet been applied to muscle. Vitamin D receptor (VDR) is a transcription factor, so mechanisms may include regulation of myokines, osteokines or perhaps regulation of mechano-stimulatory feedback.

People with deficiency, and particularly severe deficiency associated with rickets have some defects in muscle function (Girgis *et al.*, 2013a). Thus vitamin D represents another pathway by which muscle and bone interact, reviewed in (Gunton *et al.*, 2015).

Vitamin D in Bone

Bone is a classic vitamin D target, but it is also recognized to have important actions in muscle (Boland, 1986; Curry *et al.*, 1974; ADVANCE_Collaborative, 2008). Vitamin D deficiency causes rickets in children, and osteomalacia in adults due to impaired bone

mineralization. Vitamin D also stimulates calcium absorption from the intestine and decreases calcium loss in the urine. In the intestine VDR stimulates calbindin, and regulates some calcium channels. As well as active calcium absorption, passive intestinal absorption is possible if there is an appropriate calcium gradient.

Animal studies confirm these concepts. Mice with genetic deletion of VDR can still reverse rickets/osteomalacia when supplied with a diet very high in calcium and lactose; this has a "push" effect for calcium absorption. Even in people with genetic mutations in VDR, rickets can be healed with a similar diet. However, not all defects are corrected by this calcium "push." VDRKO mice on that diet still have atrophic muscle fibers and changes in osteoblast number, mineral apposition rate and bone volume (Endo *et al.*, 2003; Panda *et al.*, 2004).

Mouse models have enabled the delineation of direct effects of vitamin D in bone cells. Overexpression of VDR in mature osteoblasts increases bone formation, reduces bone resorption and inhibits bone loss with vitamin D deficiency (Gardiner *et al.*, 2000; Lam *et al.*, 2014). Recent data suggests that these mice respond more actively to mechanical loading by increasing bone formation and mineralization (Anderson *et al.*, 2013), a finding consistent with greater cortical bone mass and size in mice with elevated osteoblastic VDR levels, under normal or vitamin D-deficient conditions (Gardiner *et al.*, 2000; Lam *et al.*, 2014). The muscle phenotype of these mice has not been reported.

However, VDR activation in immature osteoblasts may have opposing effects; stimulating bone resorption and reducing bone mass (Yamamoto *et al.*, 2013). Treatment of early osteoblastic cells is also inhibitory, reducing cell activity and number (Shi *et al.*, 2007). The results in the osteoblast-specific VDR-null mouse suggests that VDR plays a systemic role to maintain serum calcium by inhibiting bone mineralization (Lieben *et al.*, 2012).

The osteoblast-specific VDR-null mouse suggests that VDR plays a more systemic role in inhibiting mineralization in order to maintain serum calcium levels (Lieben *et al.*, 2012). The direct role of VDR in osteocytes appears to be regulation of their development by effects on osteoprotegerin and maintaining calcium levels during deficiency (Takeda *et al.*, 1999). Therefore, local effects of vitamin D in bone may complement systemic vitamin D effects and may be anabolic or catabolic depending on the calcemic status and stage of bone cell differentiation.

Vitamin-D deficiency is associated with increased fracture risk and it appears that a significant proportion of this relates to muscle weakness and falls. The greatest effects are evident in those with lowest vitamin D levels (Girgis *et al.*, 2013a; Girgis *et al.*, 2014a). Low vitamin predicts future decline in physical performance (Wicherts *et al.*, 2007; Sohl *et al.*, 2013). Randomized clinical trials have been subjected to metaanalysis which confirms that vitamin D supplementation can decrease falls (Bischoff-Ferrari *et al.*, 2009). Coregulation of bone and muscle by vitamin D is suggested by coexistence of osteoporosis and sarcopenia in older, vitamin D deficient populations (Girgis *et al.*, 2013a; Onder *et al.*, 2008; Roth *et al.*, 2004; Visser *et al.*, 2003).

Vitamin D-related signals have also been implicated in muscle bone interactions (Tanaka *et al.*, 2014). Osteoglycin, produced by muscle cells under the control of vitamin D, regulates osteoblastic activity (Tanaka *et al.*, 2014). Decreased myostatin is associated with greater bone mass (Elkasrawy *et al.*, 2010), and this may be one means of the relative preservation of bone mass in VDR null mice, as vitamin D inhibits myostatin production from muscle cells (Garcia *et al.*, 2011; Girgis *et al.*, 2014b).

Vitamin D in Muscle

We and others have reviewed the roles of vitamin D in muscle (Girgis *et al.*, 2013a, 2014a; Boland, 1986; Ceglia, 2008). Whether vitamin D receptor is expressed in muscle was controversial. However, by RNA, Western immunoblot and by immunohistochemistry, VDR is present at low levels in cultured C2C12 myotubes (Girgis *et al.*, 2014b) and normal murine muscle (Girgis *et al.*, 2014c). VDR expression is often much higher in cell lines and isolated myocytes, and it is also higher in neonatal muscle. This pattern supports the concept of important developmental roles for VDR in muscle.

It has been long-recognized that vitamin D deficiency is associated with muscle weakness, especially proximal muscle weakness. There are electromyographic (EMG) features which resolve with correction of deficiency (reviewed in Girgis *et al.*, 2013a), but unfortunately the EMG findings are nonspecific. Human biopsy studies suggest that there may be preferential loss of type 2 muscle fibers which improves with supplementation (Sato *et al.*, 2005; Sorensen *et al.*, 1979). Children with rickets and adults with osteomalacia can have severe weakness (Girgis *et al.*, 2013a).

In people, it is challenging to control for sunlight and diet exposure; "healthier" individuals may have better diets and undertake more outdoor activities, including exercise, and have correspondingly better muscle and bone function. For this reason, it is useful to turn to animal models to examine the question of bone-muscle interactions and vitamin D.

Mice with mutations in vitamin D receptor are weak and can have low bone mass and less longitudinal growth. Studies of VDR-null mice where phosphate and calcium are aggressively replaced with a "rescue diet" may result in near-normal bone phenotype (Yeap *et al.*, 2014; Girgis *et al.*, 2013b). However, the muscle phenotype remains severe with a 40% decrease in muscle bulk (Girgis *et al.*, 2015). The size of muscle fibers is much smaller as well (Endo *et al.*, 2003).

Vitamin D is known to stimulate local vascular endothelial growth factor (VEGF) and IGF-1 production in muscle. Both factors are well known to have potential beneficial effects in bone. How large a contribution muscle vitamin D action makes to circulating levels of either hormone is not clear.

Another potential muscle factor which is regulated by vitamin D is IL-6 (interleukin-6). It is produced following exercise or contraction. It stimulates bone resorption, and may alter bone strength. It is decreased by vitamin D (Gannage-Yared *et al.*, 2003).

Potential Bone to Muscle Vitamin D Cross Talk

The osteocyte cell line MLO-Y4 expresses muscle anabolic factors IGF-1, MGF and VEGF after mechanical loading (Juffer *et al.*, 2012). Osteocalcin which is produced by osteoblasts has recently come to a new light for its role in regulating beta-cell function (Lalwani *et al.*, 2014). Its classic use is as a marker of bone formation. It is regulated by vitamin D and its gene contains a vitamin D response element (VDRE) indicating direct regulation by vitamin D (Girgis *et al.*, 2014d). It has potential effects in muscle, in which it alters mitochondrial function, insulin sensitivity (Lalwani *et al.*, 2014), and possibly strength in women.

FGF23 is another vitamin D responsive hormone produced by bone which has positive effects on cardiac and smooth muscle (Sherman *et al.*, 2014). The effects on skeletal muscle are the subject of current investigation.

Myokines

Myostatin

Myostatin is a hormone secreted from muscle, or a myokine. As implied by its name, it inhibits increases in muscle mass. There are several animal models of myostatin deficiency, including mice, dogs and cattle. One person with a mutation in myostatin has been found—he has a significant increase in muscle mass (Schuelke *et al.*, 2004). His bone density has not been reported. Muscle mass and bone density are both significantly increased in the myostatin mutant mouse (Hamrick *et al.*, 2006). Myostatin deficiency in this setting results in exercise-induced gains in bone mass and importantly, resistance to fracture (Hamrick *et al.*, 2006).

Myostatin expression is decreased in human muscle from 1 h after exercise with a persisting substantial decrease at 24 h (Louis *et al.*, 2007). The nadir in expression was 8 h after exercise. In that study the protocol was for 45 min of bike-riding. In another study of insulin resistant men, aerobic exercise at ~50% of VO_2 max for 6 months maintained a 21% decrease in circulating myostatin (Hittel *et al.*, 2010). Exercise at 50% or 80% of maximum lifting weight also significantly decreased myostatin, with a persisting decrease at 48 h (Schwarz *et al.*, 2016). In contrast, in older women, elastic band exercises did not alter myostatin although the exercise was enough to improve physical performance (Hofmann *et al.*, 2016). The "threshold" dose of exercise for duration or intensity of exercise is not known for myostatin, but half an hour at moderate intensity appears sufficient from the above studies.

Antibody inhibitors of myostatin in people have not produced consistent clinical results. One study in Duchenne's patients, where only two doses were received due to epistaxis and telangiectasias showed trends to improved muscle function (Campbell *et al.*, 2017). In androgen-deprived men, 28 days of myostatin inhibitor ACE-031 caused a small but significant increase in lean mass (2.2%) (Padhi *et al.*, 2014). The trials of inhibitors have mostly been of short duration, and or small in size, and there are no reports in people regarding whether there are or are not bone effects.

Interleukins

Interleukin 6 (IL6) was the first muscle-secreted cytokines to be identified (Pedersen *et al.*, 2008). It increases markedly in response to exercise, and it induces beneficial effects on metabolism and insulin sensitivity as well as myogenesis (Pedersen *et al.*, 2012). Similarly, interleukin 15 is released by exercising muscle. It has anabolic effects on muscle (Nielsen *et al.*, 2007). IL6 induces bone resorption.

Insulin-Like Growth Factor 1 (IGF1)

As well as liver and other tissues, muscle is able to synthesize and release IGF1. Its release is increased in response to exercise, and it has well described anabolic effects (Gregory *et al.*, 2013). Its use is banned in athletes due to its classification as a performance enhancing agent (Holt *et al.*, 2008). IGF1 increases bone formation (Yakar *et al.*, 2002) and bone mass (Tahimic *et al.*, 2013). However, there is a surprising lack of clinical trial evidence for beneficial effects on muscle function (i.e., strength or endurance) (Friedlander *et al.*, 2001; Mauras *et al.*, 2000; Vlachopapadopoulou *et al.*, 1995).

Osteokines

Sclerostin

Sclerostin is secreted by mature osteocytes during completion of osteon formation. It inhibits bone formation. Mutations in the SOST gene, coding for sclerostin, cause sclerosteosis with undetectable or low sclerostin levels, increased bone formation, very high bone mass and long-term neurological impairments due to entrapment of nerves (van Lierop *et al.*, 2012). Sclerostin antibodies have exciting potential in the treatment of osteoporosis. Sclerostin secretion by osteocytes increases in response to bedrest and decreases with muscle loading (Spatz *et al.*, 2012).

Vitamin D levels are inversely related to serum sclerostin. Sclerostin is a marker of osteocyte mechano-sensing, and it suppresses stimulation of bone formation by terminally differentiated osteocytes (van Lierop *et al.*, 2012). Thus, decreased sclerostin, seen with increased vitamin D, should increase bone mass.

Osteocalcin

Osteocalcin is released from osteoblasts, and is increased by exercise (Jurimae *et al.*, 2011). Its role in bone mineralization appears to be inhibitory; knockout mice have improved bone density and quality (Ducy *et al.*, 1996). It is not thought to have a major effect on muscle power, but improves muscle insulin sensitivity (Levinger *et al.*, 2016). That would improve responsiveness to insulin, but would also be expected to increase sensitivity to IGF1.

Osteoprotegerin

Osteoprotegerin (OPG) is part of the OPG/RANK/RANKL signaling system which is therapeutically targeted by denosumab. The effect of exercise on OPG is more difficult to interpret—some studies showing no effect, and some studies show an increase with exercise (Scott *et al.*, 2011). Increased OPG, by its function as a decoy receptor for RANKL would improve bone mass. Muscle does not express significant amounts of RANKL, so it is unlikely that OPG/RANK directly affects muscle function.

Conclusions

In summary, exercise induces direct mechanical effects on both bone and muscle. In addition, it regulates release of many myokines and at least some "osteokines" with effects on muscle and bone which are mostly positive. For people with sarcopenia or osteopenia, moderate exercise at 50% of maximal capacity for half an hour is sufficient to induce important changes in myostatin and sclerostin. Below that threshold, there is relatively little data. Since sclerostin decreases with load on bone, less intensive exercise which associates with some bone force may also be sufficient for benefit. This is an exciting and relatively fast-moving field. From muscle, myostatin and from bone, sclerostin are the targets of a range of therapeutic agents in current trials which have promise for preventing or treating these important aspects of frailty with disease or old age.

Bone as an Endocrine Organ

Gerard Karsenty and Stavroula Kousteni, Columbia University, New York, NY, United States

Introduction

The reasons that led to the hypothesis that bone might be an endocrine organ and that in this capacity, it should regulate energy metabolism and reproduction are probably as, if not more, important to understand as the mode of action of osteocalcin, the first hormone found to mediate endocrine functions of bone.

This hypothesis arose from cell biological and clinical observations that were placed anew in their original evolutionary context. From a cell biology perspective, bone is the only tissue in the body of vertebrates that contains a cell type, the osteoclast, the main function of which is to actively destroy the host tissue (Teitelbaum, 2000). It is as if bone had invented auto-immunity except that in that case it is a much-needed physiological process. This destruction, or bone resorption, occurs daily from birth to death in multiple locations in an organ that covers the largest surface in the body of vertebrates. Thus, because this process requires active lysis, bone resorption is likely to be energetically expensive. Bone resorption is only one aspect of a biphasic physiological process called bone modeling during childhood and bone remodeling during adulthood (Ducy *et al.*, 2000b). Bone formation is induced following bone resorption and is another energy demanding event since it entails the constant synthesis and secretion of collagenous protein. Importantly, the notion that there is a close link between bone physiology and energy metabolism is fully supported by clinical observations. Indeed, longitudinal bone growth stops in children and bone mass decreases in adults when access to food, that is, to energy, is severely limited (Legroux-Gerot *et al.*, 2005; Misra and Klibanski, 2011). Besides this link between bone (re)-modeling and energy metabolism, another well stablished and apparently unrelated clinical observation is that bone mass invariably declines in both sexes when gonadal functions end (Riggs *et al.*, 1998; Riggs and Melton, 1986). Considering these observations as a whole we formulated the hypothesis that there should be a coordinated regulation, endocrine in nature, of bone growth/mass, energy metabolism and reproduction.

This hypothesis, although seemingly vague at is birth, is in fact quite far reaching. A first justification of its application is the evolutional development of bone and the "peculiar" mechanism whereby it constantly renews itself. It simply implies that if hormones coordinating these physiological functions exist they most likely appear during evolution with bone, since it is the physiology of this tissue that requires their existence. In agreement with this prerequisite of our working hypothesis, leptin, a powerful endocrine regulator of bone mass that also controls fertility and energy metabolism, appears during evolution with bone. More to the point, the study of a mouse model of a partial gain of function of the leptin receptor showed that the amount of leptin signaling needed to influence bone mass is lower than the one needed to affect appetite, energy expenditure or fertility (Bjornholm *et al.*, 2007; Shi *et al.*, 2008). But the most original and far reaching implication of this working hypothesis was not to identify a new hormone regulating bone mass, but rather that bone should be an endocrine organ regulating energy metabolism and reproduction if not other physiological functions. It is the testing of this particular aspect of the working hypothesis that eventually led to a significant broadening of the field of bone endocrinology.

Osteocalcin Is a Bone Derived Hormone

As it is often the case in biology, the identification of a hormone synthesized by bone cells, regardless of its possible functions, required a degree of luck. At the beginning of the 90's when mouse genetics allowed physiologists to address fundamentally important questions of whole-organism physiology that could not possibly be addressed in vitro, osteocalcin was then and for several reasons the most mysterious protein in the field of bone biology. It was at the time the only protein that was solely synthesized by osteoblasts. Osteocalcin is subsequently secreted in the bone extracellular matrix (ECM) and is the most abundant non-collagenous protein of this ECM (Hauschka *et al.*, 1989; Lian *et al.*, 1978). Osteocalcin was also known to be abundant in the general circulation and its circulating levels correlate well with bone formation (Delmas *et al.*, 2000; Merle and Delmas, 1990). However why osteocalcin would be so abundant in the general circulation, was generally overlooked; yet, it is the tenth most abundant protein in bony vertebrates. Osteocalcin was known to undergo a post-translational modification whereby three glutamate residues are carboxylated to form GLA residues that traditionally confer to proteins harboring them a high affinity for mineral ions and mineral crystals (Hauschka *et al.*, 1989). Because of this post-translational modification, osteocalcin was thought to be implicated in the mineralization of the bone ECM. However, no firm evidence of such a function was available, this is why *Osteocalcin-null* mice were generated. To make a long story short, analysis of these mutants did not provide any evidence that osteocalcin was involved in any meaningful way, in bone ECM mineralization (Ducy *et al.*, 1996). Hence, taken at force value and in the most conservative interpretation what this experiment showed first is that the function of the 10th most abundant protein of our body does not affect the tissue that synthesizes it.

Even though their bones were normally mineralized, *Osteocalcin −/−* mice displayed some phenotypes that given the site of synthesis of osteocalcin and its abundance in the general circulation, could only be explained if this molecule was acting as a hormone. Indeed osteocalcin-null mice of either sex had larger fat pads without being obese and mutant mice bred poorly. The systematic study of these two phenotypes established that osteocalcin is a hormone regulating aspects of energy metabolism and male fertility (Lee *et al.*, 2007; Oury *et al.*, 2011).

Osteocalcin Regulates Energy Metabolism at Rest

The field of osteocalcin biology took from the onset the stand that it is unlikely for a hormone to have a single major function. As a result, at the time this article is being written, our knowledge about the functions of this hormone and our understanding of its mechanisms of action in its known target organs, remains a work in progress. For instance, if the increased adiposity of the *Osteocalcin −/−* mice could be ascribed to a decrease in energy expenditure and not to an increase in appetite another function regulated by bone (see below), the molecular bases of this function has not been elucidated yet.

On the other hand, what has begun to receive a molecular explanation are other ways osteocalcin affects energy metabolism. We should emphasize that throughout our investigation, the work was greatly helped by the availability of a loss of function (*Osteocalcin −/−*) and a gain of function mouse model for osteocalcin (*Esp −/−*), each of them serving as an internal control for the other, yet each model addressed a different question. The loss of function models allowed to answer the question of whether osteocalcin is necessary to up-regulate a variety of physiological processes. The gain of function models served as evidence that osteocalcin is also sufficient to up-regulate these functions. From a translational point of view this is of course of greater importance. Investigations conducted in mice fed a normal diet showed that osteocalcin is necessary and sufficient to promote *β*-cell proliferation in pancreatic islets, to enhance *Insulin* expression and secretion, to favor glucose uptake in peripheral tissues and as a result glucose homeostasis (Lee *et al.*, 2007; Wei *et al.*, 2014). The receptor mediating osteocalcin signal in pancreatic *β*-cells and other peripheral tissues is a GPCR called Gprc6a (Oury *et al.*, 2011; Wei *et al.*, 2014). Cell-specific gene deletion and genetic epistasis experiments has established that in vivo osteocalcin is the ligand of Gprc6a that explains the regulation of glucose homeostasis determined by their GPCR. Beyond the gain of function model of osteocalcin that the mice represent, the biological importance of osteocalcin regulation of glucose homeostasis was verified in wild type mice fed a cell high fat diet. Exogenous osteocalcin almost completely rescue the glucose intolerance of these animals (Ferron *et al.*, 2012).

Osteocalcin Regulates Energy Metabolism During Exercise

A question raised by the regulation of glucose homeostasis by osteocalcin is whether there was any difference between osteocalcin biology and insulin biology. An answer to this question was provided by studying the functions of osteocalcin during exercise, a physiological situation during which circulating levels of insulin decrease. An incentive to study this question came from the observation that during an endurance exercise, the circulating levels of osteocalcin nearly triple (Mera *et al.*, 2016a). Another reason to ask this question is that the mechanisms whereby muscle function increases during exercise remain poorly understood.

To be able to distinguish the role if any, of osteocalcin in muscle from its functions in other organs, this project was pursued after generating mice lacking the osteocalcin receptor only in myofibers. This investigation found that osteocalcin signaling in myofibers is necessary to increase exercise capacity because it favors uptake in myofibers of their two main nutrients: glucose and fatty acids, osteocalcin also enhances catabolism of these two nutrients to generate ATP (Mera *et al.*, 2016a). Hence, osteocalcin does have common function with insulin such as for instance glucose uptake in myofibers but unlike insulin, osteocalcin favors the catabolism of these nutrients in order to increase muscle function. Osteocalcin favors muscle function during exercise through another mechanism, by favoring the expression and release of interleukin-6 (IL-6) one of the first myokine ever described whose circulating were known to increase during exercise through unknown mechanism (Pedersen and Febbraio, 2012). In turn IL-6 signals in bone to favor bone resorption which is the mechanism whereby osteocalcin is decarboxylated and becomes bioactive (Ferron *et al.*, 2010). In other words there is a feed forward loop that takes place during exercise between bone and muscle. At the onset of exercise bone secretes osteocalcin which increases on the one hand nutrients uptake and catabolism in myofibers in order to produce ATP. On the other hand, osteocalcin signaling in myofibers enhances the production of IL-6 during exercise, IL-6 then signals into bone cells to promote the production of bioactive osteocalcin. Of note, at the same time it increases muscle function, osteocalcin signaling in myofibers also favors a gain in muscle mass (Mera *et al.*, 2016b).

As it is the case for the regulation of glucose homeostasis at rest, the regulation of muscle function and exercise capacity by osteocalcin signaling in myofibers is also sufficient to increase exercise capacity in WT mice. This was shown by delivering acutely just before an endurance exercise or chronically for 1 month bioactive osteocalcin to WT mice either young or old. Either mode of delivery resulted in a surprisingly high gain in exercise capacity in these mice (Mera *et al.*, 2016a), thus illustrating the therapeutic potential of osteocalcin in conditions such as age-related decrease in muscle function and mass.

Osteocalcin Regulates Male Fertility

The regulation of energy metabolism by osteocalcin fulfilled only one aspect of our original hypothesis. A second aspect was to determine whether osteocalcin also regulates reproductive functions. Since osteoporosis develops mostly in post-

menopausal women, it was natural to ask if osteocalcin influences fertility in females. To begin addressing this question we relied on a co-culture assay in which supernatants of mouse osteoblasts were added to ovary slices to determine if this would result in an increase in the secretion of sex steroid hormones. One negative control in this experiment was to treat testicular Leydig cells with supernatant of mouse osteoblasts. What was observed is that when cultured in the presence of supernatant of either WT or osteocalcin-null osteoblasts, ovary slices secreted the same amount of sex steroid hormones. In contrast Leydig cells of the testes did not secrete nearly as much testosterone when they were cultured in the presence of the supernatant of *osteocalcin −/−* osteoblasts, than when cultured in the presence of WT osteoblasts (Oury *et al.*, 2011). This effect was specific of osteoblasts since applying supernatant of other mesenchymal cells in culture, did not affect testosterone release by Leydig cells. As a corollary of this set of experiments, it was shown that osteocalcin favors in a dose dependent manner the release of testosterone by Leydig cells of the testes, because it favors the expression of all the genes encoding the enzyme necessary of testosterone biosynthesis (Oury *et al.*, 2011). Of note, osteocalcin does not increase the expression of the genes necessary to allow the conversion of testosterone to estrogens. These molecular and cell biological observations explain why circulating levels of testosterone are markedly lower in *osteocalcin −/−* and higher in *Esp −/−* than in WT mice. As a result male *osteocalcin −/−* mice have low testosterone impregnation and breed poorly (Oury *et al.*, 2011).

In a sense this investigation closed the first circle, after demonstrating that hormones such as leptin that are thought of exclusively belonging to the energy metabolism field are potent regulators of bone mass (Ducy *et al.*, 2000a), we had shown that indeed bone is an endocrine organ and that in this capacity it promotes several aspects of energy metabolism and male reproduction. Although these lines of research do not stop here, osteocalcin has more functions that those.

The Brain as a Target Organ of Bone; Part I: Through Osteocalcin

Greatly helped by our own work on leptin we suspected from the beginning that the functions of osteocalcin could not be restricted to the ones implied by the initial working hypothesis. Going beyond the working hypothesis was also prompted by the fact that *osteocalcin −/−* mice, were overtly passive. This phenotype could not be ascribed to their hypogonadism since it was observed in both male and female mice.

Analysis of this rather vague phenotype uncovered the importance of bone via osteocalcin for brain development and multiple brain functions. What was shown was, that when it is undercarboxylated osteocalcin crosses the blood brain barrier, binds to neurons of the dorsal raphe in the brainstem, the ventral tegmental area in the midbrain and the CA3 region of the hippocampus (Oury *et al.*, 2013). Osteocalcin also favors the synthesis of all monoamine neurotransmitters and decreases the synthesis of GABA, an inhibitory neurotransmitter. This occurs because osteocalcin signaling in neurons regulates the program of gene expression responsible for the synthesis of these neurotransmitters. Furthermore, it prevents neuronal apoptosis in the hippocampus. The consequences of these molecular events at the level of the entire animal are that *Osteocalcin −/−* mice displayed increased anxiety and depression and very poor learning skills and memory. Remarkably these phenotypes were dominant and also observed in *Osteocalcin +/−* mice (Oury *et al.*, 2013). Several lines of evidence demonstrated that this reflected the influence of bone on the brain and that this influence was independent of any other functions of osteocalcin. For instance, mice lacking *Osteocalcin* in an osteoblasts specific manner experienced the same molecular and phenotypic abnormalities, mice lacking *Gprc6a* that share with *Osteocalcin −/−* their metabolic and reproductive phenotypes did not have any behavioral abnormalities or other types of brain-related phenotypes that are seen in *Osteocalcin −/−* mice. The reason for that is that Gprc6a is not expressed in the brain. Finally delivering osteocalcin through intracerebroventricular infusion in *Osteocalcin −/−* mice at a dose that does not cross the blood brain barrier, rescued all molecular behavioral phenotypes, in *Osteocalcin −/−* mice (Oury *et al.*, 2013). This latter result indicated that it is osteocalcin itself that by signaling in the brain is responsible of all the central abnormalities noted in *Osteocalcin −/−* mice.

Osteocalcin is not expressed before E17.5 in the mouse thus it was surprising to note that the hippocampi of *Osteocalcin −/−* mice was significantly hypomorphic compared to the areas of WT mice (Oury *et al.*, 2013). That this latter phenotype was markedly more severe in *Osteocalcin −/−* mice born from *Osteocalcin −/−* mothers than in those born from *Osteocalcin +/−* mothers, allowed us to show that maternally derived osteocalcin crossed the placenta and is necessary for brain development of the embryo (Oury *et al.*, 2013). This observation identified osteocalcin as the first molecule that could explain the long noticed influence of health of the mother on the psychological health of the offspring. In agreement with this notion, delivering osteocalcin to *Osteocalcin −/−* mothers throughout their pregnancies corrected the brain development defects otherwise noticed in *Osteocalcin −/−* newborn mice.

Identification of Another Hormone Mediating Endocrine Functions of Bone: Lipocalin 2

The finding that bone is an endocrine organ formed the basis for one of the most intriguing questions in this area of research: *Does bone utilize more than one hormone to affect energy metabolism? And, in doing so, does it target additional, energy-regulating organs?* To address these questions, we generated mice lacking 50% of their osteoblasts and characterized their metabolic phenotype. These analyses showed that osteoblasts are primary cellular mediators of insulin signaling in all insulin target cells (Yoshikawa *et al.*,

2011). Remarkably, these studies also indicated that bone affects energy metabolism (a) in an additional osteocalcin-independent mechanism; and (b) by regulating an additional metabolic process, appetite. This latter study called for the identification of the anorexigenic signal(s) originating from osteoblasts. The route to identifying the new anorexigenic protein came from experiments showing that mice lacking the transcription factor *FoxO1* in osteoblasts ($FoxO1_{osb}-/-$ mice) have improved energy metabolism, partly due to an increase in osteocalcin bioactivity (Rached *et al.*, 2010). In addition, a microarray analysis identified Lipocalin 2 (LCN2) as a secreted protein upregulated in *FoxO1*-deficient osteoblasts. A comprehensive study of its pattern of expression revealed that *LCN2* is an osteoblast-enriched secreted protein that is expressed at least 10-fold higher in osteoblasts than in adipocytes or other cells in basal, non-stimulated conditions.

Regulation of Appetite by Bone

Determination of the putative metabolic functions of LCN2 and its cell of origin were obtained by generating mice lacking LCN2 in osteoblasts ($Lcn2_{osb}-/-$ mice) or in adipocytes ($Lcn2_{fat}-/-$ mice), because LCN2 had been considered an adipokine associated with obesity (Lin *et al.*, 2001; Mosialou *et al.*, 2017; Soukas *et al.*, 2000; Yan *et al.*, 2007). $Lcn2_{osb}-/-$ mice showed a 16.4% increase in food intake that correlated with increased gonadal fat weight (16.5%), total fat mass (19.6%) and a significant increase in body weight. In contrast, $Lcn2_{fat}-/-$ mice did not show any changes in food intake, fat or body weight. During growth, the increase in food intake was detected as early as 3 weeks of age, the earliest time point possible to measure appetite in weaned animals, and preceded the increase in blood glucose levels and body weight both of which manifested at 5 weeks of age. Corroborating the results obtained in $Lcn2_{osb}-/-$ mice, administration of recombinant LCN2 to lean wild type and to obese mice with a spontaneous inactivating mutation in the leptin receptor ($Lepr^{db/db}$ mice) suppressed appetite and body weight and improved glucose metabolism and insulin sensitivity throughout the entire duration of treatment.

In addition to the chronic effects of LCN2 on appetite suppression, its anorexigenic properties extend to acute post-prandial regulation of feeding. Indeed, expression in osteoblast and serum levels of LCN2 increase threefold in 1–3 h after refeeding mice. The increase in serum levels correlates with a suppression of food intake in wild type mice. This effect was specific to LCN2 and not due to other appetite regulating hormones or peptides because its inactivation in $Lcn2_{osb}-/-$ mice led to higher cumulative food intake and a twofold higher rate of food intake after refeeding. These results indicated that upregulation of *Lcn2* expression by osteoblasts following feeding may be a negative feedback mechanism to limit appetite after a meal in the mouse.

The Brain as a Target Organ of Bone; Part II: Through Lipocalin 2

How does LCN2 suppress food intake following its signaling in the hypothalamus? Understanding the mechanism of this action, revealed for a second time the ability of bone to signal to the brain. The observation that LCN2 does not regulate the expression of any peripheral hormones known to affect appetite and is not expressed in the hypothalamus (Mosialou *et al.*, 2017), raised the possibility that it may cross the blood brain barrier and act on areas that control appetite. Intraperitoneal injections of recombinant of LCN2 in $Lcn2-/-$ mice proved this hypothesis as they showed that LCN2 accumulated in the brain, mainly in the hypothalamus. Subsequent examination of hypothalamic pathways that affect appetite indicated that expression of only downstream effectors of the MC4R signaling pathway was modulated in a loss and gain of function mouse models for LCN2. It was subsequently shown that LCN2 binds to the MC4R in the paravetricular neurons of the hypothalamus with a K_d of 51.39 $\pm$ 4.78 nM and competed for binding with α-MSH at a K_i of 46.34 $\pm$ 1.11 nM. Moreover, ICV administration of LCN2 induced, *Fos* expression in PVH neurons of wild type but not $Mc4r^{-/-}$ and stimulated cellular activity of MC4R-expressing hypothalamic neurons, assessed by electrophysiological recordings. Lastly, administration of recombinant LCN2 suppressed appetite and decreased body weight in WT but not in $Mc4r^{-/-}$ mice indicating that MC4R mediates the anorexigenic function of LCN2 in vivo.

Lipocalin 2 Regulates Insulin Secretion and Production

An examination of the extent to which the anorexigenic function of LCN2 explains the metabolic phenotype of $Lcn2_{osb}-/-$ mice, revealed an additional function and direct target organ of this hormone. Pair-feeding experiments of $Lcn2_{osb}^{-/-}$ mice and their wild type littermates showed that whereas body weight, fat mass and insulin sensitivity were normalized, serum insulin levels and insulin secretion following glucose load remained compromised in $Lcn2_{osb}^{-/-}$ mice and as a result their glucose intolerance persisted. These results suggested that LCN2 may signal directly in β-cells to affect their functions. Indeed, LCN2 directly stimulated insulin secretion and β-cell proliferation in primary pancreatic islets. Therefore, whereas increased appetite accounts for the increase in fat mass, body weight and insulin resistance in $Lcn2_{osb}-/-$ mice, glucose intolerance likely reflects its direct action on pancreatic islets.

Calcium Homeostasis in Humans

Roger Bouillon, Laboratory of Clinical and Experimental Endocrinology, KU Leuven, Leuven, Belgium and University Hospitals, Leuven, Belgium

Calcium is a major ion in humans with a total mass of more than 1000 g in adults and is present is different compartments. *Intracellular calcium* plays an essential role in a variety of cellular functions from the very start of evolution of life on earth onwards. The *cytosolic ionized calcium* concentration is very low (about 10–100 nM) but can change rapidly and transiently due to exchanges with *intracellular calcium pools* or with the much higher concentration of extracellular calcium. Intracellular ionized calcium plays a vital role as second messenger (translating a variety of extracellular signals), in neurotransmitter release, contraction of all types of muscle cells or in fertilization (Berridge *et al.*, 2003). Many enzymes require calcium ions as co-factors and the blood-clotting cascade is a crucial example of this role. Chelation of calcium is therefore a straightforward strategy to avoid blood clotting after blood sampling. *Extra-cellular calcium* in vertebrates can also be subdivided in different compartments: blood, interstitial fluid, and soft tissue matrix. Serum calcium, in all vertebrates and certainly in mammals, is tightly controlled by a variety of hormones as to maintain ionized calcium concentration within narrow limits (about 1.05–1.25 mmol/L). The total body pool of calcium is maintained by strict coordination by calcium transport in three major target tissues: gut, kidney and to a much lower extend also the skin. Transport of calcium via the placenta and mammary glands can also be very important but of course only during reproduction. In this short overview, I will discuss calcium homeostasis in its different compartments and the handling of calcium in its major target tissues as well as the (hormonal) regulation of serum calcium and body calcium content.

