Previous SGA infant	Constitutionally small	

Prader–Willi syndrome is another syndrome associated with UPD of chromosome 15, and results from a loss of function of several genes including some that encode for small nucleolar RNAs (snoRNAs). The loss of a particular group of snoRNA genes, known as the SNORD116 cluster, can play a role in causing the signs and symptoms of Prader–Willi syndrome and modest prenatal growth failure (Bieth *et al.*, 2015).

Early Endocrine Axis in Infants Born SGA

Studies of the endocrine status of SGA infants in the perinatal period have been inconsistent. This is likely to reflect the range of underlying pathologies encompassing the diagnosis of SGA, and the changes that occur during the transitional period from in utero to ex utero life. One study showed that SGA infants have lower blood glucose and insulin levels than AGA infants, and higher glucose/insulin ratios. SGA infants also had higher levels of IGFBP-1, free fatty acids and beta-hydroxy butyrate (Iñiguez *et al.*, 2006). This demonstrates that these infants display an increased insulin sensitivity with respect to glucose disposal but not with respect to suppression of lipolysis, ketogenesis, and hepatic production of IGFBP-1. This can be seen as advantageous in ensuring alternative energy sources are available for these neonates who have limited glucose reserves (Bazaes *et al.*, 2003). Others have shown that both full-term and preterm SGA neonates had higher insulin concentrations, insulin to glucose ratios, triglycerides, total cholesterol and low-density lipoprotein cholesterol concentrations than AGA neonates (Wang *et al.*, 1991). This would suggest SGA neonates displaying profiles suggestive of lower insulin sensitivity and less favorable lipid metabolism in the early postnatal period.

Early Childhood Growth in SGA Children

Most children born SGA tend to gain weight rapidly in early life and historically this catch up was believed to be advantageous with potential benefits on short term survival and stature, as well as neurodevelopment (Yeung, 2006). This accelerated postnatal weight gain however has been associated with increased adiposity and metabolic disease in later life (Barker *et al.*, 1993). Catch up can be defined as growth velocity above the limits of normal for age and can be complete or incomplete. However catch-up growth is often used to categorize children into those who have moved into a defined target range for height or weight or demonstrated a significant increase in standard deviation score (>0.67) with crossing of >2 growth centiles (Hokken-Koelega *et al.*, 1995). Catch-up growth typically occurs in the first few months (approximately 80% in the first 6 months) with up to 90% showing catch up growth by 2 years of age (Karlberg and Albertsson-Wikland, 1995; Yadav and Rustogi, 2015).

Catch Up Growth and the Metabolic Syndrome

All SGA individuals, regardless of whether there is catch up growth, have a long term increased metabolic risk in adult life, with higher incidences of cardiovascular disease, hypertension and type 2 diabetes mellitus, when compared to babies born AGA (Barker *et al.*, 1993, Barker; 2006, Hales and Barker, 2013). Those with catch up growth however have an increased risk.

Mechanisms of Catch Up Growth

The mechanisms that underlie early catch-up growth are not fully understood. It is thought to be largely driven by increased appetite, and subsequent increased IGF-1 (Mericq *et al.*, 2017). Cohort studies show that sustained high levels of orexigenic hormones such as ghrelin can be demonstrated in these children following a glucose load (Iñiguez *et al.*, 2002). Alternatively, adaptive mechanisms may reduce energy expenditure to maintain adequate growth, as has been demonstrated in animal models (Vickers *et al.*, 2003; Ikenasio-Thorpe *et al.*, 2007). This may be mediated through leptin resistance in infants born SGA, as this would act to drive increased weight gain. There is altered development of adipose tissue and adipokine signaling and epigenetic changes resulting in greater expression of pathways for adipogenesis (Sarr *et al.*, 2012). This leads to altered energy partitioning resulting in increased fat stores particularly in subcutaneous abdominal and visceral compartments, at the expense of lean mass (Ong *et al.*, 2000; Stettler *et al.*, 2002).

Critical to the risk of developing glucose intolerance is the relationship between insulin sensitivity and compensatory insulin secretion. The reduced disposition index in SGA children at 3 years of age may indicate early deficiency in their first phase insulin response. In the ALSPAC cohort the compensatory increased insulin secretion for the degree of insulin resistance was related to height gain and IGF-I levels and it is possible that the insulin secretion response in relation to growth hormone mediated insulin resistance could be a factor in promoting early catch up growth particularly growth in length as opposed to weight. Overexpression of the enzyme acyl-coenzyme A synthetase 1, which is involved in transport and degradation of fatty acids, as well as lipid synthesis may also play a role. This enzyme has been associated with increased lipid loading of adipocytes and increased insulin sensitivity in infants born SGA (Joseph *et al.*, 2015). It is thought that this may help to promote rapid catch up growth in SGA infants, but in later life this overexpression may lead to excess synthesis of triglycerides, contributing to obesity, as well as increasing insulin resistance by increasing fatty acid release.

Impact of Catch Up Growth

During catch up growth fat mass is accumulated much faster than lean mass and this is related to the insulin resistance seen in SGA children who catch up (Dulloo, 2006; Dulloo *et al.*, 2006a, b). SGA children who showed catch-up growth between 0 and 2 years had greater adiposity and more central fat distribution at 5 years of age than other children (Ong *et al.*, 2000) with total and abdominal fat mass at 4 years more closely related to rate of weight gain between 0 and 2 years not 2 and 4 years (**Fig. 1**). The impact of central adiposity or visceral fat on insulin resistance may be mediated by the effects of increased nonesterified fatty acid flux to the liver and changes in the adipokines such as adiponectin (Mittelman *et al.*, 2002). Falling adiponectin levels are related to increasing age and greater weight gain. Further studies have shown that the weight gain during childhood is a stronger determinant of body composition in young adult hood than birth weight itself (Kerkhof *et al.*, 2012). A higher gain in weight for length in the first 3 months of life is associated with a higher prevalence of metabolic syndrome at 21 years of age whereas birth weight was not.

When measured at 3 years of age studies have shown that, despite there being no significant differences in weight or body mass index (BMI) between SGA and AGA children, prefeed insulin levels were also related to the rate of weight gain between 0 and 3 years. First phase insulin secretion did not differ between the SGA and the AGA infants but the SGA infants had a lower glucose disposition index demonstrating beta cell compensation which persisted after allowing for postnatal weight gain (Mericq *et al.*, 2005). The changes in insulin sensitivity are accompanied by changes in IGF-I levels. At birth SGA infants show increased insulin sensitivity, with raised IGFBP1, relative to AGA infants (Bazaes *et al.*, 2003). At 3 months of age mean serum IGF-I and IGF-BP3 are lower in SGA infants than in infants born AGA (Chellakooty *et al.*, 2006), However IGF-I levels later in life are inversely related to birth weight, with higher levels after catch up growth in SGA children, which persists into young adulthood (Fall *et al.*, 1995; Jernström and Olsson, 1998; Garnett *et al.*, 1999; Ong *et al.*, 2002).

The increased abdominal and hepatic fat deposition and reduction in insulin sensitivity in children with catch up growth, is also associated with changes in biomarkers similar to that seen in the metabolic syndrome. These include lower levels of adiponectin, FGF21, FGF19 and visfatin, and higher leptin levels, compared to those without catch up or AGA children (Mericq et al., 2005, 2017). Therefore, alterations in body composition, and biomarkers of metabolism, that are associated with adverse cardiovascular and metabolic disease risk during adult life, are already present in young SGA children with rapid catch-up growth (**Fig. 2**).

Early interventional studies of infants born SGA, which were aimed at promoting early growth with the hope of improved cognitive outcomes, have confirmed the findings from cohort studies. These studies which randomized babies at birth to standard or nutrient enriched formulas, were extended to explore cardiovascular and metabolic outcomes. They showed that at age 6–8 years those receiving the standard formula had a significantly lower mean and diastolic blood pressure (Singhal *et al.*, 2006). Current research is focusing on exploring ways of modifying nutritional content in formula, particularly protein content, as well as maternal behaviors around milk feeding to prevent over feeding during infancy as those who are bottle fed appear to be at most risk (Fewtrell *et al.*, 2001; Rolland-Cachera *et al.*, 1995, Koletzko *et al.*, 2009a,b; Socha *et al.*, 2011; Lakshman *et al.*, 2015).

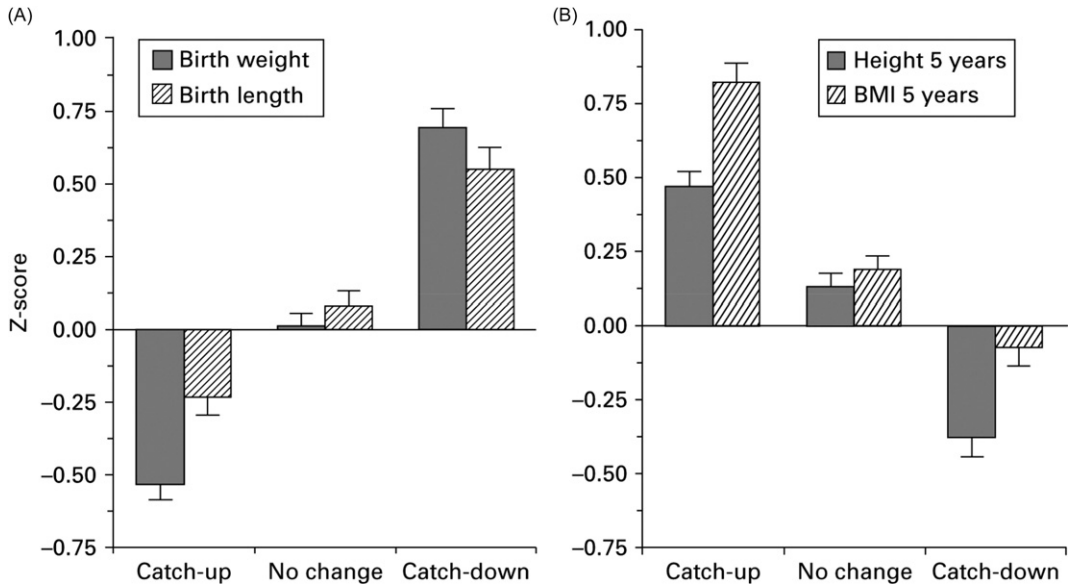

Fig. 1 Association between infant growth pattern and (A) weight and length *z*-score at birth and (B) height and BMI z-score at 5 years. Data showing mean ±standard error. This data demonstrates that in a population study at birth those who will catch-up in weight and length are born with more negative *Z*-scores, and those who catch-down are born relatively larger. By 5 years of age those who have shown catch-up have higher BMI compared to those who have no change in Z-score or who have shown catch-down. Reproduced from Wells, J. C. K. *et al.* (2016). The elevated susceptibility to diabetes in India: An evolutionary perspective. *Frontiers in Public Health*, **4**, 145.

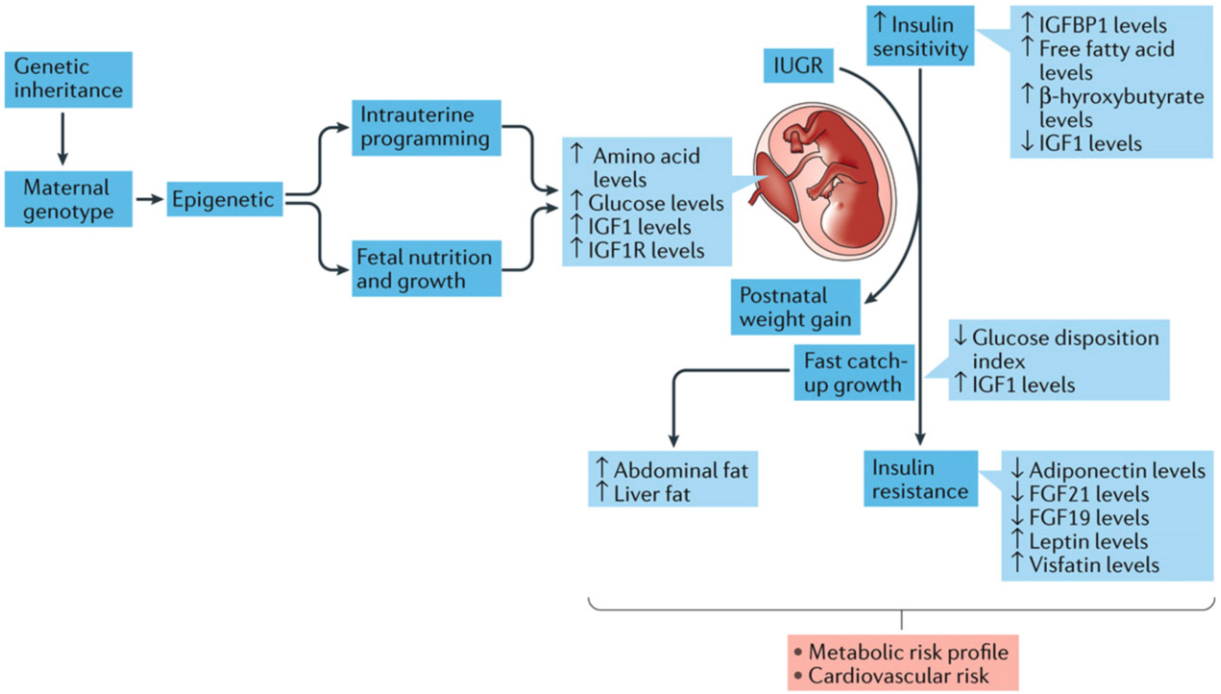

Fig. 2 Schematic diagram showing proposed links between genetic and epigenetic factors, metabolic alterations during early life and increased risk for metabolic diseases during adulthood in small for gestational age children. The placenta is critical for integration of environmental signals, thereby enabling healthy fetal growth and development. This process is mediated in part by increased expression of insulin-like growth factor 1 (IGF1) and its receptor (IGF1R), suggesting a compensatory mechanism in response to fetal growth restriction that could induce other changes to promote influx of amino acids and glucose from the maternal blood supply via the placenta to the fetus. After birth, a period of increased insulin sensitivity occurs, which gradually decreases relative to postnatal weight gain (catch-up growth). These changes could, in turn, be associated with adverse body composition and increased cardiovascular risk. Long-term metabolic risk among children born premature or small for gestational age. *Nature Reviews Endocrinology* **13** (1), 50–62. https://doi.org/10.1038/nrendo.2016.127.

Lack of Catch Up Growth and Short Stature

Children born SGA who do not catch-up by 2 years have five- to sevenfold increased risk of short stature in adult life (Albertsson-Wikland *et al.*, 1998). The licensing of the use of growth hormone (GH) for use in these SGA children who remain short, but who do not meet the classical criteria for growth hormone deficiency, raised significant debate. The benefits of height gain both physical and psychological, need to be balanced against the potential burden of treatment for the child, health care costs and unclear long-term risks and benefits (Lantos *et al.*, 1989).

Growth Hormone Treatment

SGA children who remain short at 2–4 years of age need evaluation for the use of GH treatment (Clayton *et al.*, 2007). These children are a heterogenous group and efforts should therefore be made to determine any underlying diagnosis. This is important as GH treatment is contraindicated in some disorders such as DNA repair disorders and the chromosomal breakage syndromes (e.g., Bloom and Fanconi syndromes), which may be associated with prenatal and postnatal growth failure. The efficacy and safety of GH in short children born SGA have been demonstrated in several studies over the last 5 decades and it has been licensed by the Food and Drug Administration in 2001 and the European Agency for the Evaluation of Medicinal Products in 2003 (**Table 2**). However, there are uncertainties in the specific anthropometric patient selection criteria, and the optimal dose of GH and there are therefore discrepancies in the licensing terms between the two agencies.

Treatment regimens

The short-term height gain from GH treatment is considerable; after 3 years ranging from +1.2 to +2.0 standard deviation scores (SDS) on doses ranging from 35–70 mcg/kg (Clayton *et al.*, 2007). Most of the height gain occurs in the initial catch-up period, and is then maintained up to adult height. The duration of the catch-up growth appears to be dose-dependent as the height gain of +2.0 SDS was obtained after 2.5 years with GH doses of 67 mcg/kg/day but only after 5.5 years with the dose of 33 mcg/kg/day

Table 2 Growth hormone treatment in children born small for gestational age

	FDA-approved indication (2001)	*EMEA-approved indication (2003)*
Age at start (year)	2	4
Height SDS at start	Not stated	−2.5 sd
Growth velocity before treatment	No catch-up	<0 sd for age
Reference to midparental height	Not stated	Height SDS > 1 sd below midparental height SDS
Dose (μg/kg/day)	70	35

The Journal of Clinical Endocrinology and Metabolism 92(3), 804–810.

(de Zegher *et al.*, 2000). Once started, the treatment should be continued until the adult height is reached, as discontinuation after a period of treatment leads to a significant reduction in height (Fjellestad-Paulsen *et al.*, 2004). The data on adult height in SGA children treated with GH is limited, and the studies vary considerably in terms of age at start and duration of treatment, GH dose used and the endpoints. A meta-analysis based on four randomized controlled trials showed that the overall mean difference in adult height between treated and untreated children born SGA was 0.85 SDS (5.3 cm) (Maiorana and Cianfarani, 2009). Furthermore, 80% of treated children have adult height within the normal and family target height range (Van Pareren *et al.*, 2003; Dahlgren *et al.*, 2005).

Early referral is important as starting treatment at least 2 years before puberty, and normalization of height before puberty have been shown to be crucial in normalization of adult height (Dahlgren *et al.*, 2005; Simon *et al.*, 2008). Age of onset and duration of puberty, height gain during puberty, and age of menarche are similar in children treated with GH alone and untreated children (Boonstra *et al.*, 2003). However, children who are short and have already started puberty may benefit from adjuvant GnRH analog treatment for 2 years, along with a higher GH dose as these can result in improved adult height (Lem *et al.*, 2012).

Doses of GH >35 mcg/kg/day have not been shown to provide significant benefits in long-term studies (Maiorana and Cianfarani, 2009). Studies have explored GH dose titration, based on IGF-I levels, aiming for levels between 0 and +2 SDS (Jensen *et al.*, 2014). However, patients in the titrated dose group tended to have a poorer growth response compared to the fixed dose 35 mcg/kg/day group, despite having IGF-I levels of +1.2 SDS. This suggests that a higher IGF-I level may be needed to maintain satisfactory growth velocity in these children. A positive response to GH treatment with height velocity more than +0.5 SDS is anticipated in the first year of treatment. If the response is inadequate, treatment concordance, GH dose, and diagnosis should be reevaluated and discontinuation of treatment considered (Clayton *et al.*, 2007).

Response to treatment

Considerable individual variation exists in the growth response to GH treatment in SGA children (Jensen *et al.*, 2013). It is believed that identifying the factors underlying these variations may help to personalize therapy. Ranke *et al*. based on the data from 613 children developed a growth prediction model consisting of GH dose, age and weight at start of GH treatment and mid-parental height SDS which explained 52% of the variation in the first-year height response (Ranke *et al.*, 2003). In this model, GH dose had the highest predictive value accounting for 35% of the variation. GH dose, age at start of treatment and parental adjusted height SDS (height SDS-target height SDS) also predicted long-term height outcomes (de Ridder *et al.*, 2008; Sas *et al.*, 1999). However, the effect of GH dose on final height is conflicting and other studies did not find differences (Maiorana and Cianfarani, 2009). In addition, lower adiposity, greater IGF-I levels and lower insulin sensitivity before the start of treatment, and greater genetic allele scores for insulin resistance were associated with poorer growth response (Gies *et al.*, 2012; Jensen *et al.*, 2013, 2015; Thankamony *et al.*, 2016). This suggests the possibility of modifying some of these factors to improve the height outcomes.

Adverse effects of GH treatment

Adverse events related to treatment are not more common in SGA children than in other conditions treated with GH, and standard monitoring should be applied (Clayton *et al.*, 2007). There are however potential metabolic risks, including decreased insulin sensitivity, however this is compensated by an increased insulin secretion (Jensen *et al.*, 2013). Conversely, there are also metabolic benefits, with a decrease in adipose tissue and an increase in lean body mass. During treatment with GH lipid profiles also improve, with a decrease in total high-density lipoprotein (HDL), low density lipoprotein (LDL) and cholesterol (Sas *et al.*, 2000; van Pareren *et al.*, 2003). There is also improvement in bone mineral density and a decrease in both systolic and diastolic blood pressure (BP) during long term treatment with GH (Sas *et al.*, 2000; van Pareren *et al.*, 2003). Importantly, the benefits of GH treatment on BP have been found to persist for more than 5 years after GH treatment, with both systolic and diastolic BP lower in GH treated adults than untreated short adults who were born SGA (van Dijk *et al.*, 2007). At a similar time-point there were no differences in lipid/cholesterol profiles, body composition or insulin sensitivity or insulin secretion in GH treated SGA adults,

versus nontreated short adults born SGA. Individual studies have reported increased overall mortality (Carel *et al.*, 2012) and incidence of strokes (Poidvin *et al.*, 2014) in patients treated with GH during childhood. Other studies however did not support these findings and a recent workshop concluded that the aggregate evidence did not support these associations (Allen *et al.*, 2016). Nevertheless, these reports highlight the need for longterm outcome data for GH-treated children.

Late Childhood Growth and Puberty

The impact of being born SGA and early life growth trajectories also impact on puberty. Infants born SGA are known to be at increased risk of premature pubarche and adrenarche (Verkauskiene *et al.*, 2013). Some studies have also reported an earlier onset of menstruation (Ibanez *et al.*, 2006; Yadav and Rustogi, 2015). This is most marked in those who catch up. Both timing and progression of puberty is affected in SGA children, with both peak height velocity and accelerated bone maturation occurring at an earlier pubertal stage in children born SGA. While there is conflicting evidence, a number of studies have found that earlier onset of menarche (at <12 years) is threefold commoner in girls born SGA (Ibanez *et al.*, 2006), with menarche occurring 8–12 months earlier than AGA girls (Bhargava *et al.*, 1995; Brandt *et al.*, 2005; Wehkalampi *et al.*, 2011). This therefore leads to a shorter duration of pubertal growth and a less than expected growth spurt. The mechanisms determining the differences in pubertal onset and progression between SGA and AGA children have not been full elucidated, but a number of mechanisms have been postulated, and may be linked to susceptibility to the metabolic syndrome.