Total Body Calcium

The mature human fetus is born with about 30 g of calcium and this mass rapidly increases during the first years of life (about doubling from 30 to 60 g during the first 6 months of life). Thereafter, there is a gradual increase in total body calcium along with linear growth and thus with a more rapid increase during pubertal growth spurt. Peak bone mass, and thus also peak total body mass of calcium, is reached in the 3rd and 4th decade of life and is about 1000 g in adult females and about 1200 g of calcium in adult males. Later in life, there is a gradual decrease in total body calcium due to progressive loss of bone mass, with an accelerated loss of bone during a decade after menopause in women.

Bone as Mineralized Tissue

Most of the body store of calcium is found in the mineralized matrix of bone (and to a minor extend in teeth). This represents about 99% of total body calcium and is mainly stored as hydroxyapatite crystals [$Ca_{10}(PO_4)_6(OH)_2$] embedded in collagen fibrils. The mineralization of bone matrix is an active process, mainly by osteoblasts and osteocytes (and dentinoblasts for teeth), with a complex regulation by local and systemic factors. These bone cells first synthesize and excrete the bone matrix proteins (osteoid) which later on, at a short distance from the bone forming cells, mineralize until about 70% of the bone is composed of minerals, with the remaining 30% as matrix proteins. Removal of bone minerals is only possible by combined removal of mineral and bone matrix and is mainly due to the activity of highly specialized cells, osteoclasts. More recently, it became clear that osteocytes, representing more than 90% of all bone cells, can also resorb bone and mineralize the perilacunal space. Bone is of course not a dead tissue. During growth, bone size regularly adapts in length and cross-sectional diameter by bone modeling. After the end of puberty, only bone remodeling is operational whereby old bone is removed and replaced by new bone formation. This process may take a few weeks for resorption and several months for new bone formation and mineralization. Ultimately, bone size, mass and structure remain identical during most of adult life. Later in life, bone resorption slightly exceeds formation with gradual loss of bone mass and bone strength. The bone left-over, however, is usually of normal structure and mineral density ("too little bone, but the bone there is, is normal"). The daily amounts of calcium removed and replaced by bone remodeling is about 300–500 mg of calcium, depending of total body size, age and other hormonal factors (see below). Apart from this bone remodeling, bone calcium can be released and replaced without cellular involvement.

Intracellular Calcium Homeostasis

About 1% ($\approx$1 g) of calcium is found in the intracellular compartment, blood and interstitial fluid. The intracellular calcium homeostasis is totally different from the regulation of extracellular calcium concentration. The cytosolic ionized calcium concentration is in the micromolar (10^{-6} M) range and thus about a thousand fold lower than the ionized calcium concentration in serum. This gradient is important for maintaining the electrochemical gradient (potential difference, whereby the cell interior is

 doi:10.1016/B978-0-12-801238-3.65332-1

about 20 mV lower than the extracellular potential) across excitable cell membranes. Loss of this calcium gradient may jeopardize cell viability and this is prevented by a variety of active calcium pumps (requiring energy) at the cell membrane or at the membrane of cell organelles (such as mitochondria and endoplasmatic reticulum). These calcium permeable channels include transient receptor potential (TRP) and voltage-gated calcium channels, sodium-calcium exchangers (NCX) and ATP-dependent plasma membrane calcium pumps. Inside the cell, calcium is either in a free, ionized form or bound to cytosolic calcium buffers such as calbindins or parvalbumin, or stored in intracellular compartments such as mitochondria or endoplasmatic reticulum. These organelles also have specific calcium entry or exit pumps such as SERCA or mitochondria calcium uniporter pumps. All these pumps allow rapid, dynamic and transient fluctuations of intracellular free calcium concentrations needed for a variety of cellular functions such as muscle contractions, neural function or cellular functions in general.

Extracellular Calcium Homeostasis

The serum calcium concentration is tightly regulated by a diversity of hormones and maintained between 8.6 and 10.2 mg/dL (total calcium) or between 4.2 and 5.0 mg/dL for ionized calcium. The normal range may vary depending on the method used for measurement of total calcium. Indeed, total serum calcium is for about 50% bound to several proteins (which are negatively charged) and about 10% is bound to several organic acids (such as citrate) or other ions (such as PO_4 ions). The remaining free or ionized calcium is feed-back regulated (see below). Total calcium can fluctuate according to serum protein (especially albumin) concentrations. Ionized calcium can be directly measured or calculated from total calcium and protein/albumin concentrations. For each gram of calcium above or below 4 g of calcium per dL, 0.8 mg of total calcium has to be subtracted/added to calculate protein-corrected calcium. Acidosis or alkalosis such as in renal, respiratory or metabolic diseases, can disturb the equilibrium between bound and ionized calcium and can thus influence the real ionized calcium concentration and this usually requires direct measurements to estimate the true free calcium concentration. A number of diseases can increase or decrease ionized calcium concentration (as discussed in other chapters).

Calcium Transporting Tissues

Calcium homeostasis depends on the regulation of calcium transport in several major target tissues (**Fig. 1**).

Intestine

The intestine is the major calcium transporting tissue responsible for the transport of dietary calcium and calcium added to food by secretion of fluids by salivary glands, gastric, biliary, pancreatic and intestinal fluid secretion, adding a total of about 400 mg or more of calcium per day. Dietary calcium intake is dependent of dietary habits as the calcium content of food is highly variable. The highest concentration is found in cheese (700–1000 mg/100 g), and other dairy products (yoghurt and cow milk at 120 mg/100 mL) whereas, strangely, human milk has a much lower calcium content (30 mg/100 mL). Most fish and meat have a low calcium content (less than 20 mg/100 g). Therefore, dietary calcium intake is highly dependent on the regular use of dairy products. Adult populations with little or no use of dairy products such as in many African or Asian countries have a low calcium intake, whereas countries with high dairy consumption are at the upper range of calcium intake (e.g., The Netherlands). Breastfed infants receive sufficient calcium intake but after weaning their calcium intake depend on the region-specific nutritional habits. Lack of access to dairy products for many African (young) children may result in the risk of calcium deficiency rickets, especially when total calcium intake falls below 500 mg/d (Munns *et al.*, 2016). The mean calcium intake of many subjects around the world is frequently lower than the requirement for dietary calcium as defined by the Institute of Medicine or the major scientific societies for children and adults (about 1000 mg or 25 mmol per day). This implies that, in many countries, even more than half of the population may have lower than optimal calcium intake. Dietary calcium, as found in vegetable matter, is often complexed with phytates, oxalate, citrate or other organic acids and may therefore not easily be accessible for intestinal absorption. In the absence of sufficient dietary calcium, a calcium supplement may be required especially in subjects not willing or not able to consume dairy products or elderly subjects at risk for osteoporosis.

The intestinal absorption of calcium is dependent on many factors including the integrity of the intestinal cells, the composition of food (especially the presence or not of "chelators" of calcium) and vitamin D status. The intestinal absorption of calcium is partly an active, energy dependent transport through the cell and partly passive and paracellular. The active uptake is highly dependent on the presence of $1,25(OH)_2D$ and its genomic actions in the enterocytes. This active hormone stimulates the synthesis of TPRV6 channels which, after expression at the luminal site, allows the influx of calcium molecules. Thereafter, one or more intracellular calcium binding proteins such as calbindins (also largely dependent on the genomic action of $1,25(OH)_2D$) bind calcium ions and allow their transport to the serosal site of the enterocyte. Finally, an ATP-dependent calcium transport mechanism is needed to pump intracellular calcium against a concentration and electric gradient into the blood stream. These three set of calcium transporters are all vitamin D dependent but additional transport mechanisms, not yet fully identified, are probably also operational (Christakos *et al.*, 2016). The active calcium uptake is mainly located in the proximal part of the gut

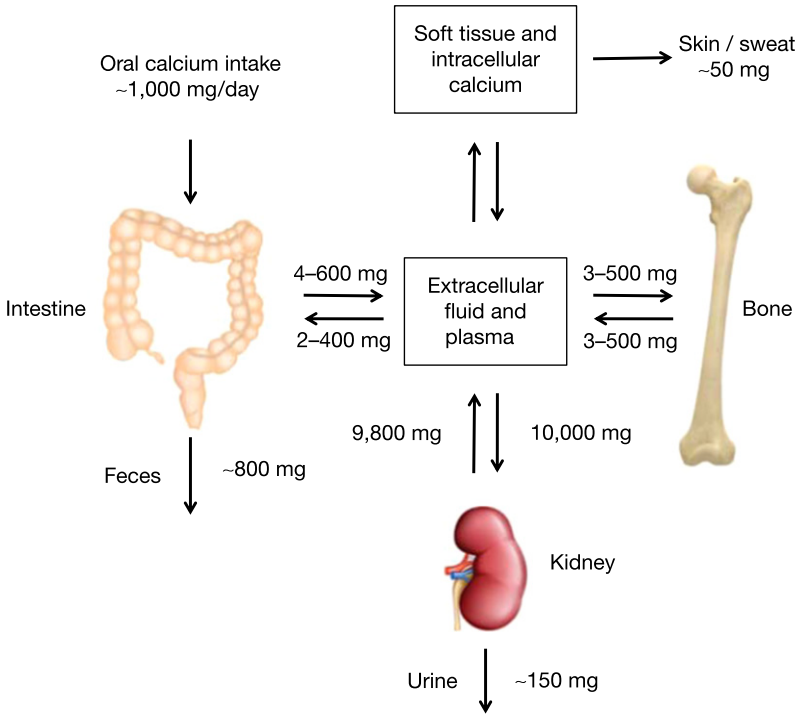

Fig. 1 The regulation of calcium transport in the major target tissues. Simplified overview of calcium homeostasis. The daily calcium intake is highly variable between persons and mainly depend on dairy intake. Dietary calcium is mixed with calcium present in all fluids reaching the intestine (from salivary, gastric, pancreatic, biliary, and intestinal origin). The large majority of dietary/exogenous and endogenous is not absorbed and excreted in the feces. The net calcium absorption is the difference between the total amount of calcium absorbed minus the sum of calcium in different intestinal secretions. The daily flux of calcium from (resorption) and into (mineralization) the bone compartment is in balance in normal healthy adults but can be positive (growth) or negative (old age/osteoporosis). The calcium loss by the skin is usually small. The kidney is responsible for the fine-tuning of the calcium balance. Serum ionized calcium is maintained by several calciotropic hormones. The flux of calcium into the fetus or in breast milk is not shown in this slide.

(duodenum and jejunum) whereas the more passive absorption is taking place in the more distal parts of the gut. The efficacy of intestinal calcium absorption can be highly variable and depend on age, $1,25(OH)_2D$ and other factors. It can exceed 60% in growing children and decrease to below 20% in case of lack of vitamin D action. The absorption efficacy is also higher in case of low calcium intake (probably highly $1,25(OH)_2D$-dependent). As shown in **Fig. 1**, the calcium intake is mixed with endogenous calcium secretion. The fractional calcium uptake then defines the net calcium absorption and fecal calcium excretion. In other words, true absorbed calcium is the total calcium absorbed from the calcium pool present in the intestines containing both dietary and digestive juice components. Net absorbed calcium is the difference between dietary calcium and fecal calcium and is the same as true absorbed calcium minus endogenous fecal calcium. At zero calcium intake, all the fecal calcium is endogenous and represents the digestive juice calcium, which has not been reabsorbed; net absorbed calcium at this intake is therefore negative to the extent of about 200 mg (5 mmol). In normal adults, fecal calcium excretion is about 0.8 g out of 1 g ingested with a net calcium absorption of 0.2 g/d. Although this seems to be only a 20% absorption, the fractional uptake of calcium (from exogenous and endogenous calcium together) is about 40% (**Fig. 1**). Correct measurements of calcium uptake is difficult and optimally requires either (1) a long term (more than 1 week) true calcium balance in specialized units (measurement of true calcium content of all food and fluids, measurement of urinary and fecal calcium content with color coding of start and end of observation period), or (2) a dual calcium isotope (preferably non-radioactive) study, whereby one isotope is given orally and one intravenously. These are very expensive and time consuming studies so that frequently a simplified method is used by measuring the absorption of a single orally given calcium isotope (Christakos *et al.*, 2016). **Table 1** summarizes the most frequent causes (physiologic or disease states) associated with increased or decreased efficacy of intestinal calcium absorption.

Kidney

Renal calcium handling is complex (Moor and Bonny, 2016). The urinary calcium excretion is dependent on the glomerular (ultra)filtration of calcium and reabsorption of this ion by renal tubular cells at different segments of the nephron. There is a massive amount (about 10 g) of calcium filtered per day (**Fig. 1**) and therefore about 99% needs to be reabsorbed. The proximal tubular cells are responsible for the large majority (65%–70%) of the reabsorbed calcium and is parallel with the massive reabsorption of water and sodium, and this absorption is mostly through a paracellular route and by passive diffusion and

Table 1 Altered efficacy of intestinal calcium absorption and its most frequent causes

Increased	*Decreased*
Growth	Vitamin D deficiency or low $1,25(OH)_2D$
Pregnancy	Chronic renal failure
Lactation	Hypoparathyroidism
Low dietary calcium intake	High dietary calcium intake
High $1,25(OH)_2D$ concentration (renal or extra-renal)	Aging
Primary hyperparathyroidism	Glucocorticoid excess (endogenous or exogenous)
Idiopathic hypercalciuria	Short bowel syndrome or "intestinal failure"

"solvent drag." The fine-tuning of calcium reabsorption takes place in the more distal parts of the tubuli (thick ascending limb of Henle, distal convoluted tubuli and collecting ducts). In the thick ascending loop, calcium reabsorption uses the paracellular pathway and is driven by the ion pumps, responsible for sodium and potassium transport, that create a transepithelial potential difference favoring calcium reabsorption. The calcium sensing receptor (CaSR) and several claudins play an important role in this ion transport. Overall, parathyroid hormone and calcitonin stimulate the active calcium uptake in the thick ascending loop. The distal tubular cells are responsible for the transcellular transport of calcium, first from the luminal site into the cytoplasma and later on by uphill (against a chemical and electrical gradient) transport to the serosal site (blood stream). The TRPV5 channel plays a very important role in this transport of calcium, in contrast to its related protein, TRPV6, that is responsible for the luminal transport of calcium in the intestine. Parathyroid hormone and calcitonin are the two major drivers of this reabsorption/excretion.

Overall, the urinary calcium excretion is kept well below 300 and 400 mg/d in adult women and men, respectively, but the median excretion varies between 100 and 200 mg/d. This minimal or "obligatory" urinary loss of calcium is already a good indicator of the minimal net intestinal calcium absorption needed to maintain a normal calcium homeostasis.

Hypercalciuria has many genetic or non-genetic etiologies and is closely linked to nephrocalcinosis and kidney stone formation (Coe *et al.*, 2016; Moor and Bonny, 2016).

Epidermal Loss of Calcium

Apart from loss of calcium in the urine and feces, some calcium is lost through the skin. This cannot be easily measured, but combined balance and isotope procedure has yielded estimates of daily insensible calcium losses in the range of 40–80 mg (1–2 mmol), and is unrelated to calcium intake. The loss of calcium through the skin is largely due to its presence in sweat and thus highly dependent on the total volume of sweat. The ion concentration of sweat (especially sodium but also calcium) is subject to acclimatization so that the total loss of ions can be minimalized in case of high transpiration. Overall, the normal loss of calcium through the skin is small (well below 100 mg/d). Calcium is an important regulator of skin homeostasis. Indeed, the epidermis of the skin is a stratified squamous epithelium composed of proliferating basal and differentiated keratinocytes. The skin is essential as physical and chemical barrier against infection and environmental insults, as well as preventing loss of water and ions from the body. Extra- and intracellular calcium is a key regulator of the proliferation and differentiation of keratinocytes.

Regulation of Extracellular Calcium Concentration

The pool of calcium in plasma is small in comparison with total body calcium but also in relation to the daily fluxes of calcium. The concentration of ionized calcium is plasma is tightly regulated within narrow limits by several mechanism and is vital for a variety of vital body functions, as mentioned in the introduction. The pool of ionized calcium in plasma is well below 500 mg and thus small in comparison with the amount of calcium filtered per day in the kidney (about 10 g) and amount of calcium released from bone (300–500 mg/d) or the dietary intake of calcium (about 1 g/d). Such a tight feed-back control of ionized calcium requires a calcium-sensing mechanism, appropriate signaling (hormonal) systems and effector target tissues. The sensor is the widely expressed, G-protein coupled receptor, *CaSR or calcium-sensing receptor*. This receptor is vital for the correct functioning of the parathyroid gland and its secretion of parathyroid hormone (**Fig. 2**). Mutations of this receptor results in an abnormal threshold for serum calcium, either too low as in case of an activating mutation or as hypercalcemia in case of a silencing mutation. This calcium sensing receptor is also highly important in the kidney to control calcium reabsorption. The *target tissues* responsible for short and long-term calcium homeostasis mainly include the intestine and the kidney as described above. *Several hormones* regulate the fluxes of calcium. Parathyroid hormone is a main stimulator of bone resorption and decreases the fractional excretion of calcium in the urine. Both mechanisms operate on a short term basis whereas PTH also stimulates the renal production of $1,25(OH)_2D$ and thus indirectly the intestinal absorption of calcium. The rapid effects of PTH on calcium handling in the kidney and on bone resorption are probably the main mechanisms allowing minute-to-minute maintenance of stable ionized calcium(Potts and Gardella, 2007). Vitamin D is metabolized into $1,25(OH)_2D$ in the kidney and then becomes a major calcium-regulating hormone. The vitamin D endocrine system started early in the evolution of vertebrates and is probable

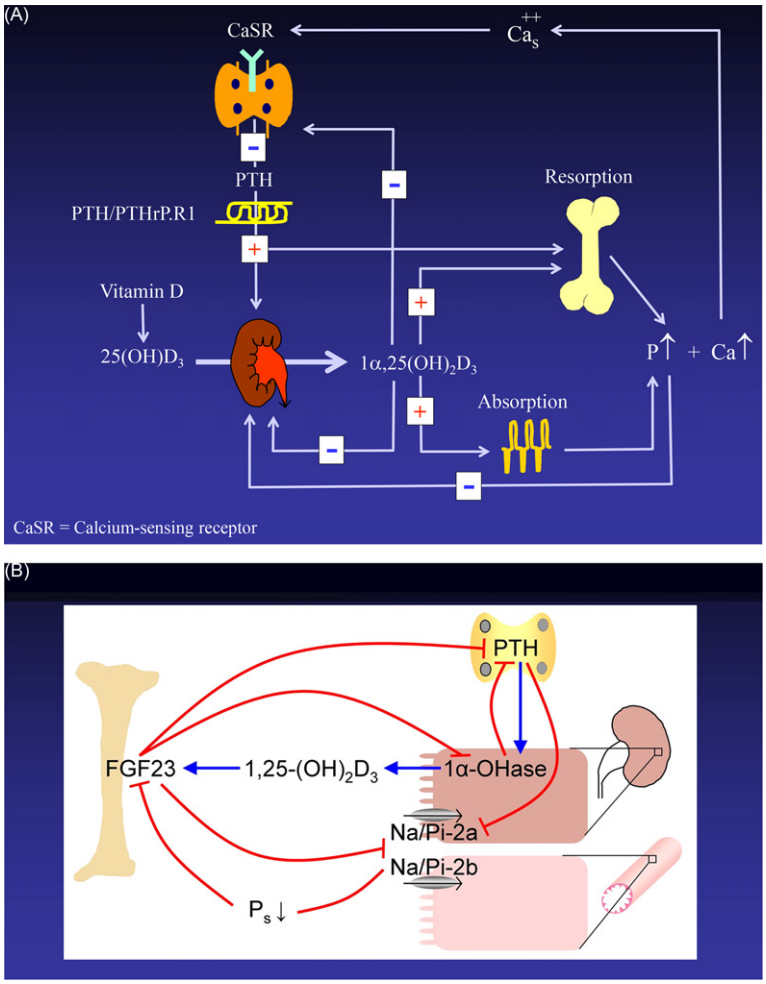

Fig. 2 (A) Control of PTH, FGF23, and vitamin D metabolism by calcium and phosphate. (B) Scheme of interaction between 1,25-$(OH)_2$D-VDR system and phosphate homeostasis.

the major hormone able to assure adequate supply of calcium even in situations of relatively low calcium intake (Bouillon and Suda, 2014). Vitamin D also plays a vital role in the normal mineralization of bone matrix but most of these effects are indirect by its effect on the intestinal absorption of calcium (Christakos *et al.*, 2016). Indeed, 1,25$(OH)_2$D stimulates the active transcellular uptake of calcium in the intestine by regulating all major genes/proteins necessary for calcium transport. Even the more passive paracellular uptake of calcium is probably partially regulated by the vitamin D hormone (Christakos *et al.*, 2016). The renal calcium handling is also partially under the control of the vitamin D endocrine system as VDR null mice loose more calcium in the urine than expected when compared with wild-type mice or mice with selective loss of VDR in the intestine. 1,25$(OH)_2$D thus stimulates the resorption of calcium in the renal tubuli and this is in line with the direct effect of 1,25$(OH)_2$D on several calcium-transporting genes in the kidney. 1,25$(OH)_2$D is able to prevent rickets by facilitating mineral deposition in bone matrix but also able to potently stimulate bone resorption and, in high concentration, also actively inhibits mineral deposition. This strongly indicate that the most important physiological role of this hormone is to maintain serum calcium homeostasis, and if needed to do so at the expense of bone calcium content.

Whereas PTH and 1,25$(OH)_2$D both increase the serum concentration of calcium, calcitonin is the only hormone able to decrease serum calcium by a combination of rapid and effective inhibition of bone resorption and increasing urinary calcium excretion. Its effects on osteoclasts is quite spectacular as it is able to immediately change the morphology of the osteoclasts whereby these large multinuclear cells loose contact with the bone and therefore stops bone resorption. The overall contribution of calcitonin to serum calcium homeostasis in mammals is, however, disputed (Davey and Findlay, 2013) as total loss of calcitonin after total thyroidectomy or large excess of calcitonin is case of medullary thyroid carcinoma hardly affects serum calcium homeostasis. Most experts therefore consider calcitonin to be a major calcium-regulating hormone for fish living in oceans with high calcium concentrations, except in situations of high bone turnover such as during lactation. PTH and especially 1,25$(OH)_2$D became more prominent hormones for animals living in an environment with lower dietary calcium access and in need for stronger bones to cope with higher gravity than in an aquatic milieu (Bouillon and Suda, 2014).

Fibroblast growth factor 23, FGF23, is a bone-derived hormone regulating phosphate homeostasis. Its secretion is stimulated by $1,25(OH)_2D$ and probably inhibited by PTH. Its receptor forms a complex with Klotho and then inhibits the membrane expression of the sodium-phosphate transporter in the renal tubular cells so that it inhibits renal phosphate reabsorption and thereby decreases serum phosphate. It therefore is also known as phosphatonin. In addition, it inhibits the renal 1α-hydroxylation (CYP27B1) of 25OHD and stimulates the degradation of 25OHD and $1,25(OH)_2D$ by enhancing 24R-hydroxylase (CYP24A1) activity. Therefore, despite being a major phosphate regulating hormone, FGF23 also has major indirect effects on calcium homeostasis, although excess or deficiency of FGF23 does not usually results in abnormal serum calcium concentrations due to compensatory activity of the other calcium regulating hormones.

Other hormones, such as sex steroid hormones, thyroid hormones, glucocorticoids, growth hormone, and IGF family members all have some effect on calcium and bone homeostasis by their effects in different target tissues. However, their effects are usually long-term effects and do not markedly influence short-term feed-back control of ionized serum calcium.

A large variety of diseases can result in hypo- or hypercalcemia, as discussed in other chapters of this handbook. These diseases either involve the calcium-sensing mechanism (CaSR mutations), the production, metabolism or action of calcium-regulating hormones (and their tissues of origin), or the target/effector tissues for calcium transport (especially kidney and intestine).

Calcium-Sensing Receptor

Giuseppe Vezzoli, Teresa Arcidiacono, Lorenza Macrina, Katia Maruca, and Stefano Mora, IRCCS San Raffaele Scientific Institute, Milan, Italy

Abbreviations

ADH	Autosomal dominant hypocalcemia
BMD	Bone mineral density
cAMP	Cyclic adenosine monophosphate
CaSR	Calcium-sensing receptor
FHH	Familial hypocalciuric hypercalcemia
GPCR	G-protein-coupled receptor
GWAS	Genome wide association studies
IGF-1	Insulin growth factor 1
NFAT	Nuclear factor of activated T cell
PTH	Parathyroid hormone
RANK-L	Ligand of receptor activator of NF-κB
TRAP	Tartrate-resistant acid phosphatase.

Introduction

CaSR is a 1078 amino acid protein that belongs to the third class of G-protein-coupled receptor (GPCR) family. It was cloned from bovine parathyroid cells in 1992 (Brown *et al.*, 1992) and two years later in human parathyroid cells and renal tubular cells (Aida *et al.*, 1995; Garrett *et al.*, 1995). It is located in caveolin-rich regions of the plasma membrane as a disulfide-linked homodimer, but may also be detected as a heterodimer with other members of the GPCR family (Kifor *et al.*, 1998). The CaSR molecule includes three domains: a large bi-lobed Venus-flytrap-like extracellular domain of 612 amino acids, a seven membrane-spanning domain of 250 amino acids and a C-terminal intracellular tail of 216 amino acids (Riccardi and Kemp, 2012). CaSR may bind cationic substances to its extracellular domain and may be considered as a sensor of environmental cations, which modulates cellular activities. Calcium ions are the main CaSR agonists, but it is also sensitive to divalent (Ni, Cd, Co, Mg, Zn) and trivalent (Gd, La, Tb, Eu) cations and to polycationic compounds like polyamines, aminoglycosides (neomycin, gentamycin) and poly-peptides (poly-L-arginine, β-amyloid) (Riccardi and Kemp, 2012). Calcium and the other agonists bind to the negatively charged residues in the pocket of the CaSR bilobed extracellular domain and induce a conformational change of the CaSR molecule that leads to the activation of an intracellular signaling cascade by the transmembrane and intracellular domains (**Fig. 1**). The intracellular signaling pathway induced by CaSR is tissue-specific and mediated by G-proteins (Magno *et al.*, 2011). Thus, CaSR may elicit the paracrine or autocrine adaptive responses of human cells to changes in extracellular calcium concentrations. CaSR is considered as ubiquitously expressed in human cells, but reaches its highest expression in parathyroid and renal distal tubular cells. In line with this tissue distribution, CaSR has acquired its main physiological role in parathyroid glands and renal distal tubules, because it enables their cells to regulate parathyroid hormone (PTH) secretion and calcium reabsorption in response to serum calcium changes (**Fig. 1**). The increase of serum calcium stimulates CaSR to inhibit calcium reabsorption in the renal distal tubules and PTH secretion in parathyroid glands; these responses restore normal serum calcium levels, whereas the opposite occurs when serum calcium decreases (Riccardi and Kemp, 2012). CaSR is also crucial for the activities of bone cells in bone remodeling and growth according to calcium levels in bone interstitium (Dvorak *et al.*, 2004). Finally, CaSR may enhance intestinal calcium absorption by stimulating 1-alpha-hydroxylation of vitamin D in the proximal tubule and acid secretion by parietal cells in the stomach (Riccardi and Kemp, 2012). All these effects indicate that CaSR is a key factor in calcium homeostasis, crucial to maintain serum calcium within the normal range and normal activities of parathyroid, bony and renal tubular cells (Riccardi and Kemp, 2012). In addition to its role in calcium metabolism, CaSR has been implicated in insulin secretion, adipocyte metabolism, smooth muscle cell activity and gastro-intestinal function (**Table 1**), but its effects in these tissues are less relevant than that in calcium-handling organs (Riccardi and Kemp, 2012).

CaSR and Parathyroid Glands

PTH has a crucial role in calcium homeostasis and the presence of CaSR on the plasma membrane of main cells of the parathyroid glands allows them to regulate PTH secretion according to the serum calcium concentration. In parathyroid cells, CaSR stimulation by serum calcium leads to adenylate cyclase inhibition, protein kinase C activation, diacylglycerol and inositol 1,4,5-triphosphate release and cellular calcium mobilization from intracellular stores, which decreases *PTH* gene transcription and PTH secretion (Kifor *et al.*, 1997). The opposite occurs in case of hypocalcemia, which may stimulate parathyroid cell activity. Hypocalcemia may also stimulate parathyroid cell proliferation to maintain high levels of PTH synthesis and secretion (Corbetta *et al.*, 2002). Prolonged hypocalcemia and low production of 1,25-dihydroxyvitamin D may result in nodular hyperplasia of parathyroid glands in patients with chronic kidney disease or hypophosphatemic rickets (Yano *et al.*, 2000). A reduced CaSR expression was found in parathyroid adenoma from patients with primary hyperparathyroidism who are less sensitive to the inhibitory effect of serum

 doi:10.1016/B978-0-12-801238-3.65826-9

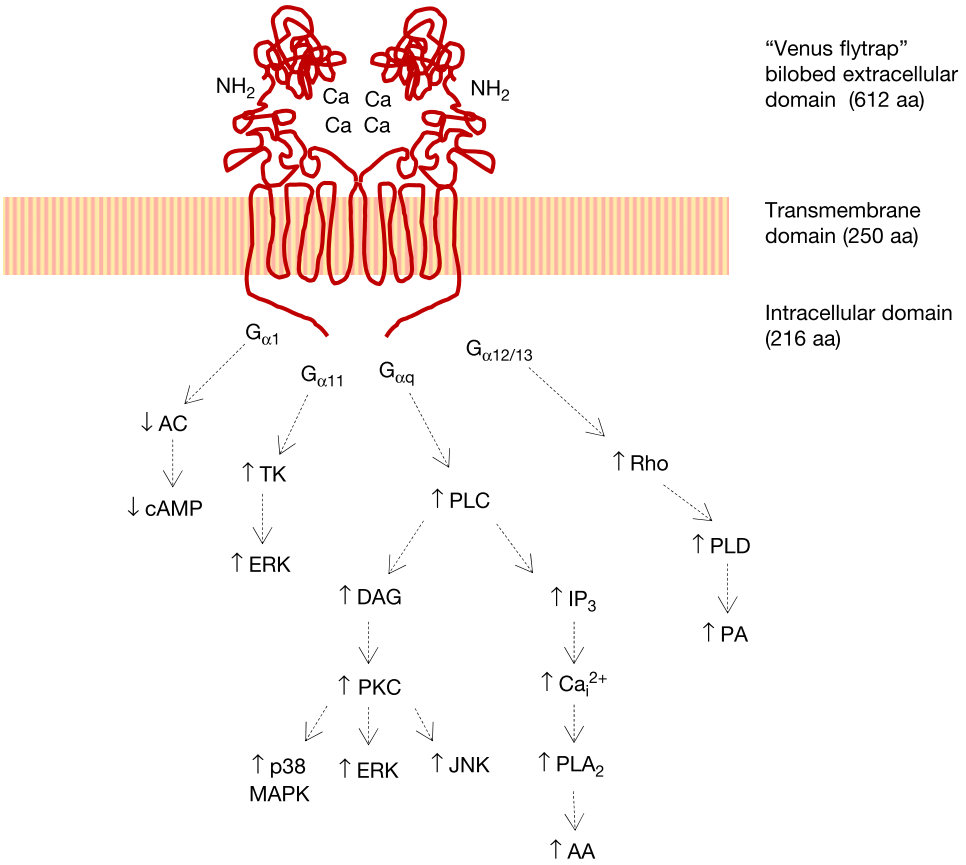

Fig. 1 Calcium ion binding to CaSR activates a complex network of intracellular signaling pathways through activation of different G-proteins. Stimulation of $G_{\alpha i}$ results in inhibition of adenylate cyclase (AC) and cAMP production. Stimulation of $G_{\alpha q}$ results in activation of phospholipase C (PLC) causing an accumulation of inositol 1,4,5-trisphosphate (IP3), rapid release of calcium from intracellular stores (Ca_i) and production of arachidonic acid (AA), as well as an increase of diacylglycerol (DAG) concentration, stimulation of proten kinase C (PKC) and activation of MAPK signal cascade: extracellular signal-regulated kinase (ERK), c-Jun NH2-terminal kinase (JNK) and p38 MAP kinase. Stimulation of $G_{\alpha 11}$ activates tyrosine kinases (TK) resulting in ERK activation. Stimulation of $G_{\alpha 12/13}$ activates low molecular weight G protein Rho and phospholipase D leading to phosphatidic acid (PA) production (Riccardi and Kemp, 2012; Magno et al., 2011).

calcium on the PTH secretion. Higher concentrations of serum calcium are requested to inhibit PTH secretion in these patients and this is due to increased parathyroid gland set-point, which is the serum concentration of ionized calcium associated with the PTH serum concentration equal to 50% of that at the maximal parathyroid secretion. The defect in CaSR expression may contribute to determine hypercalcemia in primary hyperparathyroidism and may be caused by a decreased transcriptional activity of promoter 1 (Chikatsu *et al.*, 2000). A decrease in CaSR expression has been also observed in hyperplastic glands from patients with chronic kidney disease and secondary hyperparathyroidism and may contribute to their hyperplasia (Yano *et al.*, 2000).

CaSR and Kidney

CaSR can be detected in glomerular podocytes, mesangial cells and in cells of all renal tubular segments from humans and lab animals (Riccardi and Brown, 2010). Studies in lab animals suggested that CaSR might regulate glomerular filtration. These studies showed that activation of CaSR with an agonist drug (cinacalcet) may stabilize podocyte cytoskeleton and prevent disruption of the cytoskeletal structure caused by puromycin (Oh *et al.*, 2011); it may also decrease proteinuria and glomerular damage after subtotal nephrectomy in rats (Piecha *et al.*, 2008). Despite the relevance of these findings, no data concerning CaSR and glomerular function are available in humans.

The greatest tubular expression of CaSR may be found in the thick ascending limb of Henle's loop where CaSR is located in the basolateral membrane of the tubular cells and is activated by the increase in serum calcium. In this tubular segment, approximately 25% of filtered calcium is reabsorbed, mainly through a paracellular passive pathway. Microperfusion studies showed that CaSR inhibits paracellular calcium reabsorption in the ascending limb (Riccardi and Brown, 2010); this effect is mediated by the decrease of claudin-16 activity and the increase of claudin-14 expression. CaSR may upregulate claudin-14 expression by inhibiting

Table 1 CaSR expression and activity in different organs in humans (Riccardi and Kemp, 2012)

Organ	*CaSR effect*
Parathyroid glands	Inhibition of PTH secretion
Kidney	
Glomeruli	Prevention of proteinuria and glomerular sclerosis
Macula densa	Inhibition of renin secretion
Proximal tubule	Increased phosphate reabsorption
	Vitamin D hydroxylation
Ascending limb	Inhibition of paracellular calcium reabsorption
	Inhibition of sodium reabsorption
Convoluted distal tubule	Inhibition of active calcium reabsorption
Collecting duct	Proton excretion
	Urine dilution, antagonism of ADH activity
Bones	Osteoblast activation
	Osteoclast apoptosis
	Chondrocyte activation
Ovary	Oocyte maturation
Testis	Spermatozoa motility
Colon	Epithelial cell differentiation
	Fluid secretion
Duodenum	Cholecystokinin secretion
Intestine	Secretion of antidiabetic peptides
	Fluid reabsorption
Stomach	Gastrin secretion
	Acid secretion
Breast	Milk production
Pancreas	Insulin secretion
Central nervous system	Ischemia-induced injury
Glia cells	Brain ion homeostasis
Peripheral nervous system	Synaptic transmission
Adipose tissue	Lipolysis inhibition
Tongue	Kokumi taste
Arteries smooth muscle cells	Prevention of vascular calcification
Endothelial cells	Nitric oxide production
Prostate	
Heart	Cardiomyocyte hypertrophy
Blood	B lymphocyte activation
Skin	Epidermal differentiation, Cell adhesion
Thyroid gland	Calcitonin production

the production of two microRNAs, miR-9 and miR-374, suppressing claudin-14 transcription (**Fig. 2**). Claudin-16 and claudin-19 form channels in tight junctions, which drive paracellular reabsorption of calcium and magnesium, whereas claudin-14 inhibits permeability of these channels (Gong and Hou, 2014; Toka *et al.*, 2012). Claudin-16 may contribute to form tight-junction channels after phosphorylation by phosphorylase kinase A. CaSR may inhibit this phosphorilation and hamper claudin-16 location in tight-junctions and calcium reabsorption in this way (Ikari *et al.*, 2008). To decrease calcium transport in the ascending limb, CaSR may also reduce the transepithelial electric gradient driving paracellular calcium reabsorption (**Fig. 2**). This effect results from the CaSR-mediated production of arachidonic acid and 20-hydroxyeicosatetraenoic acid leading to the inhibition of the activity of sodium-potassium-chloride cotransport (NKCC2) and potassium recycling channels (Kir1.1, Kir4.1) (Gamba and Friedman, 2009; Cha *et al.*, 2011). As in the ascending limb CaSR is located in the basolateral cell membrane of distal convoluted tubules (Gamba and Friedman, 2009; Blankenship *et al.*, 2001); experiments in a canine cell model of distal convoluted tubules showed that CaSR inhibits active calcium reabsorption in this tubular segment.

Principal and intercalated cells of the collecting duct mainly express CaSR on their luminal membrane. Therefore, they are sensitive to calcium concentration in the tubular fluid that, to some extent, results from CaSR-modulated calcium reabsorption in the ascending limb and distal convoluted tubule. Its activation by luminal calcium may decrease cAMP production and aquaporin 2 trafficking and downregulate tubular cell response to vasopressin and water reabsorption (Bustamante *et al.*, 2008). In this tubular segment, CaSR activation may also stimulate urine acidification by enhancing proton pump function in the luminal membrane (Casare *et al.*, 2014).

CaSR is also expressed on the luminal membrane of proximal tubular cells and is sensitive to calcium in the glomerular filtrate. Cell culture experiments showed that CaSR antagonizes the PTH effect and promotes phosphate reabsorption via the NPT2 sodium-phosphate cotransporter by inhibiting cAMP production (Ba *et al.*, 2004). Here, it also promotes proton secretion and

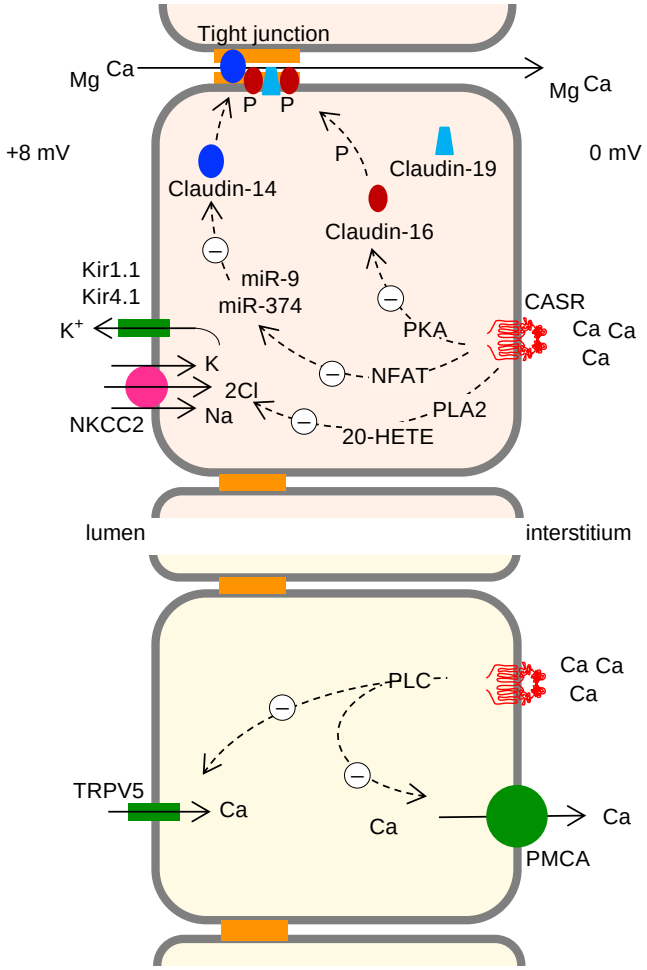

Fig. 2 Activities of CaSR in cells of the ascending limb of the Henle's loop (upper panel) and the cortical convoluted tubule (lower panel). In the ascending limb cells CaSR activation leads to (1) the inhibition of claudin-16 phosphorilation via proten kinase A (PKA) that hampers claudin-16 location in tight-junctions; (2) stimulation of claudin-14 expression through the activity of nuclear factor of activated T cell (NFAT) that inhibits the expression of two miRNA (miR9 and miR374) suppressing claudin-14 transcription; (3) reduction of sodium reabsorption through sodium-chloride-potassium cotransport carrier (NKCC2) and potassium recycling through specific channels (Kir1.1 and Kir4.1) mediated by arachidonic acid and 20-hydroxyeicosatetraenoic acid (20-HETE). These effects decrease tight-junction permeability to calcium and dissipate the electric gradient driving paracellular calcium reabsorption. In distal convoluted tubules, CaSR inhibits active calcium reabsorption by inhibiting basolateral calcium-pump (PMCA) activity and apical calcium channels by means of a pathway induced by phospholipase C (Gong and Hou, 2014; Toka et al., 2012; Ikari et al., 2008; Gamba and Friedman, 2009; Cha et al., 2011; Blankenship et al., 2001).

bicarbonate reabsorption through the NHE3 sodium–hydrogen exchanger (Capasso *et al.*, 2013), whereas it dampens 1-alpha-hydroxylation of 25-hydroxyvitamin D, thus, decreasing the production of the active metabolite of vitamin D (Egbuna *et al.*, 2009).

These findings demonstrate the integrated effects of CaSR in the kidney (**Fig. 3**). The main role of CaSR in the kidney tubule may be considered the inhibition of calcium reabsorption in the ascending limb and distal convoluted tubule that increases the risk of calcium-phosphate precipitation in the distal tubular lumen. However, this risk may be counterbalanced by the effect of CaSR in the collecting duct and the proximal tubule, where it is activated by tubular fluid calcium. CaSR in the collecting duct leads to urine acidification and dilution, while in the proximal tubule it decreases phosphate load to the distal tubule. Therefore, the effects of CaSR in the proximal tubule and collecting duct may promote calcium-phosphate solubility in urine and protect against calcium-phosphate crystalline precipitation (Renkema *et al.*, 2009).

CaSR has been also documented in the juxtaglomerular apparatus and specifically in juxtaglomerular cells and basolateral membrane of tubular cells at the macula densa. Juxtaglomerular cells secrete renin and are located in the lamina media of the afferent arteriole. CaSR activation in juxtaglomerular cells may inhibit renin release by activation of G_q protein, phospholipase C and inositol 1,4,5-triphosphate and reduction of adenylate cyclase activity and cAMP synthesis (Atchison and Beierwaltes, 2013; Ortiz-Capisano *et al.*, 2013). As a consequence, CaSR may reduce the stimulatory effect of renin on sodium reabsorption and arteriolar tone.

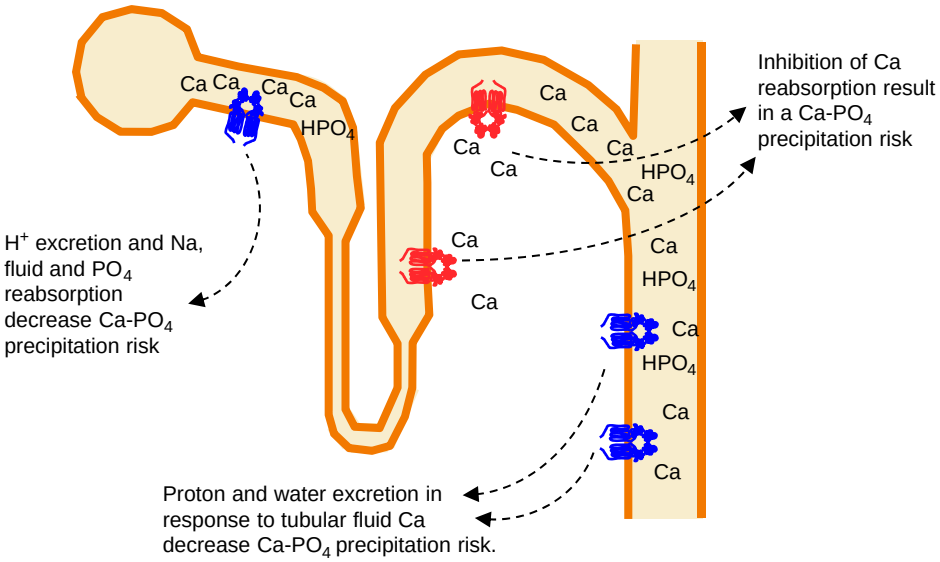

Fig. 3 CaSR decreased calcium reabsorption in the ascending limb and distal convoluted tubule. This results in calcium-phosphate precipitation risk in the tubular fluid, but this effect is counterbalanced by CaSR activities in proximal tubules and collecting ducts (Renkema *et al.*, 2009).

CaSR and Bones

There is ample evidence gathered over the last few years suggesting a strict relationship between CaSR and bone, involving regulation of the developing skeletal tissue and bone cell metabolism. Skeletal development begins at the early stages of embryogenesis and ends when peak bone mass is achieved in adulthood. During this time period the skeleton undergoes processes of elongation and modeling. The former is achieved by the coordinated differentiation, proliferation and maturation of chondrocytes in the growth plate. Extracellular calcium is important for chondrocyte differentiation and normal development of the growth plate. Calcium deficiency may cause rickets as a result of delayed chondrocyte differentiation and reduced matrix synthesis and mineralization (Thacher, 2003). Several studies showed that the extracellular calcium–sensing of chondrocytes is mediated by CaSR (Chang *et al.*, 2002, 2008). CaSR has been localized to maturing chondrocytes in the growth plate and its expression was found to increase as the cells hypertrophy, suggesting a role of the receptor in mediating terminal differentiation (Chang *et al.*, 2002). Furthermore, knocking down *CaSR* gene impaired differentiation and matrix mineralization of cultured chondrocytes induced by high extracellular calcium (Chang *et al.*, 2002). In vivo studies showed that mice with chondrocyte-specific ablation of the *CaSR* gene developed a shorter and undermineralized skeleton due to delayed differentiation of hypertrophic chondrocytes (Chang *et al.*, 2008). Hypertrophic chondrocytes from homozygous knockout mice showed a markedly reduced expression of IGF1 and IGF1 receptor, suggesting that CaSR promotes chondrocyte differentiation by enhancing IGF1 production or signaling (Chang *et al.*, 2002).

Mesenchymal progenitors are recruited at the end of chondrogenesis and they differentiate into cells of the osteoblastic lineage. The osteoblast differentiation is modulated by various local and systemic factors, including extracellular calcium. Studies performed on cells of the osteoblastic lineage demonstrated that changes in extracellular calcium affect cell proliferation, differentiation, and mineralization via the CaSR (Dvorak *et al.*, 2004; Thacher, 2003). Despite the evidence that CaSR mediates extracellular calcium-sensing in osteoblasts, its role in bone development in vivo has been controversial. The generation of a conditional CaSR knockout model, in which the receptor was broadly deleted across the osteoblast lineage (including pre-osteoblasts, proliferating, differentiating and mature osteoblasts and osteocytes) showed early lethality and skeletal abnormalities (retarded skeletal development and growth) (Chang *et al.*, 2008; Dvorak-Ewell *et al.*, 2011). From the second week of life, conditional knockout mice suffered long bone fractures along with deficient skeletal mineralization. Microcomputed tomography studies showed markedly reduced mineral content in both trabecular and cortical bone, decreased bone volume and altered trabecular architecture (Dvorak-Ewell *et al.*, 2011). Fluorescently labeled mineralizing surfaces exhibited a markedly delayed and disorganized mineralization of trabecular and cortical bone. Conversely, osteoclast numbers and activity were increased in the knockout mice and RANK-L mRNA expression was increased in femoral cortices. Cultured osteoblasts isolated from the knockouts showed an elevated osteoclastogenesis potential, stimulating the development of up to fivefold more TRAP-positive osteoclasts compared with cells from control mice (Dvorak-Ewell *et al.*, 2011). Therefore, CaSR may stimulate bone anabolism in the presence of calcium by promoting commitment, survival and differentiation of early osteoblasts and by suppressing local RANK-L-dependent osteoclastogenesis.

During bone resorption, the local calcium concentration in bone interstitium may reach 8–40 mM, and the surrounding cells are exposed to these high calcium levels. This stimulus is sensed by CaSR of cells populating the bone marrow. Mesenchymal stromal cells derived from rat bone marrow migrate and proliferate in a concentration-dependent manner and overexpress

osteogenic markers when stimulated with calcium (Gonzales-Vazquez *et al.*, 2014). Moreover, CaSR blockage inhibits the cellular response to stimulation with high concentration of calcium, indicating that CaSR is a key modulator of these cellular responses. During mice fetal life, the unusual calcium level in bone interstitial fluid also triggers hematopoietic stem cells to home to the endosteal niche within the bone marrow after migration from liver or spleen. Hematopoietic stem cells that express CaSR were able to home to bone marrow, whereas those from CaSR knockout mice could not (Adams *et al.*, 2006). This mechanism leads to the preferential localization of adult mammalian hematopoiesis in bones.

Disorders Caused by CaSR Gene Mutations and Antibodies Against CaSR

The human *CaSR* gene (3q13.3-21) spans 103 kb including eight exons and two promoters, P1 and P2 (**Fig. 4**) (Canaff and Hendy, 2002). Loss-of-function mutations of the *CaSR* gene cause familial hypocalciuric hypercalcemia (FHH, OMIM #145980) in heterozygous patients and severe neonatal hyperparathyroidism (NSHPT, OMIM #239200) in homozygous patients (Hofer and Brown, 2003; Pearce *et al.*, 1995). These patients develop hypercalcemia and low calcium excretion because mutated CaSR cannot inhibit PTH production and renal tubular calcium reabsorption appropriately.

FHH patients are usually asymptomatic; their serum PTH is normal-high and serum calcium moderately high; their calcium excretion is low and may be evaluated with the calcium-to-creatinine clearance ratio. The conventional formula to calculate calcium-to-creatinine clearance ratio is the following:

$$(\text{urinary calcium}/\text{total serum calcium}) \times (\text{serum creatinine}/\text{urine creatinine})$$

All variables in this formula are expressed as mmol/L; urine variables may be measured in 24 h urine or in 2 h urine collected in the morning during fast. Values of calcium-to-creatinine clearance ratio below 0.01 are typical of FHH patients, values between 0.01 and 0.02 may be indicative of FHH, but have uncertain meaning, and values above 0.02 are fully normal (Marx, 1996). This formula is "conventional" because, in a rigorous approach, the correct formula to calculate calcium-to-creatinine clearance ratio should include serum ionized calcium in the place of total serum calcium.

Serum PTH and calcium are markedly high in patients with severe neonatal hyperparathyroidism who also develop bone demineralization, chest deformity, fractures and failure to thrive from the first months of life. Histological analysis shows enlarged parathyroid glands, with evidence of hyperplasia. The disorder may be lethal in a few days unless patients undergo parathyroidectomy (Marx *et al.*, 1986).

Gain-of-function mutations of *CaSR* gene cause autosomal dominant hypocalcemia (ADH, OMIM #601198). These patients are characterized by high urinary calcium excretion and very low concentrations of serum PTH and calcium resulting in tetany and failure to thrive. A common finding in these patients is the extremely difficult outcome of treatment. A steady state of calcium and phosphate serum concentration is rarely reached, and nephrocalcinosis is a very frequent complication (Hu *et al.*, 2004; Mora *et al.*, 2006; Maruca *et al.*, 2017). Patients with the most severe activating mutations may also develop Bartter Syndrome type 5, a disorder caused by the inhibition of tubular sodium reabsorption by CaSR and leading to urinary potassium wastage and hypokalemia (Vezzoli *et al.*, 2006).

FHH and ADH are rare disorders and in addition to CaSR mutations, they may be caused by mutations of two other genes, *GNA11* (19p13.3) and *AP2S1* (19q13.3) causing FHH and ADH type 2 and 3, respectively. *GNA11* codes for the subunit α_{11} of G proteins used by CaSR for intracellular signaling. *AP2S1* codes for adaptor protein-2 σ subunit (AP2S1) involved in membrane protein internalization, including CaSR (Hannan *et al.*, 2016).

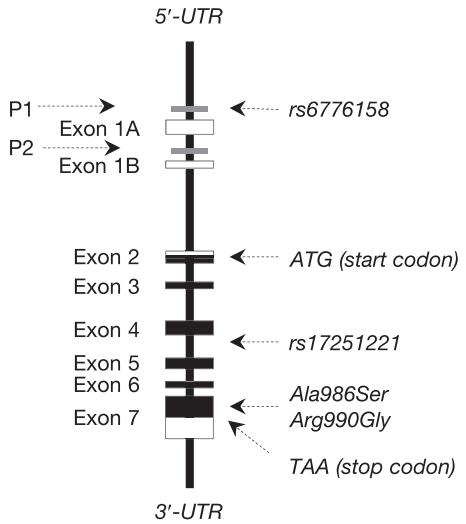

Fig. 4 The most significant polymorphisms in humans *CaSR* gene.

In addition to these genetic disorders, autoantibodies against CaSR may reduce or increase CaSR activity and cause acquired forms of hypoparathyroidism and hyperparathyroidism (Li *et al.*, 1996; Pallais *et al.*, 2004). Anti-CaSR antibodies have been found in patients with autoimmune polyendocrine syndrome, in one third of the patients with isolated acquired idiopathic hypoparathyroidism (Gavalas *et al.*, 2007) and in sporadic patients with primary hyperparathyroidism (Pallais *et al.*, 2004; Charrié *et al.*, 2009). The role of these antibodies in parathyroid disorders is under investigation, but they may be causal in a portion of cases (Makita *et al.*, 2007).

CaSR Gene Polymorphisms and Disorders of Calcium-Phosphate Metabolism

The involvement of CaSR in disorders of divalent ion metabolism has been studied by testing their association with genetic polymorphisms of the *CaSR* gene (**Table 2**). Genome wide association studies (GWAS) found that CaSR variants were associated with calcium and phosphate serum concentrations suggesting that it could be implicated in their regulation through its effects on PTH secretion and tubular reabsorption of calcium and phosphate (Kestenbaum *et al.*, 2010; O'Seaghdha *et al.*, 2010). GWAS findings indicated that rs1801725 (Ala986Ser, located in *CaSR* gene exon 7) and polymorphisms in linkage with it, like rs17251221 (located in exon 4), were associated with serum phosphate and calcium (O'Seaghdha *et al.*, 2010).

Two nonsynonymous polymorphisms of the human *CaSR* gene, rs1801725 (Ala986Ser) and rs1042636 (Arg990Gly), have been most extensively studied in humans because of their significant frequency (**Fig. 4**) (Chattopadhyay *et al.*, 2004). Both polymorphisms are located in exon 7, coding for the CaSR transmembrane and intracellular domains. In 1999, a Canadian study showed that subjects carrying the rarer allele at the polymorphism rs1801725 had higher values of serum calcium that increased with the number of copies of the minor allele (Chattopadhyay *et al.*, 2004). These findings were substantially confirmed in other studies (Hofer and Brown, 2003) and suggested that the minor allele at rs1801725 may decrease CaSR activity; however, no alteration of CaSR activity was observed when the minor allele of rs1801725 was tested in an in vitro assay using embryonic renal cells transfected with the *CaSR* gene (Pearce *et al.*, 1995). The minor allele of polymorphism rs1042636 was associated with higher urinary calcium excretion in stone formers, osteoporotic women and patients with primary hyperparathyroidism and could be responsible for idiopathic hypercalciuria (Pearce *et al.*, 1995; Marx, 1996). Experiments in embryonic renal cells transfected with the *CaSR* gene showed that the minor allele at rs1042636 caused a gain of CaSR function. This allele was also observed to increase CaSR sensitivity to calcimimetic and cell calcium oscillations; it also stimulated the activity of the endoplasmic reticulum calcium-pump that accumulates calcium within the endoplasmic reticulum (Terranegra *et al.*, 2010; Ranieri *et al.*, 2013). Therefore, the minor allele at rs1042636 could result in more efficient inhibition of calcium reabsorption in the ascending limb and increased calcium excretion (Riccardi and Brown, 2010). Hypercalciuria may predispose individuals to urinary stones and the polymorphism rs1042636 was associated with stones in some populations (O'Seaghdha *et al.*, 2010).

Another polymorphism, rs6776158, not changing amino acid sequence and located in promoter 1 was associated with calcium nephrolithiasis (**Fig. 4**) (Vezzoli *et al.*, 2013) because its minor allele was more frequent in calcium stone formers. Homozygous subjects for its minor allele had lower serum phosphate and tubular reabsorption of phosphate, consistent with a decreased CaSR influence in the proximal tubule. Accordingly, transcriptional activity of promoter 1 was decreased in two models of renal cells transfected with the minor allele at rs6776158 and CaSR expression was decreased in kidney medulla samples from patients carrying the minor allele at rs6776158 (Vezzoli *et al.*, 2013). This polymorphism was not associated with calcium excretion and could promote stones by decreasing the CaSR-mediated protective effects of urine acidification and dilution against calcium-phosphate precipitation within the tubular lumen. Contrary to what expected in the presence of a decreased CaSR expression, polymorphism rs6776158 was not related with serum calcium concentration in idiopathic stone formers; however, rs6776158 was in linkage with other polymorphisms of the 3′ untranslated region and intron 1, that were associated with stones and higher serum calcium values in patients with primary hyperparathyroidism (Vezzoli *et al.*, 2011). Findings of these studies are consistent with a decreased CaSR expression in calcium stone formers.

Table 2 *CaSR* gene polymorphisms (SNP) involved in human disorders. A list of *CaSR* gene polymorphisms is reported online in the NCBI database (http://www.ncbi.nlm.nih.gov/snp) and Calcium sensing receptor database (http://www.casrdb.mcgill.ca/)

SNP	*Domain*	*Alleles*	*Minor allele frequency*	*Amino acid change*	*Disorder associated with the minor allele*
rs1801725	exon 7	G > T	20%	986 A/S	Higher serum calcium Lower serum phosphate
rs1042636	exon 7	A > G	5%/50%[a]	990 R/G	Hypercalciuria Low serum calcium Calcium kidney stones
rs6776158	promoter 1	A > G	26%	None	Calcium kidney stones Lower serum phosphate
rs17251221	intron 4	A > G	19%	None	Higher serum calcium Higher serum magnesium

[a]5% in Caucasian population, 50% in Asian population.

Several studies investigated the association between *CaSR* polymorphisms and BMD with controversial findings. A genome-wide association study did not show any association between BMD and the *CaSR* gene locus in 2211 women and 1633 men (Gupta *et al.*, 2011). Other studies genotyped participants for rs1801725 polymorphism: a study performed in Swedish young women found a negative association of the minor allele T with BMD measured at the lumbar spine (Lorentzon *et al.*, 2001), whereas other studies did not find any association between the rs1801725 polymorphism and BMD measured at the lumbar spine, the femur or the distal forearm (Takacs *et al.*, 2002; Laaksonen *et al.*, 2009; Harding *et al.*, 2006). Conversely, two studies in patients with primary hyperparathyroidism showed that the minor allele T at the rs1801725 polymorphism was more frequent in patients who suffered from vertebral fractures; furthermore, carriers of the minor allele at rs1801725 plus two out of the following three factors, age, serum calcium concentration, and spinal BMD, showed a risk of fracture that was 4.7-fold higher than homozygotes for the more common allele (Eller-Vainicher *et al.*, 2014).

CaSR as a Drug Target

CaSR has become target for new categories of drugs, agonists or antagonists of CaSR (Nemeth and Goodman, 2016). Agonists are termed calcimimetics and may be distinguished in two groups according to their functional pattern. The first group may directly stimulate CaSR activity by binding to its extracellular domain pocket and reproducing the effect of calcium and other ligands. Calcimimetics of the other group may increase CaSR reactivity to calcium and other ligands acting as allosteric agonists interacting with the CaSR transmembrane domain (Nemeth and Goodman, 2016). Because of their stimulatory effect on CaSR, calcimimetics are used to inhibit parathyroid secretion in patients with primary hyperparathyroidism and hemodialysis patients with secondary hyperparathyroidism (Peacock *et al.*, 2009; Bover *et al.*, 2016). Two calcimimetic molecules are today available for the clinical practice: cinacalcet is a CaSR allosteric agonist used to treat both mentioned forms of hyperparathyroidism; etelcalcetide is a direct activator of CaSR, approved to treat hyperparathyroidism in hemodialysis patients. Additionally, the use of cinacalcet has been proposed in patients with FHH (Alon and VanDeVoorde, 2010). Treatment with calcimimetics also results in urinary calcium excretion and, therefore, hypocalcemia is the main, and potentially severe, complication of these drugs.

Antagonists of CaSR are called calcilytics and stimulate parathyroid gland secretion and calcium reabsorption in kidney tubules. Their clinical use in osteoporosis has been hypothesized because they could induce PTH pulsating secretion having an osteoanabolic effect in lab animals (Nemeth and Goodman, 2016). However, trials testing the calcilytic drug ronacaleret in osteoporotic patients failed to demonstrate a satisfying efficacy in this disorder, probably because it stimulated a chronic condition of "mild hyperparathyroidism" (Fitzpatrick *et al.*, 2012). Therefore, no calcilytic drug has till now been approved for the clinical use.

Conclusions

CaSR is a cation receptor through which extracellular calcium may influence cell activity, thus connecting the extracellular environment with the intracellular compartment. CaSR presence in parathyroid glands and kidney tubules has a specific relevance for calcium metabolism, because it ensures the strict control of the extracellular calcium concentration. Numerous findings have showed the relevance of CaSR for correct growth and healthy life, whereas genetic or acquired alterations of CaSR function may result in hypocalcemic or hypercalcemic disorders. *CaSR* polymorphic variants may contribute to individual variability of serum concentrations and urine excretion of calcium and phosphate; they may also predispose to calcium nephrolithiasis, whereas their effect on BMD and fracture risk remains controversial. As suggested by these functional and pathophysiological findings, CaSR has become an important target for the treatment of primary and secondary hyperparathyroidism by using calcimimetic drugs. On the contrary, calcilytic drugs have not yet found their clinical indications. However, in this field we are at the beginning of the story, because pharmacological modulation of CaSR activity could provide new instruments improving our strategy to treat disorders of calcium and phosphate metabolism or having in calcium a pathophysiological mediator.

DMP1	Dentin matrix protein 1.
ENPP1	Ectonucleotide pyrophosphatase/phosphodiesterase 1.
GAlNAc-T3	UDP-N-acetyl-alpha-D-galactosamine:polypeptide N-acetylgalactosaminyltransferase 3.
GALNT3	Polypeptide N-acetylgalactosaminyltransferase 3.
HFTC	Hyperphosphatemic familial tumoral calcinosis.
HHM	Humoral hypercalcemia of malignancy.
NPT	Sodium-phosphate cotransporter.
PHEX	Phosphate-regulating gene with homologies to endopeptidases on the X chromosome.
TIO	Tumor-induced osteomalacia.

Phosphate Metabolism

Phosphate is an essential anion in our body. Phosphate is one of components of bone and teeth. In addition, phosphate is a constituent of cell membrane, nucleic acids, high energy molecules like adenosine triphosphate (ATP), intracellular molecules such as 2,3-diphosphoglycerate, glucose-6-phosphate and many phosphorylated proteins. While it is not yet clear how intracellular phosphate concentration is regulated, extracellular phosphate level is maintained within a narrow range. Serum phosphate level is regulated by intestinal phosphate absorption, renal phosphate handling and shift between extracellular phosphate and phosphate in bone or intracellular space (**Fig. 1**). Renal phosphate handling is believed to be the most important determinant of serum phosphate level at least in a chronic state. Most phosphate filtered through glomeruli is reabsorbed in proximal tubules by type 2a and 2c sodium-phosphate cotransporters (NPT2a and NPT2b) (Segawa *et al.*, 2015). There are both saturable, transcellular route and nonsaturable, paracellular mechanisms in intestinal phosphate absorption. The saturable active transport is medicated by type 2b sodium-phosphate cotransporter (NPT2b) (Segawa *et al.*, 2015).

Regulatory Mechanisms of Serum Phosphate Level

Intestinal phosphate absorption and renal phosphate handling need to be regulated in a coordinated fashion in order to maintain serum phosphate level in a narrow range. Three hormones, parathyroid hormone (PTH), 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] and fibroblast growth factor 23 (FGF23), mainly regulate these intestinal phosphate absorption and renal phosphate handling.

PTH suppresses proximal tubular phosphate reabsorption by reducing the expression of NPT2a and NPT2b (Miyamoto *et al.*, 2004). PTH works by binding to PTH1 receptor or PTH/PTH-related protein (PTHrP) receptor (Juppner *et al.*, 1991). While PTHrP is not a hormone in a physiological state, it can induce hypophosphatemia by binding to and activating PTH1 receptor in patients with humoral hypercalcemia of malignancy (HHM) as discussed below. PTH also enhances 1,25$(OH)_2$D production in renal proximal tubules by stimulating *CYP27B1* expression which encodes 25-hydorxyivmitan D [25(OH)D]-1α-hydroxylase, an enzyme that convert 25(OH)D to 1,25$(OH)_2$D. PTH has been also reported to enhance FGF23 production (Fan *et al.*, 2016) (**Fig. 2**).

In addition to lowering serum phosphate level, PTH increases serum calcium (Ca) by enhancing osteoclastic bone resorption and Ca reabsorption in distal tubules. On the other hand, PTH secretion from parathyroid glands is mainly regulated by extracellular ionized Ca level through Ca-sensing receptor (Brown *et al.*, 1993). Activation of Ca-sensing receptor by extracellular Ca suppresses PTH secretion. Contrary, decreased serum Ca enhances PTH secretion. Thus, there is a negative feedback system between PTH secretion and serum Ca

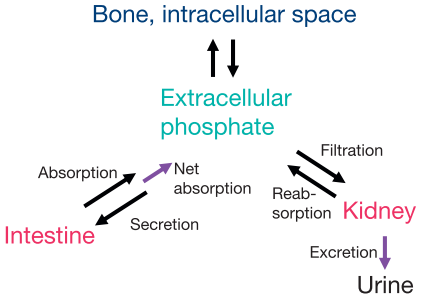

Fig. 1 Maintenance of extracellular phosphate level. Serum phosphate level is maintained by intestinal phosphate absorption, renal phosphate handling and shift between extracellular phosphate and phosphate in bone or intracellular space.

 doi:10.1016/B978-0-12-801238-3.66143-3

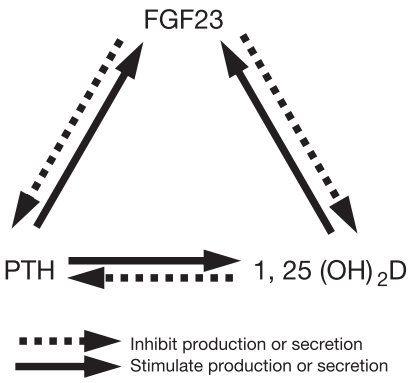

Fig. 2 Relationship among three major hormones affecting serum phosphate level.

level. It is not known whether there is a similar feedback system between PTH secretion and serum phosphate level. However, phosphate was shown to modulate PTH synthesis in animals (Naveh-Many and Nechama, 2007) (**Fig. 2**).