The rapid catch up growth in the postnatal period, with accumulation of visceral fat and hyperinsulinism resulting from insulin resistance is also associated with increased androgen levels. A combination of these factors may lead to a polycystic ovarian syndrome type picture, with earlier menarche and reduced final adult height. These SGA girls often have a combination of hyperinsulinism, central adiposity, dyslipidemia and accelerated bone maturation. It has been shown that metformin can be used to increase insulin sensitivity in these SGA girls who are showing signs of precocious pubarche (Ibáñez *et al.*, 2008, 2011). Metformin treatment lead to delayed onset of puberty, with decreased adipose tissue, while growth was maintained. There were associated improvements in lipid profiles and improved body composition, as well as decreased levels of insulin, IGF-I and leptin. Biochemical and physical improvements persisted for 12 months after metformin was discontinued. This highlights the importance of insulin in determining linear growth and pubertal progression in girls born SGA.

Lifetime Consequences of Being Born SGA

It was the early work of Barker and colleagues in the 1980s who were interested in early life origins of adult chronic diseases that lead to the explosion of interest in early growth and its effect on long term health (Barker and Osmond, 1986; Barker *et al.*, 1989). Barker used early maternity and welfare records, and linked recorded birth weight to later National Health Service registration. It was later that the opposing effects of weight at birth and in adult life became more evident (Phillips *et al.*, 1994). A wave of international studies followed which confirmed the relationship between birth weight and adult disease risk regardless of socioeconomic status and confirmed that relative weight for gestation was more important than absolute weight. Further definitive studies were those of the "Dutch Hunger Winter" a period when German occupation in the Netherlands lead to defined periods of malnutrition and a significant drop in birth weight (Stein and Susser, 1975), which was related to later obesity and cardiovascular and metabolic disease (Roseboom *et al.*, 1999, 2000a,b, 2001).

Although for SGA children early growth is an important determinant of later health risk by defining "metabolic capacity" the expression of this phenotype is dependent on the metabolic stresses put on this system. This has been described by Wells as the "metabolic load" (Wells, 2017). Key components of metabolic load extend beyond adiposity to include physical activity, smoking, psychological stress and infectious disease (Andersen *et al.*, 2006) (**Fig. 3**).

Infants born SGA also demonstrate premature activation of the hypothalamic pituitary adrenal (HPA) axis as a response to stress in utero with low birth weight associated with altered cortisol levels (Martinez-Aguayo *et al.*, 2012). This has been associated with hypertension, insulin resistance and development of the metabolic syndrome (Phillips *et al.*, 1998; Seckl, 2004; Cottrell and Seckl, 2009). An explanation of this phenomenon has been derived from animal models revealing long-term changes in the molecular expression of steroid receptors within the limbic system (Cottrell and Seckl, 2009). Additionally, there may be alteration of the renin–angiotensin–aldosterone axis in SGA infants. Male SGA infants have raised levels of angiotensin-2 and angiotensin-converting-enzyme, while female SGA infants have raised noradrenaline levels (Franco *et al.*, 2008). These factors may contribute to the finding that SGA infants have altered vascular endothelium function and raised systolic blood pressure by the age of 13 years (Franco *et al.*, 2006).

In addition to the long term metabolic risks of being born SGA, there are a number of studies that suggest that SGA children may be at increased risk of neurodevelopmental problems, with decreased cognitive and social abilities, though the data are conflicting (Castanys-Muñoz *et al.*, 2017). These data have been confounded by the inclusion of preterm infants, where the risk of poor neurodevelopmental outcomes is greater. Further work is needed to elucidate if there are certain populations at increased risk of adverse neurodevelopmental outcomes and the potential mechanisms underlying this.

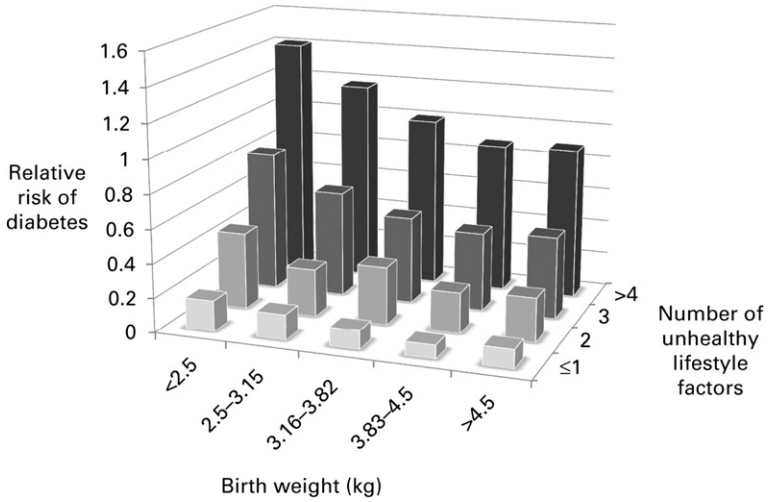

Fig. 3 The capacity-load model. This illustrates that the relative risk of diabetes is related to the interaction of the predisposition determined by birth weight combined with adult lifestyle behaviors. Future Directions

Optimal early growth trajectories that balance the benefits and risks for long-term metabolic and cognitive outcomes in children born SGA have not been clearly determined. The diversity of etiologies means that an individualized approach may be important. Therefore, understanding the mechanisms will help to inform a more personalized approach to interventions. There are critical developmental windows for growth that provide opportunities for intervention, but it is important these are managed optimally if we are not to exacerbate long-term health consequences for these children. Short-term interventions, whether pharmaceutical, feeding or behavioral will require long-term follow-up to clarify optimal treatment strategies whilst determining better biomarkers of what constitutes optimal growth.

Summary

SGA is a unifying diagnosis that encompasses multiple etiologies but is associated with significant short-term and long-term morbidity with risk dependent on early life growth trajectories. Catch up growth is associated with increased adiposity leading to insulin resistance and metabolic syndrome in later life. Growth hormone treatment is licensed for use in those who remain short, but the data on long-term outcomes are limited. It is important we understand the mechanisms driving these growth patterns if we hope to modify them and impact on long-term health at an individual or population level. The challenge going forward is to prevent intrauterine insults and, if present, to develop early lifestyle interventions and/or pharmacotherapy to reverse the pathophysiological changes to prevent the development of metabolic complications in later life.

Growth Hormone Deficiency in Children

Berit Kriström and Elena Lundberg, Umeå University, Umeå, Sweden

Abbreviations

ALS	Acid labile subunit
CT	Computerized tomography
Delta, Δ	Change
GH	Growth hormone
GHBP	Growth hormone binding protein
GHRH	Growth hormone releasing hormone
IGF-I	Insulin like growth factor 1
IGFBP-3	IGF binding protein 3
IGHD	Isolated growth hormone deficiency
IHH	Idiopathic intracranial hypertension
ISS	Idiopathic short stature
KIGS	Pfizer International Growth Study
MPH	Midparental height
MPHD	Multiple pituitary hormone deficiencies
MRI	Magnetic resonance imaging
SDS	Standard deviation score
SGA	Small for gestational age—at birth
STH	Somatotropin or somatotrophic hormone
TSH	Thyroid stimulating hormone

Introduction

Growth hormone (GH) is a highly dynamic hormone normally secreted in pulses from the anterior pituitary (Robinson, 1991a), except during pregnancy, when a special form of GH is secreted from the placenta. Via the bloodstream, the GH molecules reach the receptor at the cell surface and via interaction they start the intracellular signaling cascade (Waters and Brooks, 2011). The hormone has extensive metabolic effects on most tissues; the most obvious is the direct effect on bone, stimulating longitudinal growth, lipolysis, muscle anabolism, and on hepatic metabolism interacting with insulin, resulting in increased serum levels of IGF-I. In line with these broad metabolic effects, another name for GH is somatotrophic hormone (STH). In turn, GH secretion is highly affected by many external and internal factors: physical activity, psychosocial circumstances, pain, anxiety, somatic disease, undernutrition, inflammation, and the status of other hormones such as thyroxin, cortisol, insulin, and sex hormones.

For many children, a growth velocity deceleration or an observed short stature is the sign that raises the question of possible GH deficiency. It is of great importance that the investigation starts with a broad general pediatric approach, obtaining all available information on previous weight and height measurements, including information on heredity, that is, family heights and possible health problems (GH Research Society, 2000). The diagnosis of GHD relies heavily on auxology; however, this is not always available.

Only after the exclusion (or optimal treatment) of other reasons for low growth velocity or short stature, and with the child's health and well-being in the best state possible, are biochemical investigations for GH reliable. However, basic endocrine investigations should include thyroid function test and, IGF-I and IGFBP-3 analyses (Blum *et al.*, 1993), also repeatedly due to the common great intra-individual variations (**Fig. 1**) (Gelander *et al.*, 1999), before a decision is taken on any GH evaluation. Evaluation of GH secretory capacity in an individual has to be performed during standardized circumstances due to the pulsatility and great physiological variations during the individual's lifespan.

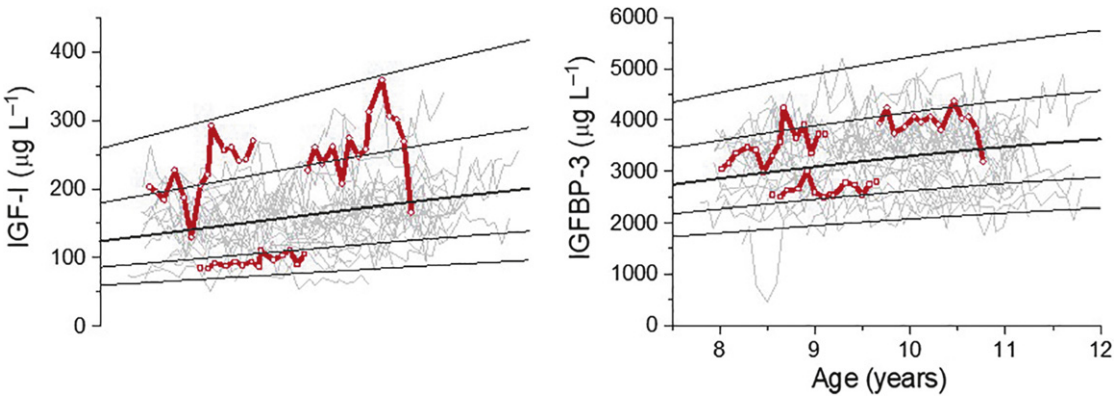

Fig. 1 Longitudinal serum concentration of IGF-I (left panel) and IGFBP-3 (right panel) in healthy prepubertal children, including 38 boys and 27 girls. All analyzed samples in one child are joined by a line. Reference lines are drawn according to IGF-I and IGFBP-3 reference values (Löfqvist *et al.*, 2001, 2005), and show the mean, +1, and +2 SDS. Gelander, L., Blum, W. F., Larsson, L., Rosberg, S. and Albertsson-Wikland, K. (1999). Monthly measurements of insulin-like growth factor I (IGF-I) and IGF-binding protein-3 in healthy prepubertal children: Characterization and relationship with growth: the 1-year growth study. *Pediatric Research*, 45, 377–383, with permission.

 doi:10.1016/B978-0-12-801238-3.66108-1

If a diagnosis of GHD is made, a MRI or CT scan of the brain (including the pituitary) will be required, with the possibility of developmental anomalies or expansive processes needing further measures.

Substitution therapy with recombinant human GH is performed by daily injections. The dose should be adapted according to individual GH responsiveness with a predefined target on efficacy, influenced by diagnose, growth period (i.e., age and maturity), and treatment phase.

Embryology and Genetics

The synthesis and secretion of GH occur from somatotrophic cells in the anterior part of the pituitary, the adenohypophysis, which originates from Rathke's pouch, which originates from invagination of the primitive pharyngeal epithelial floor. The adenohypophysis also contains cells producing thyroid stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), prolactin, follicle stimulating hormone (FSH), and luteinizing hormone (LH).

The posterior part of the pituitary, the neurohypophysis, has its origin in the brain and releases the hormones oxytocin and antidiuretic hormone (ADH). The latter is involved with water regulation.

A number of genetic mutations have been reported to be involved with the development of the pituitary (Kelberman *et al.*, 2009; Wit *et al.*, 2011). With a confirmed diagnosis of isolated GHD (IGHD) or multiple pituitary hormone deficiencies (MPHD), the question is often raised on the precise etiology, that is, what mutation the child may have. Tests for genetic mutations have hitherto not been part of clinical practice; however, in the future this may change. More important for clinical monitoring is the result of an MRI of the brain: an ectopic posterior pituitary with a hypoplastic anterior pituitary is the sign of a prenatal malformation, alerting the endocrinologist of upcoming additional hormonal deficiencies as the child grows older and increases in body size.

Growth Hormone

Structure

The human GH gene cluster is present on chromosome 17q and contains two forms: GH normal (GH-N), expressed in the pituitary, and GH variant (GH-V), expressed in the placenta. GH in humans consists of many isoforms (Baumann, 2009). The most abundant form in the human circulation is the 22 kDa GH, a single-stranded chain of 191 amino acids, responsible for 70%–75% of available GH. Due to alternative splicing, 5%–10% of serum GH are of 20 kDa size, and there are also small amounts of GH with size 27, 17, and 5 kDa. The 20 kDa isoform is generally less biologically active compared to the 22 kDa GH, but has a longer half-life in serum and is therefore more abundant during GH troughs (Baumann, 2009). Knowledge regarding the biological significance of these less abundant isoforms is limited, although the 20 kDa isoform has been suggested to have more metabolic effects (Baumann, 2009). In addition to the mentioned monomeric forms, GH also exists in oligomeric forms, composed of the different forms in the pituitary and plasma. An increased proportion of isoforms in the circulation, other than 22 kDa, has been proposed to be a reason for impaired growth in children (Boguszewski *et al.*, 1997).

Biochemical Evaluation of GH

There have been, and still are, a wide range of assays for estimation of GH, as well as IGF-I and IGFBP-3. This means that the clinician needs to be aware of the used methods (**Fig. 2**) (Clemmons, 2011; Jansson *et al.*, 1997). Efforts for standardization have

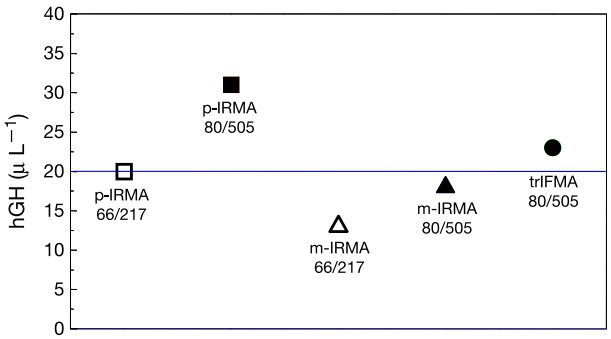

Fig. 2 Influence of the GH assay used for the estimated serum concentration of GH. The result from one sample but using two assays and two WHO IRPs 66/127 and 80/505. The assays were an immunoradiometric IRMA, using polyclonal or monoclonal antibodies and a time-resolved monoclonal immunofluorometric assay (trIFMA). Albertsson-Wikland, K. and Rosberg, S. (2011). Methods of evaluating spontaneous growth hormone secretion. In: Ranke, M.B. and Mullis, P.-E. (Eds.), Diagnostics of endocrine function in children and adolescents. 4th edn., pp 138–156. Basel: Karger.

been made; for estimation of GH nowadays, a monoclonal antibody is used with a reference preparation based on human recombinant 22 kDa (hGH 98/574) (Bidlingmaier and Freda, 2010).

Similarly, the assays and reference preparations for IGF-I and IGFBP-3 need standardization (Clemmons, 2011). However, as IGF-I and IGFBP-3 serum levels vary with a child's age and maturity, even more important is a reference from the certain assay and laboratory that accounts for sex, age, and pubertal stage (**Fig. 3**) (Juul *et al.*, 1994; Löfqvist *et al.*, 2001, 2005). Thus, IGF-I and IGFBP-3 levels should be given in SDS (standard deviation score) rather than in $\mu g\ L^{-1}$.

Regulation of GH Secretion

GH is released from the pituitary in pulses due to the balanced interaction of the hypothalamic neuro-peptides GH releasing hormone (GHRH) and the inhibitory somatostatin. GHRH is secreted in pulses every 3 h, and is stimulated by sleep, nutrition, stress, physical activity, hypoglycemia, thyroxine, estrogen, and androgen, whereas somatostatin is secreted continuously and regulated by IGF-I, free fatty acids, and cortisol (Robinson, 1991b; Tannenbaum *et al.*, 1990; Veldhuis *et al.*, 2006). In addition, GH in the circulation has a feedback on hypothalamic GHRH secretion and an auto-feedback on its own secretion in the somatotrophs in the pituitary. Negative feedback by endocrine IGF-I also contributes (**Fig. 4**) (Robinson, 1991b).

GH Secretion Pattern

GH secretion changes during lifespan. During the late fetal and neonatal period, GH is present in fetal circulation at a high and unregulated level due to the immaturity of the GHR system. GH is not of great importance for size at birth, and infants with congenital GH deficiency and defects in the GH-receptor gene have no or only a mild reduction in birth size (Albertsson-Wikland *et al.*, 1990). Defects in the IGF-I gene or any interference with IGF-I action are both associated with severe growth retardation (Woods *et al.*, 1996).

During infancy, the GH pattern of pulsatile secretion starts to be established (Zegher *et al.*, 1997). Longitudinal growth is still not GH dependent. Therefore, growth failure in children with growth hormone deficiency (GHD) commonly does not present until the childhood growth period (Karlberg and Albertsson-Wikland, 1988).

During childhood, GH secretion starts to establish a diurnal peak-and-trough pattern, with higher peaks during night-time. During this period, GH secretion is similar for both sexes. GH is the main regulator of childhood growth with a dose-dependent effect (Albertsson-Wikland and Rosberg, 1988), both directly at the growth plate (Isaksson *et al.*, 1987) and indirectly through the IGF-I (Ohlsson *et al.*, 2000). Thyroxine, insulin, and cortisol are all necessary and permissive hormones. In addition, nutrition and psychosocial factors continue to be of great importance.

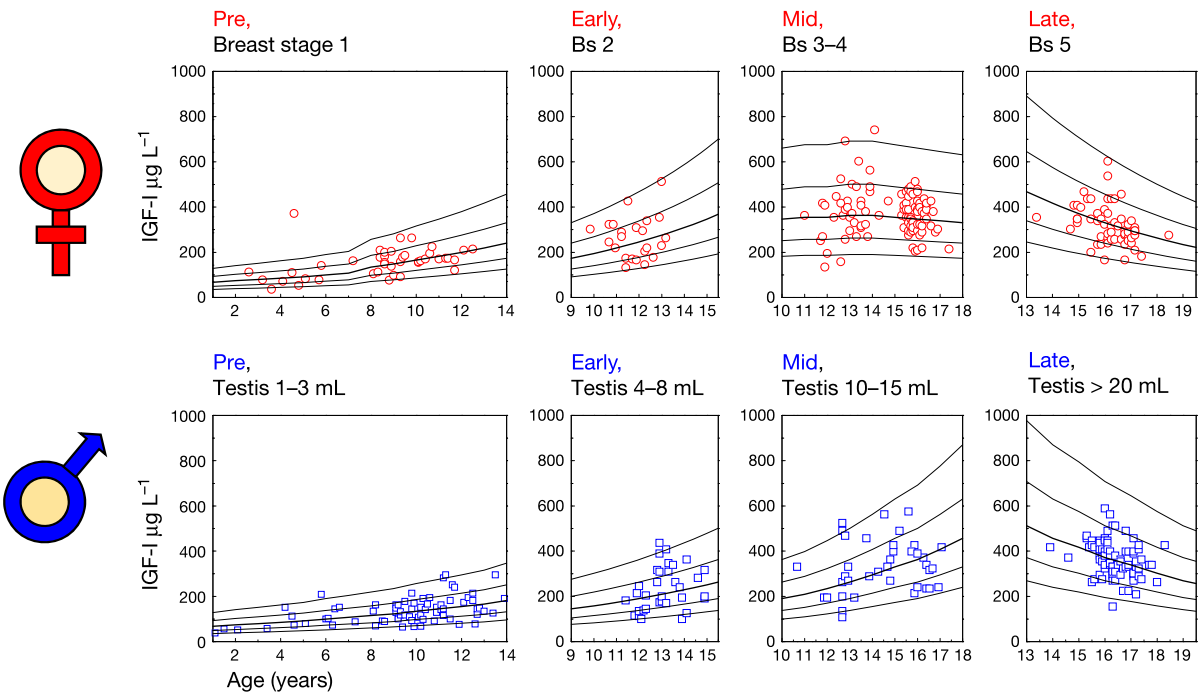

Fig. 3 The reference model for IGF-I based on values from healthy girls and boys according to age and pubertal stage. Löfqvist, C., Andersson, E., Gelander, L., et al. (2001). Reference values for IGF-I throughout childhood and adolescence: a model that accounts simultaneously for the effect of gender, age, and puberty. *Journal of Clinical Endocrinology and Metabolism*, 86, 5870–5876, with permission.

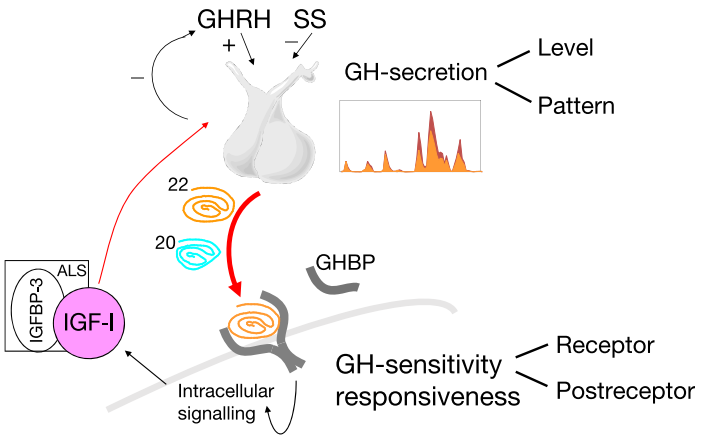

Fig. 4 The GH/IGF-I axis. A schematic overview of the GH/IGF-I feedback loop. Secretion of GH from the pituitary gland is regulated by two peptides: GH releasing hormone (GHRH) and somatostatin (SS). Secreted GH consists of several isoforms; the most abundant 22 kD form is the most biologically active form; a smaller proportion exists as 20 kD isoform. Almost 50% of the GH in blood is bound to the high-affinity GH-binding protein (GHBP), which is structurally similar to the extracellular domain of the GH receptor. After binding to the receptor, GH induces secretion of insulin-like growth factor I (IGF-I) which can elicit autocrine, paracrine, and endocrine effects, as well as feedback effects on GH secretion. The activity of IGF-I is modulated by binding proteins; the most abundant are IGFBP-3 and the acid-labile subunit (ALS).
Lundberg, E. Thesis Umeå university 2017. ISBN 978-91-7601-662-6.

During puberty, GH becomes upregulated in response to estrogen. The pulsatile GH secretion increases, with high peaks during both day and night in a gender-specific manner: there is about a threefold increase in girls and a twofold increase in boys (Albertsson-Wikland *et al.*, 1994). The pulse amplitude and amount of GH per secretory burst increase, but the pulse frequency does not change (Mauras *et al.*, 1987).

After completed growth, that is, when adult height is attained, GH secretion progressively declines, falling to very low levels in old age (Rudman *et al.*, 1981). The GH amplitude is reduced while pulsatility remains (Giustina and Veldhuis, 1998). In adulthood, the GH secretory pattern in men is characterized by peaks about every 3 h (Albertsson-Wikland and Rosberg, 2011) and low basal circulating troughs in between (Giustina and Veldhuis, 1998). The highest GH peaks are seen during slow-wave sleep, and smaller pulses occur during the day (Van Cauter *et al.*, 2000). In women, the presence of estrogen will give rise to a GH pattern that is characterized by a sustained basal level and more irregular peaks with different amplitudes (Ho *et al.*, 1987).

From rodents, we learn that sex differences were found in the pattern of GH secretion (Eden, 1979; Jansson *et al.*, 1985; Robinson *et al.*, 1998). The adult male rats had a high-amplitude, 3-hourly, pulsatile pattern of GH secretion, with low troughs in between (Wagner *et al.*, 1998), whereas females secreted GH in a more continuous pattern with a high basal level and irregular peaks (Eden, 1979). The pattern of GH secretion in rodents is an important determinant of the sexually dimorphic pattern of growth (Jansson *et al.*, 1985), liver enzyme function (Legraverend *et al.*, 1992), circulating GH-binding protein concentration (Carmignac *et al.*, 1993), and IGF-I mRNA expression in skeletal muscle and the liver (Isgaard *et al.*, 1988) in these animals.

The GH Receptor

The human GH receptor (GHR) gene is located on chromosome 5 (Leung *et al.*, 1987). The receptor is embedded in the outer membrane of cells throughout the body and is most abundant in the liver (Waters and Brooks, 2011). The GHR consists of a large extracellular part containing the GH-binding site and occurs separately as the GH-binding protein found in the circulation (Waters, 2016). GH induces the changes in the GHR starting the intracellular signaling (Brooks and Waters, 2010). The STAT5b pathway mediates the activation of different genes such as a transcription of IGF-I, IGF binding protein 3 (IGFBP-3), and the acid-labile subunit (ALS) gene in the live. A deletion in the GHR gene was shown to explain the GH insensitivity in some patients with Laron syndrome, clinically mimicking severe GHD (Godowski *et al.*, 1989).

Effects of GH

GH receptors and the GHR gene have been found in most tissue in humans, indicating that GH has effects in most tissues including protein synthesis, lipolysis, and reduced glucose utilization. Our hypothesis on varying responsiveness in different tissues was confirmed in a trial on GH treatment in prepubertal patients with different endogenous secretory capacities (**Fig. 5**) (Decker *et al.*, 2012). Considering these differences in tissue responsiveness within the child means that the complexity of clinical signs in (different degrees of) GH deficiency is much more understandable, and thereby improves the diagnostic performance of the endocrinologist.

The most responsive tissue to GH is the brain. The GHD patients in the trial after the start of treatment showed improved attention, perception, and cognitive capacities (Chaplin *et al.*, 2011, 2015). GH immunoreactivity was found in the first stage of

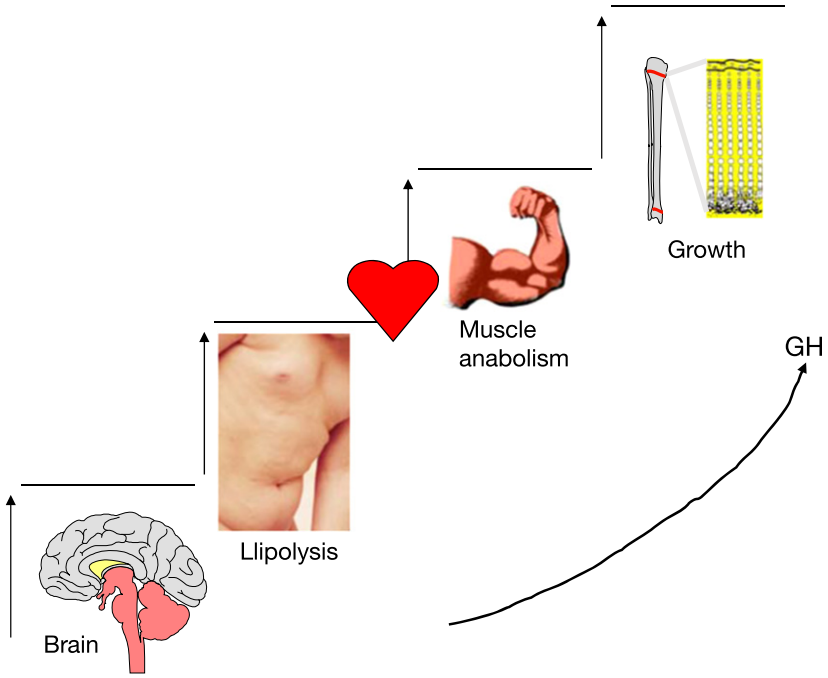

Fig. 5 Our hypothesis, which was found to be valid, according to the amount of GH needed for effect in different tissues. The most GH-sensitive tissue was the brain, and the least sensitive was the IGF-I production, which was less sensitive than bone growth. Adapted from Modified from Decker, R., Nygren, A., Kristrom, B., et al. (2012). Different thresholds of tissue-specific dose-responses to growth hormone in short prepubertal children. *BMC Endocrine Disorders*, 12, 26.

brain development with GH-binding sites in all brain structures (Nyberg, 2000). In addition, GH has been shown to be important in physiological and reparative neurogenesis, as in brain repair after injury and the development of learning capacity and cognitive function (Nyberg, 2007).

The second most responsive process is lipolysis. GH increases lipase activity in fat tissue, resulting in increased serum free fatty acids (Moller and Jorgensen, 2009). Administration of GH has been shown to reduce body fat in GHD adults (Elbornsson *et al.*, 2013). A positive correlation between leptin reduction and 1st-year growth response after the start of GH treatment was found in a group of short children treated with GH (Kristrom *et al.*, 1998).

GH has a positive effect on protein metabolism, that is, anabolism, and increases muscle tissue according to both mass and strength, as seen in studies where GH was administrated to rodents (Isgaard *et al.*, 1988) and to GHD adults (Gotherstrom *et al.*, 2001), and children (Decker *et al.*, 2010).

GH acts directly on the growth of myocardium and on inotrope heart function during fetal development (Sacca *et al.*, 1994). Additional support for the GH effect on the heart was shown in both GHD and non-GHD prepubertal patients, in whom increased cardiac size with normalized wall thickness was found (Nygren *et al.*, 2012).

The least GH-responsive (=least sensitive) tissue was the liver with the IGF-I production, that is, the GH effect on the liver (Decker *et al.*, 2012). Bone growth was the next to least responsive (Isaksson *et al.*, 1982).

In addition, GH induces an apparent insulin resistance through increased endogenous gluconeogenesis in the liver and decreased peripheral glucose disposal in muscle (Moller and Jorgensen, 2009). Insulin levels are lower than normal in untreated GHD patients, and they increase in a dose-dependent manner with GH treatment while remaining within the normal range as long as the GH dose is adapted according to individual GH responsiveness (Decker *et al.*, 2012).

Evaluation of Endogenous GH Release

When, after being fulfilled thorough pediatric investigation, an investigation of GH release is planned to confirm a clinically suspected diagnosis, it is of great importance that this investigation is performed while the child is as healthy as possible and in standardized circumstances (**Fig. 6**). Stimulation tests should be performed according to standardized protocols, in the morning after an overnight fast. The most used stimulating agents are arginine, insulin, clonidine, glucagon, and L-dopa; this number of agents indicates that none of them is optimal (Ranke, 2011). Due to side effects, potential hazards, and patient discomfort, selection of the test should be made by the responsible endocrinologist, and the test should be performed and monitored by well-trained personnel.

Even though the test stimuli and procedure are standardized, interpretation of the test results needs caution. There is the possibility of a GHRH-induced refractoriness, due to negative feedback by recent endogenous GH secretion (**Fig. 7**) (Gelander and

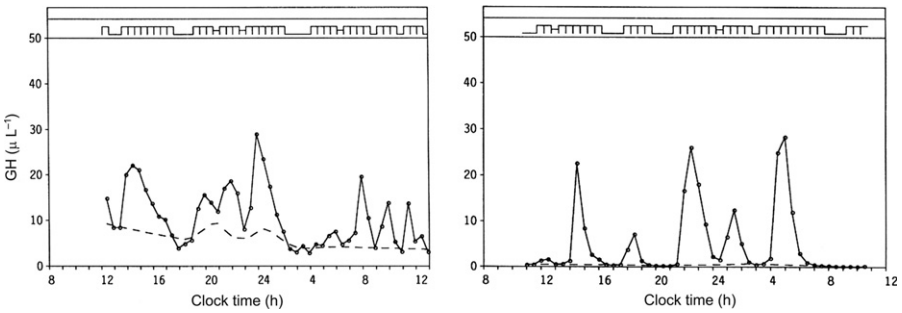

Fig. 6 Spontaneous GH secretion in a prepubertal child during an infectious disease with fever (left panel) and 2 weeks later when he was healthy again (right panel).

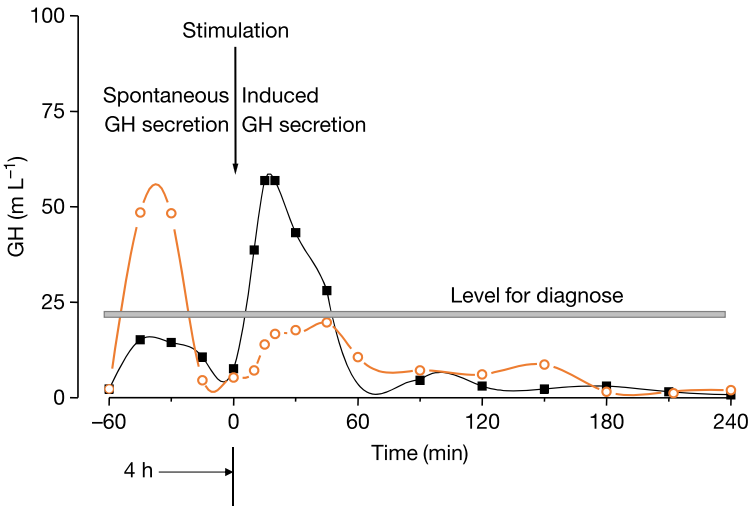

Fig. 7 The effect of refractoriness when a stimulus is given within 4 h after a spontaneous GH peak (line indicated with -o-), compared to if the stimulus has not been preceded by a spontaneous GH peak (line indicated with - ■ -). The refractoriness after the spontaneous peak may falsely indicate subnormal GH secretory capacity. Gelander, L. and Albertsson-Wikland, K. (1989). Growth hormone (GH) release after administration of GH-releasing hormone in relation to endogenous 24-h GH secretion in short children. *Journal of Endocrinology*, 122, 61–68, with permission.

Albertsson-Wikland, 1989). It is the balance between the GHRH and the somatostatin at the very moment of stimulation that accounts for the released amount of GH. This physiological mechanism is an important factor contributing to the great intra-individual variations, or low reproducibility, of repeated tests in the same individual (Cacciari *et al.*, 1992; Meazza *et al.*, 2017; Tauber *et al.*, 1997), and also explains why children are falsely diagnosed as GH deficient. In a Swedish national trial, about 50% of the children diagnosed with GHD according to clinical criteria and the arginine-insulin tolerance test (AITT) were found to have high GH peaks during a spontaneous secretion profile, and therefore were re-diagnosed with idiopathic short stature (ISS) (Kriström *et al.*, 2009a).

Thus, to escape the refractoriness problem with the stimulation tests, patient discomfort, and the problem with hypothalamic induced neurosecretory dysfunction (Gelander and Albertsson-Wikland, 1989; Spiliotis *et al.*, 1984), evaluation of spontaneous secretion over 24 or 12 h night-time can be performed (Kriström *et al.*, 2001). Allowing the child to eat, play, and sleep normally, with small amount of blood samples collected in 20–30-min. intervals without pain or anxiety, ensures that the GH release is as close to physiology as possible (Albertsson-Wikland and Rosberg, 2011). The medical risks are minimized; however, a trained nurse is still required and the obtained results need professional interpretation.

When evaluating the endogenous GH secretion, not only the highest peak matters, but also the relation between peaks and troughs, the basal serum levels. The secretion pattern contains different biological signals; the GH peaks have been shown to be most important for growth in rats while the troughs have wide effects on metabolic factors from the liver, with different effects in male and female animals (Robinson, 1991b). Adult humans received the same amount of GH in different patterns in an experimental setting; constant infusion giving constant trough levels resulted in higher IGF-I concentrations than when GH was given as daily injections, that is, as distinct GH peaks (Johansson *et al.*, 1996; Jorgensen *et al.*, 1990). Thus, GH peaks and troughs have different effects on growth and IGF-I level, which may have implications for long-acting GH. It has been difficult to decide an optimal GH dose for growth response in children when guided by the effect on IGF-I (Cohen *et al.*, 2007; Hou *et al.*, 2016; Moore *et al.*, 2016), as a larger GH dose is required to have an effect on bone growth compared to the effect on IGF-I (Decker *et al.*, 2012).

A correct estimation of the GH peak is important, as it has been shown in groups of children that growth velocity is mainly influenced by the GH pulse amplitude (Albertsson-Wikland and Rosberg, 1988; Hindmarsh *et al.*, 1988). Supporting this, when used in an auxology-based model for prediction of growth response to GH treatment, the spontaneous GH peak, followed by the area under the curve (AUC—the lower the better growth response if treatment was started), were the most important GH variables (Albertsson-Wikland *et al.*, 2000).

When the GH/IGF-I axis has a severely impaired function, clinical and metabolic signs are usually obvious, and diagnostic investigations are more focused on the level of defect (**Fig. 8**). It may be hypothalamic or pituitary with no or very low measurable GH secretion or at the tissue level with a defect in the GH receptor or in the intracellular signaling. The uniting biochemical sign is very low IGF-I and IGFBP-3 levels. However, some children with substantially low IGF-L levels may have clearly measurable GH peaks where there may be a defect within the GH/IGF axis not yet understood, but they may still have a positive growth response to GH treatment with an adapted GH dose. With the recombinant human GH becoming available in 1985–86, in clinical trials children with some endogenous GH secretion were found to respond to GH treatment (Albertsson-Wikland *et al.*, 2008). Even though many objections could be made, a cutoff value for maximal GH peak response was previously used in clinical practice about when to start GH treatment. Nowadays a more multifactorial approach considering physiology has been accepted in most societies (Bidlingmaier and Freda, 2010; Rosenfeld *et al.*, 1995). Besides GH assay and standard issues, considerations of physiological GH secretion according to age and biological maturation as well as the relation between GH peaks versus insulin and IGF-I level should be made as an indirect sign of GH effect and GH responsiveness.

Close to the onset of puberty, the GH secretion physiologically becomes so low that confusion with GH deficiency may occur. In these cases, priming with sex steroids has been suggested, but this does not solve the problem. During puberty, GH secretion is upregulated into tall and slender peaks that are 2–4-fold higher than before, higher in girls than in boys (Albertsson-Wikland *et al.*, 1994). Later, the growth plate matures under the influence of estrogen (Smith *et al.*, 1994) and the GH secretion decreases with descending levels of IGF-I and IGFBP-3 (Löfqvist *et al.*, 2001, 2005). Taking these physiological variations into account, a more dynamic approach is needed for interpretation of the individual GH/IGF-I investigation.

Clinical Presentation

In the neonatal period, the signs that bring up the question of GHD are unexplained hypoglycemia (with metabolic disorders needing to be ruled out), microphallus, jaundice, and breech presentation. Size at birth for neonates with organic GHD is normal, but children who were later, at different ages, diagnosed with isolated GHD were found to have a reduced birth size (Albertsson-Wikland *et al.*, 1990; Binder *et al.*, 2010). The GH-deficient infant in affluent Western countries typically grows with a normal infancy growth velocity in the first 6–12 months, until the transition to the childhood growth phase is expected to take place due to the GH/IGF-I axis for growth becoming active (Hochberg and Albertsson-Wikland, 2008). Although much less common, hypoglycemia during childhood may be a sign of GHD and should prompt endocrine investigation, especially if combined with midline defects.

During the preschool ages and later, the most common signs that brings children to the pediatric endocrine clinic with a GHD suspicion are low growth velocity or short stature. Auxology data are excellent when judging if and how to plan an investigation.

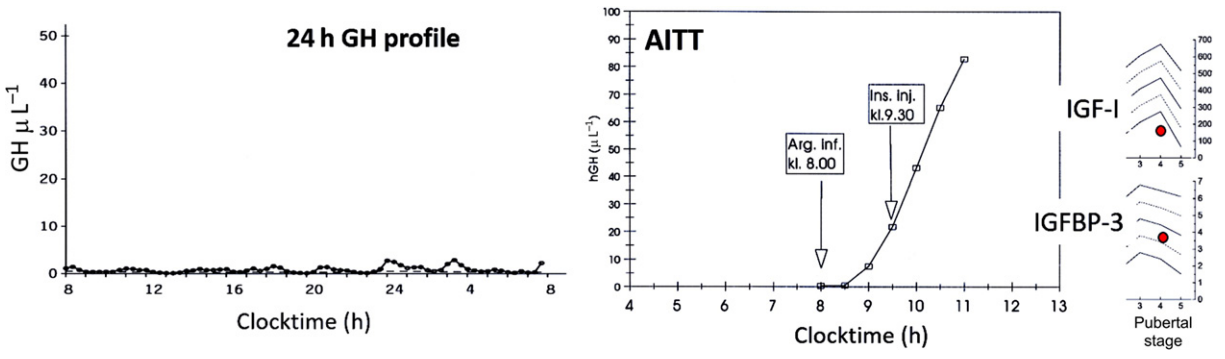

Fig. 8 GH deficiency of hypothalamic origin. Results from a GH re-investigation at adult height in a girl aged 15 years with spontaneous puberty and normal weight for height. She had received cranial irradiation some 10 years before due to high-risk leukemia. GH treatment had been inhibited for 1 month when the investigation was performed; her IGF-I SDS and IGFBP-3 SDS at the investigation are shown in the reference for pubertal stage (lines −2 to +2 SDS are shown). A spontaneous 24-hr GH profile was performed from 8 a.m. to 8 a.m. with blood sampling every 20 min. Each dot in the figure represents a blood sample. Immediately following the profile sampling, an arginine-insulin tolerance test (AITT) was performed. Observe the different scaling for the GH serum concentration for profile and AITT. During the spontaneous profile a very small amount of GH is released into the serum—much less than normally seen in a pubertal adolescent girl, in harmony with her abnormally low IGF-I SDS. During the AITT, a successively increased GH release in response to the induced stimulation/hypoglycemia was found. Her profile represents her physiologic condition, confirming the GHD diagnosis.

The descending growth velocity can appear at any age, depending on when the limit for the needed GH secretion capacity is exceeded.

An important sign is short stature in relation to relative midparental height (MPH) (usually defined as more than 1.5 SDS below MPH SDS) or the population, defined as height for sex and age 2 SDS or more below the population mean (Luo *et al.*, 1998). For evaluation of height in relation to the population, a growth reference from the appropriate population is optimal. However, if not available, for evaluation of height in relation to parents and for evaluation of growth velocity, a reference based on other populations or the WHO reference can be used. Heights expressed in SDS are preferred, rather than in percentiles, as this makes precise calculations possible. Important information in the history of the child may be craniofacial midline abnormalities, brain infection, or severe trauma, cranial or facial irradiation, or GHD in the family.