$1,25(OH)_2D$ stimulates intestinal phosphate absorption by enhancing the expression of NPT2b and works to increase serum phosphate by binding to vitamin D receptor (VDR) (Sabbagh *et al.*, 2011). In addition, $1,25(OH)_2D$ also increases serum Ca by stimulating intestinal Ca absorption and renal Ca reabsorption in distal tubules. $1,25(OH)_2D$ suppresses the synthesis of PTH and stimulates the production of FGF23 (Saito *et al.*, 2005).

FGF23 is produced by osteocytes/osteoblasts. FGF23 suppresses proximal tubular phosphate reabsorption by reducing the expression of NPT2a and NPT2b (Shimada *et al.*, 2004). FGF23 also decreases serum $1,25(OH)_2D$ level by suppressing the expression of *CYP27B1* and also stimulating *CYP24A1* expression (Shimada *et al.*, 2004). *CYP24A1* encodes an enzyme that works to reduce $1,25(OH)_2D$ level. From these effects, FGF23 reduces serum phosphate by inhibiting both intestinal phosphate absorption via reduced $1,25(OH)_2D$ and proximal tubular phosphate reabsorption. FGF23 is shown to work by binding to FGF receptor (FGFR)-Klotho complex (Urakawa *et al.*, 2006). While the expression of FGFR is not tissue-specific, Klotho is present in only limited tissues such as kidney, parathyroid gland and pituitary (Kuro-o *et al.*, 1997). In addition to reducing $1,25(OH)_2D$ level, FGF23 is reported to suppress PTH synthesis and secretion in animals (Ben-Dov *et al.*, 2007) (**Fig. 2**).

As shown above, PTH, $1,25(OH)_2D$ and FGF23 affect serum phosphate level. In addition, these hormones modulate the synthesis and/or secretion of other ones. Serum phosphate level is mainly maintained by the interplay of these hormone actions. In addition, several other hormones can affect serum phosphate level. For example, glucocorticoid can reduce serum phosphate by inhibiting proximal tubular phosphate reabsorption. Growth hormone enhances proximal tubular phosphate reabsorption through insulin-like growth factor I. Furthermore, serum phosphate can be changed by mechanisms independent of these hormone actions as discussed below.

Hyperphosphatemic Diseases

Causes

As discussed above, PTH, $1,25(OH)_2D$ and FGF23 are physiological hormones affecting serum phosphate levels. PTH and FGF23 reduces, and $1,25(OH)_2D$ works to increase serum phosphate level. Therefore, deficient actions of PTH or FGF23 result in hyperphosphatemia mainly by increased renal tubular phosphate reabsorption (**Table 1**). Enhanced signals from VDR also stimulate intestinal phosphate absorption. However, it is not common that frank hyperphosphatemia is induced by $1,25(OH)_2D$ actions if renal function is not impaired. Increased intestinal phosphate absorption can be compensated by enhanced urinary phosphate excretion in subjects with normal renal function.

Hypoparathyroidism is a disease characterized by impaired actions of PTH. This disease can be caused by impaired PTH secretion or resistance to PTH. In addition, severe hypomagnesemia also can cause hypoparathyroidism by both impaired PTH secretion and resistance to PTH. There are many causes for PTH-deficient hypoparathyroidism including gene mutations,

Table 1 Causes of hyperphosphatemia

1.	Impaired actions of PTH	Hypoparathyroidism
2.	Enhanced signals from vitamin D receptor	Granulomatous diseases, malignant lymphoma, vitamin D intoxication, overdose of active vitamin D…
3.	Impaired actions of FGF23	Hyperphosphatemic familial tumoral calcinosis (Mutations in *GALNT3*, *FGF23*, *Klotho*)
4.	Enhanced phosphate absorption	Phosphate enema, Phosphate containing laxatives…
5.	Impaired renal phosphate excretion	CKD, Acromegaly
6.	Shift from bone or intracellular pool	Bone metastases, hemolysis, diabetic ketoacidosis, tumor lysis syndrome, rhabdomyolysis…

autoimmunity, surgical removal, radiation, granulomatous diseases and so on. Resistance to PTH is observed in patients with pseudohypoparathyroidism.

Deficient actions of FGF23 cause hyperphosphatemic familial tumoral calcinosis (HFTC). This disease is characterized by hyperphosphatemia with enhanced proximal tubular phosphate reabsorption and ectopic calcification especially around large joints. Mutations in three genes have been shown to cause HFTC, *GALNT3*, *FGF23* and *Klotho* (Araya *et al.*, 2005; Benet-Pages *et al.*, 2005; Ichikawa *et al.*, 2007; Topaz *et al.*, 2004). FGF23 gene produces a peptide with 251 amino acids. A part of FGF23 protein is proteolytically cleaved between ^{179}Arg and ^{180}Ser before or during the process of secretion (Shimada *et al.*, 2001). Processed N-terminal and C-terminal fragments of FGF23 do not have an activity to reduce serum phosphate level (Shimada *et al.*, 2002). *GALNT3* gene encodes an enzyme called UDP-N-acetyl-alpha-D-galactosamine:polypeptide N-acetylgalactosaminyltransferase 3 (GalNAc-T3). This enzyme attaches *N*-acetylgalactosamine to Ser or Thr residue as an initial step of mucin-type O-linked glycosylation. It has been shown that GalNAc-T3 initiates glycosylation of ^{178}Thr of FGF23 protein and works to prevent the processing of FGF23 between ^{179}Arg and ^{180}Ser (Frishberg *et al.*, 2007). Inactivating mutations in *GALNT3* are considered to make FGF23 protein susceptible for the proteolytic processing and cause deficient actions of FGF23. This is supported by FGF23 levels in patients with mutations in *GALNT3*. There are two kinds of assays for FGF23. Intact assay uses two antibodies that recognize N-terminal and C-terminal portion of the processing site of FGF23, respectively, and measures only biologically active full-length FGF23 (Yamazaki *et al.*, 2002). In contrast, C-terminal assay employs antibodies against C-terminal portion of FGF23 protein (Jonsson *et al.*, 2003). This C-terminal assay measures both full-length and cleaved C-terminal fragment of FGF23. FGF23 levels in patients with mutations in *GALNT3* were shown to be extremely high by C-terminal assay, but rather low by intact assay (Araya *et al.*, 2005). These results indicate that there is only a little full-length FGF23 protein while quite a large amount of processed C-terminal fragment is present in these patients. Patients with HFTC by mutations in *FGF23* also show high FGF23 levels by C-terminal assay and rather low FGF23 by intact assay (Frishberg *et al.*, 2007). A mutant FGF23 protein was shown to be trapped within Golgi while processed C-terminal fragment can be secreted (Benet-Pages *et al.*, 2005). However, other mechanisms are also proposed to explain impaired actions of FGF23 in these patients (Shawar *et al.*, 2016). FGF23 levels are high by both intact and C-terminal assay in a patient with HFTC by *Klotho* mutation (Ichikawa *et al.*, 2007). This condition is considered to be caused by resistance to FGF23 because Klotho works as a co-receptor for FGF23.

In addition to aberrant functions of these hormones, hyperphosphatemia can be induced by enhanced intestinal phosphate absorption, impaired renal phosphate excretion or shift from bone or intracellular pool (**Table 1**). Clinically, chronic kidney disease (CKD) is by far the most prevalent cause of hyperphosphatemia. During the progression of CKD, it is FGF23 that first increases followed by PTH and phosphate (Isakova *et al.*, 2011). FGF23 starts to increase in patients with CKD stage 2. It is not knows what triggers this increase of FGF23 in patients with early CKD. However, FGF23 and PTH are considered to enhance urinary phosphate excretion and prevent the development of hyperphosphatemia in these patients (Hasegawa *et al.*, 2010).

Clinical Manifestations

Acute hyperphosphatemia can cause hypocalcemia by physicochemical complex formation. Chronic hyperphosphatemia is a risk factor for ectopic calcification including vascular tissues. Hyperphosphatemia was shown to induce vascular smooth muscle cells to obtain osteoblastic characteristics (Nishizawa *et al.*, 2005). In patients with advanced CKD, hyperphosphatemia contributes to the development and progression of secondary hyperparathyroidism by enhancing PTH synthesis and parathyroid cell proliferation (Naveh-Many *et al.*, 1995; Naveh-Many and Nechama, 2007).

Treatment

Treatment of hyperphosphatemia is different depending on the causes. Hyperphosphatemia by drugs such as phosphate containing laxatives may improve spontaneously if the drug administration is stopped and renal function is maintained. Hyperphosphatemia by hypoparathyroidism usually improves by treating hypocalcemia. Hyperphosphatemia in patients with CKD is managed by dietary phosphate restriction and phosphate binders. Dialysis is the final method for patients with severe hyperphosphatemia especially when renal function is compromised. In patients with HFTC, acetazolamide has been tested in a couple patients together with phosphate restriction and phosphate binders (Lammoglia and Mericq, 2009; Yamaguchi *et al.*, 1995). Surgical treatment for calcified mass may be necessary in some patients with HFTC.

Hypophosphatemic Diseases

Causes

Hypophosphatemia also can be caused by aberrant signals from hormone receptos. As PTH binds to PTH1 receptor, enhanced signals from this receptor can cause hypophosphatemia. This is typically seen in patients with primary hyperparathyroidism. PTHrP is a cytokine regulating proliferation and function of many tissues including cartilage, bone, pancreas, keratinocyte, mammary gland and vasculature (Martin, 2016). However, in patients with HHM, PTHrP produced by tumor cells works as a systemic humoral factor and cause hypercalcemia and hypophosphatemia by binding to PTH1 receptor. Hypophosphatemia by

enhanced signaling from PTH1 receptor can also be found in patients with familial hypocalciuric hypercalcemia and Jansen's metaphyseal chondrodysplasia (Schipani *et al.*, 1995).

Vitamin D deficiency is defined by low circulatory 25(OH)D levels. Serum level of $1,25(OH)_2D$ in patients with vitamin D deficiency can be variable. It is not entirely clear why low 25(OH)D level causes impaired actions of vitamin D metabolites while $1,25(OH)_2D$ is considered to be an active hormone. Recent studies revealed that *CYP27B1* is expressed in several other tissues than kidney such as parathyroid gland, osteoblasts, keratinocytes and so on (Adams *et al.*, 2014). It is possible that vitamin D deficiency causes impaired synthesis of local $1,25(OH)_2D$ and results in impaired actions of local $1,25(OH)_2D$. Patients with vitamin D-dependent rickets show frank hypocalcemia and hypophosphatemia because of impaired systemic actions of $1,25(OH)_2D$. Some drugs such as diphenylhydantoin and rifampicin can reduce 25(OH)D level (Grober and Kisters, 2012).

Since the identification of FGF23, several kinds of genetic and acquired hypophosphatemic diseases have been shown to be caused by excessive actions of FGF23 (**Table 3**). Of these, X-linked hypophosphatemic rickets (XLH) caused by inactivating mutations in *phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEX)* is by far the most prevalent cause of genetic hypophosphatemic rickets. Several terms such as vitamin D-resistant rickets and hypophosphatemic rickets have been used as a synonym for this disease. *PHEX* was identified in 1995 by positional cloning (The HYP Consortium, 1995). PHEX protein is a single membrane spanning protein which shows some homology to endopeptidases such as endothelin-converting enzyme-1 and Kell antigen (Turner and Tanzawa, 1997). It was shown that *Fgf23* is overexpressed in bone in model mice of XLH (Liu *et al.*, 2003). However, it is not clear how mutations in *PHEX* result in overproduction of FGF23 in bone. Mutations in *FGF23* in patients with autosomal dominant hypophosphatemic rickets (ADHR) changes ^{176}Arg or ^{179}Arg to other amino acids (ADHR Consortium, 2000). The mutant protein was shown to be resistant for the proteolytic processing of FGF23 protein between ^{179}Arg and ^{180}Ser (Shimada *et al.*, 2002; White *et al.*, 2001). It is known that symptoms and biochemical abnormalities can wax and wane with time in patients with ADHR (Imel *et al.*, 2007). It has been suggested that iron deficiency enhances FGF23 production and causes hypophosphatemia in patients with ADHR (Imel *et al.*, 2011). There are several other genes such as *dentin matrix protein 1 (DMP1)* (Feng *et al.*, 2006; Lorenz-Depiereux *et al.*, 2006) and *ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1)* (Levy-Litan *et al.*, 2010; Lorenz-Depiereux *et al.*, 2010) whose mutations cause genetic FGF23-related hypophosphatemic rickets (**Table 3**). In these diseases, FGF23 is considered to be overexpressed in bone. However, it is largely unknown how mutations in these genes cause overproduction of FGF23.

FGF23 can also induce hypophosphatemia in patients with tumor-induced osteomalacia (TIO). TIO is a paraneoplastic syndrome usually caused by benign mesenchymal tumors (Minisola *et al.*, 2017). However, there are several cases of TIO caused by malignant tumors. These tumors are considered to be ectopically producing FGF23. FGF23 is also high in hypophosphatemic patients with intravenous administration of iron preparations (Schouten *et al.*, 2009; Shimizu *et al.*, 2009). It was reported that FGF23 is expressed in liver and can produce hypophosphatemia in patients with biliary atresia (Wasserman *et al.*, 2016).

Hypophosphatemia can also be caused by impaired intestinal phosphate absorption, renal phosphate wasting and shift into bone or intracellular pool independent of signals from these hormone receptors mentioned above (**Table 2**).

Differential Diagnosis

Renal tubular phosphate reabsorption can be evaluated by tubular maximum transport of phosphate per glomerular filtration rate (TmP/GFR) (Walton and Bijvoet, 1975). Low TmP/GFR in hypophosphatemic patients indicates impaired renal phosphate reabsorption. In addition, measurement of several hormones is useful for differential diagnosis of various causative diseases in hypophosphatemic patients (**Fig. 3**). Clinical information usually indicates the presence of conditions that cause phosphate shift into bone or intracellular pool. Hypophosphatemic patients by enhanced signaling from PTH1 receptor typically show

Table 2 Causes for hypophosphatemia

1. Enhanced signals from PTH1 receptor	Primary hyperparathyroidism Humoral hypercalcemia of malignancy (PTHrP-secreting tumor) Ectopic PTH-secreting tumor Familial hypocalciuric hypercalcemia Jansen metaphyseal chondrodysplasia (Activating mutations in *PTH1 receptor*)
2. Impaired signals from vitamin D receptor	Vitamin D deficiency Vitamin D-dependent rickets (VDDR) type 1 (Inactivating mutations in *CYP27B1*) Vitamin D-dependent rickets (VDDR) type 2 (Inactivating mutations in *VDR*) Drugs (diphenylhydantoin, rifampicin…)
3. Excess actions of FGF23 (**Table 3**)	
4. Impaired phosphate absorption	Malnutrition, Short bowel syndrome, Alcoholism, Drugs (antacids with aluminum or magnesium)…
5. Renal phosphate wasting	Fanconi syndrome, Hereditary hypophosphatemic rickets with hypercalciuria, Dent disease, Cushing syndrome, Drugs (adefovir dipivoxil, iphosphamide…)…
6. Shift into bone or intracellular pool	Hungry bone syndrome, Refeeding, Leukemia blast crisis, Treatment of diabetic ketoacidosis…

Table 3 FGF23-related hypophosphatemic diseases

	Responsible gene
X-linked hypophosphatemic rickets: XLH	*PHEX*
Autosomal dominant hypophosphatemic rickets: ADHR	*FGF23*

Jansen-type metaphyseal chondrodysplasia	*PTH1R*
Hypophosphatemia, dental anomalies and ectopic calcification	*FAM20C*
Hypophosphatemia, skin and bone lesions	*HRAS, KRAS, NRAS*

Tumor-induced osteomalacia: TIO
Hypophosphatemia by iron polymaltose, saccharated ferric oxide or ferric carboxymaltose
Biliary atresia

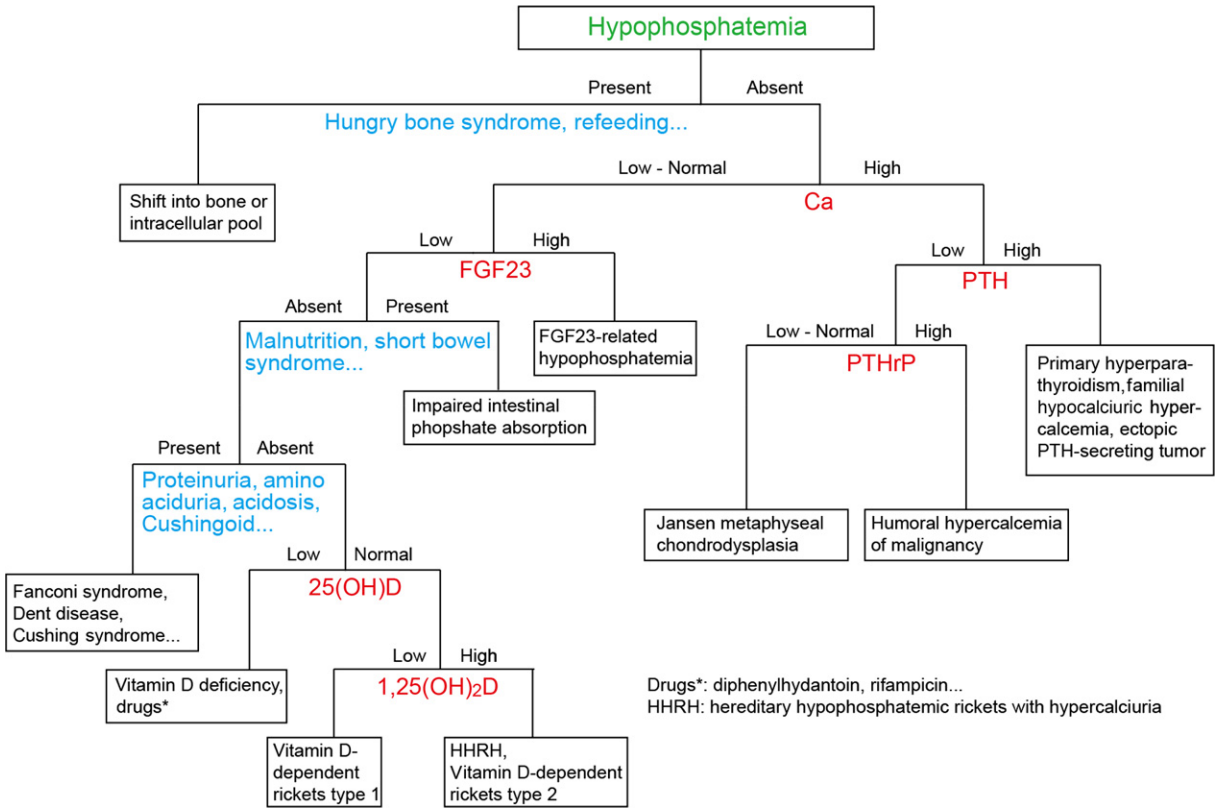

Fig. 3 Flowchart for differential diagnosis of hypophosphatemic diseases. PTH, $1,25(OH)_2D$ and FGF23 modulate the production or secretion of other hormones each other. PTH stimulates $1,25(OH)_2D$ and FG23 production. $1,25(OH)_2D$ enhances FGF23 production and suppresses PTH synthesis. FGF23 inhibits $1,25(OH)_2D$ production and suppresses PTH production and secretion.

hypercalcemia. High FGF23 level in hypophosphatemic patients indicates the presence of FGF23-related hypophosphatemic diseases. On the other hand, FGF23 is rather low in patients with chronic hypophosphatemia by other causes (Endo *et al.*, 2008). This suggests that endogenous FGF23 production is suppressed in these hypophosphatemic patients. Furthermore, other clinical data can indicate impaired intestinal phosphate absorption and renal phosphate wasting. Finally, measurement of vitamin D metabolites is useful for differential diagnosis of several hypophosphatemic diseases.

Symptoms

Hypophosphatemia can cause several symptoms. Because of decreased 2,3-diphosphoglycerate in red blood cells, severe hypophosphatemia causes tissue hypoxia. In addition, hypophosphatemia can reduce cellular ATP content and impair cellular function. Hypophosphatemia can result in heart failure, rhabdomyolysis, hemolysis, muscle weakness, arrhythmia and abnormalities in central nervous system such as delirium and coma.

Chronic hypophosphatemia causes rickets and osteomalacia characterized by impaired mineralization of bone matrix. Rickets develops in children before the closure of growth plate. Growth retardation and bone deformities such as genu valgus and valgum are typical problems of rickets. On the other hand, osteomalacia occurs in adult. Bone pain and muscle weakness are usual symptoms of patients with hypophosphatemic osteomalacia. While there are many causes for rickets and osteomalacia, chronic hypophosphatemia is present in most cases of rickets/osteomalacia.

Treatment

If the cause for hypophosphatemia can be corrected, that should be done. Acute symptomatic hypophosphatemia can be treated by parenteral phosphate administration. Treatment for hypercalcemia is usually more important for hypophosphatemic patients by enhanced signals from PTH1 receptor. Vitamin D deficiency is basically treated by native vitamin D and vitamin D-dependent rickets type 1 can be managed by a physiological amount of active vitamin D. Large amount of active vitamin D and calcium are used for patients with vitamin D-dependent rickets type 2 while the response is variable depending on the mutations in *VDR* gene.

Patients with TIO can be cured by complete surgical removal of responsible tumors. In addition, hypophosphatemia improves after cessation of intravenous iron preparations. Patients with other FGF23-related hypophosphatemic diseases including those with TIO whose tumors cannot be resected are currently treated with oral phosphate and active vitamin D. While these drugs are effective, they also have several limitations (Carpenter *et al.*, 2011). New treatment methods for patients with FGF23-related hypophosphatemic diseases are now being considered. Other chronic hypophosphatemia is usually treated by oral phosphate supplementation.

Vitamin D☆

Ian R Reid, University of Auckland, Auckland, New Zealand

Glossary

Alfacalcidol 1α-Hydroxyvitamin D.
Calcifediol 25-Hydroxyvitamin D.
Calcitriol 1,25-Dihydroxyvitamin D.
International unit Doses of the calciferols are often expressed in international units (IU), there being 40 IU/μg of cholecalciferol and 38.8 IU/μg of ergocalciferol.

Vitamin D is a term encompassing the two chemical entities cholecalciferol (vitamin D_3) and ergocalciferol (vitamin D_2). The vitamin Ds are secosteroids, which act as the substrate for the synthesis of a family of compounds involved in the regulation of calcium metabolism.

Introduction

Vitamin D is misnamed in that it is not a vitamin and this problem leads to fundamental confusion regarding its role in health and disease. Vitamins are usually defined as essential dietary constituents. Although vitamin D can occur in the diet, endogenous production is quantitatively much more important in most individuals. Therefore, vitamin D should be regarded as a substrate that is necessary for the synthesis of a family of hormones primarily recognized for their regulation of calcium metabolism. As a result, vitamin D status is not really a nutritional issue, but is determined by sunlight exposure and supplement use. The parent compounds are metabolized to a number of other secosteroids of varying, and sometimes uncertain, biological activity. Some of these compounds are important regulators of calcium metabolism, although they are recognized as having other important activities as well. Some are available as pharmaceuticals and play important roles in the management of conditions such as vitamin D deficiency, chronic renal failure, hypophosphatemia, and hypocalcemia. Novel pharmaceuticals, which may find applications in other conditions, are being developed within this class.

Structure and Synthesis of Vitamin D and Its Metabolites

Vitamin D_3 is a 27-carbon secosteroid (**Fig. 1**) that is derived from 7-dehydrocholesterol as a result of the action of ultraviolet (UV) light in the skin of animals (Bikle *et al.*, 2013). The UVB spectrum (wavelength 290–320 nm) results in the rupture of the bond between C-9 and C-10 in 7-dehydrocholesterol, leading ultimately to the production of vitamin D_3. A similar process takes place in some plants, leading to the conversion of ergosterol to vitamin D_2, which has a methyl group attached to C-24 and is widely used as a vitamin D supplement. With sustained exposure to sunlight, there is increased production of inactive vitamin D metabolites, such as lumisterol, providing a mechanism for preventing vitamin D intoxication. Cutaneous vitamin D production is related to the intensity of UVB irradiation and thus diminishes with increasing latitude. It is also diminished by skin pigmentation (particularly in individuals of African and Indian origin) and by advancing age. Covering the skin, whether with clothing or sunscreens, also provides an effective barrier to vitamin D production. Vitamin D_2 and vitamin D_3 have usually been regarded as having comparable biological effects, though some studies have suggested that metabolites in the vitamin D_3 series may have greater biological potency. The calciferols are fat-soluble and are absorbed primarily in the jejunum and ileum. This process involves bile acids and any disease state associated with malabsorption of fat is likely to be associated with malabsorption of vitamin D. Vitamin D is relatively uncommon in an unsupplemented diet, occurring in fish oils, egg yolk, butter, and liver. In the United States, supplementation of food (particularly dairy products) with vitamin D is common, though it has been demonstrated that actual levels of vitamin D in foods are sometimes widely different from those claimed on the packaging.

Transport

Following its synthesis in the skin or absorption from the gastrointestinal tract, vitamin D circulates bound to vitamin D-binding protein. Vitamin D-binding protein is encoded by a gene located on chromosome 4 and is structurally related to α-fetoprotein and

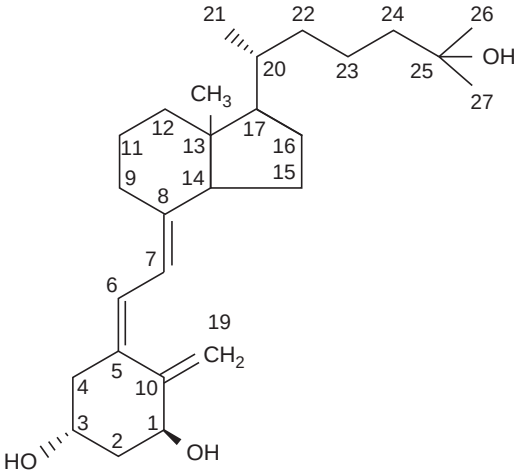
This chapter is an update of Ian R. Reid, Vitamin D, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 657–665.



1,25(OH)$_2$D$_3$

Fig. 1 Structure of 1,25(OH)$_2$D$_3$.

albumin. It circulates at a concentration of 4–8 μM and there is one binding site for a vitamin D metabolite on each molecule. Thus, only approximately 5% of the binding sites are usually occupied. The affinities of the vitamin D metabolites for vitamin D-binding protein are in the following order: 25(OH)D$_3$ > 24,25(OH)$_2$D$_3$ > vitamin D$_3$ ≈ vitamin D$_2$ > 1,25(OH)$_2$D$_3$ > 1,24,25(OH)$_3$D$_3$.

Most circulating vitamin D-binding protein is synthesized in the liver. Its circulating concentrations are increased by pregnancy and estrogen therapy and are decreased in conditions associated with hypoproteinemia (e.g., liver disease, malnutrition, nephrotic syndrome) and inflammation. The role of vitamin D-binding protein is probably to prevent rapid fluctuations in the levels of the vitamin D metabolites. Vitamin D-binding protein deficiency in humans has not been identified but a knockout mouse does exist. This animal is more susceptible to hypocalcemia when fed a vitamin D-deficient diet than is a wild-type animal. Despite its size (58 kDa), vitamin D-binding protein appears to be filtered at the glomerulus and is then reabsorbed in the proximal tubule via the receptor protein, megalin, a member of the low-density lipoprotein receptor family. Mice deficient in megalin who survive long enough to develop a bone phenotype have severe rickets. Approximately 10% of vitamin D metabolites circulate bound to albumin. Once vitamin D metabolites have entered their target cell, their transport to the appropriate intracellular organelle may be facilitated by a different group of intracellular vitamin D-binding proteins, related to the heat shock proteins.

Activation

The first step in the activation of vitamin D is its 25-hydroxylation, to form 25-hydroxyvitamin D [25(OH)D]. This takes place in the parenchymal cells of the liver and is mediated by the enzyme from the cytochrome P450 family, coded for by the gene *Cyp2r1*. There appears to be very little regulation of the 25-hydroxylase and only in very advanced liver failure does its activity become limiting to normal vitamin D metabolism.

25(OH)D formed in the liver returns to the circulation bound to vitamin D-binding protein. If it is to be further hydroxylated, this takes place in the proximal tubular cells of the kidney. The entry of 25(OH)D into these cells is dependent on the action of megalin. Further activation of 25(OH)D is accomplished by 25-hydroxyvitamin D 1α-hydroxylase, which is also a mitochondrial P450 enzyme encoded by the *CYP27b1* gene. It shows significant homology to the 25-hydroxylase. The proximal tubular cells that contain the 1α-hydroxylase have parathyroid hormone (PTH) receptors, which stimulate enzyme activity. This accounts for the increased levels of 1,25-dihydroxyvitamin D [1,25(OH)$_2$D] in states of hyperparathyroidism. The 1α-hydroxylase is also expressed in distal tubular cells and, again, megalin is present in these cells. In contrast to the proximal tubule, the PTH receptor is not present, but the receptor for calcitonin is and appears to have a stimulatory effect on 1α-hydroxylase activity. 1,25(OH)$_2$D directly inhibits the expression of the *Cyp27b1* gene at both sites in the renal tubule. The structure if 1,25(OH)$_2$D is shown in **Fig. 1**.

The kidney is clearly the most important site of 1,25(OH)$_2$D synthesis since anephric individuals have dramatically reduced concentrations of the hormone. However, 1,25(OH)$_2$D is still measurable in such patients, suggesting that there is extrarenal synthesis of the hormone. This 1α-hydroxylase gene is expressed in skin but even patients who are deficient in the gene still have measurable levels of 1,25(OH)$_2$D, suggesting that other enzymes might mediate 1-hydroxylation of 25(OH)D. Extrarenal synthesis of 1,25(OH)$_2$D clearly occurs in granulomatous diseases and in some lymphomas, where unregulated production of the hormone results in hypercalcemia. During pregnancy, the placenta produces 1,25(OH)$_2$D.

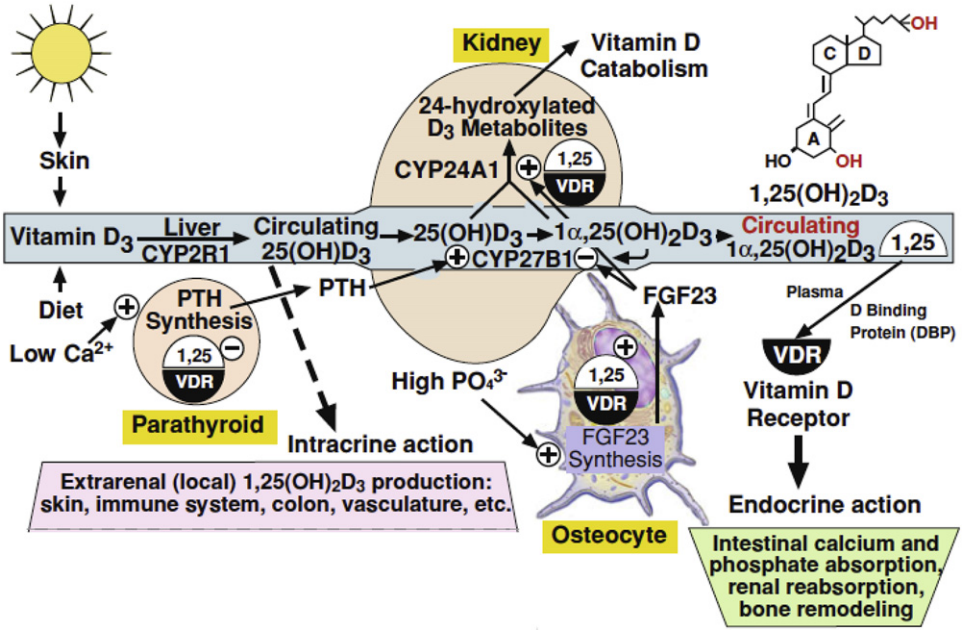


Fig. 2 Regulation of vitamin D metabolism, and principal site of its actions. Modified from Haussler et al., "Molecular Mechanisms of Vitamin D Action." Calcified Tissue International 92(2): 77–98, used with permission.

An alternative fate for 25(OH)D is to be hydroxylated on C-24, to produce 24,25-dihydroxyvitamin D. This conversion is mediated by vitamin D 24-hydroxylase, encoded by the gene *Cyp24a1*. This enzyme can also 24-hydroxylate $1,25(OH)_2D$ and is regarded as the principal pathway for deactivating vitamin D metabolites. As a consequence, it is widely expressed throughout the body, particularly in vitamin D target tissues, including the proximal and distal tubules of the kidney. Vitamin D metabolites then undergo further hydroxylations and side chain cleavage, resulting in the production of water-soluble calcitroic acid, which has no biological activity.

Regulation of Vitamin D Metabolism

The key points of regulation of vitamin D metabolism are the 1α-hydroxylase and the 24-hydroxylase (**Fig. 2**) (Haussler *et al.*, 2013). As noted above, the 1α-hydroxylase gene is directly regulated by PTH, calcitonin, and $1,25(OH)_2D$, the latter two hormones having the predominant effect under normocalcemic conditions, whereas the effect of PTH predominates over that of calcitonin under hypocalcemic conditions. Phosphate concentration is also an important regulator of 1α-hydroxylase activity, which is suppressed by high concentrations of phosphate and stimulated by low concentrations. Calcium concentration impacts on 1α-hydroxylase activity, mainly through its effect on circulating levels of PTH, though there is some evidence that it can directly influence enzyme activity as well. There is also evidence for effects of other growth-related hormones, such as estrogen, prolactin, and growth hormone, but these appear to be relatively minor.

$1,25(OH)_2D$ is the principal regulator of 24-hydroxylase activity. This is a genomic effect mediated by vitamin D-response elements in the promoter for the 24-hydroxylase gene. In the renal proximal tubule, PTH inhibits 24-hydroxylase activity, though it may have an opposite effect in the distal tubule. The induction of 24-hydroxylase by $1,25(OH)_2D$ also leads to accelerated catabolism of 25(OH)D. This explains the low levels of this metabolite seen in patients treated with calcitriol and in those suffering from primary hyperparathyroidism.