Basal investigations include measurement of body proportions; they are normal in a child with GHD. Measurement of body proportions of a parent with short stature may give valuable information. Before any evaluation of the GH/IGF axis is performed, other causes of impaired growth should be considered and appropriately excluded, as signs of chronic systemic disease, genetic syndromes (i.e., for Turner syndrome, karyotype is needed; do not rely on clinical signs), or hypothyroidism (GH Research Society, 2000).

Radiological Evaluation

Radiological evaluation of the biological maturation of the bone, that is, "bone age," may be a valuable part of the investigation; in GHD it is most often retarded. Bone age is estimated from an X-ray of the left wrist and hand, and compared by a trained person with results from healthy children with a known age. For very young children, aged below 1–2 years, X-rays of the knee and ankle may be informative (GH Research Society, 2000).

Imaging the brain by MRI or CT is required in children who are diagnosed with GHD, in order to study the midline structures, the position, size, and morphology of the two parts of the pituitary and the stalk, considering the possibility of an expansive or destructive process interfering with the hypothalamic or pituitary function.

Individualization of GH Treatment

The growth phases in a normal child are divided into Infancy, Childhood, and Puberty, the Karlberg "ICP-model" (Karlberg, 1987, 1989), with a juvenility phase being included later, between childhood and puberty, before reaching adult height (**Fig. 9**) (Hochberg and Albertsson-Wikland, 2008). After the start of GH treatment we identify three treatment periods that may need a different approach: the catch-up growth period, the maintenance period, and the pubertal growth period. The catch-up period is defined from the start of GH treatment until height SDS has reached the normal range according to MPH SDS for the child (Boersma and Wit, 1997). The maintenance period is characterized by a normal growth velocity that keeps the height SDS within a variability normal for age and sex, and lasts from the end of the catch-up period until the onset of puberty. Thereafter the pubertal

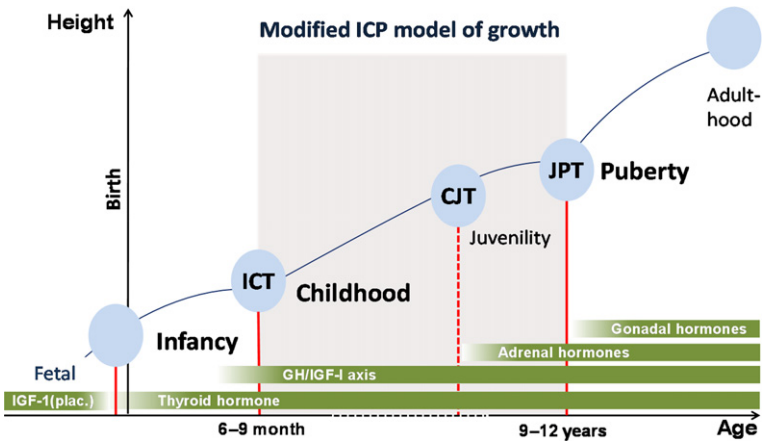

Fig. 9 Modified model of infancy-childhood-puberty growth in relation to endocrine regulation. The transition phases between different growth periods are marked with circles. The fetal growth is influenced by IGF-I from the placenta and thyroid hormone. Thyroid hormone is a major regulator during infancy and together with cortisol influences all growth periods afterwards. The GH/IGF-I axis starts to regulate growth from age 6–12 months, the infancy-childhood transition (ICT). For the childhood-juvenility transition (CJT), adrenal hormones take the lead. The juvenility-puberty transition (JPT) is influenced by the gonadal hormone. From Hochberg, Z. and Albertsson-Wikland, K. (2008). Evo-devo of infantile and childhood growth. *Pediatric Research*, 64, 2–7.

growth period lasts until adult height is attained, often simply defined as a growth velocity below 1–2 cm/year with concomitant advanced bone age (**Fig. 10**).

The recommended range for GH doses varies between countries, also for the same diagnosis. When deciding on a within-label GH treatment dose, estimations of individual GH release, with tests or a profile, are of great value as a GH dose needs to increase the GH effects more than the endogenous GH has done. We are discarding the "fixed-dose wait-and-see" approach in favor of a more active and adaptive dosing strategy (Ranke, 2010). The exogenous GH peak can be regarded as a substitute for the endogenous GH peak, the signal for growth. Exogenous GH downregulates the endogenously released GH for 36 h (Rose *et al.*, 2000) through the feedback systems. However, spontaneous GH pulses were seen after just 6 h in a study on GH pharmacokinetics after subcutaneous GH injections (Lundberg *et al.*, 2018). The IGF-I pretreatment level may be associated with growth response when studied in a group, but is a weak indicator of GH responsiveness for an individual child (Kristrom *et al.*, 1997). More important for growth response is the on-treatment dose effect on ΔIGF-I SDS shown in both prepubertal children (Cohen *et al.*, 2007, 2010) and pubertal children (Lundberg *et al.*, 2015). Already after 1–3 months on treatment, a ΔIGF-I SDS more than 1 SDS is often associated with a substantial growth response (Cohen *et al.*, 2010; Lundberg *et al.*, 2015), even if there is individual variability also for IGF-I responsiveness. However, evaluation of growth response/GH responsiveness preferably needs 12 months (Ranke *et al.*, 2013).

By using a model for prediction of growth response, an indirect estimate of individual responsiveness is received already before the start of treatment by the prediction interval (Kriström and Albertsson Wikland, 2002). Therefore a suitable dose can be selected in order to attain a satisfying catch-up growth and reach the growth target within 2–3 years (**Figs. 11** and **12**) (Kriström *et al.*,

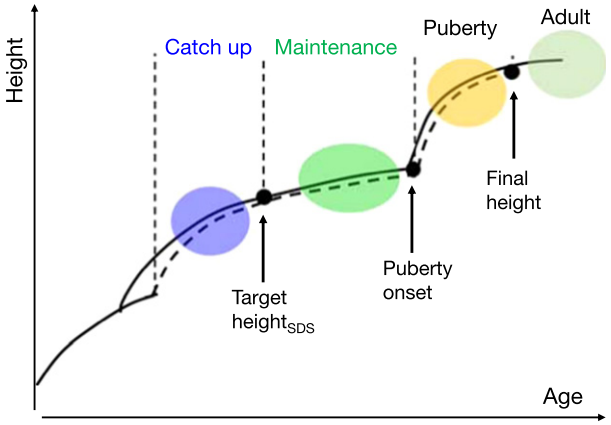

Fig. 10 The different growth periods on GH treatment: the catch-up period with high growth velocity ends when the height SDS of the child has reached within the normal range for target height (midparental height) SDS. The maintenance growth period is characterized by normal prepubertal growth velocity. The pubertal growth spurt is finalized when adult height is reached.

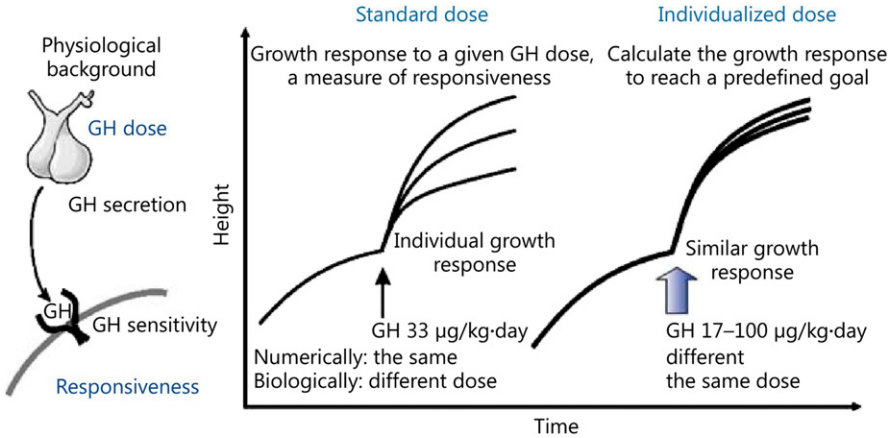

Fig. 11 Schematic illustration of GH effect relying on the balance between individual GH secretion and individual GH responsiveness, with the extremes GH deficiency and GH insensitivity. When GH treatment is performed, the dose replaces the GH secretion but tissue responsiveness cannot be replaced or affected. This is well known as the great variation in growth response to GH treatment within groups of children. Actually the growth response to a given dose is a sign of (a bioassay) the individual GH responsiveness. When instead the dose is adapted according to the responsiveness, more children achieve their growth response target. Kriström, B. and Albertsson Wikland, K. (2002). Growth prediction models, concept and use. *Hormone Research in Paediatrics*, 57, 66–70.

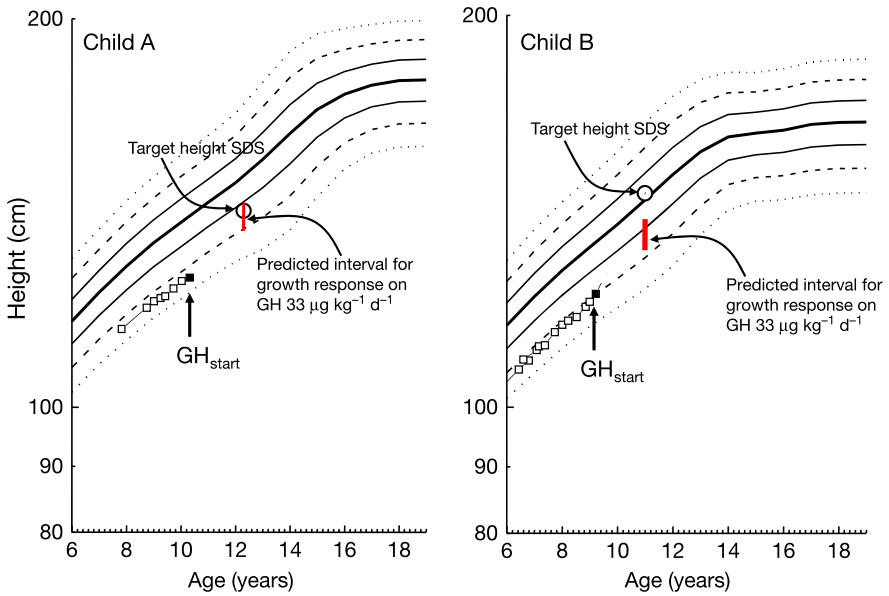

Fig. 12 Principle for selection of GH dose guided by prediction of growth response to GH treatment. Included in the height growth chart are pretreatment heights, predicted intervals for growth response if the child were to start GH treatment with a daily dose of 33 μg kg^{-1}, and target height SDS, as the common goal for catch-up growth response. Child A (left panel) is predicted to have a height gain resulting in a height SDS within target height SDS, thus the dose fits well. Child B (right panel) is predicted to attain a height SDS substantially below target height with the dose 33 μg kg^{-1}, which means that a higher GH dose is needed if target height SDS will be attained during the catch-up growth. Kriström, B. and Albertsson Wikland, K. (2002). Growth prediction models, concept and use. *Hormone Research in Paediatrics*, **57**, 66–70.

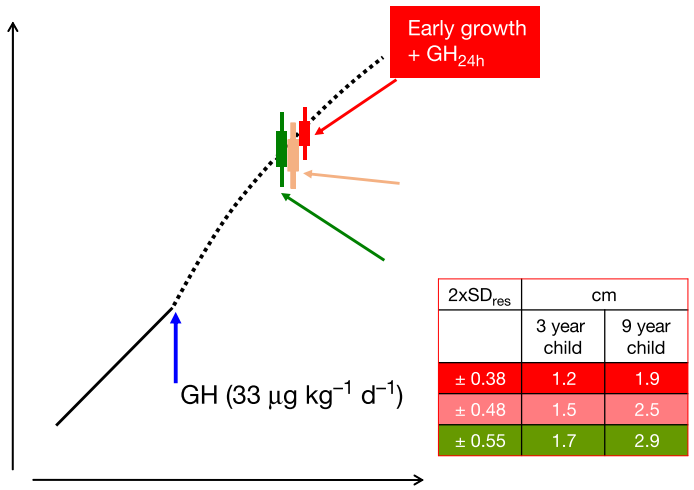

Fig. 13 Performance of the prediction models depending on included variables. The prediction interval is calculated as ±two times the SD of the residuals (=the SD of the differences between observed and predicted growth response) and should preferably be low. All models were accurate, with the most narrow prediction interval resulting from the model that included all auxology data and the 24-h GH$_{max}$ from the spontaneous profile. Kriström, B. and Albertsson Wikland, K. (2002). Growth prediction models, concept and use. *Hormone Research in Paediatrics*, 57, 66–70.

2009a). The prediction models are mathematical/statistical equations, all constructed on observed (empirical) data on GH treatment growth responses from large groups of children. Thereafter the models have been tested on new cohorts of data and found to be correct, that is, validated, with only small differences (=residuals) between predicted (=calculated) and observed growth responses (**Fig. 13**) (Albertsson-Wikland *et al.*, 2000; Kriström *et al.*, 2001; Ranke *et al.*, 1999). Even though the statistical approaches have been slightly different when constructing the Swedish and KIGS models, a strength was that the variables found to be of importance were the same, that is, large intra-familial height deficit, low age of the child, and low GH secretion capacity—as previously reported using a more simple method of analysis (Kristrom *et al.*, 1995). If these important variables are missing, the 1st-year treatment growth response reveals the responsiveness (Kriström *et al.*, 2009b), but as the growth response during the 1st year is always the greatest, optimal dosing from the very start is important. The approach of using a prediction model estimation of

responsiveness was found to be valid in our randomized trial in GHD and ISS prepubertal children during the catch-up period, not only for growth (Kriström *et al.*, 2009a), but also for metabolism (Decker *et al.*, 2010), self-esteem and behavior (Chaplin *et al.*, 2011), and cognition (Chaplin *et al.*, 2015).

During the maintenance growth phase there is some evidence that the dose needed to maintain normal growth velocity is lower than for the catch-up period, as has been reported from a SGA cohort (De Zegher and Hokken-Koelega, 2005). Taking the reduced GH secretion seen in healthy children during the juvenility phase, this dosing strategy is fully compatible with physiology (Westphal, 1987).

For puberty, however, many years of experience with the same dose as during prepuberty have given the impression that gain in height SDS during puberty was not possible, and therefore all gain in height SDS had to be achieved before puberty (Coelho *et al.*, 2008; Reiter *et al.*, 2006). To have normalized height SDS before puberty onset is still our goal. However, some children come late to diagnosis, and for those we have shown that an increased dose during puberty, resulting in GH serum levels seen in healthy pubertal children and high enough to increase their prepubertal IGF-I SDS, may also result in increased height SDS during puberty (Albertsson-Wikland *et al.*, 2014; Lundberg *et al.*, 2015).

However, growth response is not only about the dose, but also about adherence to the daily injections and the injection technique. For optimal growth response, it is important to inject deep enough to reach close to the muscle layer to attain as high a GH peak (C_{max} in pharmacokinetics) as possible in relation to the injected dose. GH injected into the fat tissue is absorbed through the lymphatics, which means a lower GH peak and 30% of the dose is lost (Christiansen *et al.*, 1983; Lundberg *et al.*, 2018), while GH injected into the muscle is more rapidly absorbed through capillaries (**Fig. 14**) (Laursen, 2004).

GH Treatment Safety

Over the years there have been a number of publications on GH safety, with a recent report on many aspects to consider in clinical situations (Allen *et al.*, 2016). Due to multiple national registers and post-marketing registers, it is well-known nowadays that headache, idiopathic intracranial hypertension (IIH), and slipped femoral epiphysis may occur during GH treatment. The incidence was found to be higher in the groups diagnosed with craniopharyngeomas, congenital GHD, and brain tumors in a post-marketing register following children who had been treated for 0.4–2.5 years. In children with a diagnosis of isolated GHD, IIH had a lower incidence than in children with Turner syndrome, congenital GHD, Prader Willi syndrome, or chronic renal failure (Darendeliler *et al.*, 2007). Free thyroxine decreases during GH treatment in most diagnoses, but in a SGA cohort it was neither associated with an increase in TSH nor affected the response to GH treatment (De Kort *et al.*, 2008).

In 2012 the French SAGhE group reported increased cancer mortality in adults who started GH treatment as children between 1985 and 1996 due to the diagnoses of GHD, neurosecretory dysfunction, ISS, or SGA. The mortality was related to cancer (bone tumors) and diseases in the circulatory system, and associated with a higher GH dose (Carel *et al.*, 2012). However, in a

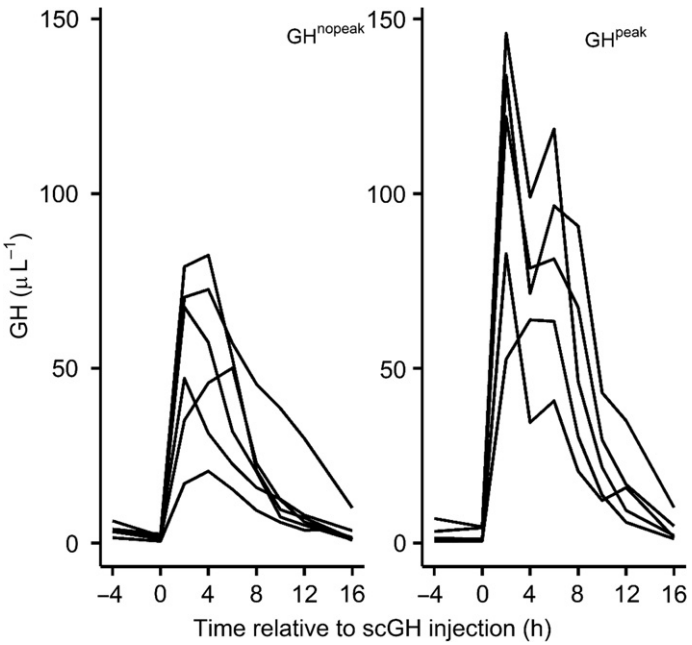

Fig. 14 GH serum curves from two children followed yearly during GH treatment, visualizing intra-individual variation of GH injection uptake; six curves from a boy in whom no peaks from endogenous GH secretion could be detected (left panel) and five curves from a boy in whom endogenous GH secretion was suspected due to the serum curves (right panel). Lundberg E. Thesis Umeå university 2017. ISBN 978-91-7601-662-6.

corresponding study in Belgium, the Netherlands, and Sweden, none of the 21 deaths found in 2543 patients was due to cancer or cardiovascular disease (Sävendahl *et al.*, 2012). Instead the majority of deaths were due to accidents and suicides. In order to evaluate mortality further in childhood GH-treated patients, now also in relation to birth characteristics, a mortality model was constructed based on the Swedish general population born between 1973 and 2010. The rhGH-treated population differed from the general population regarding size at birth and congenital malformations, making inclusion of these variables necessary. This model was applied to assess the expected deaths in the Swedish rhGH-treated patients diagnosed with IGHD, ISS, and SGA. When the model that adjusted for birth characteristics was applied, the ratio of observed/expected deaths was not increased in the childhood rhGH-treated group (Albertsson-Wikland *et al.*, 2016).

Evaluation of the risk for mortality in cancer, myocardial infarction, and stroke from the HypoCCS study in adult patients who had received pediatric GH treatment due to GHD did not find any increased risks compared with a reference population during a follow-up period mean (SD) of 3.7 (3.3) years (Mo *et al.*, 2014). The risk for cancer was further studied in the European SAGhE cohort in those countries having a population-based cancer register (Swerdlow *et al.*, 2017). The mean follow-up time was 16.5 years/patient for mortality and 14.8 years/patient for cancer incidence. The mean age for GH-treated individuals was 27.1 years for cancer mortality and 25.8 years for cancer incidence analyses. The oldest individual in the study cohort was approximately 35 years. Focusing on the "isolated growth failure" group, which included the SGA group together with isolated GHD and the ISS children, overall the cancer risk was not raised. However, there were significant rising cancer incidence risks with increasing time from the first treatment and treatment duration. Mean daily doses of GH were 26.0 $\mu g\,kg^{-1}\,d^{-1}$ for the IGHD individuals, 33.8 $\mu g\,kg^{-1}\,d^{-1}$ for the ISS individuals, and 49.5 $\mu g\,kg^{-1}\,d^{-1}$ for the SGA individuals. However, some results certainly need further studies: the rising cancer mortality associated with a greater daily dose in cancer patients, and the trend of cancers (primarily Hodgkin's lymphoma) in patients with initially noncancer diagnoses with follow-up times of more than 20 years. However, even with this large study group and study design, results do not suggest that GH treatment affects the risk of cancer incidence or mortality (Swerdlow *et al.*, 2017). As malignant diseases have increasing incidence at higher ages, future studies in cohorts with older subjects are needed.

Introduction

GH insensitivity (GHI) *(OMIM #262500* and *#245590)* was first described by Laron *et al.* in 1966, with the description of three siblings from a consanguineous family with extreme growth failure who had the phenotype of hypopituitarism with high serum GH concentrations (Laron, 2004; Laron *et al.*, 1966). Although an abnormal GH molecule was initially suspected, this disorder, referred to as "Laron syndrome," was caused by a defect in the GH receptor (GHR) (Eshet *et al.*, 1984). This rare phenotype, which was untreatable at that time, became synonymous with the diagnosis of GHI. In the late 1980s, two developments brought important changes to the field, first the development of recombinant human IGF-I (rhIGF-1) for therapy (Laron *et al.*, 1988; Walker *et al.*, 1991), and secondly the advent of molecular diagnostic techniques, which led to the cloning and characterization of the human *GHR*, and hence the understanding of the pathophysiology of GHI (Godowski *et al.*, 1989; Amselem *et al.*, 1989).