Actions of Vitamin D and Its Metabolites

Mechanisms of Action

The classic mechanism of action of vitamin D metabolites on their target tissues is similar to that of other steroid hormones and is mediated by the vitamin D receptor (VDR), a member of the steroid hormone receptor superfamily. Both $1,25(OH)_2D$ and 25(OH)D bind to this receptor, though the affinity of $1,25(OH)_2D$ for the receptor is 1000-fold higher. However, it should be remembered that 25(OH)D circulates in concentrations 1000-fold higher than those of $1,25(OH)_2D$, so both may contribute to receptor activation. The vitamin D metabolites bind to the VDR, which then forms a heterodimeric complex with the retinoic acid X receptor. This complex then interacts with vitamin D-response elements associated with a variety of genes. The VDR gene contains nine exons and encodes a protein of 427 amino acids. In humans, the gene is located on chromosome 12q. The DNA-binding domain is located in the amino-terminal

region and consists of a double zinc-finger structure. The ligand-binding domain is in the C-terminal region of the molecule. Mutations of the VDR have been identified in humans and result in vitamin D resistance, producing the clinical picture of rickets. Polymorphisms of the VDR gene have also been observed. These variations in nucleic acid sequence do not result in differences in the amino acid sequence of the expressed protein, but may impact on the transcription or stability of the mRNA for the VDR. Despite extensive clinical studies, it remains unclear whether these polymorphisms are consistently associated with changes in calcium metabolism or bone mass.

Calcium Metabolism

$1,25(OH)_2D$ is one of the classic calcitropic hormones. In humans and animals lacking the vitamin D receptor, the only abnormality observed at birth is in hair follicle development (Bouillon *et al.*, 2008). Subsequently, however, hypocalcemia and the development of rickets are observed. The abnormalities in bone development can be prevented by restoration of normal serum calcium concentration, suggesting that maintenance of normocalcemia and maintenance of normophosphatemia are the principal biological roles of the vitamin D metabolites. It is likely that this is achieved primarily by increasing the absorption of calcium in the small intestine (Carmeliet *et al.*, 2015). Vitamin D receptors are found throughout the small intestine but are most abundant in the duodenum. Administration of calcitriol to animals or humans leads to increases in intestinal calcium absorption, though the precise mechanism by which this occurs is not fully understood. $1,25(OH)_2D$ regulates the production of the cell membrane protein TRPV6 (a calcium-binding protein within the intestinal epithelial cell), calbindin D8k, and the activity of an ATP-dependent calcium pump at the basolateral membrane. It was thought that these proteins together facilitated the transport of calcium into, through and out of the intestinal epithelial cells, but there appears to be redundancy in the system since deletion of either *Trpv6* or *CaBP-9k* alone permits normal basal calcium absorption, though the double knockout does not. Calcium is also absorbed by a paracellular pathway present throughout the length of the intestine, in which transmembrane proteins known as claudins facilitate calcium transport across the tight junctions. Claudin expression in the distal intestine is regulated by $1,25(OH)_2D$. 1,25(OH)2D also stimulates intestinal phosphate absorption, through induction of Na^+-dependent phosphate co-transporters in enterocytes.

The direct effects of $1,25(OH)_2D$ on bone act in concert with those already described in the intestine, to maintain or increase serum calcium concentrations (Reid and Bolland, 2014). $1,25(OH)_2D$ acts on osteoblasts and their precursors, causing the production of RANK-L, which binds to pre-osteoclasts to stimulate their development into osteoclasts. This leads to an increase in osteoclastic bone resorption. However, other studies in vitro suggest an anabolic effect of $1,25(OH)_2D$ in osteoblasts with increased alkaline phosphatase activity, increased production of osteopontin and osteocalcin, and increased LRP5 expression, but the significance of this in human physiology is unclear. Although it has been suggested that $1,25(OH)_2D$ may directly influence skeletal mineralization, the majority of evidence suggests that this occurs indirectly, as a result of vitamin D effects on serum calcium and phosphate concentrations. A further important action in bone is on the osteocyte, where $1,25(OH)_2D$ stimulates production of fibroblast growth factor-23, which acts in the kidney to reduce phosphate reabsorption and to reduce 1α-hydroxylase activity. $1,25(OH)_2D$ also acts directly on the kidney, regulating calcium reabsorption in the distal nephron via a transcellular pathway similar to that in the proximal intestine. In addition, $1,25(OH)_2D$ induces its own catabolism by the 24-hydroxylase in the kidney.

The parathyroid glands are regulated by $1,25(OH)_2D$, where its binding to the vitamin D receptor directly decreases expression of the PTH gene. This genomic effect is reinforced by the action of $1,25(OH)_2D$ to increase serum calcium and thus diminish PTH secretion. The effects of vitamin D metabolites on PTH secretion are particularly important in the management of the secondary hyperparathyroidism of chronic renal failure. They may also be important in the prevention and treatment of primary hyperparathyroidism, since this condition may be exacerbated by the low levels of 25(OH)D with which it is frequently associated.

Other Tissues

$1,25(OH)_2D$ receptors are expressed in a wide variety of tissues other than those classically involved in mineral and bone homeostasis. In keratinocytes and in some white blood cells or their precursors, $1,25(OH)_2D$ has anti-proliferative and pro-differentiation effects. Thus, in psoriasis, it appears that the hyperproliferative state of skin cells can be controlled with the use of vitamin D analogues. There is also experimental evidence that some leukemic cell lines show similar responses to vitamin D metabolites. Despite the existence of promising preliminary results in these areas for a number of years, the vitamin D metabolites do not have an established therapeutic role in any of these malignant conditions. Vitamin D metabolites may also have direct actions on muscle cells, on adipocytes, in immune regulation, and on endocrine tissues, such as the pancreatic beta cell but, again, clear evidence of clinical benefit is lacking.

Assessment of Vitamin D Status

25(OH)D is the principal circulating vitamin D metabolite and it is the entity that should be assessed when determining an individual's vitamin D status. Because ingested or endogenously produced calciferols are converted to 25(OH)D with very little regulation, serum levels of this metabolite accurately reflect both excess and deficiency states. As noted above, 25(OH)D circulates bound to vitamin D-binding protein, so any condition associated with hypoproteinemia or inflammation may produce falsely

depressed levels of 25(OH)D. Caution is required in interpreting measurements of vitamin D metabolites in these situations, because it is uncommon to measure vitamin D-binding protein in routine clinical practice.

When assessing vitamin D status, it is important to consider whether the "normal" range—which varies with latitude—can be regarded as optimal. This has been addressed by Malabanan et al. (1998), who demonstrated that vitamin D supplementation suppressed parathyroid hormone levels only in subjects whose baseline serum 25(OH)D was <50 nmol/L. This suggests that 50 nmol/L is an appropriate target concentration for serum 25(OH)D.

Measurement of serum $1,25(OH)_2D$ is also available, though its value in clinical medicine is small. It is sometimes helpful in elucidating the cause of hypercalcemia, being high when hypercalcemia is a direct consequence of overproduction of $1,25(OH)_2D$, as in some granulomatous conditions and lymphomas. The widespread impression that $1,25(OH)_2D$ is the only biologically active vitamin D metabolite frequently leads to the inappropriate use of vitamin D assays and supplements. This belief results in the expectation that levels of $1,25(OH)_2D$ are all that will influence calcium metabolism, whereas this is clearly not the case. As vitamin D deficiency develops, serum 25(OH)D declines. In response to this decline, secondary hyperparathyroidism develops and with it there are increases in serum $1,25(OH)_2D$. Thus, the paradoxical situation can develop, in which a patient with clinical and histological evidence of osteomalacia has a serum 1,25(OH)D level that is either normal or supranormal.

In summary, measurement of serum 25(OH)D suffices for the detection of vitamin D deficiency or vitamin D intoxication, and measurement of $1,25(OH)_2D$ is usually indicated only in the diagnosis of difficult cases of hypercalcemia. Because vitamin D assays are expensive and of variable reliability, many clinicians provide low-dose supplements based on clinical risk factors for deficiency rather than assay results.

Therapeutic Use of Vitamin D and Its Metabolites

Vitamin D Deficiency and Osteoporosis

Vitamin D deficiency is common in the elderly, particularly those who are no longer fully independent and therefore less exposed to sunlight. The problem is often greater at higher latitudes, though it can also occur in very hot climates where the sun is often avoided because of the heat. Vitamin D deficiency leads to secondary hyperparathyroidism and a resulting increase in bone loss (Reid and Bolland, 2014).

Physiological supplements of calciferol (e.g., 400–800 IU/day) reduce parathyroid hormone concentrations (Bacon *et al.*, 2009) and lead to increases in bone density in those with 25(OH)D levels below 30–50 nmol/L (Reid *et al.*, 2017). Similar changes in biochemical end-points can be achieved with regular sunlight exposure for 15–30 min daily (Reid *et al.*, 1986). However, meta-analyses of untargeted use of vitamin D alone show no benefit on either bone density (Reid *et al.*, 2014) or fractures (**Fig. 3**) (Bolland *et al.*, 2014).

In a study which co-administered calcium with calciferol to frail elderly subjects, Chapuy et al. demonstrated a reduction of more than 25% in non-vertebral and hip fracture rates in a cohort of 3000 elderly women studied over a period of 3 years (Chapuy *et al.*, 1992). It should be noted that serum 25(OH)D levels in the placebo group during the study were about 14 nmol/L (after correction for errors in assay calibration) so many trial participants probably had osteomalacia. Setting this study aside, trials of calcium plus vitamin D are comparable to those of calcium alone in their effects on bone density and fracture (Tang *et al.*, 2007). Thus, supplementation is important for those at risk of severe deficiency and osteomalacia, but seems to produce no benefit in those who are already vitamin D replete, as defined above.

The dose–response relationship between calciferol intake and serum 25(OH)D levels is relatively flat up to intakes of several thousand international units per day (Gallagher *et al.*, 2012). Thus, this intervention is safe, and doses of 400–1200 IU/day are routinely used. Calciferol is stored in adipose tissue and has a half-life of many weeks. Therefore, it can be administered in larger doses less frequently. Single doses of up to 500,000 IU have been used to correct severe deficiency, and monthly oral supplements of 50,000 IU maintain 25(OH)D levels of $\sim$70 nmol/L (Bacon *et al.*, 2009). There are anecdotal reports of wide variability in the bioavailability of different preparations of calciferol, and dietary vitamin D intakes also vary widely from country to country. Therefore, each region needs to determine what regimen of replacement is safe and effective in that environment.

The use of vitamin D as a physiological supplement is fundamentally different from the use of high doses of calciferol or 1α-hydroxylated vitamin D metabolites (e.g., alfacalcidol, calcitriol) to pharmacologically manipulate intestinal calcium absorption. Both of these strategies bypass the normal homeostatic controls of vitamin D metabolism and therefore carry a significant risk of hypercalcemia and hypercalciuria. The use of pharmacological doses of calciferol has not been demonstrated to confer any beneficial effects on bone density. Trials of the use of alfacalcidol or calcitriol in the prevention and treatment of osteoporosis have shown mixed results, including both significant increases and significant decreases in bone density and fracture rates. This variability in results may be attributable to a different balance of the potentially beneficial effects on intestinal calcium absorption versus the potentially damaging effects on osteoclast recruitment in the different populations studied. As a result, alfacalcidol and calcitriol are not generally regarded as appropriate therapies for osteoporosis. A newer more potent analogue (Matsumoto *et al.*, 2011) has shown greater anti-fracture efficacy than alfacalcidol in a Japanese study, and is used for osteoporosis in that country.

Fig. 3 Random effects meta-analyses of the effect of vitamin D on total fracture and hip fracture. The meta-analytic relative risks were 0.97 (0.88–1.08) for any fracture and 1.11 (0.97–1.27) for hip fracture. From Bolland, M. J., Grey, A., Gamble, G.D., and Reid, I. R. (2014). The effect of vitamin D supplementation on skeletal, vascular, or cancer outcomes: a trial sequential meta-analysis. *Lancet Diabetes & Endocrinology* 2(4): 307–320. Used with permission.

In conclusion, suboptimal vitamin D status is very common in the elderly, mainly because of reduced sunlight exposure. The provision of a daily intake of 400–800 IU is a straightforward, safe, and inexpensive means of prevention and appears to produce substantial reductions in fracture rates in deficient populations.

Other Conditions

Failure of the 1α-hydroxylation of 25(OH)D is probably the single most important contributor to the hypocalcemia of renal failure and the resulting development of renal bone disease. Thus, the availability of $1,25(OH)_2D$ (calcitriol) and 1α-hydroxyvitamin D (alfacalcidol) as pharmaceuticals has revolutionized the management of calcium metabolism in renal failure. The development of hypercalcemia can be dose-limiting when using vitamin D metabolites to reverse secondary hyperparathyroidism in renal failure. This has led to the development of synthetic vitamin D analogues that suppress parathyroid hormone secretion but have less effect on serum calcium.

The 1α-hydroxyvitamin D metabolites have also revolutionized the management of other conditions associated with either hypocalcemia (e.g., hypoparathyroidism) or hypophosphatemia (e.g., X-linked-hypophosphatemia, oncogenic osteomalacia). Previously, these conditions were managed with very large doses of calciferol, which can result in sustained hypercalcemia because of calciferol's long half-life.

As noted above, the anti-proliferative actions of the vitamin D metabolites are being used in the management of psoriasis. There is also epidemiological evidence suggesting that high vitamin D levels are associated with a lower incidence of cardiovascular disease, infection, obesity and diabetes (Reid and Bolland, 2014). This work is potentially subject to a number of biases (e.g., people who are more physically active and therefore at lower risk of these conditions, spend more time outdoors and therefore

have better vitamin D status). Intervention studies are being carried out to assess the value of vitamin D supplementation in a number of conditions, but results to-date have not been encouraging.

Safety of Vitamin D and Its Metabolites

The use of replacement doses of calciferol is a very safe intervention, as would be expected since the intention is to restore circulating levels of 25(OH)D to the levels that are present in the healthy population. Thus, in the study by Chapuy in which more than 1600 women were treated with calciferol, the only individual who developed hypercalcemia was subsequently found to have primary hyperparathyroidism. A similar zero-incidence of significant hypercalcemia has been reported by other investigators using low-dose regimens of calciferol administration.

In contrast, with the use of pharmacological doses of calciferol, there are case reports of severe hypercalcemia, often of long duration and sometimes associated with renal failure. In trials, bolus dosing with 500,000 IU annually has been associated with increases in rates of fractures and falls (Sanders *et al.*, 2010), and daily dosing of $\geq$4000 IU has been associated with more frequent falls (Smith *et al.*, 2017). Calcitriol and alfacalcidol frequently cause hypercalcemia and hypercalciuria, but their short half-lives result in this being readily corrected by dose adjustment. However, close monitoring is necessary when these drugs are being introduced or their doses increased. Changes in calcium intake can also affect serum calcium concentrations in patients using these compounds.

The hypercalcemia of vitamin D intoxication was formerly attributed to increased intestinal calcium absorption, but bone resorption is also increased and bisphosphonates are effective in its treatment. The long duration of hypercalcemia associated with calciferol (Rizzoli *et al.*, 1994) means that this compound is substantially less safe at high doses than its more active and shorter half-life metabolites, such as alfacalcidol and calcitriol.

Nutrition and Bone

Peter Burckhardt, Hirslanden Clinic, Lausanne, Switzerland

Glossary

BMD and BMC Bone mineral density and bone mineral content internationally used parameters of bone mass and/or bone density.

Effect of Nutrition on Bone Health: General Considerations

The influence of nutrition on bone health is relatively weak, in addition to the negative effect of severe deficiencies. However, it is still significant, and it has the advantage that it can be modified, and actively used as an adjunctive prophylactic or therapeutic measure, for prolonged periods and even lifelong. For this reason, it deserves major attention. Stronger factors such as genetics or concomitant diseases and their pharmacological treatments cannot be changed in order to develop stronger bones.

The knowledge about the influence of nutrition on bone health stems from research. It is difficult to capture, because research is applied to all ages (embryos, babies, children, adolescents, adults, the elderly), to several nutritional constituents (calcium, proteins, vitamins), and to many nutrients (dairy products, meat, vegetable, fruits, and in particular milk, yogurt, onions, kale, blueberries, soya, mineral water, etc.). Research is performed with cross-sectional studies, and with longitudinal studies, where BMD could be used as an outcome (and in very large surveys, also fracture incidence), or with intervention trials, usually short-term, with markers of bone metabolism as an outcome. Some intervention trials produced results in BMD, but usually only when applied to states of nutritional deficiency at the baseline. In this context it has to be remembered that research results from animals cannot be applied directly to humans.

From all this heterogeneous data, the major conclusions are presented here. Unfortunately, single items of data of doubtful quality are often brought from this large puzzle of knowledge to the lay press and to dieticians, and directly applied to the public and to patients. However, the fact-based physicians and scientists base their knowledge and recommendations exclusively on research data, even in such a popular domain as nutrition.

Even when there is a correlation between bone health and a given nutrient, intakes beyond the physiological needs do not produce a benefit. The nutrient can even have a negative impact by displacing other useful nutrients within the frame of the required caloric intake. On the other hand, any nutritional deficiency results in low bone mass or low bone density, in growth delay during childhood, and in enhanced bone loss in adulthood. Nutritional interventions in deficiency states usually provide positive bone effects, which are difficult to reproduce in states of sufficiency.

There are ethnic differences in dietary needs for optimal bone metabolism and bone acquisition; these are not discussed in detail here

Dairy Products

General Considerations

Dairy products, such as milk, yogurt, curd, and cheese, are the best and the most important (but not the only) sources of dietary calcium, at least for Western nutrition. Among these, milk is the most studied dairy food. About half of nutritional calcium stems from dairy food. Higher figures were found in more superficial investigations, where minor nutrients, which all contain some calcium, were not included in the analysis. In Asia, dairy products are consumed less and contribute only 20%–23% of the total calcium intake. Some diets with no dairy products, which are meant to lower cholesterol, increase the risk of osteoporosis. A vegan diet is generally poor in calcium, despite the relatively high amount of calcium in certain vegetables and nuts.

The recommended calcium intake is 800–1000 mg calcium per day. A Western diet with no dairy products can deliver 250–300 mg calcium or more per day, when special attention is given to mineral water, calcium-rich vegetables, nuts, and seeds in sufficient amounts. On average, humans absorb about 30% of the calcium present in food.

As noted, the minimal requirement is set at 800 mg per day, and 1000 mg would not be excessive. In one large survey, milk intake was identified as being associated with mortality. This survey showed that ≥ 3 glasses of milk per day (≥ 600 mL) was associated with higher mortality in adults and with higher fracture incidence in women (Michaëlsson *et al.*, 2014). However, a meta-analysis of 29 prospective cohort studies on milk and mortality did not find such an association (Guo *et al.*, 2017), and several published comments contradict this survey.

Calcium deficiency disturbs growth and the maintenance of bone mass during adult life, and increases the risk of osteoporosis. It was recognized by 1985 that milk stimulates BMD by inhibiting bone turnover and resorption markers in postmenopausal women and in elderly men; this was reconfirmed later. Milk also increases IGF-1 (insulin-like growth factor 1) in elderly men.

 doi:10.1016/B978-0-12-801238-3.65206-6

Dairy products provide more than calcium supplements, for example, protein, phosphorus, magnesium, etc. In postmenopausal women, the supplementation of a diet with milk improved the nutritional quality of the diet to a greater extent than calcium alone. But compliance to supplements might be better than adherence to milk, and therefore lead to a higher calcium intake.

The fear of increasing the cholesterol intake with dairy products concerns only high-fat products, including soft cheeses, butter, and cream. The cholesterol content of a menu of milk, hard cheese, and yogurt providing 1000 mg of calcium has <90 mg cholesterol. This is several times below the recommended intake. Eventual negative cardiovascular effects are due to the content of saturated fatty acids.

Bioavailability of Dairy Calcium

Calcium from dairy products is highly bioavailable, and well absorbed (20%–30%), but shows individual differences. Its absorption is facilitated by lactose and certain caseino-phospho-peptides, formed during the digestion of milk caseins. Like calcium supplements, calcium from dairy products exerts its biological effects immediately after intake, for example, inhibition of parathyroid hormone (PTH) secretion. For lactase deficiency, see the next article.

Effect of Nutritional Calcium on BMD

The assessment of the bone effect of dietary calcium is difficult. The assessment of food intake cannot definitively confirm that it reflects precisely the intake of the tested days, months, or years, and certainly not of the total adult life. In addition, the measurement of the effect on bone is problematic because of confounding factors, including first of all physical activity (known of for many years), but also lower alcohol intake and higher energy intake, which go along with the consumption of milk, or milk consumption during teenage years, which influences the results observed later in life. In addition, women who consume dairy products are less likely to smoke. For these reasons, contradictory results can be found in the literature.

Calcium is especially important in children and adolescents. There are four times more favorable results than negative ones in studies of subjects younger than 30 years, while in older subjects there is no overall effect (Weinsier and Krumdieck, 2000). This means that dairy calcium intake is mostly effective during growth. There are undoubtedly also positive associations between the calcium intake and BMD in adults according to large cross-sectional and longitudinal surveys or follow-up studies over long periods. If one might question the positive bone effects of nutritional calcium, there is no doubt that low calcium intake has a negative effect.

Low intake of dairy products is very often attributed to lactase deficiency. Lactase deficiency is found in 80% of US blacks, and in 80%–100% of Asians. It is rare in US Caucasians (15%) and in northern Europe (10%). In any case, it is of minor importance. First, self-perceived milk intolerance leads to self-imposed reductions in milk consumption, increased bone turnover, and increased risk of fracture, independent of the presence or absence of lactase deficiency. Second, fermented dairy products, such as mature hard and medium hard cheeses, as well as yogurts, do not contain lactose, and can be consumed by those with lactase deficiency. For this reason, lactose genotype and phenotype did not influence BMD in a population with high milk consumption. Intolerance to milk is often misinterpreted as lactase deficiency. Milk allergy, on the other hand, leads to a low calcium intake and to lower BMD values.

In children

In the first 6 months of life, human milk provides adequate amounts of calcium and phosphorus. Later, supplemental minerals are consumed in food.

A low calcium intake has a negative effect on growth and bone development, and a low milk intake in childhood is associated with lower BMD and smaller bones. The intake of dietary calcium, with and without vitamin D, correlates significantly with spine and total body BMC (bone mineral content; this replaces BMD during growth), but only in children with low baseline intakes, according to a meta-analysis of 21 randomized controlled trials (Huncharek *et al.*, 2008). The effect on BMD was still measurable in adult life, but no effect on hip fracture incidence could be found. In another study, women with a high intake during childhood and adolescence had not only a higher bone mass in adulthood, but also a smaller risk of fracture. A review in 2011 revealed that increasing calcium and vitamin D intake in infants and young children above the basic physiological needs had no long-term benefit. This shows again that nutrition has to meet the requirements and to avoid deficiencies, but intake beyond these needs does not offer additional benefits.

The age of accelerated growth seems to be especially sensitive to adequate intakes. In adolescent girls, consumption of milk, but of no other calcium source, was tightly associated with BMC and BMD, mainly at the hip, as well as with serum IGF-1 and negatively with serum PTH. Regular milk intake during growth was also associated with higher BMD in adulthood and postmenopause, either because of a higher peak bone mass, or as a consequence of a lifelong adherence to dairy products. Milk intake during teenage years was also associated with greater BMD of the total body in young adulthood.

The main knowledge stems from cross-sectional and follow-up studies. There are some interventional trials with milk, milk powder, and dairy products in children and adolescents showing a positive effect on BMD. This is not evident in adults and the elderly (Weinsier and Krumdieck, 2000), probably because the concomitant intake of protein, phosphorus, and IGF is particularly

essential during growth; milk improves the nutritional quality of the diet more than a calcium supplement. Milk undoubtedly stimulates growth. One glass of milk added to the diet of adolescent girls increased the bone accrual by 3 g per year, and a milk supplement of 300 mg calcium increased BMD. The bone effect is particularly evident in populations with a low calcium intake such as Asians, where supplementing the diet of children with milk powder or with milk equivalent to 1300 mg calcium enhanced bone accretion.

These positive results were opposed by a review that concluded that there is no reason for promoting milk or dairy consumption in children and adolescents (Lanou *et al.*, 2005). However, on the other hand, a more recent analysis of the studies with dairy food demonstrated that most of the observational studies and all interventional trials—this is the crucial point—showed a positive association with BMD or BMC (Heaney, 2009). Nevertheless, the effect of 2 years of school milk intake disappeared after withdrawal, probably because the calcium intake dropped again to low values.

In adults

The studies searching for a bone effect of nutritional calcium provided contradictory results in adults, except in high-risk populations and in populations with a low calcium intake. Positive results should be mentioned first in young adult women on oral contraceptives, where nutritional calcium showed a dose-dependent effect against the decline of BMD and BMC, especially with 1000–1100 mg calcium. Then, in adolescent mothers, dietary calcium was positively associated with the total body calcium of the infants. Finally, in elderly individuals, several studies showed that dairy intake was linked to higher bone density. However, in early postmenopausal women, where the prevailing influence on bone is estrogen deficiency, calcium intake does not correlate with BMD.

In general, in the elderly population as well as in children, nutritional calcium is more effective than calcium supplements. Only a cross-sectional survey of elderly subjects in the USA (National Health and Nutrition Examination Survey, or NHANES; Anderson *et al.*, 2012) concluded that a high calcium intake is not beneficial to bone. However, the sensitivity of this survey was questioned, because it could not reproduce the negative effect of a low intake.

Although short intervention trials, using bone markers as outcome, showed positive effects on bone metabolism, many intervention trials with milk, milk powder, and dairy products in adults showed no effect. However, the literature also reports several positive results. In an intervention trial, dairy products decreased bone loss in premenopausal women. Calcium supplementation with dairy products was associated with a higher hip BMD in men, and a smaller bone loss in men and women. Positive effects could also be found in postmenopausal Caucasian women and in the elderly. Positive bone effects were especially evident in countries with a low baseline intake of calcium, such as China or Malaysia.

Effect of Nutritional Calcium on Fracture Risk

In 1988, the protective effect of dietary calcium on the hip fracture risk was suggested by a follow-up study in elderly subjects. No other nutrient showed this effect. Not only the actual intake but also the intake of milk in childhood decreased the risk of fracture in adult women. However, one of the largest follow-up studies in postmenopausal women, the Nurses' Health Study (Feskanich *et al.*, 2003), showed no such association.

Only in 2011 was the question systematically examined. A meta-analysis of follow-up studies showed the absence of a significant association between milk intake and hip fracture incidence in women. In men, each glass of milk per day was associated with a marginally significant lower risk (Bischoff-Ferrari *et al.*, 2011). Although no association between milk and yogurt consumption and hip fracture risk could be found in the Framingham cohort, a year later the same authors found that the hip fracture risk was decreased by 42%, although not significantly, in elderly men and women who consumed regularly milk (Sahni *et al.*, 2014).

The opposite was found in two large Swedish cohorts. Surprisingly, women had a significant 9% greater risk of hip fracture for every glass of milk consumed per day, whereas no association was observed in men (Michaëlsson *et al.*, 2014). This increase of the fracture risk was thought to be due to galactose, because fermented milk and yogurt (all low in galactose) were linked to a significant decrease of the hip fracture risk by 11% per daily serving in women, as could be expected. In addition, cheese, which contains almost no galactose, was also associated with a decrease of the hip fracture risk by 14%. This discrepancy with milk remains mainly unexplained, and shows how difficult it is to assess dietary intakes over a long period. In a recent major study in Caucasian men aged 50 and older, and women past menopause, each additional serving of milk per day was associated with a significant 8% lower risk of hip fracture, as could be expected again. Here milk intake was assessed as a long-term cumulative average, and the intake was updated every 4 years, while in other studies it was assessed only once or twice, which cannot be guaranteed to reflect long-term habits.

While the antifracture effect of dairy products is debated, there is no doubt that low calcium intake increases the hip fracture risk (Warensjö *et al.*, 2011) and that a calcium intake above the maximal needs (over ca. 1500 mg/day) is not particularly protective, and is eventually even associated with higher cardiovascular risk (Michaëlsson *et al.*, 2013). One large European survey associated milk consumption with higher fracture risk and higher mortality (Michaëlsson *et al.*, 2014). But this could not be confirmed, and was contradicted by a meta-analysis of numerous studies (Soedamah-Muthu *et al.*, 2011) and by many published comments. There are no intervention trials with dairy products and fracture incidence as an outcome. This would need very large populations and long observation periods. Intervention trials with calcium supplements provided contradictory results. Only when combined with vitamin D could a small reduction in fracture risk be obtained.

Fortified Milk

Milk is an excellent carrier of supplemental calcium. Fortified with calcium and given to postmenopausal women over the course of 2 years, it delayed bone loss and decreased resorption markers. Calcium fortification of milk can optimize the calcium intake in infants, when human milk does not meet the requirements. In premature infants, fortification of mother's milk improved bone mineralization. Calcium-fortified soy milk is a valuable source of calcium, but is less effective than cow's milk. Calcium-enriched orange juice had less effect on infants than dairy food. Ice cream fortified with calcium is a convenient vector of alimentary calcium, since it lowered bone resorption.

The additional fortification of food with vitamin D, tested in several studies, provided essential results due to vitamin D. This vitamin is not discussed here, since it is not a nutrient.

Cheese and Yogurt

Cheese and yogurt have been tested specifically. The most relevant study is the 12-year follow-up Framingham Offspring study, which revealed that the intake of fluid dairy and milk was positively associated with BMD of the hip, but not of the spine, and that yogurt intake was positively associated with trochanter-BMD, while cheese intake was not associated with BMD. Fracture data were only suggestive for milk and yogurt intakes.

Some cheeses that are rich in sodium or in fat, as well as cream or ice cream, may even have a negative effect on bone (Weinsier and Krumdieck, 2000).

Yogurt: A small intervention study in postmenopausal women with a low dietary calcium intake of <600 mg per day showed that three servings of yogurt lowered N-telopeptides, a marker of bone resorption, to 22% lower values than the control snack did (Heaney *et al.*, 2002). This is mainly a calcium effect. Calcium from yogurt has a high bioavailability. In addition, yogurt contains proteins and phosphorus, which are also important for bone. Yogurt can be consumed by those with lactose intolerance.

In the large observational Framingham study mentioned above, participants consuming >4 servings of yogurt per week had a higher trochanteric BMD, while the association with femoral neck BMD was weak (P: 0.09) (Sahni *et al.*, 2013).

The additional effect of the probiotics in yogurt, as the promotion of calcium absorption, has only been documented in animal studies.

Cheese: Calcium in cheese is as well absorbed as calcium in yogurt, despite the absence of lactose which promotes the absorption of milk calcium. This concerns low-fat hard cheeses. They are rich in calcium, but usually also rich in sodium. When consumed regularly, these cheeses increase the sodium intake by several grams, which has to be taken into account. In prepubertal girls, cheese had a stronger effect on bone than calcium tablets with vitamin D, and appeared to be more beneficial for cortical bone mass accrual than supplements of calcium with or without vitamin D.

Fruits and Vegetables

When dairy intake is low, as for example, in Asian countries, calcium content in plants becomes crucial. It is difficult to match the requirements for calcium intake without dairy products in the Western-type diet. By including dairy products, lacto-vegetarians, but not vegans, are able to meet the recommended amounts of calcium. Vegetarianism is not a risk factor for osteoporotic fracture (Lanham-New, 2009). This is different for vegans. The vegan diet is, on average, low in protein and calcium, and increases the risk of osteoporosis. This negative effect on bone is not more important because of the alkalizing effect of fruits and vegetables, which protects bone (Burckhardt, 2016; Weaver, 2009). In several studies, a low acid load of the diet went with a higher BMD, and a low intake of fruits and vegetables was associated with lower BMD and vice versa (New *et al.*, 2004). The positive effect of fruits and vegetables is also due to the high potassium intake, which lowers calcium excretion. In general, a healthy diet which contains a lot of fruits and vegetables was associated with higher BMD (Hardcastle *et al.*, 2011). Alkalizing food promotes bone formation and inhibits bone resorption. The strongest inhibition of bone resorption and stimulation of BMD has been found to be caused by tomatoes, berries, salad, and green vegetables. Blueberries and plums contain anthocyanins, which inhibit bone resorption.

The calcium content of a vegetable does not indicate its nutritional value as a source of calcium. Some substances in vegetables decrease calcium absorption, such as oxalic acid (spinach, collard greens, sweet potatoes, rhubarb, beans) or phytic acid (fiber-containing whole-grain products and wheat bran, beans, seeds, nuts, and soy isolates). This explains, for example, the high availability of calcium in broccoli and kale (40.9%, higher than milk at 32.1%) which is low in oxalate, and the low availability of calcium in spinach (only 5.1%), which is rich in oxalate. Other substances enhance calcium absorption, such as lactose and certain caseino-phospho-peptides formed during the digestion of caseins from milk. Bioavailability is crucial, not the calcium content.

Nuts and Grain Products

Nuts are a natural source of dietary calcium, but they are usually consumed in small amounts. Sesame can be recommended for its exceptionally high calcium content (about 800 mg/100 g). One spoonful of sesame kernels provides 90–135 g of calcium. Some oriental food and sweets are rich in sesame.

Wholegrain products, such as ryebread, contain significant amounts of calcium. When consumed regularly, they can contribute significantly to the total calcium intake. However, bakery products made with wheat flour have little calcium. Bran interferes with calcium absorption; leavening improves it.

Tortillas are the second most important source of calcium among Mexican Americans.

Soy and Soy Products

Soy and some soy products are significant sources of protein ($\pm$ 38 g 100 g^{-1}) and calcium (almost 300 mg calcium 100 g^{-1}), although they contain less calcium than dairy products. Their content of oxalate and phytate is variable, and accordingly so is the bioavailability of their calcium. Similar to meat, soy protein contains the essential amino acids, which are lacking in other vegetal protein sources. Soy milk is often preferred to cow's milk because of its low-fat content. But its calcium content is also low. When fortified with calcium, soy milk becomes equivalent to cow's milk in terms of bioavailability of calcium. The intake of fortified soy milk is associated with less osteoporosis, and is comparable to the effect of dairy products. Tofu, a popular soy product, contains about 185 mg calcium 100^{-1} mg or several times more, depending on the use of calcium sulfate for its coagulation. The great variety of soy or tofu products, all different in their content of calcium and oxalate, excludes general statements.