However, GHI is not a single entity, but a broad diagnostic category comprising a range of molecular defects (David *et al.*, 2011). These defects, which may involve genes coding for proteins that regulate GH binding or signal transduction and IGF-I synthesis, transport or delivery to key target tissues, are associated with a varied range of phenotypes and biochemical abnormalities. Previous texts have mostly described the characteristics of the extreme phenotype (Laron, 2004; Rosenfeld *et al.*, 1994). We discuss the genetic causes of primary GHI and also aim to update clinicians in the diagnostic approach to children with growth failure.

The IGF System in Human Growth

Physiology of the IGF System

The actions of GH are mediated by components of the IGF system, including IGF-I, IGF-binding proteins (IGFBPs), the IGF-I receptor (IGFIR), and IGF-independent effects through direct GH action. The GH–IGF axis is shown in **Fig. 1**. The original "somatomedin hypothesis" proposed that GH binding to its receptor stimulated IGF-I production, which independently affected growth (Salmon and Daughaday, 1957). However, IGFs are expressed in most tissues and the "dual effector hypothesis" in 1985, suggested that GH regulates locally produced IGF-I, which then acts in an autocrine/paracrine manner (Green *et al.*, 1985). Direct injection of GH into the cartilage growth plate of hypophysectomized rats resulted in increased longitudinal bone growth (Isaksson *et al.*, 1987) suggesting that GH has local IGF-1-independent effects, specifically on differentiation of chondrocytes in the growth plate, whereas IGF-I stimulated their clonal expansion.

Le Roith *et al.* presented a revised hypothesis (Le Roith *et al.*, 2001) that questioned the role of liver IGF-I and its circulating endocrine form in controlling post-natal growth. Liver-specific *Igf1* knockout mice continued to grow normally despite a reduction in circulating IGF-I, indicating that locally produced IGF-I was an important growth mediator (Le Roith *et al.*, 2001). About 75% of serum IGF-I is liver-derived, whereas the remainder originates from non-hepatic tissues. In addition, serum levels of the acid-labile subunit (ALS) and IGF binding protein (IGFBP)-3 are important in maintaining circulating IGF-I (Kaplan and Cohen, 2007).

Mechanisms of GH and IGF-1 Action

GH regulates IGF-I production through the signal transducer and activator of the transcription (STAT)-5b signaling system. The binding of GH to the cell surface GHR (a cytokine receptor that lacks intrinsic kinase activity) recruits and induces signal transduction through cytosolic Janus kinase 2 (JAK2). The complex signaling pathways activate four STATs, the phosphoinositide-3 kinase (PI3K) and the mitogen-activated protein kinase (MAPK) pathways (David *et al.*, 2011). Signal transduction through the STAT5b pathway requires STAT5b to associate with one of several JAK2 phosphorylated tyrosines on the intracellular domain of GHR (Derr *et al.*, 2011). STAT5b, recruited to GH-activated GHR, is phosphorylated by JAK2, whereupon the tyrosyl-phosphorylated-STAT5b forms a homo-dimer and translocates to the nucleus. The phosphorylated STAT5b binds to GH responsive elements (GHRE) and drives transcriptional regulations of STAT5b-dependent genes, including *IGF1*, *IGFBP3* and *IGFALS genes*, encoding for IGF-I, IGFBP-3 and acid labile subunit (ALS), respectively (Wang and Jiang, 2005).

IGF-I circulates in a ternary complex with liver-derived IGFBP-3 and ALS, and is delivered to IGF-I responsive cells and tissues (Fig. 1). The mitogenic and metabolic effects of IGF-I are mediated through type I IGF-I receptors (IGFIR) encoded by the *IGF1R* gene. The IGF1R undergoes post-translational glycosylation and is proteolytically cleaved into α- and β-chains (David *et al.*, 2011). The binding of IGF-I to IGF1R leads to receptor autophosphorylation, resulting in recruitment of cytoplasmic components of downstream signaling pathways, including the PI3K/Akt and MAPK/Erk pathways, ultimately leading to cell proliferation and other metabolic effects.

Effects of Human GH–IGF Axis Mutations on Linear Growth

Normal GH secretion and the integrity of the IGF system are essential for normal linear growth. Defects that have been identified to cause impaired growth due to GHI are shown in Table 1. A summary of phenotypic and biochemical features in GH–IGF-I axis defects is shown in Fig. 2. Human pre-natal growth is regulated principally by nutritional supplies, which influence fetal IGF-I. The importance of normal fetal IGF-I production and action was confirmed by the pre-natal growth failure reported in patients with *IGF1* and *IGF1R* mutations (Netchine *et al.*, 2011). Post-natal growth may be disrupted by mutations that disturb the functional integrity of the cascade of GH–GHR interaction, GH signal transduction, and IGF-I production, transport, delivery and action (David *et al.*, 2011; Argente *et al.*, 2017). In states of GHI resulting from impaired GH–GHR function, IGF-I deficiency is the cardinal biochemical feature, whereas in mutations specifically involving the *IGF1* or *IGF1R*, GHR function remains intact (David *et al.*, 2011).

Molecular Defects and Phenotypes Associated with GH Insensitivity

GH Receptor (GHR) Mutations

Molecular characteristics

GHR mutations associated with a range of phenotypes

Since 1966, >250 patients with genetic GHI have been identified worldwide (David *et al.*, 2011). The most severe phenotype is also known as Laron syndrome *(OMIM #262500)* (Laron, 2004). Most GHI cases have autosomal recessive inheritance with

defects involving either homozygous or compound heterozygous mutations (David *et al.*, 2011). >70 mutations of *GHR* have been identified to date, ranging from deletions to point mutations including missense, nonsense, and splice mutations (David *et al.*, 2011). Splice mutations represent approximately 20% of *GHR* defects and usually disrupt major regulatory elements such as the donor and acceptor splice sites. Both severe and mild phenotypes may occur within the same family (Milward *et al.*, 2004).

The GHR pseudoexon mutation

Among the defects causing aberrant *GHR* splicing, an intronic base change leading to the activation of a pseudoexon sequence and insertion of 36 new amino acids within the receptor extracellular domain was first reported in 2001 in a consanguineous Pakistani

Fig. 3 Typical facial features of a child with classical GH insensitivity (Laron syndrome). Note the depressed nasal bridge, prominent forehead and mid-facial hypoplasia (published with the written consent of the parents).

family with a mild GHI phenotype (Metherell *et al.*, 2001). This mutation leads to recognition of the pseudoexon and inclusion of an additional 108 bases between exons 6 and 7, impairing the function of the mutant GHR protein. The phenotypes (see below) occurring with this mutation range from severe to mild growth failure (David *et al.*, 2007).

Dominant negative heterozygous and compound heterozygous GHR mutations

A mild phenotype of GHI is also associated with heterozygous *GHR* mutations causing a dominant negative effect (Vairamani *et al.*, 2017). These splice site mutations (c.876-1G > C) and (c.945 + 1G > A) form heterodimers with the wild-type GHR and exert a dominant negative effect on the normal protein. A mild phenotype was also reported in two patients with compound heterozygous GHR mutations (Fang *et al.*, 2007). Both had undisputed GHI, but functional studies suggested incomplete GHR defects that determined the phenotype by an additive effect of each heterozygous mutation.

Range of phenotypes

The classical phenotype of GHI, so-called Laron syndrome, consists of a near normal birth weight followed by severe and dramatic post-natal growth failure. There is cranio-facial disproportion due to lack of growth of the sphenoid bone, which results in mid-facial hypoplasia, depressed nasal bridge and a prominent forehead **Fig. 3**. Childhood growth is severely impaired leading to adult height of approximately 120 cm. Asymptomatic hypoglycaemia is frequently present due to the extreme GH resistance. Serum concentrations of IGF-1, IGFBP-3 and ALS are severely subnormal or undetectable. Growth hormone secretion is increased with elevation of basal and peak serum GH concentrations (Laron, 2004).

The concept of genotype: phenotype relationships in endocrinology evolved from evidence that genetic defects can influence phenotypic expression based on the degree of disturbance of key mechanisms. This reasoning can be applied to defects of the GH–IGF axis causing GHI. A range of phenotypes was noticeable in 82 European GHI patients, who were identified in the early 1990s for rhIGF-I therapy (Woods *et al.*, 1997). There was a gradation of severity of short stature, with height SDS ranging from -2.2 to -10.4 and a strong positive correlation ($r^2 = 0.45$, $P \leq .001$) between height SDS and IGFBP-3 SDS. The serum GHBP level also varied and when very low or absent was associated with more severe short stature (height SDS -6.45) whereas normal GHBP values were associated with milder short stature (height SDS -4.89) (Woods *et al.*, 1997).

A study of cranio-facial phenotypes in the same subjects reported that those with normal facial appearance, as opposed to the dysmorphic features of Laron syndrome, had milder short stature (Burren *et al.*, 2001). In populations of patients from Ecuador with the homozygous E180 splice *GHR* mutation, heterogeneity of statural phenotype was also seen with height SDS values ranging from -5.3 to -11.5, and height SDS correlated positively ($P < .01$) with IGF-I SDS and IGFBP-3 SDS values (Guevara-Aguirre *et al.*, 1993).

Study of genotype: Phenotype relationships in GHR mutation patients

Thirty-eight patients with GHI, studied at St Bartholomew's Hospital in London, were identified to have homozygous or compound heterozygous or heterozygous dominant negative *GHR* mutations (David *et al.*, 2011). Assessment of height SDS and type of *GHR* mutation, was performed in these and 32 subjects, fulfilling the same GHI criteria, who were added from the literature. Relationships between *GHR* mutation type and height SDS are shown in **Fig. 4**. Dominant negative *GHR* mutations and *GHR* intronic pseudoexon mutations had less severe growth phenotypes ($P < .05$) than *GHR* missense and nonsense mutations. The probable explanation is that in the case of the dominant negative mutations, there will still be a proportion of normally functioning receptors dimerized with second normally functioning receptors resulting in effective GH signal transduction (David *et al.*, 2011).

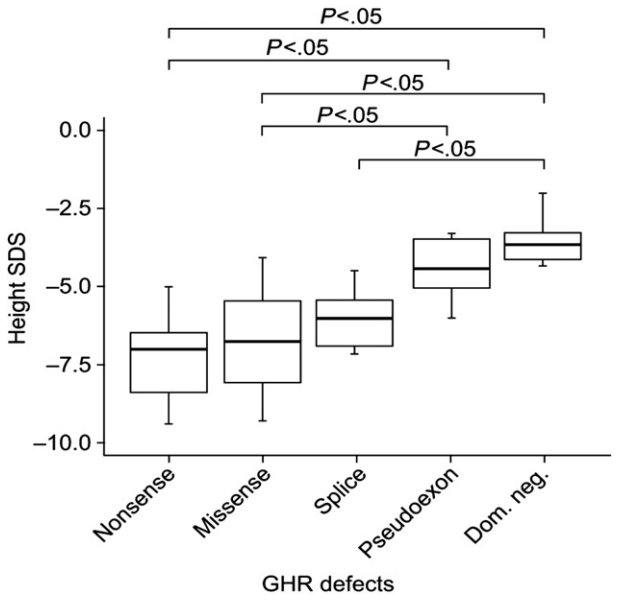

Fig. 4 Height SDS values in 70 children with GHI and *GHR* mutations divided according to the type of mutation. Each *boxplot* depicts the median and the 25th and 75th percentiles. *Whiskers* depict minimum and maximum values. Statistical analyses were performed using R version 2.6.2 (R Development Core Team, 2008, R Foundation for Statistical Computing, Vienna, Austria). Numerical values were expressed as median (range). Comparison between continuous variables was performed using Student's test. A two-sided $P < .05$ was considered significant. Bonferroni adjustment was performed to reduce the likelihood of type 1 error. Dom. neg, Dominant negative. From David, A., Hwa, V., Metherell, L. A., *et al.* (2011). Evidence for a continuum of genetic, phenotypic and biochemical abnormalities in children with growth hormone insensitivity. *Endocrine Reviews* **32**, 472–497.

Extended study of pseudoexon mutation patients

In the case of the GHR pseudoexon mutation, a range of phenotypes is seen. In patients with mild phenotypes, it is likely that there is a small residue of normally spliced receptor that will result in a degree of normal GH signaling. The ranges of phenotypic and biochemical abnormalities are shown in **Table 2** (H.L. Storr, personal communication).

STAT5B Mutations

Molecular characteristics

STAT5B mutations present a characteristic phenotype combining GHI and immunodeficiency *(OMIM #245590)*. The binding of GH to the GHR activates signaling cascades that include a number of the STAT pathways. Recent identification of human *STAT5B* mutations causing severe growth failure, as well as marked IGF-I deficiency and GHI, demonstrated that STAT5b signaling is critical for GH-induced IGF-I production and normal linear growth in humans (Rosenfeld *et al.*, 2007).

In support of the in vivo observations, studies employing primary fibroblasts from an affected patient (Kofoed *et al.*, 2003) and reconstitution systems, demonstrated that GH activated STAT5b preferentially, which correlated with the induction of IGF-I and IGFBP-3 expression (Hwa *et al.*, 2004). The resulting STAT5b deficiency not only abrogated GH-induced IGF-I production as indicated above, but IL-2-induced expression of $CD25^{high}$ was also demonstrated to be aberrant (Cohen *et al.*, 2006).

The unusual combination of GHI and immune deficiency in the first patient to be described was due to a homozygous, missense, mutation in Exon 15 of the *STAT5B* gene (Kofoed *et al.*, 2003). The single *G* to *C* transversion at nucleotide 1888 of the *STAT5B* mRNA resulted in an Ala630 (GCT) to Pro (CCT) substitution, predicted to cause loss of thermodynamic stability and aberrant folding and aggregation of the mutant STAT5b protein. Additional human *STAT5B* gene mutations have been documented, with two of the mutations, c.*1680delG* and c.*424_427del* found in siblings (David *et al.*, 2011).

Phenotypic features

The first human *STAT5B* mutation was identified in a 16-year-old female from a consanguineous Argentine family (Kofoed *et al.*, 2003). Birth weight in affected patients is generally normal, but is followed by severe post-natal growth failure, with resistance to GH therapy (David *et al.*, 2011). With respect to growth in STAT5B deficient patients, height SDS values ranged from −5.6 to −9.9. The majority of these patients also had serious immunological abnormalities.

The biochemical profile shows normal or elevated GH secretion, normal GHBP values and severe deficiencies of IGF-I, IGFBP-3, and ALS which fail to increase on GH stimulation (David *et al.*, 2011). A key feature was immune dysfunction and in several patients, repeated pulmonary infections occurred from infancy, including episodes of lymphoid interstitial pneumonia (Hwa *et al.*, 2007). All reported mutations were homozygous. The only reported patient without immune deficiency, the first male proband in

the cohort, contracted hemorrhagic varicella at 16 years of age and had congenital ichthyosis and erythema but otherwise appeared healthy (Vidarsdottir *et al.*, 2006). One other patient was diagnosed with juvenile idiopathic arthritis at an unusually young age of 2 years (Hwa *et al.*, 2007).

STAT5b deficiency was associated with abnormally high levels of prolactin in six of the cases (David *et al.*, 2011). It remains unclear whether the hyperprolactinaemia is a direct or indirect consequence of *STAT5B* mutations. In a large Brazilian pedigree, height SDS, IGF-1 SDS and IGFBP-3 values were compared in subjects with homozygous and heterozygous *STAT5B* mutations and wild-type family members (Scalco *et al.*, 2015). All three variables were decreased in heterozygous compared with non-carrier wild-type individuals. The heterozygous subjects also had an average height SDS of -1.4 ± 0.8 when compared with normal population-matched controls. These findings support a negative impact on height of heterozygous *STAT5B* mutations.

IGF1 Gene Defects

Molecular characterization

The first human *IGF1* gene defect was described in 1996 by Woods *et al. (OMIM #608747)* (Woods *et al.*, 1996). Molecular analysis revealed a homozygous deletion of exons 4 and 5 of the *IGF1* gene. If translated, the resulting protein would be severely truncated, lacking 45 of the 70 IGF-I amino-acids. Genetic analyses of *IGF1* in the second case (Bonapace *et al.*, 2003) showed a homozygous T → A transversion in exon 6 resulting if translated into an altered E domain of the IGF-I precursor. It has been argued that this variant may be a polymorphism and thus not causative of the patient's phenotype, which was nevertheless strikingly similar to the other cases.

The third reported patient had a serum IGF-I level that was significantly increased (+7.3 SDS), explained by the fact that the patient's homozygous missense mutation of *IGF1*, a G → A nucleotide substitution at position 274, changing valine at position 44 in the A domain of the IGF-I protein to methionine (p.V44M), resulted in a recombinant protein (IGF-1 V44M) with normal binding to IGFBP-3 but decreased affinity (90-fold) for its receptor, IGF1R (Walenkamp *et al.*, 2005). This patient therefore had bio-inactive IGF-I caused by an *IGF1* mutation. Family members who were heterozygous carriers of this mutation were shorter than the non-carrier family members. In the fourth patient, who had a milder phenotype, sequencing of *IGF1* revealed a homozygous missense mutation resulting in the change of a highly conserved arginine located in the C domain of the protein into a glutamine (p.R36Q). Affinity for the IGF1R decreased two-to-threefold, resulting in decreased IGF1R autophosphorylation.

Phenotypic features

Four patients with IGF-1 gene defects have been published. Their characteristics are shown in **Fig. 2**. The first patient, a male, was born by Caesarean section because of poor fetal growth (Woods *et al.*, 1996). Placental weight was diminished (350 g) and he had

severe intrauterine growth retardation (IUGR) with a birth weight of 1.4 kg (− 3.9 SDS), birth length of 37.8 cm (− 5.4 SDS), and microcephaly (head circumference 27 cm, − 4.9 SDS). His growth failure worsened post-natally and at 15.8 years his height was 119.1 cm (− 6.9 SDS) and his weight was 23.0 kg (− 6.5 SDS). He had delayed psychomotor development and sensorineural deafness. During adolescence he became insulin-resistant. Serum IGF-I was undetectable even after 4 days of GH stimulation. Spontaneous 12-h GH secretion showed elevated baseline and peaks. ALS and IGFBP-3 values were normal. At 16.1 years (bone age, 14.2 years), recombinant IGF-I therapy was initiated and resulted in beneficial effects on insulin sensitivity, body composition, bone size, and linear growth (Woods *et al.*, 2000).

Intrauterine growth retardation (IUGR), microcephaly, retarded intellectual development and severe post-natal growth failure were present in the other cases with homozygous *IGF1* mutations. Deafness was present in all the cases except the child with the mildest phenotype. The microcephaly which these patients had appears to be a cardinal feature of the phenotype. Serum IGF-I has been variable in *IGF1* mutation cases. The third case to be described (Walenkamp *et al.*, 2005) shared an identical clinical phenotype with the index case, and had a younger brother with similar features who died in childhood. Serum IGF-I in the fourth patient was also variable and not severely decreased (Netchine *et al.*, 2009). In all reported subjects serum IGFBP-3 and ALS levels were normal.

A definite short stature phenotype was reported with a novel heterozygous mutation of the *IGF1* gene (van Duyvenvoorde *et al.*, 2010) supporting the hypothesis, suggested from larger family studies (Walenkamp *et al.*, 2005), that heterozygosity for certain *IGF1* mutations may cause significant short stature. The spectrum of *IGF1* defects was further broadened by the report of a child with short stature (height − 4.0 SD) and a dominant pattern of inheritance who had IGF-I deficiency and a novel heterozygous donor splice site mutation at the exon 4–intron 4 junction of *IGF1* (Fuqua *et al.*, 2009).

IGFALS Mutations

Molecular characterization

IGFALS mutations cause GHI and severe ALS, IGF-I and IGFBP-3 deficiencies (*OMIM #601489*). Characteristics of patients with IGFALS mutations are shown in **Fig. 2**. *s*ALS is a soluble protein and member of the leucine-rich repeat family, being expressed by hepatocytes and secreted into the circulation (Leong *et al.*, 1992). GH is the main inducer of ALS, which circulates as a free peptide or bound to IGF-1 or -2 and IGFBP-3 or -5, to form a ternary complex, which prevents IGFs and IGFBPs from leaving the circulation, thus prolonging their half-lives and decreasing their availability at a tissue level (David *et al.*, 2011). ALS is encoded by the *IGFALS* gene, located on chromosome 16p13.3 and spanning 3.3 Kb. A review of published cases described 16 mutations of the human *IGFALS* gene in 21 cases (Domené *et al.*, 2009). Eleven were homozygous and six were compound heterozygous. Family studies confirmed autosomal recessive inheritance. *IGFALS* mutations have included missense and nonsense mutations, deletions, duplications, and insertions resulting in frameshift and premature stop codons and in-frame duplications leading to insertion of extra amino acid residues.

Phenotypic features

The first patient with a homozygous mutation of *IGFALS* was reported by Domené *et al.* (2004) and presented a new combination of genetic, biochemical, and phenotypic findings. There is a mis-match between deficiencies of circulating IGF-I, IGFBP-3, and ALS and relatively mild growth failure, even leading to a normal adult height in some patients (Domené *et al.*, 2009). All reported cased had extreme deficiency of circulating ALS, with inability to form the ternary complex. Circulating levels of IGF-I and IGFBP-3 are severely reduced, due to their rapid clearance, however local IGF-1 production in peripheral tissues, notably the growth plate, appears to be preserved or even increased due to up-regulation of GH secretion (Domené *et al.*, 2004). Insulin resistance, with hyperinsulinemia and low IGFBP-1, has also been described in these patients (Domené *et al.*, 2009).