Soy and soy products have a "bone sparing" effect because soy protein is not acidifying, contrary to meat. The pretended positive bone effect of their phytoestrogens, resp. isoflavones, could not be confirmed in several meta-analyses (Lagari and Levis, 2013).

Meat and Proteins

Bone health requires a sufficient protein intake, which is often lacking in populations that are advanced in age and/or malnourished. Protein directly promotes bone anabolism, stimulates IGF-1, and increases calcium absorption. The latter compensates for the increased urinary excretion of calcium.

Meat is the most important (but not the only) source of protein (ca. 27.5 g 100 g^{-1}) after dairy products (hard cheese ca. 28 g 100 g^{-1}). It contains the essential amino acids, such as soy, which are partially missing in vegetable proteins. The frequently formulated recommendation of 0.8 g protein kg^{-1} body weight (BW) per day is too low for an anabolic bone effect. With age, the caloric needs decrease, but the needs of protein do not. Therefore, protein intake should increase percentage-wise with age. However, low protein intake is frequent in the elderly. This increases hip fracture incidence.

Protein intake is correlated with BMD, as shown by several studies (Langsetmo *et al.*, 2015). There is some relationship with hip fracture. A meta-analysis of 2009 was not conclusive concerning the antifracture risk (Darling *et al.*, 2009). However, more recent studies were more positive (Fung *et al.*, 2017). A protein intake above the usual recommendations decreased the hip fracture risk, especially when the caloric intake was also increased. In older men, protein intake was associated with fewer hip fractures, but not with fewer clinical spine fractures.

The bone effect of protein is lacking when calcium intake is low, and is increased by calcium supplementation (Dawson-Hughes and Harris, 2002).

Meat is acidifying, which has a negative influence on bone (New *et al.*, 2004), but its positive bone effect is maintained if the overall nutrition contains enough alkalizing nutrients, such as fruits and vegetables. Vegetal proteins seem to have a stronger bone effect than meat, perhaps because of their low acid load, but they can miss essential amino acids. But in general, the effect of plant protein is questioned.

In children, a high protein intake increased bone modeling in a longitudinal study. In children with an intake of 1.5 g protein kg BW^{-1} per day, BMC and cortical bone surfaces were higher than in children consuming 1.2 g protein kg BW^{-1} per day. Protein supplements given to elderly patients with hip fractures diminished their bone loss.

Mineral Water

Calcium-rich mineral water can contain up to 500 mg calcium l^{-1}, especially some European types. Water's calcium is as well absorbed as calcium from milk. It lowers PTH and bone resorption markers within 1 h. The effects of calcium-rich mineral water on bone, including the improvement of BMD or the lowering of its decrease, were also observed in long-term studies, especially in women with a low calcium intake.Mineral waters can provide an alkali load, which is beneficial for bone. The rare mineral waters that are rich in both bicarbonate and calcium inhibit bone resorption even in calcium sufficiency, while calcium-rich waters with low bicarbonate show no effect.

Regular consumption of these rare waters with a very high fluoride content resulted in an elevated BMD, but this was mainly a Fluor effect and less a consequence of their alkalinity. Sulfate probably has no effect on urinary calcium excretion in humans.

Vitamins

Vitamin D is not a nutrient. Nutrition is a negligible source of vitamin D, since the skin delivers sufficient amounts if it receives enough ultraviolet irradiation. In northern Europe, nutrition delivers about 100 IU, far below the daily need of 800 IU. But fatty fishes are rich in vitamin D.

Vitamin A, resp. retinol accelerates bone catabolism and increases fracture risk, when taken in high amounts (Michaëlsson *et al.*, 2003). Vitamin A deficiency can also have a negative influence on bone, but few instances of this are known.

Vitamin K is a cofactor of carboxylase and as a result stimulates the solidification of the bone matrix (carboxylation of osteocalcin). For this reason, vitamin K deficiency is associated with decreased bone density and increased hip fracture risk. Vitamin K is mostly taken in with salads and green vegetables. Small amounts are present in cheeses and fermented soy beans. The daily need for an optimal bone effect is 109 µg vitamin K (Feskanich *et al.*, 1999). This exceeds the amount needed for optimal blood coagulation. The need for vitamin K is covered by the regular intake of salad and vegetables. Pharmacological studies with high doses of vitamin K had a positive effect on bone and decreased the fracture risk. However, these amounts cannot be obtained with nutrition.

Vitamin B12 and folic acid: Deficiency in vitamin B12 is associated with low BMD (Clemens, 2014), eventually because it decreases the synthesis of IGF. The need for vitamin B12 is usually covered by the intake of dairy products, meat, and fish. Folic acid is consumed with legumes, green vegetables, and wholegrain products. Deficiency in folic acid increases the level of homocysteinic acid, which is associated with lower bone density and higher fracture risk, since it leads to a stimulation of the formation of osteoclasts and disturbs bone formation.

Vitamin C: Vitamin C, which is found in many fruits and vegetables, has a positive influence on bone. However, in the published studies, this effect was not well separated from that of confounding factors. Nevertheless, in a longitudinal study over 4 years, vitamin C intake could be associated with a decrease of bone loss (Sahni *et al.*, 2008).

Food Patterns

Nutritional research succeeded in identifying many food items with a significant bone effect. But human nutrition is a mixture of a great number of nutrients with various bone effects. In general, nutrition rich in calcium has a higher health value than a nutrition poor in calcium, because of its general composition. To capture the effect of nutrition overall, recent studies linked nutritional patterns or habits to bone health, essentially in large cross-sectional surveys with hip fractures as an outcome. These surveys showed that adherence to the Mediterranean diet is associated with a decreased risk of hip fracture (Benetou *et al.*, 2013; Byberg *et al.*, 2016).

A generally healthy diet, as evaluated by various scores, is associated not only with fewer cardiovascular diseases, but also with fewer hip fractures, as well as a higher BMD (Hardcastle *et al.*, 2011).

Fortified Food

Many nutrients are fortified with vitamins and microelements. In terms of bone effects, fortification is usually achieved with calcium or vitamin D, and often with both. In order to strengthen the bone without negative side effects, the fortified food has to be consumed regularly, and the calcium content must be harmless in the case of high intake. The calcium used for fortification is the same as that used for supplements. It is served in the form of cow's milk, soy milk, orange juice, soft drinks, flour bread, cereals, snacks, rice and rice products, etc. Bioavailability varies with the calcium salt used and with the food itself, but only slightly. An especially high bioavailability was found for calcium sulfate in white bread. Calcium in orange juice is as well absorbed as it is from milk or supplements, and calcium carbonate in fortified bread is absorbed even more efficiently than calcium from milk. Fortification of nutrients that children like does not guarantee long-term intake.

QCT	Quantitative computed tomography

Introduction

Peak bone mass is the maximal amount of bone accrued within bone during the childhood and especially the during adolescence growth phase plus the consolidation that continues beyond the attainment of final height (**Fig. 1**). Almost half of the adult bone mineral mass is accrued by the skeleton in the 3–4 years following the onset of puberty, making adolescence the most critical period of skeletal bone mass development (Theintz *et al.*, 1992). At peak height velocity, adolescents have reached 90% of their adult stature, but only 57% of their adult bone mass (Bailey *et al.*, 1999), whereas by the end of the pubertal growth, more than 90% of the adult bone mass is formed (McCormack *et al.*, 2017; Henry *et al.*, 2004). The age of attainment of peak bone mass is influenced by the tempo of pubertal maturation, as reflected by a later peak in males compared to females and a later obtainment in late maturing males in comparison with early maturers (Chevalley *et al.*, 2009b; Darelid *et al.*, 2012).

It is generally assumed that optimizing bone mass accrual in childhood and adolescence is beneficial in the prevention of osteoporosis later in life, since it may compensate for aging-associated bone loss, reducing the risk bone fragility associated with adult onset osteoporosis (Bradney *et al.*, 2000). Furthermore, maximizing bone mass during the growth period might also prevent fractures during the building of the skeleton: children and adolescents with distal forearm fractures have deficits in cortical bone and microarchitecture at the distal radius, but also in bone mass at other bone sites (Chevalley *et al.*, 2011; Määttä *et al.*, 2015).

Mechanisms

Bone mass accrual during childhood and adolescence is mainly the result of an increasing bone size, although also significant changes in bone macro- and microstructure occur, especially during adolescence (Henry *et al.*, 2004). Bone mass as well as bone structure contribute to an increasing bone strength during childhood and adolescence in order to adapt to changing mechanical loads and increased muscle development.

Growth in bone length occurs via endochondral ossification at the growth plate, whereas changes in bone width result from periosteal expansion. The superior and inferior endplate contribute equally to the vertebral bone growth, whereas the growth plate

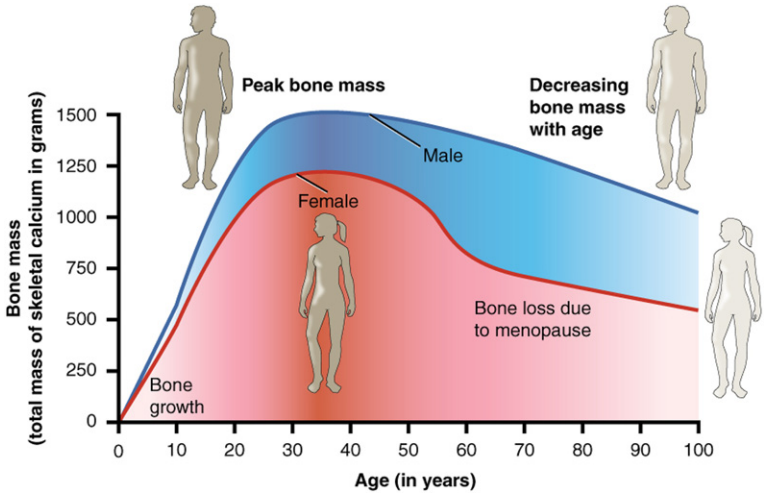

Fig. 1 Evolution of bone mass during life. From Wikimedia Commons, the free media repository.

at the distal radius contributes to 75% of the longitudinal growth of the radius, while about 45% of the longitudinal growth of the tibia is provided by the distal physe. Longitudinal and radial bone expansion occur in synchrony to maintain the bone strength in the growing skeleton (Xu *et al.*, 2009).

The greatest changes in bone mass occur at the cortical bone compartment, whereas the contribution of the trabecular compartment, particular in girls, in bone mass accrual is more static. The increase in the amount of trabecular bone during puberty is underpinned by thickening of trabeculae, with little to no change in number or separation of the trabecula (Gabel *et al.*, 2017). The increase in cortical bone is to a great extend reflected by an increase in cortical bone area during puberty (**Fig. 2**). Cortical bone mass accumulation at the long bones is not only driven by periosteal bone apposition, but also by endosteal bone resorption and formation. In the early stages of puberty both the periosteal and endocortical diameters of the bone increase significantly, whereas in late puberty there is a contraction of the endocortical diameter, increasing the cortical thickness. Periosteal apposition assembles most of the cortical mass in males, while endocortical apposition assembles about 25% of the cortical thickness in non-weight bearing bones (Seeman, 2001). While periosteal apposition slows down in later puberty, endocortical bone formation ensues continuing to increase the cortical thickness (Wang *et al.*, 2006; Ohlsson *et al.*, 2011).

Bone modeling, the process of adapting bone structure to loading by changing bone size and shape, as well as remodeling, the process of replacing old bone by a coupled action of osteoclasts and osteoblasts, are responsible for the accrual of bone mass and the changes in bone structure during childhood and adolescence (Slemenda *et al.*, 1997). Bone remodeling during childhood is characterized by a positive coupling between bone formation and bone resorption, while once final adult height is reached, the neutral coupling results in a stationary state of bone mass. In children about 3% more new bone is deposited than removed in the bone forming units. Remodeling is influenced by mechanical (muscle activity, weight bearing), systemic (calcium delivery, hormonal activities of IGF1 and sex steroids) as well as local (bone cell to bone cell and muscle and adipose tissue to bone tissue) interactions.

A high sensitivity of bone to loading, an increased intestinal calcium absorption, as well as an increased renal absorption of phosphate and an increased calcitriol production, probably related to the increased IGF-1 production during puberty, are some of the factors explaining the enormous capacity of adolescents to increase their bone mineral content in a short period of several years (Abrams *et al.*, 1995).

Changes in Bone Mass

The current understanding of bone mass acquisition during childhood and adolescence is largely based on the results of large longitudinal DXA studies (Bailey *et al.*, 1999; Zemel *et al.*, 2011).

Bone mass accumulation occurs heterogeneously in the skeleton during the skeletal growth period (Henry *et al.*, 2004). The peak bone mass gain is acquired earlier at the level of the femur neck than at the lumbar spine. The peak gain occurs last at the distal radius. The peak in bone mass accumulation during puberty lags by 0.7–1 year behind the peak acquisition of standing height, explaining in part the increased bone fracture rate around this period (McKay *et al.*, 1998).

Until puberty, no important differences in bone accrual exists between boys and girls, as observed by their similar increases in whole body and lumbar spine BMC (De Schepper *et al.*, 1991). From the onset of puberty, gender dysmorphisms in skeletal development occur, to a great extend related to the different actions of oestradiol and testosterone on bone mineral accrual and more specifically on periosteal bone apposition (Riis *et al.*, 1985). Girls have an earlier increase in bone mass accretion (12.5 vs. 14.2 years), but boys accumulate finally more bone than girls at all skeletal sites (Mølgaard *et al.*, 1999).

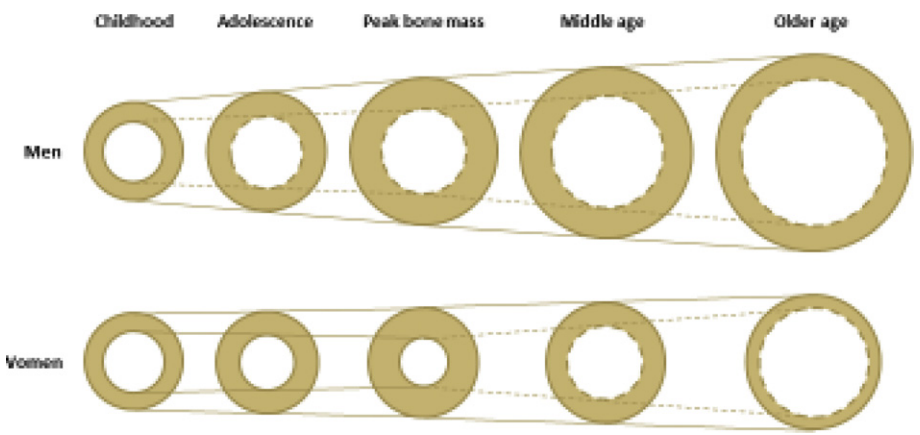

Fig. 2 Changes in cross sectional bone diameters during life.

Changes in Bone Mineral Density, Bone Structure, Bone Robustness, and Bone Strength

By the use of pQCT at the radius or tibial shaft, bone macrostructure, such as total bone cross sectional area, cortical cross sectional bone area, and the cortical thickness, as the net effect of periosteal expansion and endosteal resorption, can be measured easily in children from the age of 5 to 6 years (Neu *et al.*, 2001). Up to now, the growth related changes in bone mineral density and microstructure have been documented by only a limited number (and mainly transversal), QCT, pQCT, and HR-pQCT studies.

Since pQCT measurements in longitudinal studies are repeated in a volume of interest located relative to limb length and not at a fixed rate and bone elongation proceed symmetrically with varying contribution of distal or proximal growth plate depending on age and pubertal stage, observed differences in bone parameters might in part be related to positioning defects. Furthermore, changes in bone geometry and microstructure are site specific: cortical thickness increment at the radius remains relatively stable until late puberty, whereas at the tibial shaft, thickening of the cortex is more evident throughout the growth phase (Schoenau *et al.*, 2002; Roggen *et al.*, 2015). These differences can be explained by the greater forces at the weight bearing tibial site, contributing to greater differences in growth related adaptations. On the other hand, at the end of pubertal development trabecular bone mineral density and trabecular separation are lower at the radius compared to the tibia (Liu *et al.*, 2010).

Most bone parameters as studied by pQCT and HR-pQCT increase from childhood to early adulthood (Gabel *et al.*, 2017), although gains in trabecular BMD and cortical BMD are limited and even a transient decrease in cortical bone mineral density can be observed during midpuberty at the distal radius and tibia (Gabel *et al.*, 2017; Kirmani *et al.*, 2009; Wang *et al.*, 2006). Also at these sites, the porosity index decreases during pubertal development, although more rapidly in the females than the males (Nishiyama *et al.*, 2012). On the other hand, trabecular bone density at the lumbar spine increases linearly at the latest stages of pubertal development (stages 3–5) (Gilsanz *et al.*, 1988). The increase in trabecular BMD in the appendicular and axial skeleton is mainly explained by an increase in trabecular thickness rather than in trabecular number (Kirmani *et al.*, 2009). Using the individual trabecula segmentation technique, a greater increase in plate-like trabecula number and density than in rodlike structures has been evidenced during adolescence, at least in girls (Mitchell *et al.*, 2018).

Whereas cortical bone mineral density increases more in girls than boys at the tibia and the radius during puberty, trabecular bone volume fraction and cortical area are higher in boys, especially post puberty (Kontulainen *et al.*, 2006; Moyer-Mileur *et al.*, 2008; Wang *et al.*, 2010). On the other hand, cortical porosity declines more in females than in males during pubertal growth (Nishiyama *et al.*, 2012). The more porous cortices of boys reflect their higher rates of intracortical remodeling associated with their greater bone size, electing an increased demand for calcium. The peak of cortical porosity at the forearm aligns with the peak time of forearm fractures incidence in boys and girls (Kirmani *et al.*, 2009).

The robustness of the long bones, reflected by the size of the bone cross-section relative to the bone length decreases around the age of peak height, especially at the metaphysis (Rantalainen *et al.*, 2016). The persistent increase in bone diameter, although at a slower speed, into early adulthood in contrast to a stopped increasing bone length at the end of puberty, coincides with the wane in fracture risk in late adolescence (Xu *et al.*, 2009).

An increase of bone strength between 100% and 400% is observed during childhood and adolescence, depending on the skeletal site and the parameter measured. The most common pQCT derived indices of bone strength are the bone strength index at the distal ends of the long bones and the polar strength-strain index at the shaft. By the end of puberty, bone strength in males is 10%–38% higher in males than females, despite a slightly lower cortical bone mineral density and a greater cortical porosity (Nishiyama *et al.*, 2012). This is mainly due to their large bone diameters and their greater trabecular bone volume.

General Characteristics in Bone Mass and Bone Structure Development

Changes in bone mass and bone cortical parameters during growth are race dependent, even after correction for anthropometric differences: Black children and adolescents have a greater lumbar spine and whole body bone mineral content, as well as a greater cortical bone mineral density and size at the tibia (Kalkwarf *et al.*, 2007; Warden *et al.*, 2013).

The variability in most bone parameters increase with age, necessitating the use of a large reference sample to characterize the normal range of age related changes, especially during adolescence (Kalkwarf *et al.*, 2007; Zemel *et al.*, 2011).

Another important phenomenon in bone mineral accrual during growth is tracking. Tracking of bone mass has been documented especially during childhood but less during adolescence, even after correction for body height and weight changes (Loro *et al.*, 2000; Kalkwarf *et al.*, 2010; Foley *et al.*, 2009).

The timing of puberty appears of importance in bone mass accrual, as late menarche is associated with thinner cortices and lower trabecular BMD at the distal tibia and a lower areal bone mineral density at several sites (Chevalley *et al.*, 2009a).

Determinants of Bone Mass Accrual

Major factors influencing the accumulation of bone mass during childhood and adolescence, are heredity, life style (such as diet, physical activity, and cigarette smoking) and hormonal status.

Genetic factors play the greatest role in peak bone mass determination. About 40%–70% of the bone phenotype variance is derived from heritable variables, as suggested by family and twin studies (Havill *et al.*, 2007). Inheritance is polygenic and several

genomic loci have been identified that predict skeletal health in children (Duren *et al.*, 2011). Vitamin D receptor and estrogen receptor polymorphisms have been found to be related to bone mass in male and female adolescents.

On the other hand, a healthy life style including regular milk intake and regular sport activities, can increase bone mass accrual. Calcium supplementation during childhood or adolescence can modestly (2%–5%) increase bone mass, in general more at cortical sites and when habitual calcium intake is low (Bonjour *et al.*, 1997; Johnston *et al.*, 1992). Replacement of milk by soft drinks in female adolescents might compromise their optimal bone accrual, whereas the combination of vitamin D and calcium may enhance trabecular bone mineral density (Whiting *et al.*, 2004).

Physical activity is important for bone mass at all periods of life, but especially during the growth phase. This positive effect is mostly observed at weight bearing sites (lumbar spine and femoral neck), before pubertal onset and in males (Bielemann *et al.*, 2013; Bailey *et al.*, 1999; Behringer *et al.*, 2014). More physically active children accrue not only more bone mass, but develop also a more robust long bone geometry (greater cross sectional diameter, smaller endosteal bone diameter) than their less physically peers (Rantalainen *et al.*, 2015; Duckham *et al.*, 2014).

On the other hand, early initiation of smoking is inversely associated with late adolescence forearm and femur bone mineral density in girls, whereas bone acquisition at the lumbar spine might be reduced during adolescence by the use of contraceptive oral estrogens, especially those containing very low dose of EE (Cibula *et al.*, 2012; Dorn *et al.*, 2011).

During puberty, the dramatic changes in sex steroids and IGF-1, have been related to the rapid changes in bone structures (Vanderschueren *et al.*, 2006). Estradiol is required for the attainment of maximal peak bone mass in both sexes, whereas action of testosterone on stimulating periosteal apposition accounts for the larger size and thicker cortices of the adult male skeleton (Chevalley *et al.*, 2011; Gabel *et al.*, 2015).

Glossary

Biochemical markers of bone turn-over (BTM's) Analytes (mostly different circulating collagen or procollagen fragments commonly called CTX and P1NP) measured in urine or serum to assess bone turn-over.

Bone mineral density (BMD) The amount of mineral present in a defined volume of bone. A "true density" (g cm^{-3}) can only be measured by CT scan. DXA measures an areal bone mineral density (BMD_a, g cm^{-2}), an apparent bone density which is the bone mineral content in g (BMC) divided by the area of bone scanned.

Dual X-ray absorptiometry (DXA) The most used technique to assess bone mass, using the absorption of two X-rays of different energies to separate that caused by mineral and that caused by soft tissues.

Finite element analysis (FEA) A mathematical technique using differential and integral calculus to simulate the resistance of bone to a defined force applied to its surface, using the structural parameters derived from QCT or HRpQCT.

High resolution peripheral computed tomography (HRpQCT) A CT scanner designed to measure peripheral bone density (radius, tibia) with a high resolution (80 μm). The apparatus allows to measure separately cortical and trabecular true density (g cm^{-3})and to measure structural parameters like cortical thickness and porosity, trabecular thickness or trabecular separation.

Least significant change (LSC) The minimal change necessary between two measurements to be significant rather than a measurement error as defined by the precision error of the measurement. In bone densitometry, the LSC is defined by the in vivo precision error of repeated measurements multiplied by the confidence level desired to be certain that a change in bone mineral density (BMD) or of bone markers (BCM) is real rather than due to a measurement error.

NHANES III—National Health and Nutrition Examination Survey III The study from which the reference values for BMD were established.

Prevalence The percentage of the population being studied that is affected by a particular disease at a given time. In bone densitometry, prevalence is usually applied to the percentage of the population above or below a certain standard deviation cut-point from the mean BMD of the reference population.

Quantitative ultrasound measurements (QUS) Ultrasounds are used to estimate bone strength (limited to the peripheral skeleton). Two main parameters are determined, the speed of sound (SOS) and broadband attenuation (BUA), which depend of bone density and probably microarchitecture.

Quantitative computed tomography (QCT) A radiologic tomographic technique allowing to compute a three dimensional view of the organs and to derive true volumic density (BMD_v, g cm^{-3}).

Risk The possibility of loss, injury, disadvantage, or destruction. In bone densitometry, risk is used to define either the relative or absolute risk of fracture at any given BMD value at a particular age.

Trabecular bone score (TBS) A score derived from image analysis of the DXA anteroposterior view of the spine to estimate trabecular architectural modifications susceptible to fragilize bone.

Vertebral fracture assessment (VFA) Vertebral heights measurement on a quick lateral view of the spine using DXA device to diagnose vertebral fractures at the time of BMD measurement.

Introduction

Bone mass measurements were developed by radiologists before World War II, but begun to be currently used in the clinic about 50 years ago, when Cameron *et al.* (1968) first described single photon absorptiometry (SPA) to measure radius bone mineral content (BMC) and apparent density (BMD). It was the introduction of dual X-ray absorptiometry (DXA) allowing quantification of the central skeleton (mainly spine and hip) that allowed the tremendous development of studies in osteoporosis. The clinical application of bone densitometry is one of the advances in the field of osteoporosis that has led to increased patient awareness of this increasingly prevalent disease. Bone densitometry has made it possible for clinicians to diagnose osteoporosis before the first fracture has occurred and to predict risk for fracture in postmenopausal women, men, and patients receiving glucocorticoids. It can

be used as a surrogate marker to follow the efficacy of therapies and to examine those patients that might be osteoporosis-specific therapeutic nonresponders. Hence, there are three reasons clinicians perform bone mineral density (BMD) measurements: diagnosis using the World Health Organization criteria for osteoporosis, fracture risk prediction, and monitoring the natural progression of diseases that affect BMD or monitoring the therapeutic response to osteoporosis-specific treatments. This article examines each of these applications of bone mass measurements and provides principles of clinical application.

Diagnosis

In 1994, the World Health Organization (WHO) selected a bone mineral density (BMD) cut-point for defining the prevalence of osteoporosis in the Caucasian postmenopausal female population. The main intent of the WHO committee was to assess the prevalence of low bone mass in the population and relate bone mass to the anticipated lifetime fracture risk in order to advise health policymakers of the potential medical and economic burden of osteoporotic fractures in this population. The use of standard deviation (SD) scores (T-score) rather than absolute BMD in grams per centimeter squared was decided upon because of the known different absolute BMD calibrations that exist between the BMD measuring devices. A SD score mitigates some of the variance in absolute BMD measured by different manufacturer devices. In the densitometry nomenclature, T-score is the difference, expressed in SD units, between a BMD value observed in a patient and the mean BMD in the reference population during young adulthood (peak bone mass).

The WHO cut-point of $T = -2.5$ or lower used for the diagnosis of osteoporosis is based on a close association between prevalence at this cut-point and lifetime fracture risk of hip fractures or all fractures (hip, vertebrae, forearm, humerus, and pelvis). At the femoral neck, as assessed by the young, normal reference population database, 16% of postmenopausal women 50 years of age or older have a score of -2.5 SD or less, and the lifetime hip fracture risk after age 50 in postmenopausal Caucasian women is 16%. In addition, approximately 30% of this population has a score of -2.5 SD or less as measured at the hip, spine, and wrist, which approximates the lifetime fracture risk of all or global fractures after age 50. However, the relationship between low BMD and increased fracture risk is a gradient and not a threshold. Thus, the WHO created a separate classification, osteopenia, to recognize this gradient of risk and to help clinicians assess additional risk factors besides the level of BMD that may lead to increased fracture risk. In this regard, in the National Osteoporosis and Risk Assessment (NORA) dataset, although the 1-year fracture rates and relative risk for fracture/SD reduction in BMD were highest at T-scores of -2.5 SD or lower, the largest number of fractures, partially related to the larger sample size of the population with T-scores between -1.0 and -2.5 SD, was seen in this osteopenic category (Siris *et al.*, 2004). This conclusion derived from peripheral measurements was confirmed when considering central DXA (Pasco *et al.*, 2006).

The T-score based interpretation of BMD has been debated: though it resolves the problem of machine calibration, it only partially resolves that of a unifying definition of osteoporosis diagnosis. T-scores are indeed dependent on the mean and SD of the reference population, being lower if the mean is higher and/or SD lower (Chen *et al.*, 1998). So, the choice of the reference database has an impact on the diagnosis, independently of absolute BMD values, and using T-scores implies an agreement on which reference data base should be used for calculation, a question still controversial as far as gender and ethnicity are concerned. Abandonment of the T-score has been suggested for all BMD devices and skeletal sites with the exception of the hip, for which there is a uniformly accepted Caucasian database with NHANCEIII (Looker *et al.*, 1998). However, replacing T-scores by absolute BMD values would be impractical because of the lack of uniformity of the results between the different DXA devices. For example, the average BMD of the axial skeleton (L2–L4) in a healthy 20-year-old Caucasian women is 1.25 g/cm^2 by Lunar-GE and 1.00 g/cm^2 using a different device. Large comparison trials have been conducted to derive equations to convert values obtained from different devices. Though these equations can be useful for follow up when a patient was measured previously with another device, the residual error is too important for an exact standardized BMD to be calculated (Bonnick, 2010).

Regarding gender, two positions concurred: using the female NHANCE III database for both genders, or using gender specific reference data (Melton *et al.*, 2001; Binkley *et al.*, 2002). The tenants of the first position argue that males fracture at the same absolute BMD as females, those of the second that using female reference data for T-score calculation in males will result in underdiagnosing osteoporosis in men (Vallarta-Ast *et al.*, 2002). The percentage of men with T-scores <-2.5 SD at the femoral neck when the T-scores are calculated from a male database is 6% and that from the female database is 4% (Orwoll, 2000). Thus, when considering only the hip, the small differences in prevalence between the two genders using NHANES III databases will not miss many men at risk. On the other hand, when the prevalence of osteoporosis by WHO criteria is determined in men from a male or a female database by using the spine, wrist, and hip measurements, it is 19% when the T-score is calculated from a male database and 6% when calculated from a female database. Thus, when T-scores are calculated from a female database, men are underdiagnosed if the clinician examines multiple skeletal sites. Therefore, the number of men determined to be at risk for fracture is underestimated when all three central DXA-measured skeletal sites are combined if a female reference population database is used. In a recent longitudinal study however (Leslie *et al.*, 2014), it was shown that men were at slightly lower risk for incident major osteoporotic fractures than women for an equivalent lumbar spine BMD, supporting the use of a female Caucasian database to diagnose osteoporosis in men.

What about ethnicity? The NHANES III reference database provides the only head-to-head ethnic comparison in which both T- and Z-scores are calculated from both gender- and ethnic-specific databases for prevalence comparisons. Ethnic-specific databases were calculated from Caucasian, Hispanic, and African American male and female populations ranging in age from 20 to 80 years. There are no Asians populations in the NHANES III database. In this robust study, there are clear prevalence differences when T- or

Z-scores from different ethnic groups are calculated from a non-ethnic-specific database. However, no fracture data correlate with the T- or Z-scores from the NHANES III database. Hence, there are no data regarding whether there are differences in fracture rates as a function of the ethnicity-derived T-scores from this valuable dataset. Concerning Asians, there are recent studies showing important misclassification when Caucasian or Asiatic database were used for T-score calculation (Namwongprom *et al.*, 2012), but there are no fracture data either.

The only multiethnic head-to-head prevalence and fracture data derive from NORA, in which all SD scores were calculated from the Caucasian female reference population database. The relative risk (RR) per SDs decrease for global fractures are similar between Caucasians, American Hispanics, and Native Americans and lower for the American Asian and African American populations. On the other hand, the fracture rates across all ethnicities at T-scores <-2.5 SD are very similar. In the WHO-defined osteopenic category in NORA, American Asians had an unexpectedly low rate of fracture events. The reasons for this are unclear. However, because all of the risk calculations in NORA were done using a Caucasian female reference population database and fracture rates were not too dissimilar across ethnicities, at least for the U.S. multiethnic female postmenopausal population, it might be acceptable to calculate risk from a Caucasian female database, regardless of ethnicity. Native Chinese have a lower hip fracture risk (but similar vertebral fracture risk) despite having a much lower absolute BMD, even after adjusting for body mass index. It is possible that in the United States, lifestyle, nutrition, or even some elements of gene pool mix may result in non-Caucasian ethnic groups having the same fracture risk as Caucasians. The last ISCD recommendations suggest using uniformly white Caucasian female database for T-score calculation across genders and ethnicities (ISCD, 2015). The debate over reference data bases could be solved if the definition of osteoporosis changes towards one based on fracture risk, instead of epidemiology. But this will require a consensus over the fracture risk calculators, their validation, and the definition of a risk threshold.

A second important debate concerns the skeletal sites to measure (Faulkner *et al.*, 1999). Absolute BMD's measured at different skeletal sites are quite well correlated in the statistical sense, but do not predict each other tightly because residual variance is high (Mazess and Barden, 1990). Also, they change less or more rapidly with age and menopause according to the site measured, i.a., because of the different proportion of cortical and trabecular bone and because mechanical stress influences the bone physiology in supporting bones like femurs and tibias as compared with upper limb skeleton (radius). Hence, the evolution of T-scores with age or menopause may differ greatly between sites and if methods other than DXA are used for measurement (for instance, volumetric BMD of a central vertebra measured by QCT decreases much more rapidly than areal BMD of the same vertebra measured by DXA; conversely, the evolution of QUS parameters measured on peripheral bones (usually calcaneus) is much slower. Thus, if a low BMD in the postmenopausal population assessed by any BMD device and by any database is predictive of an increased fracture risk, a relationship also seen in the multiethnic U.S. population, for various reasons, T-scores obtained by peripheral devices may not always be as low as T-scores determined from central DXA devices and peripheral devices underestimate osteoporosis prevalence. The prevalence of WHO osteoporosis (≤ -2.5 SD) in the NORA dataset of postmenopausal women 50 years of age or older averaged 7% for all four peripheral devices combined, half of the prevalence that was determined by measuring only the femoral neck.

For these reasons, recommendations for the diagnosis of osteoporosis have been progressively adapted since 1994, limiting the technologies accepted to DXA and restricting the skeletal sites included for osteoporosis diagnosis to the lumbar spine, total hip and femoral neck (Hans *et al.*, 2006; ISCD, 2015), except in some special cases like primary hyperparathyroidism or extreme obesity where measurement of the 1/3 proximal radius remains advised. Thus, a central BMD should be performed in any patient with risk factors that would lead the clinician to suspect osteoporosis. Though a less expensive and more universally accessible peripheral BMD can be a first screening test, it must be followed by central BMD when the measured value is low, for instance if the calcaneal DXA T-score is ≤ 0 (Sweeney *et al.*, 2002) or if the heel measurement by ultrasound is <-1.0. However, a first screening using a peripheral device is not currently recommended (ISCD, 2015).