An analysis of 21 patients with homozygous or compound heterozygous *IGFALS* mutations and their family members who were either heterozygous carriers or homozygous wild-type normal has been published (Fofanova-Gambetti *et al.*, 2010). Mean height SDS was -2.31 ± 0.87 in the homozygous patients and heterozygosity resulted in approximately 1.0 SD height loss compared to wild-type, whereas homozygosity or compound heterozygosity resulted in a further loss of 1.0–1.5 SD, suggestive of a gene–dosage effect. The term partial acid-labile subunit deficiency was coined to describe subjects with heterozygous *IGFALS* mutations. A recent report described 50 subjects from five Turkish families carrying three different *IGFALS* mutations (Işik *et al.*, 2017). Height SDS, head circumference SDS, and BMI SDS were lower ($P < .01$) in the 24 subjects with homozygous mutations compared to 26 with heterozygous mutations. Similarly IGF-1, ALS and IGFBP-3 were lower ($P < .001$) in the subjects with homozygous mutations (Işik *et al.*, 2017).

IGF-1 Receptor (IGF1R) Mutations

Molecular characterization and phenotypic features

IGFIR mutations are characterized by IGF-I resistance causing impaired fetal and post-natal growth (*OMIM #270450*). Characteristics of patients with heterozygous *IGFIR* mutations are shown in **Fig. 2**. The IGF1R is a transmembrane receptor and belongs to the insulin receptor family, which includes the IGF2R and insulin receptor. The IGFIR is expressed widely and binds IGF-1 and -2 with high affinity, mediating their biological actions by activating a complex intracellular signaling cascade leading to the transcription of IGF target genes. The *IGF1R* gene is located on chromosome 15q26.3 and spans 315Kb.

Mutations in *IGF1R* were first reported in two subjects in 2003 by Abuzzahab *et al.* (2003) following analyses of DNA from children with short stature and unexplained IUGR. The first child was a compound heterozygote for point mutations in exon 2 of the *IGFIR* gene that altered the amino acid sequence to p.Arg108Gln in one allele and p.Lys115Asn in the other. The birth weight was −3.5 SD with childhood short stature and an adult height of −4.8 SD. The second patient, a boy, had a heterozygous nonsense mutation (p.Arg59stop) that reduced the number of IGF1Rs on fibroblasts. He also had low birth weight (−3.5 SD) and birth length (−5.8 SD) with microcephaly and post-natal growth failure (height − 3.8 SD) at age 14 months. Serum IGF-I levels were normal or elevated in both patients and GH secretion was normal.

Familial *IGF1R* mutations have been described, with mother and offspring affected (David *et al.*, 2011). A heterozygous mutation in the cleavage site of the proreceptor of *IGF1R* was reported in a 6-year-old Japanese girl and her mother and the research team of Wit in Leiden described a mother and daughter with a heterozygous missense mutation in the intracellular part of the *IGF1R* (Walenkamp *et al.*, 2006). Small birth size, childhood short stature, small head size, relatively high IGF-I levels, developmental delay, and micrognathia are the main predictors for the diagnosis of an *IGF1R* deletion (David *et al.*, 2011; Ester *et al.*, 2009).

PAPP-A2 Mutations

Molecular and clinical characteristics

The first mutations of the metalloproteinase pregnancy-associated plasma protein-A2 (PAPP-A2) were described in five patients with GHI from Madrid and Cincinnati by Dauber *et al.* (2016). This was the first report of autosomal recessive mutations in a gene which encodes the IGF binding proteins (Argente *et al.*, 2017). The clinical syndrome of PAPP-A2 deficiency is caused by loss-of-function mutations in the gene encoding PAPP-A2, which has an essential proteolytic function in the cleavage of the circulating ternary complex. Consequently *PAPP-A2* mutations prevent this cleavage and inhibit the liberation and delivery of free IGF-1 to its target tissues. The clinical features were relatively subtle with mild short stature, thin long bones with long, slender fingers and toes, mild microcephaly and long thin nose and small chin.

However, the biochemical findings were striking with markedly elevated levels of IGF-1, IGFBP-3, IGFBP-5 and ALS. Growth hormone secretion was also increased, reflecting the failure of delivery of free IGF-1 and IGF binding proteins to peripheral tissues from the ternary complex. Concentrations of bioactive IGF-1 were very low, which were interpreted to be the cause of the poor linear growth. Treatment with rhIGF-1 improved short-term linear growth in patients both from Madrid (Muñoz-Calvo *et al.*, 2016) and Cincinnati (Cabrera-Salcedo *et al.*, 2017).

GH1 mutations Causing Biologically Inactive GH

Certain *GH1* mutations cause biologically inactive GH resulting in a form of GHI *(OMIM #262650)*, first described by Kowarski *et al.* (1978). The molecular basis of this rare cause of GHI was clarified by Takahashi *et al.*, who reported two cases with heterozygous mutations in the *GH1* gene (Takahashi *et al.*, 1997). The first was a boy with severe short stature (height − 6.1 SD) who had increased immune-assayable GH and IGF-I deficiency, which responded, as did his growth, to exogenous hGH therapy. The mutation was a single-base missense substitution (p.R77G) in exon 4 of the *GH1* gene. However, his normal-stature father also had the same mutation. Functional studies demonstrated that the mutant GH molecule had higher binding affinity for the GHR and inhibited its activation by wild-type GH in a dominant-negative fashion, thus impairing GH bioactivity. The second case, a girl, had similar endocrine features and short stature associated with a heterozygous single-base change (A → G) causing a p.D112G substitution in *GH1*. A child with short stature (height −3.6 SD at age 9 years) from a consanguineous Serbian family was reported to have a homozygous missense mutation, Cys53Ser, of *GH1* leading to the absence of the disulfide bridge Cys-53 to Cys-165 in the GH molecule (Besson *et al.*, 2005). Functional studies demonstrated that GH binding and JAK2/STAT5 signaling pathway activation was reduced in the mutant GH-C53S compared with wild-type-GH. Both growth and serum IGF-I responded well to GH therapy.

GHI Gene Deletions (Type IA GH Deficiency) with Anti-GH Antibodies

A rare form of GHI occurs due to acquired GH-inhibiting antibodies in children with familial isolated GH deficiency (IGHD) *(OMIM #262400)* (Cogan and Phillips, 2006). Autosomal recessive IGHD, caused by deletions of the *GH1* gene, results in severe IGHD (type IA) with undetectable GH secretion. Such patients have post-natal height usually < −4.5 SD. Most *GH1* deletions are 6.7, 7.0 or 7.6 kb in length. Microdeletions and frameshift mutations have also been reported (David *et al.*, 2011). These patients frequently develop growth-inhibiting anti-GH antibodies during treatment with hGH due to immunological intolerance. They may respond to therapy with recombinant human IGF-I, which becomes the only effective management for their growth failure (Riedl and Frisch, 2006).

Diagnosis of GH Insensitivity

The evaluation of a child with short stature and possible GHI should comply with the classical paradigm of clinical assessment followed by general (i.e., non-endocrine) investigations, hormonal assessment, and possible genetic analyses. An algorithm

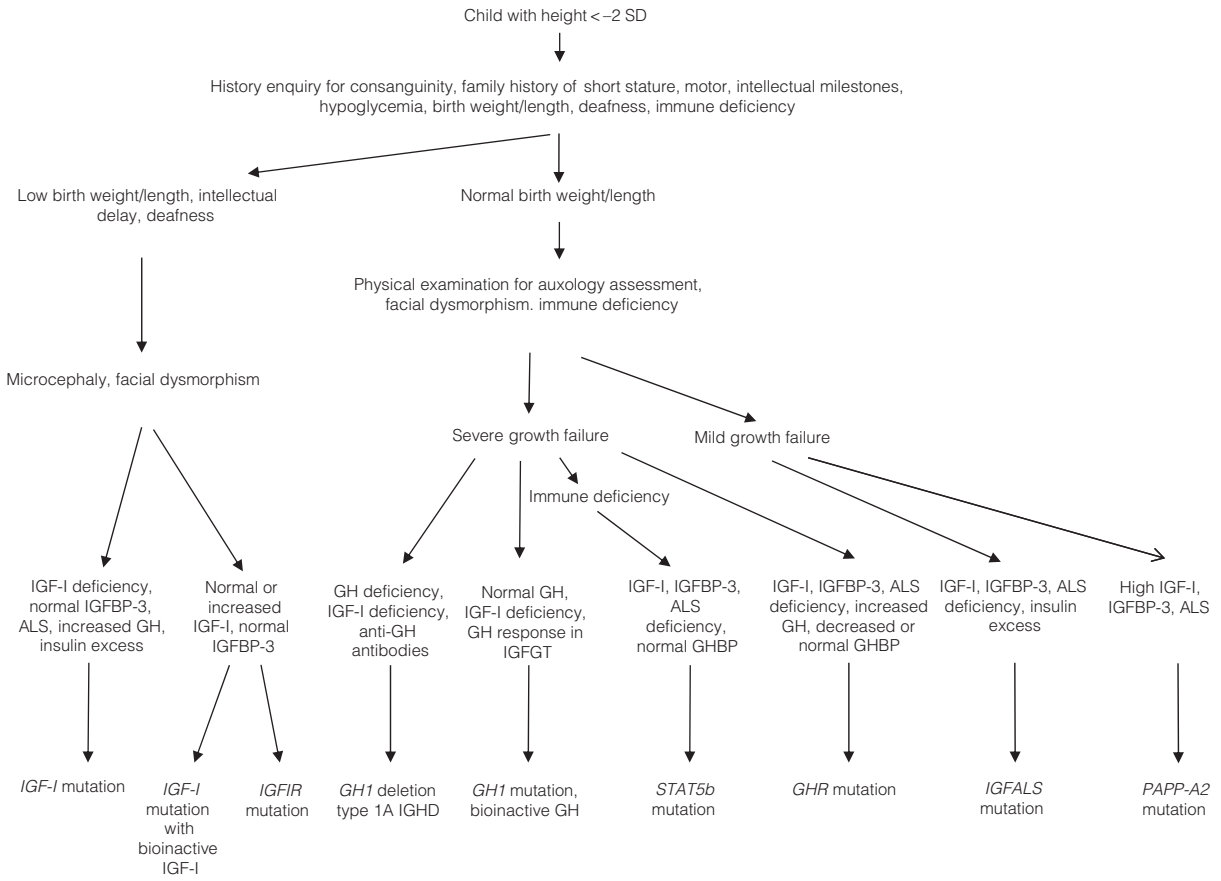

Fig. 5 Algorithm for diagnosis of genetic GH insensitivity disorders.

showing key steps in the diagnosis of genetic GH–IGF-I axis defects is shown in **Fig. 5**. As advances in molecular endocrinology progress, the importance of detailed phenotypic evaluation and documentation is emphasized. The urge to obtain a molecular diagnosis at the onset of the investigations should be resisted until clinical and endocrine evaluation has been performed. Clinical assessment should include enquiries about family history of growth disturbance, consanguinity, birth weight and length, and recurrent infections (Savage *et al.*, 2010). Examination should specifically assess the presence of possible facial dysmorphic features and microcephaly in addition to anthropometric evaluation (Cohen *et al.*, 2008).

Investigations of the GH–IGF-I Axis

Investigations of the GH–IGF-I axis consist of determination of GH secretion and exploration of the IGF system. A GH provocation test is recommended unless the child has normal auxology or a basal IGF-I level above the mean for age (Cohen *et al.*, 2008). In a child with clinical criteria of GHD, a peak GH level of <7 ng/mL is recommended to support this diagnosis (Wagner *et al.*, 2014). Basal IGF-I levels should be determined, but are influenced by age, nutrition, chronic illness, and puberty. In the initial assessment, IGFBP-3 adds little, except in children under 3 years of age, where low IGFBP-3 is helpful in the diagnosis of GHD (Cianfarani *et al.*, 2005). Reliable assay performance and appropriate normative data for IGF-1 and IGFBP-3 are essential (Juul *et al.*, 1994, 1995).

A diagnosis of GHI follows from the demonstration of abnormal auxology, normal GH secretion, and IGF-I deficiency. However, the pathogenesis will not have been elucidated from these investigations. The nature of the defect can often be defined by additional measurement of IGFBP-3, ALS, and GHBP (David *et al.*, 2011).

The IGF-I Generation Test (IGFGT)

The IGFGT was designed to predict growth responses to GH in GH deficient patients. This was unsatisfactory and the test was abandoned. Normative data were also not established. Interest in the IGFGT was renewed when molecular evidence of GHI was demonstrated and subjects were selected for rhIGF-I therapy. Criteria for diagnosis of GHI were defined as: failure to increase IGF-I and IGFBP-3 by >15 and 400 ng/mL, respectively (Blum *et al.*, 1994). However, as the spectrum of GHI disorders expanded, these criteria became too strict for more mildly affected subjects (Coutant *et al.*, 2012). Attempts to refine the IGFGT for investigation of

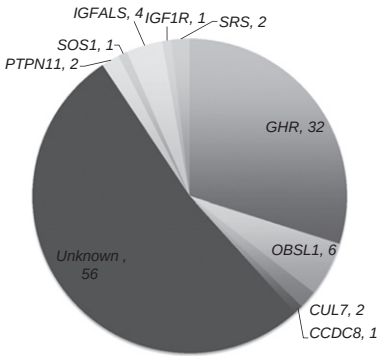

Fig. 6 Genetic diagnoses obtained from candidate gene sequencing and whole exome sequencing in a selected group of 107 patients with GH Insensitivity (Shapiro *et al.*, 2017).

milder GHI demonstrated that patients with idiopathic short stature produced a subnormal response (Buckway *et al.*, 2001) and subjects with IGF-I deficiency and normal GH secretion also had subnormal ability to generate IGF-I. However, additional sensitivity for the diagnosis of GHI was not seen with a low-dose GH protocol (Buckway *et al.*, 2001). For these reasons, the IGFGT is not recommended in the routine investigation of short stature and its principle use is for confirmation of extreme or severe GHI (Coutant *et al.*, 2012).

Genetic Investigations

A genetic diagnosis is of benefit to families and clinicians in understanding causality and prognosis in GHI and to direct the appropriate management. Defects in genes coding for key functional proteins regulating GH action are responsible for GHI (Shapiro *et al.*, 2017). Mutations of the growth hormone receptor (*GHR*) gene are the commonest defects but, as discussed above, mutations in *STAT5B*, *IGF1*, *IGFALS*, *IGF1R and PAPP-A2* genes are also described (David *et al.*, 2011). These defects cause a spectrum of genetic, phenotypic and biochemical abnormalities. Disorders that may overlap phenotypically and biochemically with GH–IGF-1 axis defects include 3 M Syndrome (caused by mutations in *CUL7*, *CCDC8* and *OBSL1*), Noonan syndrome (*PTPN11*, *SOS1* and others) and Silver-Russell Syndrome (Shapiro *et al.*, 2017).

Accurate clinical and biochemical phenotyping is essential to orientate the clinician and the molecular genetics laboratory to the most likely candidate gene defect, for example, facial features of Laron syndrome or associated immunodeficiency may suggest a GHR or STAT5B defect. Sequencing of candidate genes associated with GHI will reveal a diagnosis in ~30%–40% of patients (Wit *et al.*, 2016; Storr *et al.*, 2015). However, more extensive genetic testing, for example, whole exome sequencing can improve the diagnostic yield in selected patients with GHI to approximately 50% (Shapiro *et al.*, 2017) **Fig. 6**. Therefore, although genetic analyses are important, accurate clinical and biochemical characterization is essential for optimal patient care.

Treatment of GH Insensitivity

The logical therapy for patients with GHI is administration of subcutaneous rhIGF-1. It is important to state that rhIGF-1 therapy has been problematic for a number of reasons. First, regular supplies of this recombinant hormone, produced since the late 1980s and licensed for GHI therapy by the FDA and EMA since 2005 and 2007 respectively, have not been available. A succession of pharmaceutical companies developed and then discontinued rhIGF-1 production resulting in relatively few definitive therapeutic trials. Nevertheless, rhIGF-1 is the recognized therapy for GHI patients and its efficacy in promoting growth in patients with extreme growth failure is now established (Laron *et al.*, 1988; Ranke *et al.*, 1999; Chernausek *et al.*, 2007; Guevara-Aguirre *et al.*, 2013). Gain in stature to adult height, using the recommended regimen of 80–120 μg/kg twice daily, has been documented, with advantage during puberty demonstrated by addition of a GnRH analogue to rhIGF-1 to delay epiphyseal fusion (Backeljauw *et al.*, 2013) (**Fig. 7**). However, most severely affected patients did not reach their genetic targets.

Most studies have been performed in patients with severe GHI, who have very low levels of IGF-1, IGFBP-3 and ALS. These low concentrations influence the kinetics of injected rhIGF-1 so that it is rapidly cleared from the circulation (Grahnen *et al.*, 1993) necessitating twice daily administration. There are few studies showing efficacy of rhIGF-1 in more mildly affected patients. One study from the United States showed variable efficacy in subjects with mild GHI (Midyett *et al.*, 2010). Publication of the results of a post-marketing European registry of rhIGF-1 therapy in 195 children with growth failure described the efficacy of treatment in the "real world" as being similar to that seen in randomized controlled rhIGF-1 trials (Bang *et al.*, 2015).

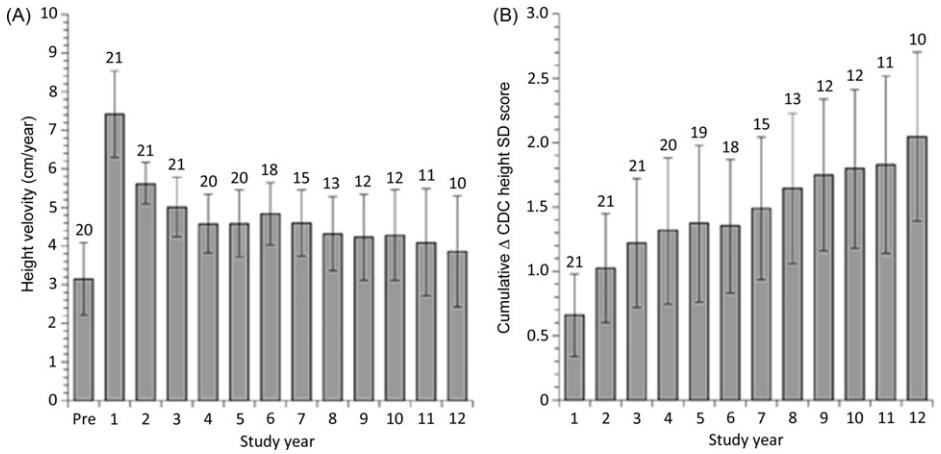

Fig. 7 (A) Individual growth during IGF-I therapy for 12 male patients, compared with the US National Center for Health Statistics standards *(upper shaded area)* and the mean ± 2 SD for height for untreated Laron syndrome patients *(lower shaded area)*. The growth curves for Laron syndrome constitute a reference range for patients with presumed GH receptor abnormalities. (B) Individual growth during IGF-I therapy for nine female patients, compared with the US National Center for Health Statistics standards *(upper shaded area)* and the mean ± 2 SD for height for untreated Laron syndrome patients *(lower shaded area)*. The growth curves for Laron syndrome constitute a reference range for patients with presumed GH receptor abnormalities (Backeljauw et al., 2013). From Backeljauw, P. F., Kuntze, J., Frane, J., Calikoglu, A. S., Chernausek, S. D. (2013). Adult and near-adult height in patients with severe insulin-like growth factor-I deficiency after long-term therapy with recombinant human insulin-like growth factor-I. *Hormone Research in Pædiatrics* **80**, 47–56.

Adverse events related to rhIGF-1 have been clearly documented since its early use in the late 1980s. These are more troublesome in the most severely affected patients, that is, children with the classical Laron syndrome phenotype. Hypoglycaemia, lipoatrophy at the injection sites, enlargement of lymphoid tissue, including tonsillar swelling, and rarely, benign intracranial hypertension are recognized potential adverse events (Chernausek *et al.*, 2007). There are clearly benefit versus risk evaluations to be made in the management of GHI patients. However, the extreme short stature of the most severely affected patients, with the prospect of adult height in the region of 120 cm, with its accompanying disadvantages, provides a compelling argument to initiate rhIGF-1 therapy, which is safe and well tolerated in most patients (74, Bang *et al.*, 2015).

Tall Stature

Sabine E Hannema, Leiden University Medical Centre, Leiden, The Netherlands
Lars Sävendahl, Karolinska Institute, Stockholm, Sweden

Glossary

Camptodactyly Congenital digital flexion deformity.
Epiphysiodesis Surgical ablation of a physis to stop its growth.
Marfanoid habitus A tall, slender build with long limbs, fingers and toes which may be accompanied by scoliosis and/or pectus deformity.

Introduction

Tall stature is usually defined as height above $+2$ SDS or height >2 SDS above the target height SDS. It is important to use reference data appropriate for the ethnic background of the individual. Different formulas are available to calculate target height (van Dommelen *et al.*, 2012); ideally height of both parents should be measured. Sudden growth acceleration may also warrant evaluation even if height is still $<+2$ SDS and within the target height range. To be able to identify growth acceleration it is important to collect growth data, ideally from birth onwards, and plot these in a growth chart to assess the growth pattern.

Defining tall stature as height $>+2$ SDS means that 2.5% of the population has tall stature. Interestingly, short stature is a much more common reason for medical consultation than tall stature. This is probably due to greater social acceptance of tall stature. However, some may worry about excessive height and request counseling on predicted adult height and possibilities to reduce growth. Some may also worry about an underlying disorder. Most individuals do not have an underlying pathological cause of their tall stature but it is important to identify those that do, as some of these conditions are associated with significant morbidity for which regular screening is advised, such as cardiovascular pathology in Marfan syndrome and increased tumor risk in Beckwith-Wiedemann syndrome (BWS) and PTEN hamartoma tumor syndrome (PHTS).

Tall stature can be the result of a number of different conditions. A thorough medical history, a detailed physical examination and careful evaluation of the growth chart may lead to the conclusion that there is a benign cause such as familial tall stature, and should otherwise narrow the differential diagnosis and give direction to further investigations.