On the other hand, vertebral quantitative computerized tomography, which is more sensitive than DXA to document vertebral bone loss, underestimates T-scores and overestimate the prevalence of osteoporosis in the population. It is not accepted to diagnose osteoporosis according to the WHO definition.

A third important point in osteoporosis diagnosis is accuracy of the DXA measurement. Accuracy is the capacity of a method to give a result as close as possible to the "real" value of the object, here bone density, as a surrogate of bone strength. Accuracy as determined in cadaver studies is typically 3%–7%; it is influenced by soft tissue composition, mainly adipose tissue content, which differs from patient to patient: fat indeed absorbs less the X-rays than water, and changes the soft tissue correction (Blake *et al.*, 2013). Accuracy can also be affected by artefacts like spondylarthritis, which provokes a positive bias on the spine BMD. A (less important) effect of arthrosis has been observed at the hip site. Aortic calcifications can also increase artefactually spine BMD, so as the presence of radiological contrast product or metallic pieces in the measurement field. Eventually, as areal BMD is the ratio of BMC by estimated area, different positioning of the bone can give rise to substantial accuracy errors, particularly for the hip: a different rotation will modify the projected surface but is without effect on BMC. Hence the importance of formation and experience of the personal committed to bone density measurement.

A problem with the WHO osteoporosis T-score definition of osteoporosis is that, if it predicts adequately a higher risk of fracture, more than 50% of the fractures occur in persons in the osteopenic range (Pasco *et al.*, 2006). This is due in part to limitations of the definition of osteoporosis using the WHO criteria, not the least being that bone mass is only one component of bone strength, although an important one. Other factors designed globally as "bone quality" are also important. They include bone architecture (trabecular orientation and density, cortical thickness, geometry) and elastic properties, or brittleness, of the bone "fundamental material," this tight association of proteins, mainly collagen, and mineral, mainly hydroxyapatite. At the end of the next section, we shall briefly describe new techniques which can capture some of these properties and could add to the

accuracy of fracture prediction. This will never be perfect since fractures will most often result from random events (falls), themselves dependent upon non skeletal functions: muscular strength, sight, equilibrium… and from the force of impact, which depends of patient's weight. Some of these "non BMD factors" may be captured by clinical risk factors now included in several "fracture risk predictors," the most popular being the FRAX©.

It must be underlined that these considerations on osteoporosis diagnosis are valid only for post-menopausal women and men older than 50 years old. For younger people, and particularly for children, the use of T-scores is inappropriate and Z-scores, that is the difference between the BMD value measured in a patient and the mean of a sex and age matched reference population, must be used to diagnose a low bone mass (Z-score <– 2.0 SD).

Prediction

From a clinical point of view, fracture risk prediction is much more important than osteoporosis diagnosis, even if it is clear that both are linked, and that these two points of view should be reconciled in a more comprehensive definition of osteoporosis than the WHO T-score criteria. Work is in progress to try that reconciliation (see position paper by Siris *et al.* in 2014). It is fracture risk prediction which will allow to select groups of patients at high risk who will receive the highest benefit of osteoporosis treatment in terms of fracture prevention and thus to be most cost/benefit efficient.

Both central and peripheral BMD devices can predict an increased risk for fracture. Risk approximately doubles for each standard deviation reduction in BMD in the postmenopausal population. However, the risk associated with low BMD is very dependent on the age of the patient. Risk is far greater as age increases. In fact, the risk for hip fracture is approximately 4.5-fold greater at age 80 than at age 50, even at the same BMD or T-score (Hui *et al.*, 1988). Although some of the increased risk seen with advancing age may be related to an increase in falls, there are bone quality changes with aging that render a bone more susceptible to fracture at equivalent BMDs. Clinicians cannot capture these qualitative features with BMD devices.The best documented application of peripheral technologies is fracture risk prediction. However, estimated fracture risk varies widely when BMD is measured at different peripheral sites (Blake *et al.*, 2002). The first prospective observation documenting the ability of BMD technology to predict fracture risk was made in 1988 when forearm BMD was shown to predict an increased risk for nonspinal fractures in postmenopausal women (Hui *et al.*, 1988). This study was followed by a large metaanalysis that documented the ability of multiple technologies, both peripheral and central, to predict an increased risk for vertebral, nonvertebral, and hip fracture risk (Marshall *et al.*, 1996). It has been suggested that the femoral neck is a more robust skeletal site for predicting the risk of hip fracture (RR/SD = 2.4). Although this suggestion is based on the Study of ostoporotic fractures (SOF) head-to-head hip/heel ultrasound device study, the hip fracture risk that was predicted in NORA using wrist or heel DXA was also 2.4, and the receiver operating characteristic (ROC) curves of the two peripheral devices used in NORA match the ROC curves seen with femoral neck DXA obtained from SOF (Miller *et al.*, 2002). NORA was not a head-to-head comparison with hip DXA. Nevertheless, it appears that low peripheral device values in the postmenopausal population are powerful predictors of hip fracture risk in untreated postmenopausal women.

Whatever the measurement site and device, measurement of BMD alone predicts fracture risk with an insufficient sensitivity. There are several reasons therefore, inherent to the factors governing bone resistance and to factors unrelated to bone. Bone mass is indeed only one of the components of bone strength: geometry, architecture and the intrinsic quality of bone material (all grouped in what one call "bone quality"). Factors unrelated to bone are falls (a main determinant of hip fractures) and death, which is a competing risk with fractures. To increase the predictive value of bone mass measurements, models were constructed which take into account clinical risk factors such as age, BMI, prevalent fragility fractures, parental hip fracture, smoking, alcohol consumption or glucocorticoid excess (Kanis *et al.*, 2007). The clinical factors are supposed to take at least in part into account "bone quality." The most popular fracture risk calculator, developed under the auspices of the WHO, is FRAX®, which allows to calculate the absolute fracture risk for 10 years in men and women between 40 and 90 years old (Kanis *et al.*, 2011). There are other tools, like the Garvan nomogram (Australia) (Bolland *et al.*, 2011) or Q-fracture (England) (Hippisley-Cox *et al.*, 2014), differing by the duration of fracture prediction and by a number of risk factors taken into account. FRAX® has been constructed from a huge international database from which the absolute fragility fracture risk was estimated from clinical factors and BMD, and it is the only one which takes into account the competing risk of death. Prediction varies according to nationality and ethnicity, due to the distribution of risk factors and different risk gradients, and thus the model has to be adapted and validated for each population (Kanis *et al.*, 2012). FRAX® has been validated prospectively in different countries (a.o. Leslie *et al.*, 2010).

Taking into account the limitations of the WHO definition of osteoporosis, based on T-scores, in terms of recognition of the patients most at risk for fracture and thus for whom the cost/benefit ratio of treatment would be optimized, some experts plea for an extension of this diagnosis to persons with a history of hip fracture, independently of bone mass measurement, to osteopenic persons with a history of major osteoporotic fracture or to those with a 10 year fracture risk estimated by FRAX® higher than a predefined level (3% for a hip fracture or 20% for a MOF in the USA) (Siris *et al.*, 2014). This extended definition, for which measurement of bone mass remains essential, would have the advantage to reconcile diagnosis and fracture prediction. It would also reflect more accurately the clinical definition of osteoporosis as "a systemic skeletal disease characterized by low bone mass and microarchitecture deterioration of bone tissue, with a counterpart increase in bone fragility and susceptibility to fracture" (Consensus, 1993).

Among the clinical risk factors, one of the most important is the presence of a prevalent fragility fracture, among which vertebral fractures, which are frequently asymptomatic. A history of vertebral fracture increases greatly indeed the risk of further lesions. Hence the importance of vertebral fracture assessment (VFA) which has been added to modern DXA machines, based on a quick lateral view of the

spine (Rea *et al.*, 2000). Use of VFA allows to detect, at the time of bone mass measurement, if there are prevalent vertebral fractures, an observation which will change risk assessment and therapeutic decisions. The interpretation of VFA is not always that simple, particularly in patients with spine deformities, and fractures should be confirmed by a lateral spine X-ray when suspected.

Modern DXA machines also include a "Trabecular bone score (TBS)" tool, which allows to derive from image analysis an index reflecting the quality of trabecular organization. TBS could add to fracture prediction in some groups of patients with osteopenia or with diseases with an increased fracture risk associated with a normal or even supra-normal BMD, such as type 2 diabetes (Silva *et al.*, 2014). The introduction of the TBS value in the fracture risk calculator is now optional and has still to be validated in large cohorts of osteopenic patients (McCloskey *et al.*, 2015).

Bone geometry is also important for bone strength. With the Hip Structural Assessment (HSA), available on DXA and CT devices, it is possible to calculate the length of the femoral neck, the mineralized cross sectional area and the mass distribution around the longitudinal axis, and the ratio between the cortical thickness of the neck and the width of the femoral neck (called buckling ratio, BR), all parameters linked to mechanical resistance (Kaptoge *et al.*, 2008). Until now, there was no formal proof for these parameters to improve fracture risk prediction above BMD measurement. HSA has nevertheless allowed some interesting observations like that of a benefit for bone development of a high level physical activity (Maïmouna *et al.*, 2013). Femoral mapping by CT, as described by Poole *et al.* (2017), is perhaps more promising, showing that patients with hip fractures are characterized by regional bone loss limited to some areas of the superior femur. Vertebral and hip QCT also allow interesting structural studies, and include the possibility to simulate bone strength, an option which can be interesting in understanding the mechanism of action of drugs during osteoporosis treatment (Graeff *et al.*, 2015).

Eventually, high resolution peripheral quantitative computed tomography (HRpQCT) (and other high resolution radiographic techniques) allows to investigate volumetric cortical and trabecular BMD and even trabecular architecture; it is also possible, using finite element analysis (FEA), to calculate the resistance of bone to a simulated applied force. Some of the derived parameters predict fracture risk independently of BMD alone (Sornay-Rendu *et al.*, 2007; Vico *et al.*, 2008; Chevalley *et al.*, 2013; Edwards *et al.*, 2016; Ohlsson *et al.*, 2017). HR pQCT can also be applied to the investigation of the mechanism of action of anti-osteoporosis drugs (Tsai *et al.*, 2016).

The only technique allowing to test directly the resistance of bone fundamental material is reference point microidentation. Different instruments allow to measure in vivo the resistance of cortical bone to penetration by a calibrated weight. These are promising but invasive techniques which are used actually in a research context only (Jenkins *et al.*, 2016).

Monitoring

BMD, and also biochemical markers of bone turn over (BTM's), for which there is increasing evidence for clinical application (Cavalier *et al.*, 2016), allow to confirm that antiosteoporotic drugs have the expected effect (increase in BMD and decrease of BTM's for antiresorptive drugs, or increase of BTM's for anabolic drugs).

These surrogate markers are largely used in clinical trials to validate antiosteoporotic treatments, even if the primary end-point is the reduction of fracture risk. They are particularly useful in first phases trials, before undertaking longer and more costly trials powered on fractures (Leder *et al.*, 2015).

Although the FDA requires proof of a significant 3-year vertebral fracture reduction for registration of PMO osteoporosis-specific therapies, surrogate measurements can be accepted for bridging studies comparing analogous drugs belonging to the same class, or two administration schedules. For instance, the FDA has approved both the once-a-week alendronate and the once-a-week risedronate formulations not based on any prospective-derived fracture data but on evidence that these weekly formulations increase BMD and reduce BCM to equivalent degrees as daily dosing. Hence, the FDA acknowledges that these surrogate markers for bisphosphonates demonstrate improvement in bone strength and a reduction in fracture incidence. However, to the extent that the bone half-life may not reflect the bone biological, functional, bisphosphonate half-life, and because the bone binding and alteration in activation frequency of bisphosphonates differ between amino bisphosphonates, these assumptions may or may not be entirely valid. More recently, surrogate markers were also used as primary end-point in a study comparing 6–9 years of zoledronate treatment in osteoporosis (Black *et al.*, 2012).

The use of these surrogate markers is only justified if their evolution correlates with the reduction of fracture rate. This was shown in several studies examining the relationship between the changes in BMD and/or BTM's and the magnitude of reduction in either vertebral or non-vertebral incident fractures by robust metaanalysis of randomized, controlled clinical trials (Wasnich and Miller, 2000; Hochberg *et al.*, 2002). In general, the metaanalyses are in agreement that a portion (24%–54%) of the risk reduction of antiresorptive agents can be attributed to the increase in BMD. Also, these metaanalyses are in agreement that there is an approximately 24% reduction in vertebral fracture risk at the intercept (no change in BMD), indicating that other non-BMD mechanisms play a role in the improvement in bone strength. The metaanalysis of the relationships between the changes in BMD and BTM due to antiresorptive agents and the reduction in nonvertebral fractures shows that all of the effects of the antiresorptive agents that reduce the incident of nonvertebral fractures can be attributed to either the magnitude of increase in BMD or the magnitude of reduction in BCM of bone turnover. In this metaanalysis, risk reduction related to either the increase in BMD or the reduction in BTM could not be distinguished because the adjusted variances that the components contribute to risk reduction are so similar. In studies of newer antiresorptive agents of the same class (zoledronate) (Jacques *et al.*, 2012) or with a different mode of action (denosumab) (Austin *et al.*, 2012), the relation between BMD change and fracture rate reduction was comparable, as in

studies using an anabolic agent like teriparatide (Tanaka *et al.*, 2014). A predictive value of BMD changes on fracture rate reduction was also observed in daily practice (Leslie *et al.*, 2016).

Usually, not all the antifracture effect can be explained by BMD. By reducing bone turnover, there may be microarchitectural changes in bone not necessarily reflected in BMD measurements that lead to increased bone strength. Moreover, the areal BMD measurements that are routinely used in bone densitometry may underestimate the real magnitude of BMD increases because the areal BMD measured by DXA is a quotient of BMD by calculated area. The bone area may increase without any change or a small change in BMC; thus, the calculated BMD would decline, not necessarily due to any reduction in BMC but due to an increase in bone area. Evidence for this effect of bone area on calculated BMD derives from studies measuring changes in areal BMD by DXA versus quantitative computerized tomography (QCT), which measures the true bone mass and volumetric changes in bone mineral content. QCT changes were larger than DXA changes in this intermittent PTH study, even though BMC increased in both, suggesting that areal BMD measurements may underestimate the change in BMD (Hodsman *et al.*, 2003; Rehman *et al.*, 2003). Nevertheless, areal BMD at both baseline and longitudinal over time reflects both the basal bone strength as it relates to fracture prediction and the improvement in bone strength as it relates to changes in BMD that are induced by antiresorptives.

The use of sequential BMD measurements in the individual patient management was more subject to discussion, because they are neither a perfect indicator of pharmacological response or nonresponse to therapeutic interventions to antiresorptive agents and there is no formal proof that adding these measurements to the clinical follow up protocol improves the treatment efficacy. The prevention or reduction of fractures is the ultimate goal of treatment. However, for drugs which have been shown to increase BMD, and with a validated antifracture effect in clinical trials, changes in BMD can be a surrogate endpoint marker for monitoring the efficacy of osteoporosis-specific agents in real life. The rationale for follow up in individual patients is that: 1° since no treatment completely eliminates fracture risk, the occurrence of another (i.e., vertebral) fracture while on antiresorptive agents does not necessarily mean that the patient has not had a pharmacological effect of antiresorptive treatment; 2° clinicians are uncomfortable about waiting for another fracture event in order to define treatment effectiveness; thus, the use of surrogate markers to assist therapeutic strategies is analogous to lowering blood pressure or cholesterol to measure treatment effect of antihypertensive or cholesterol-lowering agents. As for all laboratory determinations, it is crucial to interpret changes in DXA values in the light of the intra-individual variability, which must be assessed in vivo. Thus, for DXA to be useful in follow up, you need an excellent precision, or reproducibility (Bonnick *et al.*, 2001). Precision depends on the quality of the DXA device but mostly of the experience of the DXA laboratory, which has to be alert to measurement drifts (use phantoms) and to be most meticulous in the patient preparation (no interfering objects in the field), positioning and in the image treatment (selected areas for calculation). The lowest precision is, as compared with the expected change during natural evolution or therapy, the sooner a significant evolution will be detected. For a clinician to know with certainty that a change in BMD between two measurements in an individual patient is real as opposed to an inherent measurement error of the DXA device or an error of the researcher performing the test, the in vivo precision error, which is the coefficient of variation % (CV%) between multiple measurements with repositioning, must be known for the DXA site. It is 1.0%–1.5% in normal subjects, thus much higher than the 0.3%–0.4% measured on phantoms. Performing daily phantom (in vitro) scanning is important in order to detect a "drift" in serial BMD values that may indicate the need to obtain manufacturer assistance to search for problems that affect machine performance, such as X-ray tube viability and software deterioration. However, phantoms do not move, whereas patients do. The densitometry community has set a standard requiring a 95% confidence limit for determining whether a difference between two BMD measurements in an individual patient is significant. Using this standard, the least significant change (LSC) in BMD is 2.8 times the CV % (precision error), thus 3%–5% for the spine or hip. If the independent precision error is not known for a DXA site, changes in BMD may be assumed to be significant (or nonsignificant) when in fact they may not be. Unfortunately, when the BMD change is within the LSC but misinterpreted to be significant, many patients are often taken off therapy or their therapy is changed. Unfortunately, none of the peripheral devices have shown BMD changes in any antiresorptive clinical trials, except recently for denosumab (Simon *et al.*, 2013).

The pertinence of DXA follow up and the frequency of sequential measurements remain debated. Because of the magnitude of BMD changes expected, and of in vivo precision of the DXA machines, a first control is generally proposed at 2 years, in order to surpass the LSC. Ideally, the treatment goal should be that BMD under treatment surpasses the critical value of a T-score above -2.5 (Kuroda *et al.*, 2012), but it is rarely the case in patients with very low basal values (Cummings *et al.*, 2017). Also, it is not proven that the threshold of -2.5 chosen for untreated patients is also valid for patients receiving treatment, since architecture is not or insufficiently restored and bone quality can be changed by treatment (Kanis *et al.*, 2014). As it is now recommended that antiresorptive treatment be suspended after 5–7 years, to avoid oversuppression of bone turn-over (treatment holiday), a DXA control should be done before treatment arrest, and after two years to see if bone gain is maintained (McNabb *et al.*, 2014). Biochemichal markers of bone turn-over (BTM's) can also be used to monitor the evolution of bone turn-over during treatment arrest.

The use of BTM's of bone turnover is now largely recommended indeed to assess early the biological response to the antiosteoporotic agent or to its withdrawal. Data suggest that if there is at least a 30% decline (LSC) in serum collagen cross-link markers 1–3 months after initiating a bisphosphonate, there is a greater likelihood that the 2-year follow-up repeat DXA will increase or at least not decline. In addition, data on the relationship between the magnitude of increase in BMD and the magnitude of decrease in BTM with the various antiresorptive agents suggest that the greater the decrease in BTM, the greater the risk reduction in vertebral as well as non-vertebral fractures, and prospective longitudinal studies have shown a relationship between BTM decrease and fracture risk reduction. No professional scientific organization recommends substitution of BTM for DXA as a means of monitoring therapy. The two are

complementary. The advantage of the 1- to 3-month BTM assessment is that it provides earlier feedback to the patient and the clinician: if it does decline below the LSC for BTM, then it is fair to assume that the patient will benefit from the treatment in the long run.

Conclusion and Perspectives

BMD testing has allowed clinical application in diagnosis, risk prediction, and monitoring of disease or therapy in osteoporosis. However, like all biological measurements, BMD testing at baseline and/or longitudinally is imperfect. First, it must be measured in laboratories with sufficient experience to get the best accuracy and precision, and to avoid pitfalls in its interpretation. Second, it is only useful if integrated in the clinical context. The definition of osteoporosis based on the calculation of T-scores proposed in 1994 by the WHO is evolutive. The acceptable methods for evaluating bone mass to diagnose osteoporosis were restricted to DXA and the skeletal sites to the spine and hip, limiting the use of peripheral measurements by any other methods to fracture prediction. The reference data bases acceptable to calculate T-score remains debated, though the trend is to use uniformly the female Caucasian values. The efforts to integrate prevalent fractures and absolute fracture risk calculation in the osteoporosis definition should eventually reconcile osteoporosis diagnosis and fracture prediction. A definition based on risk calculation only would be the most rational for clinical applications, but should await risk calculators to be uniformly validated and accepted, which is not yet the case, and a consensus on the risk level defining the disease and the intervention threshold. Perhaps that in the future, BTM's and new parameters describing bone architecture and quality, like TBS or HRpQCT, will allow to predict fractures with better positive and negative predictive value.

X-Ray Based Imaging Methods to Assess Bone Quality

Klaus Engelke, University of Erlangen-Nürnberg, Erlangen, Germany

Nomenclature

BMC	Bone mineral content. BMD = BMC/ volume
BMD	Bone mineral density measured in g/cm^3. BMD is measured by QCT and pQCT
aBMD	Areal bone mineral density measured in g/cm^2. aBMD is measured by DXA
CT	Computed tomography
DXA	Dual X-Ray Absorptiometry
FDA	US Food and Drug Administration
FEA	Finite element analysis
HR-pQCT	High resolution peripheral quantitative computed tomography
HSA	Hip structure (or strength) analysis; special analysis applied to DXA images to estimate bone strength
MrOS	A large epidemiological study funded by the National Institutes of Health. MrOs was initially designed to describe the epidemiology of osteoporosis and fractures in older men, including the identification of risk factors for fracture and bone loss. MrOS has described diagnostic methods for fracture assessment including identification of vertebral fracture
pQCT	Peripheral quantitative computed tomography
QCT	Quantitative computed tomography.
SOF	Study of osteoporotic fracture—a large epidemiological study in women. SOF, a nationwide research study funded by the National Institutes of Health, began in 1986. The study was originally focused on risk factors for fractures and falls and has grown to look at various determinants of successful aging
WHO	World Health Organization
TBS	Trabecular bone score

Glossary

3D-DXA Technique to estimate CT like images from one or multiple DXA images using atlas based procedures.

Attenuation The decrease in the intensity of X-rays when passing through matter; the extent of attenuation is a property of the material which is exposed to radiation and is quantitatively described by the linear attenuation coefficient.

CT X-ray based technique to produce cross-sectional images of a human subject, for example. Standard method in diagnostic radiology.

CT number The final result of the CT measurement; the CT number is calculated from the linear attenuation coefficient μ.

CT value Synonymous with CT number.

DEXA Dual energy X-ray absorptiometry (see also DXA).

DPA Dual photon absorptiometry using radioisotopic sources.

DXA Dual energy X-ray absorptiometry (manufacturer specific acronyms: DER, DEPR, QDR, DPX). Radiological technique for measuring areal bone density. Two different X-ray energy spectra are used.

FEA Finite element analysis (also termed FEM: finite element modeling); special analysis applied to CT images to estimate bone strength.

Helical CT Synonymous with spiral CT.

Hounsfield unit (HU) Unit of the CT number scale; the Hounsfield unit expresses the relative deviation of the measured linear attenuation coefficient from that of pure water, multiplied by 1000.

LSC Least significant change; the change between two measurements that can be measured with 95% confidence.

Motion artifact Artifact caused by movements of the object during data acquisition; in QCT the inconsistencies of the measured projections not only result in unsharpness, as in absorptiometry, but can also cause long-range artifacts in the CT image.

Pixel Abbreviation of "picture element."

QCT Quantitative computed tomography: CT with added calibration to quantify bone mineral density.

Partial volume artifact Artifact caused by severe inhomogeneities of the materials within the beam on the corresponding attenuation measurement (e.g., bone and air). The averaging of the incident intensity within the detector element is not equivalent to an averaging of the attenuation coefficient itself; this is a source of nonlinear errors and thereby inconsistencies for attenuation measurements along different directions.

ROI Region of interest; subset of pixels which lie within an arbitrary (circular, rectangular etc.) geometrical shape at a freely selectable position within a 2D image.

Spiral CT Method of CT scanning with continuous gantry rotation and simultaneous continuous object translation in z-direction; in contrast to the sequential scan technique, with spiral CT the volume to be examined is sampled continuously along the z-axis; during data acquisition the focus of the X-ray tube follows a spiral trajectory relative to the object; the z-interpolation is introduced as an additional step during data preprocessing and allows a retrospective and arbitrary selection of the positions at which images are reconstructed.

TBS Trabecular bone score; special analysis applied to DXA images to measure bone texture.

 doi:10.1016/B978-0-12-801238-3.65815-4

VOI Volume of interest; subset of voxels which lie within an arbitrary (cubical, spherical etc.) geometrical shape at a freely selectable position within a 3D image cube.

X-ray absorption Basic physical ability of a material to absorb x-rays and to transform their energy into other forms of energy, such as visible light, heat or fluorescence; in diagnostic imaging this process is dominated by Compton scatter and photoelectric absorption.

X-ray attenuation The physical law, which quantitatively describes the attenuation of the incident X-ray intensity I_0 when passing through a homogeneous object of thickness d and total linear attenuation coefficient μ.; μ depends on the energy of the X-ray quanta; the intensity of the radiation I measured behind the object can be calculated from $I = I_0 e^{-\mu d}$ (Lambert–Beer law); it should be mentioned here that this formula only holds for ideal conditions, that is, in the absence of X-ray scatter and for monochromatic radiation, that is, when all incident quanta have the same energy level.

Introduction

Dual X-ray absorptiometry (DXA) is one of the best-researched quantitative imaging modalities in medicine. Its physical basis, technical features and limitations have been addressed in hundreds of papers and summarized in a report on bone densitometry of the International Commission on Radiation Units (ICRU) that also covers quantitative computed tomography (QCT) and describes performance measures used in densitometry (Kalender *et al.*, 2009). The primary output of DXA is areal bone mineral density (aBMD). Its clinical relevance for the diagnosis of osteoporosis, fracture prediction, and monitoring of treatment and age related changes has been investigated in multiple very large epidemiological and pharmaceutical studies of more than 2,00,000 subjects worldwide. aBMD is the basis of the WHO working definition of osteoporosis (Kanis and WHO Study Group, 1994). It is a strong predictor of fracture risk, but even in combination with other risk factors it cannot predict whether an individual subject eventually will fracture or not. Today, about 50–100 patients with osteoporosis must be treated to prevent one fracture (Albert and Reddy, 2017); vice versa, about 50% subjects who fracture do not have osteoporosis (Schuit *et al.*, 2004; Siris *et al.*, 2004).

Nevertheless, DXA remains the workhorse in clinical practice and aBMD serves as a powerful surrogate of bone quality. In patients with idiopathic and most types of secondary osteoporosis, tissue mineral density is normal, that is, bone loss is primarily caused by a loss/thinning of trabeculae and an increasing porosity/thinning of the cortex. Apparently, aBMD is such a strong surrogate of bone strength because the remaining bone is optimally distributed to support maximum strength for the given amount of bone.

In contrast to BMD, bone quality is not a well-defined physical parameter. Bone quality is often used as a concept to address deficiencies of BMD to fully explain bone strength and fracture risk (Donnelly *et al.*, 2014). A number of advanced imaging techniques have been developed to quantitatively asses aspects of bone quality. This article will introduce these techniques and will discuss their clinical value or to be more precise, their added clinical value to DXA, which is a well-standardized, widely available and affordable technique.

Concepts of Bone Quality

It is hypothesized that the determination of bone strength and fracture resistance requires a comprehensive assessment of "… bone quantity and bone quality, defined broadly as all geometric, micro architectural, and material factors (e.g., trabecular architecture, collagen crosslinking, mineralization, microcracks)…" (Donnelly *et al.*, 2014). These factors are controlled and regulated by a large number of cellular activities and by external forces that impact on bone (Turner, 2006). The concept of bone quality has been criticized as too vague (Sievanen *et al.*, 2007) but over the years a number of physical parameters that describe material and structural bone properties as well as bone geometry have been identified as determinants of ultimate force (or load) to fracture a bone and of energy to failure (**Fig. 1**). Material and structural properties can be experimentally determined from biomechanical testing of bone samples or whole bone specimen (Jepsen *et al.*, 2015; Turner and Burr, 1993).

Material properties that characterize bone tissue can be determined from the stress–strain curve obtained from mechanical testing of cortical or trabecular bone samples. Material properties subsume microscopic parameters such as collagen crosslinking, mineralization, microcracks, trabecular structure, and cortical porosity. Specific parameters are the elastic or Young's modulus E and the ultimate stress σ^{ult}, required for material failure. Toughness, the shaded area under the curve is the energy of mechanical deformation per unit volume prior to fracture. The Young's modulus is the slope of the linear portion of the stress–strain curve. For fatigue strength, multiple loading cycles are required.

Structural properties are determined from the force-displacement curve obtained from mechanical testing of whole bones. Whole bone structural properties depend on the material properties of the trabecular and cortical bone and on the specific bone geometry. As shown in **Fig. 1**, stiffness is the slope of the linear section of the force-displacement curve. It characterizes how much the entire bone deforms under load. F^{ult} is the ultimate force (sometimes also called ultimate load) that a bone can withstand before it breaks. Work or energy to failure, the area under the force displacement curve, is a measure of a structure's overall resistance to failure.

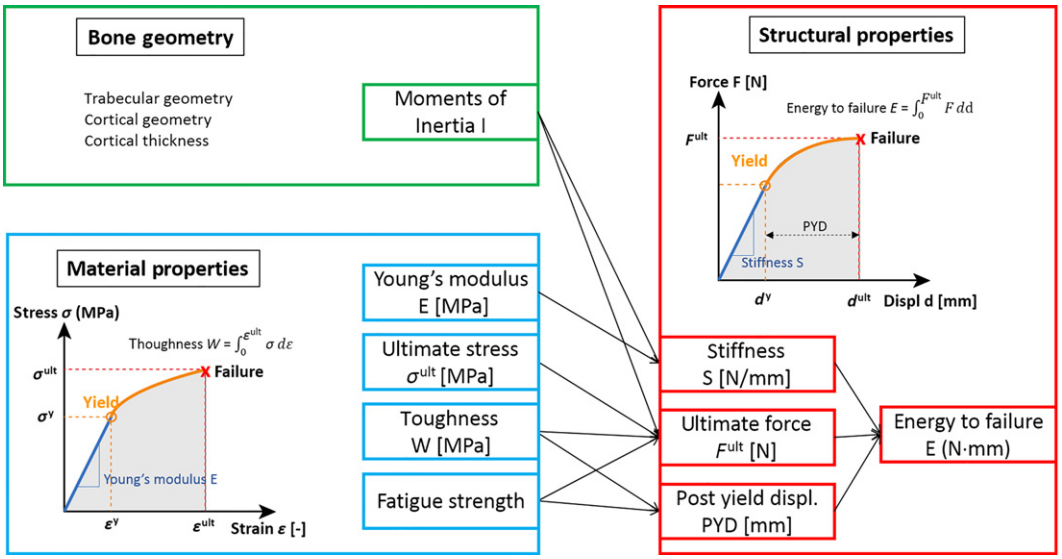

Fig. 1 Concept of bone quality.

An important contributor to energy to failure is post yield displacement PYD $= d^{ult} - d^{y}$. When loaded beyond the yield point, the deformation is no longer reversible, that is, elastic but plastic. The mechanical behavior of bone is altered and stays permanently deformed after unloading. If PYD is low the structure is called brittle, if it is high the structure is called ductile. A ductile bone can better deform plastically without fracturing than a brittle bone (Krichner, 2006; Peterlik *et al.*, 2006).

Whole-bone structural parameters depend on bone size, whereas tissue-level material parameters are size-independent. Typically, mechanical parameters are expressed in terms of load (N) and displacement (mm), whereas tissue-level material parameters are expressed in terms of stress (N/mm^2) and strain (mm/mm or %), that is, they are normalized to area. Whole bone strength is often used synonymously with ultimate load.

It is interesting that apparently, stress and force instead of strain and displacement are the independent parameters. However, an external force creates a strain/displacement that causes an internal reactive stress/force. Thus, stress and force are indeed the resulting parameters. In tension tests, typically, the displacement is controlled and stress is measured as dependent variable. Of course, in equilibrium the external force/force per area is equal to the internal force/stress.

In Vivo Imaging Techniques to Assess Bone Quality

The most widely applied quantitative imaging technique in osteoporosis is dual X-ray absorptiometry (DXA) to measure aBMD in g/cm^2. aBMD is a macroscopic surrogate of bone quality but it does not capture the underlying mechanisms that result in low or high BMD. Thus, a number of advanced imaging techniques have been developed to quantify bone quality beyond BMD (**Table 1**).

QCT

Computed tomography (CT) is an X-ray based technique resulting in an image of the total linear X-ray absorption coefficient μ. For clinical CT applications, the values of μ are calibrated to the X-ray attenuation of water (w) resulting in a CT number measured in Hounsfield units (HU):

$$\text{CT number} = \frac{\mu - \mu_w}{\mu_w} \times 1000[\text{HU}]$$

μ_w is the attenuation coefficient of distilled water at room temperature. In a calibrated scanner, the CT numbers of water and air are 0 and -1000, respectively. For quantitative computed tomography (QCT), an additional calibration is required to obtain BMD from the HU values (Kalender *et al.*, 2009). In contrast to aBMD from DXA, QCT measures a physical density and BMD values are given in g/cm^3. Typically, the subject is scanned on top of a calibration phantom with inserts of known BMD values (**Fig. 2**). There is a linear relation between measured CT numbers and known BMD values of the inserts. The resulting calibration equation is then applied to all bone voxels in the image for which BMD should be measured. This procedure is called simultaneous calibration. Recently a number of alternate approaches, for example, measuring a calibration phantom separately from the subject (Brown *et al.*, 2016) or using the absorption of internal organs and air (internal calibration) (Lee *et al.*, 2017) have been suggested. Thus, BMD measurements could be obtained from CT scans without calibration phantom but further validation of these techniques is required (Engelke *et al.*, 2015).