Causes of Tall Stature

A few key questions can be helpful to determine the most likely cause of tall stature, as outlined in the flowchart (**Fig. 1**). In addition to height, head circumference, arm span and sitting height should be measured. However, in syndromes associated with disproportionate tall stature the sitting height-to-height ratio and arm span-to-height ratio may still be within the normal range. In addition, these ratios cannot be used in the presence of severe scoliosis and different reference values for body proportions apply to various ethnicities (Reeves *et al.*, 1996). If present at the consultation, parents should be measured rather than relying on reported height, and their head circumference and body proportions may also be informative.

Syndromic Causes of Tall Stature

The medical history, family history and physical examination may reveal clues to a syndromic cause of tall stature (**Table 1**). To determine which syndromes are most likely in an individual we have chosen to distinguish between syndromes with and without macrocephaly and those with and without a Marfanoid habitus, that is, tall, slender build with long limbs, fingers and toes which may be accompanied by scoliosis and/or pectus deformity (**Fig. 1**). However, this distinction is not absolute as the phenotype may vary between individuals.

Although specific features may point towards a syndrome for which directed genetic testing can be performed, there is considerable overlap between the phenotype of various syndromes. Gene panels or exome sequencing are now more widely available and may gain a more important position in the diagnostic evaluation of syndromic tall stature. Using exome sequencing, a recent study in individuals with height $\geq +2$ SDS and intellectual disability identified a genetic cause in 45%, suggesting exome sequencing might be considered as a first-line diagnostic tool in this group (Tatton-Brown *et al.*, 2017). The yield was even higher if subjects also had head circumference $\geq +2$ SDS (59%). Many of the identified mutations were in genes involved in epigenetic regulation, most commonly *NSD1* (Sotos syndrome). Another group of genes in which mutations were found were those of the PI3K/AKT pathway, most commonly *PTEN* (PTEN hamartoma tumor syndrome) (Tatton-Brown *et al.*, 2017).

Syndromes with macrocephaly

Sotos syndrome is an autosomal dominant disorder caused by mutations in the *NSD1* gene with an incidence of approximately 1:14,000. Dysmorphic features include a long face, frontal bossing and a prominent chin. Affected children are tall from birth onwards with an advanced bone age but they usually have a normal adult height. Sotos syndrome is associated with macrocephaly, brain abnormalities, neonatal hypotonia and feeding problems, developmental delay and intellectual disability. A score has been developed based on several of these clinical findings to estimate the probability of Sotos syndrome (de Boer *et al.*, 2004). Similar disorders also characterized by tall stature with advanced bone maturation, macrocephaly, dysmorphic features and developmental delay are Malan syndrome, caused by mutations in *NFIX* and Weaver syndrome, caused by mutations *EZH2*. Several other genes that are involved in epigenetic regulation, such as *DNMT3A*, *EED*, *CHD8* and *HIST1H1E* have also been implicated in tall stature and/or macrocephaly (Tatton-Brown *et al.*, 2017).

PTEN hamartoma tumor syndrome (PHTS) is a term used to describe several syndromes caused by mutations in *PTEN*, including Cowden syndrome, Bannayan–Riley–Ruvalcaba syndrome and possibly Proteus syndrome. It is inherited in an autosomal dominant way. The prevalence of PHTS is unknown but that of Cowden syndrome is estimated to be at least 1:250,000 (Nelen *et al.*, 1999). PTEN is a negative regulator of the PI3K-AKT-mTOR pathway which is involved in control of the cell cycle and cell proliferation (Song *et al.*, 2012). Macrocephaly is characteristic of Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome and affected individuals may have mucocutaneous manifestations such as trichilemmomas and penile macules, and hamartomas. Individuals with PHTS have an increased risk of intellectual disability and/or autism spectrum disorders. Tall stature has been reported in childhood but adult height seems normal (Parisi *et al.*, 2001). In childhood affected individuals may develop benign or malignant tumors of the thyroid for which screening is warranted (Smpokou *et al.*, 2015). At adult age they are at increased risk of various tumors including breast cancer, endometrial cancer and colorectal cancer. Mutations in several other genes in the PI3K-AKT-mTOR pathway, such as *AKT3*, *PIK3CA*, *MTOR* and *PPP2R5D*, have been found in individuals with macrocephaly with or without tall stature (Tatton-Brown *et al.*, 2017).

Simpson–Golabi–Behmel syndrome is a rare X-linked disorder caused by mutations in the *GPC3* gene. It is characterized by macrosomia and postnatal overgrowth, macrocephaly, dysmorphic features such as coarse facial features, macroglossia, a groove of the lower lip and supernumerary nipples, organomegaly and congenital abnormalities such as cardiac defects (Tenorio *et al.*, 2014). Affected children are at an increased risk of embryonal tumors.

Syndromes with Marfanoid habitus

Marfan syndrome is a connective tissue disorder caused by mutations in the *FBN1* gene with variable clinical expression and is inherited in an autosomal dominant way. Its prevalence is approximately 1:5000. The diagnosis is made using the revised Ghent criteria which are based on clinical characteristics (ectopia lentis, aortic root dilation and systemic features), family history and/or

Table 1 Clinical features of various conditions associated with tall stature and diagnostic tests that may be used to investigate these conditions.

Disorder	*Clinical features*	*Diagnostic test*
Sotos syndrome	Intellectual disability/developmental delay. Neonatal hypotonia, feeding problems. Long face, frontal bossing, prominent chin. Macrocephaly	Use Sotos score (de Boer *et al.*, 2004). Bone age (usually advanced). Evaluation by clinical geneticist. *NSD1* sequencing
PTEN hamartoma tumor syndrome	Intellectual disability, autism spectrum disorder. Macrocephaly. Lipomas, trichilemmomas, oral papillomas, penile freckling	*PTEN* sequencing
Marfan syndrome	Severe myopia, lens luxation, pneumothorax, long face, wrist or thumb sign, pectus deformity, hindfoot deformity, scoliosis, skin striae	Evaluation by ophthalmologist, cardiologist, clinical geneticist. Use revised Ghent criteria (Loeys *et al.*, 2010). *FBN1* sequencing
Homocystinuria	Intellectual disability, severe myopia, lens luxation, thrombo-embolism, scoliosis, pectus excavatum	Plasma homocysteine level
Fragile X syndrome	Intellectual disability, autism spectrum disorder, behavioral problems. Large head, long face, large ears, hypermobility, pectus excavatum. In boys: large testes after puberty	*FMR1* CGG repeat number
MEN2B	Long face, scoliosis, joint laxity, alacrima and mucosal neuromas	*RET* sequencing
Beckwith–Wiedemann syndrome	Macroglossia, ear creases or pits, naevus flammeus, abdominal wall defects, hemihyperplasia. Neonatal hyperinsulinism	Methylation analysis, *CDKN1C* sequencing
Klinefelter syndrome/Triple X syndrome	Delayed speech/language or motor development, social/emotional/behavioral problems. In boys: small penis, cryptorchidism, small testes in puberty	Karyotype
Other syndromes	Intellectual disability, dysmorphic features, macrocephaly	Evaluation by clinical geneticist; specific DNA tests, next generation sequencing
Precocious puberty	Breast development in girls, testicular enlargement in boys	LH, FSH, estradiol or testosterone; GnRH test; bone age
Pseudoprecocious puberty	Pubarche, penile enlargement, breast development	Adrenal androgens, AFP, hCG; bone age
Pituitary gigantism	Sometimes acromegalic features such as large hands/feet, thick skin. Headache/visual problems (in case of macroadenoma)	GH, IGF-I, IGFBP3; GH suppression test (OGTT)
Hyperthyroidism	Goiter, tachycardia, weight loss, exophthalmos	TSH, FT4
Familial glucocorticoid deficiency	Hyperpigmentation, hypoglycaemia, seizures	ACTH, cortisol
Estrogen deficiency/resistance	Continued growth into adulthood	LH, FSH, estradiol; bone age
Constitutional advancement of growth	May have early puberty and/or develop obesity	Bone age

genetic testing (Loeys *et al.*, 2010). Systemic features include a positive wrist or thumb sign, pectus deformity, hindfoot deformity, pneumothorax, scoliosis, specific facial features, skin striae and myopia >3 diopters. If Marfan syndrome is suspected, the child should be referred to the cardiologist and ophthalmologist, keeping in mind that the absence of cardiac or eye pathology does not rule out Marfan syndrome and that the phenotype may evolve over time so that repeat evaluation may be indicated. It is important not to miss this diagnosis because of the serious comorbidity associated with Marfan syndrome, such as aortic aneurysm and dissection, for which screening is indicated. Growth charts have been developed for children with Marfan syndrome and show that from birth onwards children with Marfan syndrome are taller than the general population and that their growth velocity peaks 2–2.5 years earlier than that of unaffected children (Erkula *et al.*, 2002).

Several other disorders are associated with disproportionate tall stature and a Marfanoid habitus. These include congenital contractural arachnodactyly, caused by mutations in *FBN2* and characterized by folded upper ear helices and joint contractures.

Homocystinuria is an autosomal recessive disorder caused by cystathionine β-synthase deficiency; its clinical expression is variable. In addition to disproportionate tall stature, scoliosis and pectus excavatum, affected individuals may have mental retardation, thromboembolism and severe myopia and/or lens luxation although the luxation is usually inferonasal rather than superotemporal as seen in Marfan syndrome. Recognition of this disorder and appropriate treatment can prevent thromboembolic complications that are the major cause of morbidity and mortality.

Fragile X syndrome is caused by mutations of the X-chromosomal *FMR1* gene resulting in the presence of >200 CGG repeats in the 5′ untranslated region and abnormal methylation. Characteristics of fragile X syndrome are mental retardation, autism spectrum disorders, behavioral problems, a large head, long face, large ears, hypermobility, pectus excavatum and large testes after puberty (Lozano *et al.*, 2014). Females have a second copy of the gene and have a more variable phenotype.

Lujan–Fryns syndrome is a clinical diagnosis based on the presence of intellectual disability and a Marfanoid habitus in combination with specific facial features such as a long face, maxillary hypoplasia, small mandible and a prominent forehead, nasal speech and X-linked inheritance (Van Buggenhout and Fryns, 2006). It is a genetically heterogeneous disorder, caused by

MED12 mutations in some affected individuals (Hackmann *et al.*, 2016). There seem to be various overlapping disorders characterized by intellectual disability and Marfanoid habitus.

Multiple endocrine neoplasia type 2B (MEN2B) is a rare autosomal dominant disorder caused by mutations in the *RET* gene. Clinical manifestations include a Marfanoid habitus, a long face, scoliosis, joint laxity, alacrima and mucosal neuromas on the tongue, lips, oral cavity and conjunctivae (Castinetti *et al.*, 2017). These neuromas are white-yellow papules a few millimeter in size and may be present at birth and can usually be found by age 10 yrs (Castinetti *et al.*, 2017). Affected individuals are at high risk of developing medullary thyroid cancer at a very young age and have an increased risk of pheochromocytoma. Gastrointestinal complaints caused by diffuse gastrointestinal ganglioneuromatosis may be present from infancy or early childhood.

C-type natriuretic peptide (CNP) is a paracrine factor produced by chondrocytes that acts through the natriuretic peptide receptor 2 (NPR2) to induce endochondrial ossification. Both increased production of CNP due to genomic rearrangements and increased activity of *NPR2* caused by activating mutations are rare causes of tall stature (Bocciardi *et al.*, 2007; Moncla *et al.*, 2007; Miura *et al.*, 2012; Hannema *et al.*, 2013; Miura *et al.*, 2014). Several but not all affected individuals had a Marfanoid habitus, scoliosis and very long halluces. Downstream of NPR2 the signaling cascade converges with that of the FGFR3. Interestingly, loss-of-function mutations in FGFR3 have also been reported in individuals with tall stature, who also had camptodactyly and hearing loss (*CATSHL syndrome*) (Toydemir *et al.*, 2006; Makrythanasis *et al.*, 2014). Affected individuals were also reported to have long fingers and some had scoliosis.

Syndromes without Marfanoid habitus

The prevalence of *Beckwith–Wiedemann syndrome (BWS)* is approximately 1:1000 newborns (Mussa *et al.*, 2013). The diagnosis can be made based on clinical criteria and genetically confirmed in 85%–90% (Bliek *et al.*, 2001). Most affected individuals have an imprinting disorder of one or two gene clusters that contain the *IGF2* and *H19* genes, under control of chromosome 15 imprinting centre 1 (IC1), and the *CDKN1C* and *KCNQ1OT1* genes, under control of imprinting centre 2 (IC2), but some have mutations in *CDKN1C*. Approximately 65% of children with BWS have a birth weight above the 90th percentile (Maas *et al.*, 2016). They are tall in childhood and mean adult height has been reported to be 1.8 $\pm$ 1.2 SDS (Brioude *et al.*, 2013). Congenital anomalies such as macroglossia, ear creases or pits, naevus flammeus and abdominal wall defects are characteristic of BWS as is hemihyperplasia (Maas *et al.*, 2016). Children may develop hypoglycaemia due to hyperinsulinism in the neonatal period and have an increased risk of embryonic tumors, especially Wilms tumor. The tumor risk depends on the underlying genetic abnormality, ranging from 28% in IC1 hypermethylation to 2.6% in IC2 hypomethylation, and recommended tumor surveillance differs between the genetic subgroups (Maas *et al.*, 2016).

Klinefelter syndrome, characterized by karyotype 47,XXY is a common disorder with an incidence of approximately 1 in 500–1000 boys although it is estimated that >50% of men are never diagnosed (Bojesen *et al.*, 2003; Nielsen and Wohlert, 1991). Clinical findings that are suggestive of Klinefelter syndrome are micropenis and/or undescended testes, delayed motor and/or speech/language development, learning and behavioral problems, small testes (usually not larger than 7 mL in adults), hypergonadotropic hypogonadism and infertility (Aksglaede *et al.*, 2011). *Triple X syndrome* (47,XXX), with an incidence of 1:1000 girls, has a variable phenotype and many affected women go undiagnosed. Triple X syndrome shares many features with Klinefelter syndrome such as delayed motor and speech development, lower IQ than siblings and behavioral problems. *Other sex chromosomal disorders* that have overlapping features include 47,XYY, 48,XXYY, 48,XXXY, 49,XXXXY and tetrasomy and pentasomy X.

Although birth length is not increased in Klinefelter syndrome, growth velocity increases between age 5 and 8 years and adult height is above the target height although often within the normal range (Ratcliffe, 1999; Ottesen *et al.*, 2010). The increase in height that is associated with an increased number of sex chromosomes has been attributed to the presence of extra copies of the *SHOX* gene, located on the pseudoautosomal region of the sex chromosomes (Ottesen *et al.*, 2010). However, individuals with four sex chromosomes in females and five in both males and females do not have an increased height possibly due to a negative effect of overdosage of other genes (Ottesen *et al.*, 2010).

Tall stature with growth acceleration with signs of puberty

Precocious or early puberty may lead to temporary tall stature because of the early growth spurt although adult height may actually be compromised in precocious puberty because of premature epiphyseal closure. If the growth chart shows a growth acceleration and signs of puberty are present it is important to distinguish between central and peripheral puberty. The presence of breast development in girls and increased testicular volume in boys in combination with elevated basal gonadotropins or a positive GnRH test is consistent with central puberty. Genetic factors play an important role in the timing of puberty and information on the onset of puberty in parents and other family members may indicate familial early maturation. In central precocious puberty (before age 8 years in girls and 9 years in boys) an underlying CNS disorder may be present, especially in boys, but in girls it is usually idiopathic. Central precocious puberty can be treated with a GnRH analogue. When signs of puberty are present in the absence of central activation of the hypothalamus-pituitary-gonadal axis the differential diagnosis includes congenital adrenal hyperplasia and McCune–Albright syndrome.

Tall stature with growth acceleration in the absence of puberty

Growth acceleration without signs of puberty may be a physiological phenomenon in the first few years of life when children find their own growth channel. This will usually be within the target height range but may also be above the target height range in children with constitutional advancement of growth. This term is used to describe a growth pattern that is the opposite of

constitutional delay of growth and puberty (Papadimitriou *et al.*, 2010). In the prepubertal years growth accelerates but so does bone maturation so that height for bone age is usually within the target height range. Children may go on to have an early puberty. Family history may indicate that one of the parents had a similar growth pattern and/or early puberty. Growth and bone maturation may also accelerate when children become obese.

However, when growth suddenly accelerates after a period of stable growth in the absence of pubertal signs or obesity endocrine disorders such as hyperthyroidism and growth hormone excess should be considered. Clinical signs of hyperthyroidism include goiter, weight loss, tachycardia and exophthalmos in Graves' disease. Growth hormone excess may lead to thickened skin and acromegalic features, although these are not as common in children as in adults, and may be accompanied by deficiencies of other pituitary hormones and headache or visual defects due to a macroadenoma. Thyroid function tests and IGF-1 measurement can be used as first line investigations. If IGF-1 is elevated, an oral glucose tolerance test can be used to assess growth hormone suppression. It is important to be aware of the fact that this test may be false positive in constitutionally tall children and adolescents (Holl *et al.*, 1999). Some have used a higher glucose dose of 2.35 mg/kg up to a maximum of 100 g rather than the standard dose of 1.75 mg/kg up to a maximum of 75 kg in the oral glucose tolerance test and found only 1 false positive result among 107 children (Misra *et al.*, 2007).

Growth hormone excess can be caused by a pituitary adenoma and may be associated with an underlying disorder such as multiple endocrine neoplasia type 1, *AIP*-related familial isolated pituitary adenomas or McCune-Albright syndrome. Growth hormone excess has also been observed in individuals with neurofibromatosis type 1 with an optic pathway glioma (Bizzarri and Bottaro, 2015). It is hypothesized that the glioma disrupts somatostatin tone leading to increased growth hormone secretion. Treatment depends on the cause. Transsphenoidal surgery is used for pituitary adenomas; non-surgical treatment options are radiotherapy or medical therapy including somatostatin analogues, dopamine agonists and growth hormone receptor antagonists which have been used with variable success.

Tall stature without recent growth acceleration outside the target height range

Stable growth outside the target height range may have been preceded by a growth acceleration related to weight gain or constitutional advancement of growth. Usually this is accompanied by an advanced bone age. When determining if the child is growing outside the target height range one should also consider the limitations of formulas used to calculate the target height range, especially if one parent is very tall and the other parent much shorter. In this situation children may have a growth pattern that resembles that of the tall parent and grow outside their target height range even though their tall stature is familial.

Delayed epiphyseal closure may lead to increased height with decreased sitting height-to-height ratio in adolescents with hypogonadotropic hypogonadism. This same phenomenon is more extreme in rare cases of estrogen deficiency due to aromatase deficiency or estrogen resistance due to estrogen receptor alpha mutations. Delayed puberty or primary amenorrhoea in tall girls may also be caused by a disorder/difference of sex development with a 46,XY karyotype. Signs of adrenal insufficiency such as hyperpigmentation should raise the suspicion of familial glucocorticoid deficiency.

Tall stature without recent growth acceleration within the target height range

If a child is tall but grows within the target height range then constitutional tall stature is most likely (Upners and Juul, 2016; Thomsett, 2009). However, a heritable disorder associated with tall stature should be considered; a parent may be affected without having been diagnosed. A careful history, family history and physical examination is therefore always indicated to exclude an underlying disorder.

Treatment of Tall Stature

Tall stature in itself is not a medical condition that needs treatment. However, individuals may feel that extreme tall stature is unpractical in the sense that they might have problems finding clothing and they might not fit in a regular bed or car; they may also worry about the social consequences. Therefore some adolescents and their parents request treatment to reduce adult height. However there is no evidence that such treatment leads to a better quality of life in adulthood, and if and when this treatment is ethical is subject to debate. Generally treatment is only considered in adolescents whose predicted adult height is greater than $+2.5$ SDS. Careful counseling of the adolescent and parents is required on the efficacy and safety of the available treatments, which are high dose sex steroids and epiphysiodesis.

Predicting Adult Height

Accurate adult height prediction is important because it may reassure adolescents if they are not expected to become excessively tall, and otherwise the predicted height forms the basis of a decision to treat or not, and decide on the timing of treatment. Several methods are available to predict adult height of which Bayley and Pinneau (B&P) and Tanner-Whitehouse (TW2) are most widely used. Their performance differs depending on age and sex. Prediction is more accurate in constitutionally tall girls (absolute errors of prediction 2.0 cm for B&P and 2.3 for TW2) than in boys (absolute errors of prediction 3.3 and 3.9 cm) and becomes more accurate with increasing age (De Waal *et al.*, 1996). In adolescents with Marfan syndrome neither method was found to be precise

(Rozendaal *et al.*, 2005). More recently a method for adult height prediction has been developed based on automated bone age determination (Thodberg *et al.*, 2009). In addition to height and bone age this method takes parental height into account. However, no data are available on the performance of this method in (constitutionally) tall children.

High Dose Sex Steroids

High doses of sex steroids lead to fusion of the growth plate. Based on this principle, high dose sex steroid treatment has been used to reduce adult height in tall adolescents. In boys treatment often consists of intramuscular testosterone injections at doses of 250 mg every week or 250–500 mg every 2 weeks. The efficacy of this treatment depends on the bone age at the start of treatment; after bone age 14 yrs. treatment does not result in reduced adult height and may even increase adult height (De Waal *et al.*, 1996). Similar results of this treatment were found in boys with Marfan syndrome, without any serious short-term (cardiovascular) side effects (Rozendaal *et al.*, 2005).

Short-term side effects of high dose testosterone treatment include acne, weight gain, gynecomastia, muscle aches and oedema, aggressive behaviour and troublesome erections (Drop *et al.*, 1998). A study that investigated long-term side effects found no effect on fatherhood or semen parameters in a group of 60 treated men at an average age of 35 yrs. compared to untreated controls, although total sperm count and serum inhibin B levels seemed to decline more rapidly over time in treated men (Hendriks *et al.*, 2010). In addition, serum testosterone and AMH levels were significantly lower in treated men (Hendriks *et al.*, 2010).