Table 1 Overview of advanced in vivo imaging techniques to assess bone strength and quality

Technique	*Advantages*	*Limitations*
DXA	● Standard method to quantify aBMD in the spine, hip, and forearm ● Used in almost all epidemiological and treatment studies during the last 20 years ● Low aBMD predicts vertebral and proximal femur fractures	● Projectional 2D technique ● No separation of trabecular and cortical bone ● aBMD depends on bone size ● Under treatment the increase in aBMD does not reflect the observed rate of fracture reduction
HSA	● Can be easily applied to DXA images ● Estimates bone strength parameters	● Requires many assumptions on hip geometry and BMD distribution ● No evidence that HSA parameters add value to standard DXA parameters with respect to monitoring BMD changes and for fracture risk assessment
TBS	● Can be easily applied to DXA images ● Has shown fracture prediction independent of aBMD	● Not fully clear what bone property is really quantified ● Not recommended to monitor BMD changes under bisphosphonate treatment
QCT	● Fast 3D imaging method ● Trabecular and cortical bone can be separated ● Cortical thickness, geometrical, and bone strength related parameters can be quantified ● QCT of the spine better predicts vertebral fractures than DXA ● Provides a more comprehensive insight into bone pathophysiology than DXA ● More sensitive than DXA to monitor changes of trabecular BMD	● Less standardized than DXA ● Analysis software not integrated in CT scanner and most of the software is not commercially available yet ● Spatial resolution not adequate to quantify trabecular architecture ● Generates a wealth of parameters but it is not fully clear yet, which ones should be used for which purpose
CTXA	● Estimation of DXA images of the hip from QCT scans ● T-scores of CTXA and DXA of the hip are equivalent –> CTXA can be used for diagnosis of osteoporosis	● See DXA
pQCT	● Same as for QCT with the exception of speed	● The forearm and tibia are less sensitive to pharmacological treatment ● Only one or two single slices are measured
HR-pQCT	● Trabecular architecture and cortical porosity can be quantified	● Scans length limited (1 cm in standard mode), long scans times, frequent motion artifacts
QCT-based FEA	● Integrates BMD and geometry to estimate bone strength ● FEA of the spine may better predict vertebral fractures than DXA	● Results depends on loading conditions assumed during the simulations ● Results depend on material properties assigned to the individual elements ● Expert analysis required
3D-DXA	● Estimation of CT-like 3D dataset from DXA scan including FEA	● Clinical validation pending

QCT was first developed to measure BMD of the spine (Genant *et al.*, 1982; Kalender *et al.*, 1987). After introduction of spiral CT (Kalender *et al.*, 1990), which allowed for rapid 3D scanning, QCT of the hip was introduced (Lang *et al.*, 1997, 2002). The analysis of QCT images starts either with a slice by slice or with a more advanced 3D segmentation process of the bone to be analyzed (Kang *et al.*, 2003). Then dedicated volumes of interest (VOIs) are defined. In contrast to DXA, QCT is not a projectional technique. Thus, cortical and trabecular bone compartments can be analyzed separately. Recommended VOIs for the spine are L1 + L2 (Engelke *et al.*, 2008) and for the hip, femoral neck, trochanter, intertrochanter, and of lesser importance the femoral head and shaft. For each VOI, integral, cortical, trabecular and sometimes, subcortical BMD, BMC and volume can be determined (**Fig. 3**). Cortical thickness and other geometrical parameters related to bone strength such as buckling ratio, section moduli, axial, and polar moments of inertia in the neck or cross-sectional area in the spine have also been analyzed (Borggrefe *et al.*, 2016; Khoo *et al.*, 2012; Museyko *et al.*, 2016). However, material or structural properties (**Fig. 1**) cannot directly be assessed by QCT.

For QCT of the spine and hip, clinical whole body CT scanners as manufactured by most large medical device companies are used. These are general purpose devices for radiological diagnosis. They provide a spatial resolution of about 0.5 mm. Consequently, in the reconstructed CT image thin structures such as cortical bone of the vertebral body ($\lesssim$0.5 mm) and the femoral neck ($\lesssim$1 mm) are blurred, a consequence of so-called partial volume artifacts. Thin structures appear to be thicker and have lower contrast than in reality. This results in accuracy errors of cortical BMD and thickness measurements, which increase with decreasing cortical thickness. Several cortical segmentation techniques have been proposed (Prevrhal *et al.*, 1999; Treece and Gee, 2015; Museyko *et al.*, 2017) and it is important to understand their respective impact on cortical measurements (Engelke, 2017). In order to reduce the impact of segmentation, the use of cortical BMC has been suggested (Newman *et al.*, 1998; Dougherty and Newman, 1999), which to a certain degree counterbalances the inaccurate decrease in cortical BMD and increase in cortical thickness.

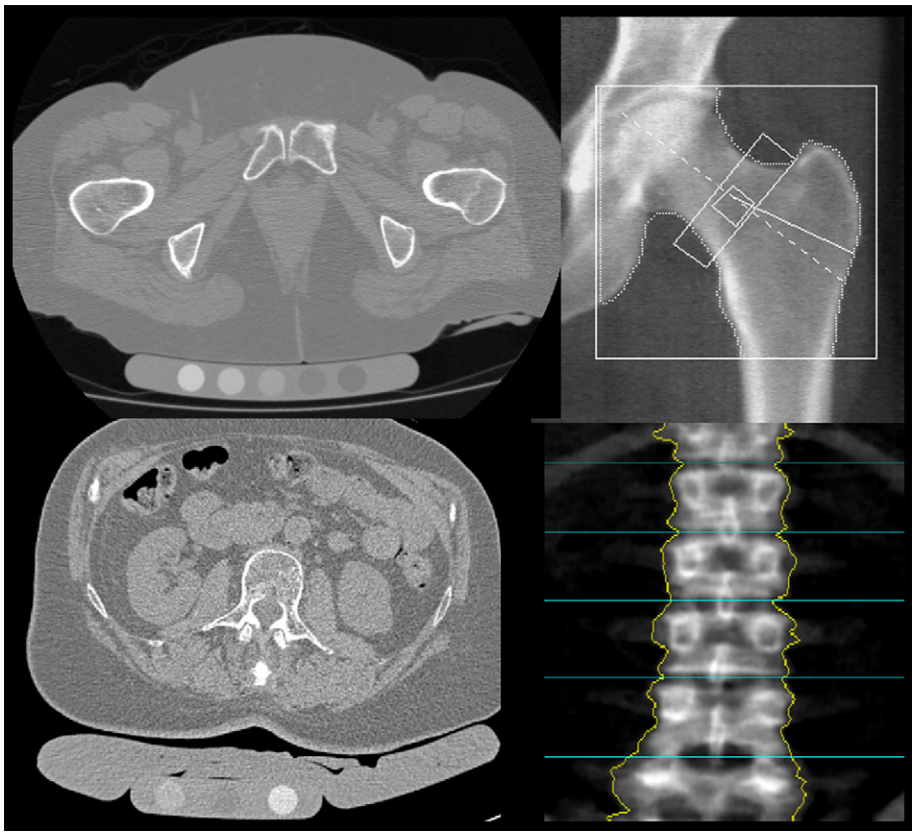

Fig. 2 QCT (left) and DXA (right) images of the hip (top) and spine (bottom). For QCT analysis the patient is scanned on top of a calibration phantom (hip scan on top of Mindways calibration phantom; Mindways Software, Inc., Austin, TX; spine scan on top of QRM Bone density calibration phantom (BDC); QRM Möhrendorf, Germany).

Peripheral and High-Resolution Peripheral QCT

Clinical whole body CT scanners can also be used for QCT of peripheral sites such as arms or legs (Engelke *et al.*, 2009a) but this is the domain of dedicated peripheral QCT (pQCT) scanners. They are widely used in pediatric research (Adams *et al.*, 2014), where CT scans of the spine or hip are avoided because of radiation exposure. Dedicated high-resolution pQCT (HR-pQCT) scanners with a spatial resolution of 120 μm (Burghardt *et al.*, 2013) have been developed to image trabecular bone structure at peripheral sites such as the distal radius and tibia (Laib *et al.*, 1998) (**Fig. 4**).

Cortical and trabecular regions of HR-pQCT scans can be segmented using semiautomatic (Laib *et al.*, 1998) or automatic methods (Nishiyama *et al.*, 2010; Buie *et al.*, 2007; Burghardt *et al.*, 2010a). In addition, a histomorphometric analysis can be used to assess the microstructure of the trabecular network. Average trabecular thickness (Tb.Th) and separation (Tb.Sp) are derived from bone volume fraction (BV/TV) and average number of trabeculae (Tb.N) (Laib *et al.*, 1998). BV/TV is determined from BMD of the trabecular compartment by assuming a density of 1200 mg/cm^3 for fully mineralized bone. Tb.N is directly measured using ridge extraction methods (Hildebrand and Rüegsegger, 1997). A newer HR-pQCT scanner model with improved spatial resolution allows for direct quantification of trabecular bone indices (Manske *et al.*, 2015) that do not depend on trabecular BMD.

Due to the high spatial resolution, larger cortical pores can be detected. Cortical porosity (Ct.Po) is calculated as percentage of void voxels in the cortex (Nishiyama *et al.*, 2010) after thresholding the image. Another method (Zebaze *et al.*, 2013) uses cortical density to estimate pores by assuming that BMD of fully mineralized bone is 1200 mg/cm^3. Both techniques showed strong correlations with synchrotron CT (Jorgenson *et al.*, 2015), but absolute values of porosity differ significantly.

Finite Element Analysis

FEA is widely used in mechanical engineering to calculate the strength and other properties of complex structures under the action of external forces. A given structure is divided into a large number of small finite elements of a simple geometry, for which deformations, stresses or even failure can be calculated easily if material properties are known for each element. In the musculoskeletal field, FEA is typically applied to CT datasets.

For the analysis of bone strength, two types of FEA are used (Pahr and Zysset, 2009). If the spatial resolution of the CT images is high enough, each trabecula can be segmented and divided into small finite elements. This approach is called μFE. Typical

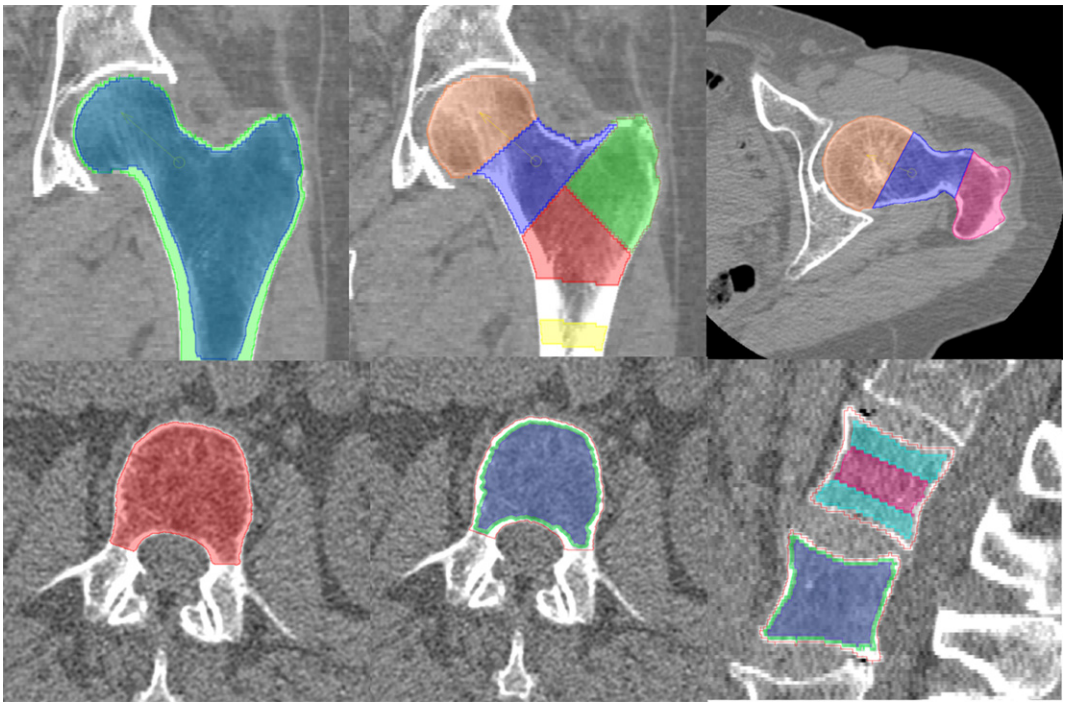

Fig. 3 Advanced QCT analysis of the hip (top) and spine (bottom). Top left: coronal MPR showing cortical and trabecular bone compartments; Top center: integral bone compartments of head (*brown*), neck (*blue*), trochanter (*green*), intertrochanter (*red*), and shaft (*yellow*) VOIs in coronal and top right in axial MPR. Bottom left and center: integral (*red*), subcortical (*green*), and trabecular (*blue*) bone compartments in axial view, integral bone is also shown as red contour; bottom right: sagittal MPR; In the upper vertebra the trabecular compartment is further subdivided in superior, mid and inferior compartments. 3D segmentation results are shown as 2D contours or overlays (Medical Image Analysis Framework (MIAF), University of Erlangen, Germany).

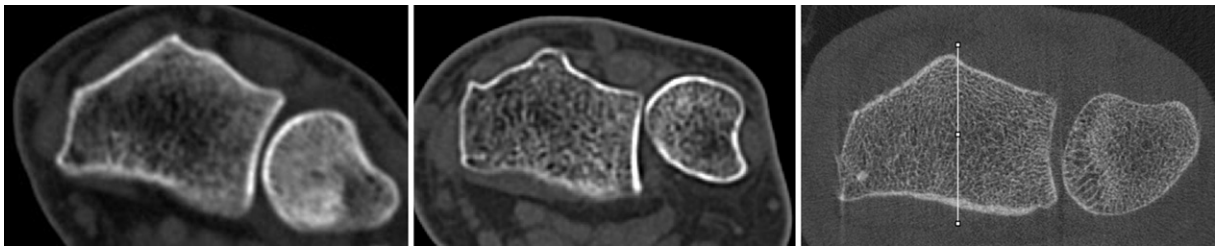

Fig. 4 Comparison of spatial resolution of distal forearm. Left and center: CT of the forearm using whole body CT scanner, left: standard body reconstruction kernel; center: bone reconstruction kernel; right: HR-pQCT scan (images from different patients).

applications are the analysis of trabecular bone samples imaged with μCT or the analysis of trabecular architecture in vivo using HR-pQCT scans of the distal radius or tibia. In CT scans of the spine and hip, the spatial resolution is much lower and a segmentation of individual trabeculae is not possible. Instead, a mesh is applied to the entire vertebral body or proximal femur resulting in individual elements with a size in the millimeter range (Eswaran *et al.*, 2009). Material properties are then assigned to each finite element based on its calibrated BMD value. These are the so-called homogenized FE models. The term homogenization denotes the averaging process used in determining the apparent material properties of the bone—marrow mixture (**Fig. 5**). The material properties are essential input parameters for FE analysis (Bayraktar *et al.*, 2004; Zysset, 2003). Another input is the so-called loading scenario describing the direction, magnitude, and insertion point(s) of the external force(s) (Bessho *et al.*, 2009; Buckley *et al.*, 2009). The FEA outcome also depends on the specific algorithm used for FEA simulation (Keyak and Rossi, 2000) and on criteria when the bone actually fails.

Vertebral bodies are typically loaded in compression. For the femur, usually a fall to the side is simulated (Keaveny *et al.*, 2014, 2018; Kopperdahl *et al.*, 2014). The outcome of FEA is a simulated load-displacement curve. The linear part of the curve, that is, stiffness, can be obtained with linear FEA. The simulation of the yielding of the curve, the maximal force and the energy to failure requires nonlinear FEA (Keyak, 2001; Nawathe *et al.*, 2015). For in vivo measurements, estimated failure load, reported in kN, is the most widely used parameter and is often reported as bone strength not to be confused with ultimate stress, which is a material variable.

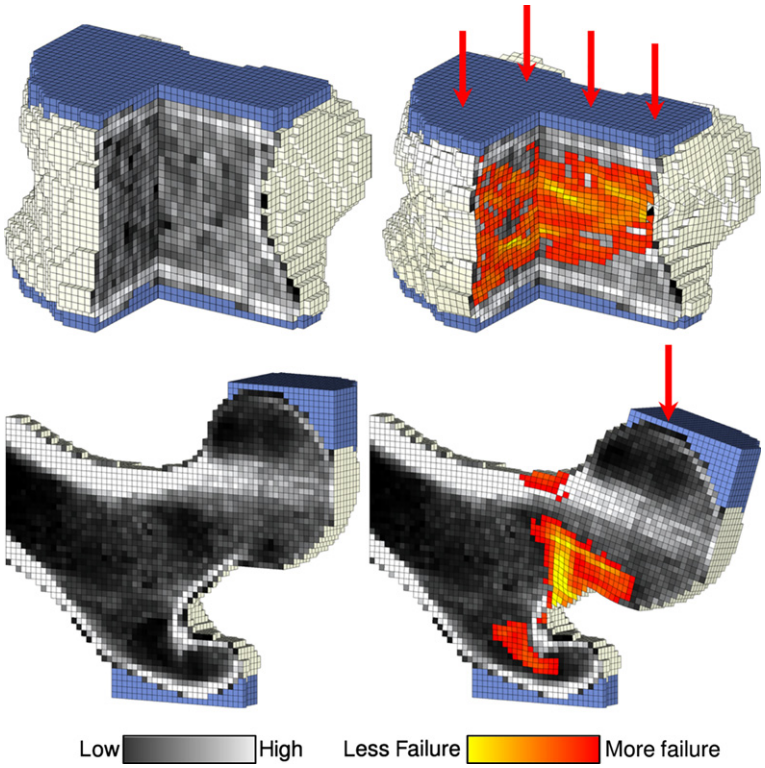

Fig. 5 Left: Cut-out views of finite element models depicting the distribution of volumetric BMD and derived from CT attenuation data from an L1 vertebral body and left proximal femur. Right: Nonlinear stress analysis results for compressive loading of the spine and a sideways fall of the hip with colors depicting bone tissue failure. Deformations are magnified. Advanced DXA Methods

Advanced DXA methods can be divided into two categories: 2D-based measurements such as hip strength analysis (HSA) or trabecular bone score (TBS) that are applied directly to the DXA image. In contrast, 3D measurements are derived from CT-like images estimated from one or multiple DXA images using atlas-based procedures.

The calculation of geometrical parameters related to bone strength such as cross-sectional area (CSA), cross-sectional moments of inertia (CSMI), section moduli or buckling ratio are based on the analysis of the BMC distribution along one-dimensional profiles in the DXA image. This technique was already applied to single-photon absorptiometry of the forearm (Martin and Burr, 1984). Hip Structural and a variant called hip strength analysis, both abbreviated as HSA, denote extensions to DXA of the hip (Beck *et al.*, 1990; Yoshikawa *et al.*, 1994). In simple objects such as homogeneous beams or pipes, the geometrical parameters determined by HSA are indices of resistance to bending (CSMI, section modulus, buckling ratio) and compression (CSA) (Beck, 2003). HSA for DXA of the hip is based on assumptions that the bone cross-section is circular at the femoral neck and shaft, and elliptical at the intertrochanteric region. It is further assumed that tissue mineral density is constant and that there is a constant proportion of cortical and trabecular bone in the cross-section (Beck, 2003; Uusi-Rasi *et al.*, 2006). Further, the one-dimensional profiles required for the analysis should be perpendicular the neutral axis of the structure. In a tube, which may be used to approximate a radius, this is the central axis. For the proximal femur, the neutral axis was determined using a curved beam model (Mourtada *et al.*, 1996). Despite all the limitations and assumptions, correlations between HSA parameters determined from DXA and the corresponding parameters directly obtained from QCT scans are high ($r = 0.89–0.95$) (Ramamurthi *et al.*, 2012).

Based on the curved beam model, 2D DXA images of the hip have been used to derive internal stresses directly (Mourtada *et al.*, 1996). A further refinement called composite curved beam analysis included the BMC distribution (Yang *et al.*, 2009). A stress distribution of the hip has also been calculated by 2D-FEA applied to DXA scans (Testi *et al.*, 1999). In a recent study, correlations of maximum load between DXA based 2D-FEA and QCT based 3D-FEA were $r^2 = 0.76$ (Dall'Ara *et al.*, 2016).

A further step toward a volumetric assessment of BMD and 3D geometry is 3D-DXA initially termed volumetric DXA (VXA) (Ahmad *et al.*, 2010). Statistical atlases generated from site-matched CT scans are used to determine shape and BMD variations across a population. An atlas is characterized by so-called Eigenvectors. About 10–20 eigenvectors suffice to describe the shape of an individual femur of this population with about 95% accuracy (Whitmarsh *et al.*, 2011). Originally, several (<5) DXA projections were taken from the proximal femur using different angles by rotating the C-arm of the DXA scanner. Newer techniques just use the standard DXA image (Whitmarsh *et al.*, 2011; Grassi *et al.*, 2017; Humbert *et al.*, 2012; Humbert *et al.*, 2017). The projection(s) are fitted to the statistical 3D atlas. The result is an estimation of the corresponding CT 3D dataset, which can be

segmented and analyzed using algorithms applied in QCT. For example, 3D-FEA results can be estimated from such a dataset. The opposite of 3D-DXA is CTXA, which generates 2D projectional images from a CT acquisition (Cann *et al.*, 2014). The purpose is to obtain DXA equivalent data that can be used for the diagnosis of osteoporosis according to the WHO definition.

Another potential application of 3D-DXA is the separation of cortical and trabecular bone compartments. In a validation study (Humbert *et al.*, 2012) of 157 subjects correlations between QCT and 3D-DXA were 0.95 for total hip cortical density and 0.91 for total hip cortical thickness with mean absolute differences of 72 mg/cm^3 or 7.6% and 0.33 mm or 18.3% for density and thickness, respectively. Results of three subjects are shown in **Fig. 6**. Graphs of correlations or Bland–Altman plots were not presented. Compared to QCT, 3D-DXA images are blurred, which is understandable as shape and density information is described by a limited number of Eigenvectors that is extremely small in comparison to about 3–4 million voxels of a femur in a CT dataset.

A different approach not related to strength is TBS (Harvey *et al.*, 2015), which performs a texture analysis of the BMD distribution of a DXA image of the spine. First attempts to use texture parameters to quantify trabecular architecture were developed using high resolution X-ray films of the calcaneus, where cortical bone is rather thin (Benhamou *et al.*, 1994, 2001). Obviously, the spatial resolution of DXA images is much lower than in X-rays. In addition, a DXA image not only includes the trabecular network but also mostly cortical structures such as the pedicles and spinal process. Therefore, the claimed association of TBS with trabecular structure has been criticized (Maquer *et al.*, 2016). However, TBS adds information to aBMD.

Clinical Relevance of Assessing Bone Quality

Several recent reviews have addressed the performance of imaging techniques assessing bone quality (Hunt and Donnelly, 2016; Link and Heilmeier, 2016; Griffith *et al.*, 2010; Bouxsein and Seeman, 2009). The International Society of Clinical Densitometry (ISCD) has instituted an evidence based consensus process to develop positions on how to use these techniques clinically (Engelke *et al.*, 2008, 2015; Zysset *et al.*, 2015; Broy *et al.*, 2015; Silva *et al.*, 2015). The official positions for DXA, QCT, FEA, HSA, and TBS are summarized in **Table 2**. Empty fields indicate that ISCD positions are not available for this technique. So far, no positions have been developed for DXA-based FE methods or HR-pQCT, although a number of publications have investigated performance characteristics of these techniques (Kawalilak *et al.*, 2016; Zhou *et al.*, 2016; van Rietbergen and Ito, 2015). By definition, techniques other than DXA cannot be used for the diagnosis of osteoporosis because the WHO definition is based on DXA

M. (2017). 3D-DXA: Assessing the femoral shape, the trabecular macrostructure and the cortex in 3D from DXA images. *IEEE Transactions on Medical Imaging* **36**(1), 27–39.

Table 2 Official positions for women of the International Society of Clinical Densitometry (ISCD) on clinical utility of advanced imaging methods

	Location	*Diagnosis of osteoporosis*	*Site matched fracture prediction*	*Monitoring age related changes*	*Monitoring treatment effects*	*Initialization of treatment*
DXA based parameters						
Hip axis length	Hip	n	0[a]	n	n	n
HSA parameters		n	n	n	n	n
TBS	Spine	0[b]	0[b,c]	n[d]		0[c]
CT based parameters						
int BMD	Spine	n		0[f]	0[f]	y
	Hip	n		y	y	
trab BMD	Spine	n	y	y	y	y
	Hip	n	y	y	y	
CTXA	Hip	y				
int BMD	pQCT UD	n	y[e]	y		y
trab BMD	radius	n	y[e]	y		y
FEA strength	Spine	n	y	y	y	y
	Hip	n	y	y	y	y

[a]Association with hip fracture.
[b]Association with hip and spine fracture.
[c]Only in combination with other parameters.
[d]In patients under bisphosphonate treatment.
[e]Predicts hip fracture, no position for radius fracture.
[f]There was insufficient evidence at the time (2007) when ISCD positions for QCT of the spine were issued, however, there is now plenty of evidence that integral BMD of the spine can be used as for monitoring.
trab, trabecular; *int*, integral. For a complete list of positions, see www.ISCD.org. *y*, technique can be used; *n*, technique should not be used; field empty, no recommendation available.
Note: In men, there are fewer studies and several of the positions that are supported for women are not supported for men because of missing evidence.

T-scores. T-scores can be calculated for all techniques listed in **Table 1** but these are not equivalent to DXA T-scores (Engelke *et al.*, 2008). The only exception is CTXA of the hip for which T-scores can be directly calibrated to DXA hip T-scores (Khoo *et al.*, 2009).

CT Based Techniques

It is important to compare imaging techniques with DXA because aBMD is a strong surrogate of bone quality and it is unlikely that new techniques will replace DXA unless they show superior performance or add information. This is in particular important for CT based applications, because CT adds complexity, cost and radiation exposure. For typical QCT acquisition protocols, radiation exposure is about 1.5 and 2.5 mSv in the spine and hip, respectively (Engelke *et al.*, 2008). This is comparable to the natural background radiation of about 2.5 mSv but higher than for DXA (<0.01 mSv).

In vitro, aBMD correlates highly ($r = 0.6$–0.9) with bone strength of the femur (Keyak *et al.*, 1998; Cody *et al.*, 1999; Bousson *et al.*, 2006) and spine (Ebbesen *et al.*, 1999; Dall'Ara *et al.*, 2012; Mosekilde *et al.*, 1989; Hayes *et al.*, 1991). In studies, in which correlations with or predictions of bone strength have been assessed with multiple imaging modalities, typically QCT was a slightly better predictor than DXA (Bousson *et al.*, 2006; Lochmuller *et al.*, 2002) and FEA was superior to the other two (Cody *et al.*, 1999; Dall'Ara *et al.*, 2012; Danielson *et al.*, 2012; Johannesdottir *et al.*, 2017).

However, in vivo, FEA, and QCT improve hip fracture prediction or discrimination only marginally compared to DXA (Bousson *et al.*, 2011; Cheng *et al.*, 2007; Orwoll *et al.*, 2009; Johannesdottir *et al.*, 2011). Technical improvements are possible but probably non-bone related factors such as the risk of falling are important and independent contributors to assess hip fracture risk. FE models should not only focus on accurate prediction of bone strength, but also consider applied loads (Falcinelli *et al.*, 2014; Qasim *et al.*, 2016). As described above, the primary input to homogenized FE models is BMD, but anisotropy of trabecular bone is neglected. Integrating fabric, a parameter to assess anisotropy, into the FE model (Maquer *et al.*, 2015; Chevalier *et al.*, 2009) may also improve fracture risk prediction. For QCT, cortical thickness of the neck adds independent information to BMD for fracture prediction (Museyko *et al.*, 2016; Treece and Gee, 2015; Poole *et al.*, 2011). AUC values have been further increased by adding parameters describing the amount of adipose tissue and the distribution of fat within muscle. (Mühlberg *et al.*, 2018; Lang *et al.*, 2008, 2010).

In the spine, vertebral fracture risk assessment by QCT and FEA seem to be superior to DXA. Wang showed significantly higher hazard ratios and AUC values for ultimate load and integral BMD (AUC both 0.83) of the total vertebral body than for aBMD (0.76) (Wang *et al.*, 2012). Similar results in the spine were reported for Japanese women (Imai *et al.*, 2009). Evidence is still poor, based only on one longitudinal prospective and some cross-sectional studies but the findings are not surprising, as aBMD cannot

be measured separately for the vertebral body. aBMD includes cortical contributions from the spinal process and the vertebral arch and is falsely increased by degenerative changes and aortic calcifications.

With QCT but not DXA, differential BMD, and BMC effects in cortical, subcortical and trabecular BMD can be determined. Together with measurements of cortical thickness and of bone volume to potentially identify periosteal apposition, a detailed understanding of treatment effects has been achieved. In future, these differential effects combined with measurements of strength and trabecular architecture may be important for the characterization of different phenotypes of osteoporosis in order to develop individual treatment (Jepsen *et al.*, 2015; Litwic *et al.*, 2017; Vranken *et al.*, 2017; Edwards *et al.*, 2016).

Precision errors of QCT using advanced segmentation are comparable to DXA (Lang *et al.*, 1997; Museyko *et al.*, 2016; Engelke *et al.*, 2009b). However, QCT is more sensitive to monitor trabecular BMD changes than DXA because age or treatment related changes of trabecular BMD are higher than for integral BMD. Treatment related increases in bone strength in osteoporotic patients are usually higher than integral BMD increases (Zysset *et al.*, 2015) but precision errors for strength have not be published for strength so far.

QCT and FEA techniques are highly relevant for opportunistic screening, the use of existing clinical CT images for the diagnosis of osteoporosis and fracture prediction (Engelke, 2017). If widely implemented, opportunistic screening could significantly improve the identification of patients at high risk for fracture. A secondary analysis of CT data obtained for tumor and other routine clinical diagnoses could be used to categorize fracture risk as low, medium or high. It has been suggested that subjects with high fracture risk could be followed up with DXA or could be directly referred to counseling or appropriate intervention even without an additional DXA scan. Both scenarios are convenient and cost effective because DXA scans and associated logistics are not required. An additional benefit of the dual use of CT scans is the possibility to use a lateral scout view or a lateral projection of the spinal column to assess fractures.

The relevance of trabecular architecture for fracture prediction is not fully clear yet (Boutroy *et al.*, 2005; Folkesson *et al.*, 2011; Burghardt *et al.*, 2010b; Khosla *et al.*, 2006). In two recent studies, quantification of trabecular structure contributed moderately to fracture risk independent of DXA aBMD of the forearm (Sornay-Rendu *et al.*, 2007; Vilayphiou *et al.*, 2010) but results were not adjusted for integral, trabecular or cortical forearm BMD, which are also available from an HR-pQCT scan. Differences in trabecular architecture may be more relevant for phenotyping the association of bone with fracture (Litwic *et al.*, 2017; Edwards *et al.*, 2016). Trabecular architecture has also been estimated for the vertebral body using optimized acquisition and reconstruction protocols on clinical whole body CT scanners (Krebs *et al.*, 2009; Graeff *et al.*, 2007, 2015) but the technique is still in an experimental status.

Cortical BMD and thickness of the forearm are associated with severity of vertebral fractures (Sornay-Rendu *et al.*, 2009; Szulc *et al.*, 2011). The measurement of cortical porosity is relevant in patients with diabetes type 2, which despite normal aBMD and increased trabecular bone density have higher fracture risk than controls. As shown by HR-pQCT, these patients have reduced cortical vBMD (Burghardt *et al.*, 2010c) and in case of fragility fractures increased cortical porosity (Patsch *et al.*, 2013). For other applications, it is still debated whether at the spatial resolutions achievable with current HR-pQCT equipment, cortical porosity is just a surrogate of cortical BMD. Differential treatment effects on cortical and trabecular structure induced by a variety of antiosteoporotic drugs have been summarized recently (Lespessailles *et al.*, 2016): "Responses to therapies were treatment-specific and divergent effects in cortical and trabecular bone with antiresorptive or anabolic agents were observed." Often, effects were stronger in the tibia than in the radius. Results for cortical thickness and porosity depended on segmentation and revealed challenges to monitor changes, particularly in instances of endocortical or periosteal resorption or apposition.

DXA Based Techniques

A big advantage of 3D-DXA imaging techniques is the possibility to apply them directly to an existing DXA scan without additional imaging of the subject. Just special software is required. As standard DXA results are available, only information independent of aBMD will justify an additional analysis. For example the ISCD positions on HSA that were based on more than 50 studies concluded that this technique and other geometrical parameters such as the neck-shaft angle should not be used for fracture prediction because of lack of evidence that HSA parameters improved fracture prediction independent of aBMD. HSA should also not be used for monitoring of osteoporosis, because of insufficient precision (Broy *et al.*, 2015). The only exception with regard to fracture prediction was the neck axis length.

In contrast, TBS adds independent information for hip and spine fracture prediction and has been integrated as risk factor into the FRAX algorithm for calculation of fracture risk. Recently, a large metaanalysis of 14 prospective studies with 17,800 patients confirmed TBS as moderate aBMD independent risk factor of incident hip fractures (McCloskey *et al.*, 2016). Although the FDA has approved TBS for monitoring treatment effects in osteoporosis, the ISCD positions currently discourage monitoring in patients under bisphosphonate therapy due to small changes of TBS (Silva *et al.*, 2015).

It is too early to give clinical recommendations for 3D-DXA methods as most of the published studies have been dedicated to technical issues. In 65 cadavers the in vitro correlation between 2D-FEA derived and experimentally determined strength was $r^2 = 0.6$ (Naylor *et al.*, 2013). For 3D-FEA only a small pilot study in three cadavers has been published (Grassi *et al.*, 2017). In postmenopausal women of the large epidemiological study of osteoporotic fracture (SOF), estimated femoral strength from 2D-FE analysis of DXA scans was an independent predictor and performed at least as well as FN BMD in predicting hip fracture (Yang *et al.*, 2014). In a subgroup of men of the MrOS study similar results were reported. In a third study, again in women, AUC values

for femoral neck aBMD combined with 2D-FEA strength estimates (0.69) were slightly higher than for neck aBMD alone (0.66) (Naylor *et al.*, 2013).