Girls have been treated with ethinyl estradiol 100–500 mcg/day. The height reduction achieved depends on the bone age at the start of treatment; treatment is ineffective form bone age 14 yrs. (De Waal *et al.*, 1996). High dose estrogen treatment did not have a statistically significant effect on adult height in a group of girls with Marfan syndrome in whom treatment was started at a mean bone age of 11.4 years (Rozendaal *et al.*, 2005). Possibly this was already too late because of the earlier growth spurt in adolescents with Marfan syndrome.

Short-term side effects of high-dose estrogen treatment include weight gain, nausea, headaches, hypertension and venous thromboembolism. Several studies have reported long-term negative effects on fertility. Time to pregnancy was increased in treated versus untreated women, the use of fertility treatments was increased and the number of live births reduced (Venn *et al.*, 2004; Hendriks *et al.*, 2011; Hendriks *et al.*, 2012). These effects were dose-dependent (Hendriks *et al.*, 2012). In addition treated women were more frequently diagnosed with imminent ovarian failure, characterized by an FSH $>$ 10 IU/L on day 3–5 of the menstrual cycle (Hendriks *et al.*, 2011). There are also worries that high-dose estrogen treatment may increase the risk of (reproductive) tumors. Although no significant increase of these tumors was found in a study of women treated with very high doses of ethinyl estradiol (250–1000 mcg), further follow-up studies are needed because most women were only in their forties at the time of the study (Benyi *et al.*, 2014). This same study suggested that the risk of melanoma might be increased although absolute tumor numbers were small (Benyi *et al.*, 2014).

Epiphysiodesis

An alternative to hormonal treatment is surgical treatment, usually bilateral percutaneous epiphysiodesis. This treatment aims to destroy the growth plates of the distal femur and proximal tibia and fibula to limit further leg growth but does not affect growth of the back and arms. The procedure is performed under general anesthesia and takes approximately 1 h. After treatment weight baring is allowed but adolescents are advised to refrain from sports for 4 weeks. The growth reduction achieved depends on bone age at the time of the procedure but is approximately one third of the remaining growth. In girls treated at bone age 12.5 yr growth was reduced by 4 cm and in boys treated at bone age 14 yr growth reduction was 6 cm (Benyi *et al.*, 2010). This is more than the growth reduction seen in adolescents treated with high dose sex steroids at a similar bone age. Body proportions are altered by this treatment but as tall individuals generally have long legs the sitting height-to-height ratio after treatment usually is within the normal range and the relatively long arms are generally not experienced as problematic. However, if the procedure is performed at a very young bone age or in individuals with a high sitting height-to-height ratio abnormal body proportion is a potential concern.

Surgery under general anesthesia always carries a small risk. However, few complications of the procedure itself have been reported. These include a cutaneous infection in 1 of 21 treated adolescents, which resolved spontaneously, and postoperative pain for which oral analgesics were used for up to 2 weeks in 9 of 21 adolescents (Benyi *et al.*, 2010). Another study of 15 treated adolescents reported fibula exostosis in one patient and angular leg deformities in two patients (2–8 degrees) but no treatment was necessary for these complications (Odink *et al.*, 2006). The surgery leaves small scars. Because of the skeletal abnormalities associated with Marfan syndrome there may be concerns about the safety of epiphysiodesis in adolescents with Marfan syndrome but no complications have been reported in three individuals (Benyi *et al.*, 2010).

Compared to high-dose sex steroid treatment epiphysiodesis can be performed at a more advanced bone age, when adult height prediction is more accurate, with superior efficacy. In addition epiphysiodesis seems safe with few complications whereas serious long-term side effects of especially high-dose estrogen treatment on fertility have become clear. We therefore recommend that if there is a strong treatment wish from an adolescent with an extremely tall predicted adult

height epiphysiodesis should be considered the treatment of choice. We recommend against the use of high-dose estrogen treatment.

In conclusion, even though constitutional tall stature is the most common diagnosis among tall adolescents a careful evaluation is warranted to exclude underlying pathology which may have serious health consequences. When considering growth reducing treatment it is important to be aware of the limitations of adult height prediction and to discuss and weigh the pros and cons of treatment together with the adolescent and parents.

Growth in Childhood Chronic Conditions

Kung-Ting Kao, Syed Faisal Ahmed, and Sze Choong Wong, Royal Hospital for Children, Glasgow, United Kingdom

Glossary

Chronic condition A condition, usually of complex causality, that leads to a prolonged course of illness, often leading to other health complications and associated functional impairment or disability.

Cytokines Cytokines are small proteins that are released by cells that have a specific effect on the interaction and communications between cells.

Glucocorticoid A class of steroid hormones with important effects on the cardiovascular, metabolic, immunologic, and homeostatic functions, often used in high doses to suppress inflammation.

Growth Growth is a complex process where a child increases in size and stature in a predictable pattern over time, usually divided into three periods: infancy, childhood, and puberty.

Growth hormone (GH) Growth hormone is a 191-amino acid peptide hormone secreted by the anterior pituitary gland that promotes growth, cell reproduction, and regeneration.

Growth plate Growth plate is a region of hyaline cartilage located between the epiphyses and diaphysis of long bones where longitudinal bone growth takes place.

Inflammation Inflammation is a protective biological response to harmful stimuli for removing the source of injury and to initiate healing.

Insulin-like growth factor-1 (IGF-1) Insulin-like growth factor-1 is a 70-amino acid protein produced mainly by the liver in response to growth hormone stimulation that promotes cellular growth.

Nutrition Nutrition is the intake of food, in relation to the body's dietary requirements, required to maintain health.

Puberty Puberty is a process of physiological changes characterized by the development of secondary sexual characteristic and rapid physical growth.

Introduction

Growth failure and delayed puberty are common consequences of childhood chronic illness and are frequent referrals to the pediatric endocrine clinic. In conditions like cystic fibrosis (CF), inflammatory bowel disease (IBD), juvenile idiopathic arthritis (JIA), and duchenne muscular dystrophy (DMD), several factors contribute to growth failure and pubertal abnormalities. These include the direct effect of pro-inflammatory cytokines as a result of the underlying condition, use of glucocorticoid, and suboptimal nutrition (Wong *et al.*, 2016). The triad of these factors affects growth and pubertal development via their impact on the endocrine axis and at a local level (**Fig. 1**). While there is no doubt that the use of glucocorticoid itself contributes to poor growth, in recent times, greater focus is given to the role of the underlying disease process itself due to the deleterious impact of pro-inflammatory cytokines like tumor necrosis factor-α (TNFα), interleukin-1 (IL-1), and IL-6. On the other hand, systemic glucocorticoid is often used for longer periods in those whose disease is suboptimally controlled. Therefore, glucocorticoid use may be a marker of severity of the underlying disease. This article will provide an update of growth failure in childhood chronic illness and discuss endocrine growth-promoting therapies in these conditions.

Definition of Growth Failure in Childhood Chronic Conditions

Clinical studies of growth failure in chronic childhood illness may vary depending on the underlying condition, treatment regimen, and definition of growth failure. Older studies largely rely on reports of height, but this does not provide information on growth rate. This may only capture the end result of prolonged and severe growth failure. While height velocity is more appropriate to study growth, there are some inherent difficulties including the lack of robust contemporary normative data. An alternative would be to evaluate change in height standard deviation scores (SDS) over time (Wong *et al.*, 2016). There is also a lack of consensus on the appropriate method to adjust for delayed puberty, which needs to be taken into account whether growth is reported as height velocity or change in height SDS. These methodological issues need to be carefully considered in growth studies involving adolescents with chronic ill health.

Rationale for Addressing Growth in Childhood Chronic Conditions

Despite the limitations of reporting height to determine growth failure, reduction in adult height is seen in 20% of individuals with Crohn's disease (CD), approximately 40% with systemic JIA and CF, and up to 78% of young men with DMD, reflecting that persistent and severe growth failure is still observed in a subset of these people (**Fig. 2**) (Gorman *et al.*, 2005; Lai *et al.*, 1999; Minden, 2009;

 doi:10.1016/B978-0-12-801238-3.65161-9

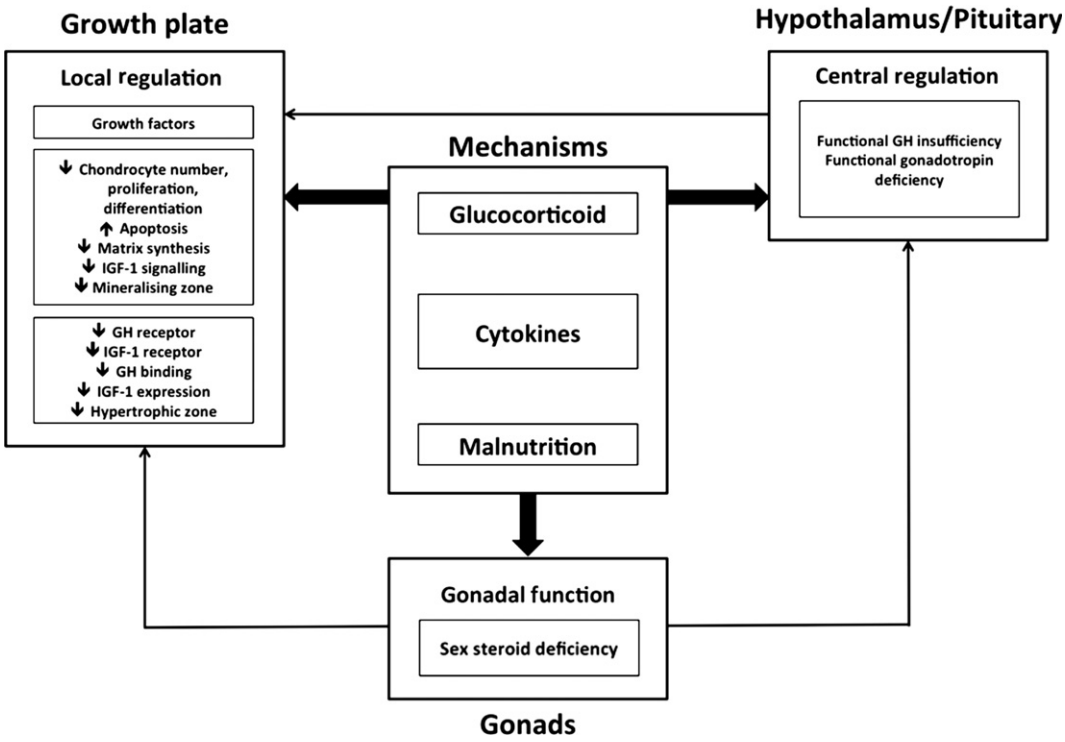

Fig. 1 Mechanism of growth failure in chronic inflammatory conditions.

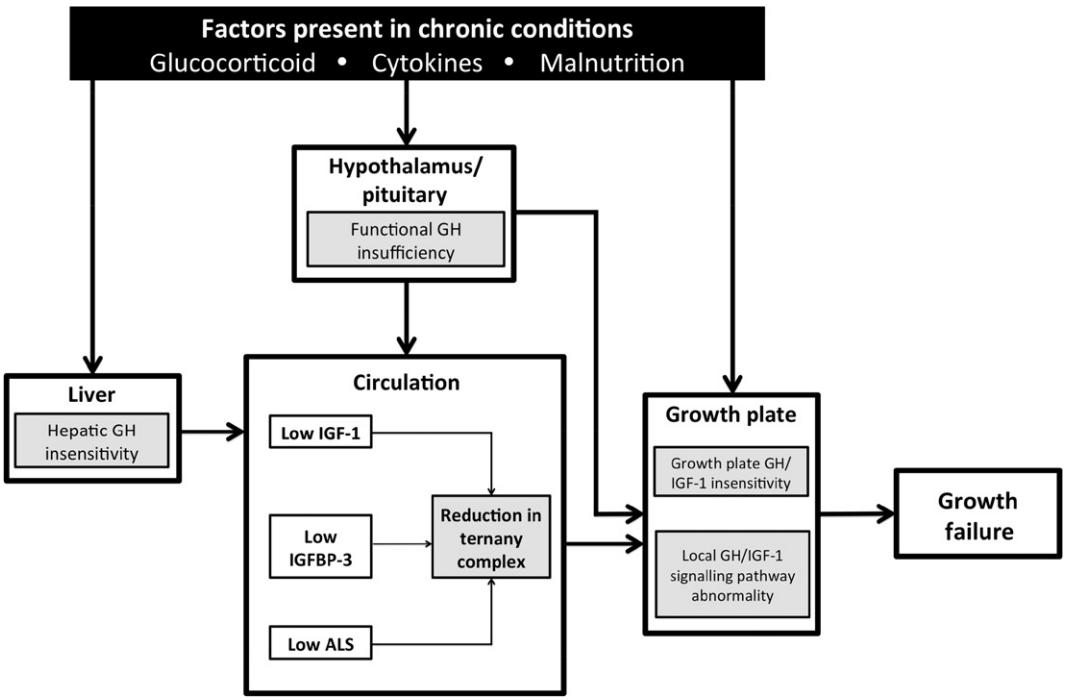

Fig. 2 GH/IGF-1 axis abnormalities in children with chronic conditions.

Sawczenko *et al.*, 2006; Wong *et al.*, 2017). Emerging evidence suggests that there may be a link between poor growth in children with chronic ill health and quality of life, independent of underlying disease severity (Mason *et al.*, 2015). Linear growth and pubertal progression are intimately linked to bone development. Osteoporosis in childhood chronic ill health is a systemic disorder of low bone turnover resulting from poor longitudinal bone growth (Wong *et al.*, 2014; Joseph *et al.*, 2016), and improving growth is a critical strategy

to improve bone development in childhood chronic conditions. In some conditions, the possibility of improving the underlying disease by promoting growth via manipulation of the growth hormone (GH) axis deserves further research (Denson *et al.*, 2010; Hardin *et al.*, 2006). In summary, despite modern therapies, endocrine growth-promoting therapies may need to be considered.

There are numerous chronic conditions in childhood that can lead to growth failure and pubertal disorders. In this article, we will focus our attention on a small group of conditions with underlying chronic inflammation. We will subdivide the discussions into three groups of childhood chronic conditions based on glucocorticoid requirement:

1. Minimal or no systemic glucocorticoid (e.g., CF)
2. Intermitted systemic glucocorticoid (e.g., JIA and IBD)
3. Continuous systemic glucocorticoid (e.g., DMD)

Normal Growth

The infancy, childhood, and puberty (ICP) model divides human growth into three phases, reflecting the endocrine control of the growth process. The infancy phase spans from birth to the first 2–3 years of life and is a period of rapid growth. Growth in the infancy phase is largely nutrition-dependent but closely linked with the actions of insulin-like growth factors (IGF) (Leger *et al.*, 1996; Wang and Chard, 1992). Growth rate begins to decelerate after the first 3 years of life (childhood phase). It remains stable for several years, with the fiftieth percentile of height velocity during mid- and late childhood approximating 5–6 cm/year. Growth during this phase is largely influenced by the GH/IGF-1 axis.

Normal Puberty

Puberty is the stage of development during which adolescents develop secondary sexual characteristics and is influenced by genetic, nutritional, environmental, and socioeconomic factors. In girls, puberty normally begins between 8 and 13 years of age and in boys between 9 and 14 years of age. The pubertal growth spurt encompasses the second most rapid phase of postnatal growth after the neonatal period. During adolescence, height velocity increases from prepubertal rates of 5–6 cm/year to a peak height velocity of 10–15 cm/year, corresponding to genitalia stage 3–4 in boys and breast stage 2–3 in girls. The production of sex steroids during adolescence contributes to the pubertal growth spurt by direct effects on growth plate chondrocytes and indirect effects on GH secretion by increasing the amplitude of spontaneous GH secretion, resulting in increased IGF-1 production systemically and locally (Callewaert *et al.*, 2010; Smith *et al.*, 2010).

The GH/IGF-1 Axis

The GH/IGF-1 axis is the main regulator of linear growth via its endocrine effects systemically and at a local level. Pituitary-derived GH increases hepatic IGF-1, which circulates systemically bound to IGF-binding proteins (IGFBP): IGFBP-3 and acid labile subunit (ALS), collectively known as the ternary complex. IGF-1 induces growth by promoting cell division, inhibiting apoptosis, and stimulating protein synthesis. IGFBP may play a direct role on maintenance of growth although the precise mechanism is still unclear (Duan *et al.*, 2010). Both systemic IGF-1 and GH have separate and independent effects on regulation of linear growth. GH also induces the expression and action of IGF-1 at the level of the growth plate. A comprehensive summary of the complex interplay between systemic and local factors on growth is summarized in the revised somatomedin hypothesis (Kaplan and Cohen, 2007).

Mechanisms of Growth Failure in Chronic Inflammation

As mentioned, chronic inflammation, glucocorticoid use, and suboptimal nutrition contribute to the underlying pathophysiology of growth failure in chronic childhood condition via systemic and local effects on the GH/IGF-1 axis (Wong *et al.*, 2016; MacRae *et al.*, 2006a). The deleterious effect of chronic inflammation on the GH/IGF-1 axis occurs at multiple levels (**Fig. 2**). It is often difficult to tease out the relative impact of cytokines, glucocorticoid, and poor nutrition on growth as they are closely related.

Systemic Abnormalities of the GH–IGF-1 Axis in Childhood Chronic Inflammation

Hormone insensitivity

It is recognized that chronic inflammation is often associated with a state of relative GH insensitivity, reported in children with IBD (Chong *et al.*, 1984; Wong *et al.*, 2010), JIA (Bechtold *et al.*, 2012; Saha *et al.*, 2004; Tsatsoulis *et al.*, 1999), and CF (Ciro *et al.*, 2013). Evaluation of the GH axis with dynamic stimulation tests often reveals elevated GH levels but low IGF-1 levels. In 28 children with IBD evaluated with the insulin tolerance test, relative GH insensitivity (defined as peak GH $>$ 6 μg/L to insulin tolerance test and IGF-1 SDS $<$ 0) was observed in almost 40% of the cohort (**Fig. 3**) (Wong *et al.*, 2010).

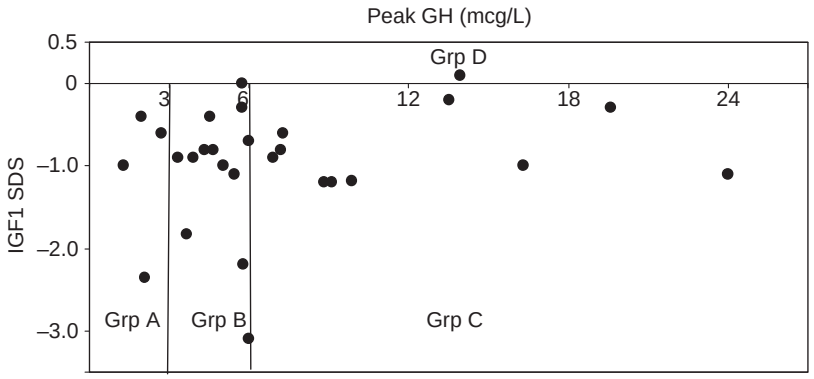

Fig. 3 GH and IGF-1 levels in response to insulin hypoglycemia in children with IBD and growth failure. Reproduced from Wong, S. C., *et al.* (2010). The growth hormone insulin-like growth factor 1 axis in children and adolescents with inflammatory bowel disease and growth retardation. *Clinical Endocrinology (Oxford)* **73**, 220–228, with permission © Wiley.

Different proinflammatory cytokines may lead to hepatic GH insensitivity via separate mechanisms. TNFα and IL-1 appear to exert negative effects on the GH receptor, whereas IL-6 affects downstream signaling proteins like the signal transducer and activator of transcription (STAT) pathway and the suppressor of cytokine signaling (SOCS)-3 protein (Yumet *et al.*, 2006; Zhao *et al.*, 2014a).

Undernutrition itself is also associated with a state of GH insensitivity (Bang *et al.*, 1994; Counts *et al.*, 1992), thought to be due to a protective metabolic adaptation as a result of undernutrition. Recent studies have identified several proteins as important regulators of GH sensitivity in states of nutritional deprivation, including fibroblast growth factor (FGF) 21 and sirtuin (SIRT) (Fazeli and Klibanski, 2014). FGF21 and SIRT are upregulated in malnutrition and inhibit hepatic STAT5 phosphorylation that in turn reduces IGF-1 production.

Less well recognized but reported in chronic inflammation is IGF-1 insensitivity, likely to be due to chronic elevation of pro-inflammatory cytokines (O'Connor *et al.*, 2008). Two out of the 28 children with IBD and growth failure who underwent evaluation of the GH/IGF-1 axis had evidence of combined GH/IGF-1 insensitivity with elevated GH levels and IGF-1 SDS > 0 (**Fig. 3**) (Wong *et al.*, 2010).

Hormone insufficiency

GH insufficiency is commonly observed in those with chronic glucocorticoid use, as glucocorticoid suppresses pulsatile GH release centrally (Barkan *et al.*, 2000). In a study of 83 slow-growing glucocorticoid-treated boys with DMD, stimulated GH was sub-optimal in 37% (Allen *et al.*, 1998). Similarly, in a group of slow-growing children with JIA treated with glucocorticoid, 40% had evidence of GH insufficiency when evaluated with combined arginine–clonidine stimulation test (Bechtold *et al.*, 2012; Saha *et al.*, 2004; Tsatsoulis *et al.*, 1999). However, GH insufficiency has also been reported in children with chronic conditions not treated with glucocorticoid (Bechtold *et al.*, 2012; Saha *et al.*, 2004; Tsatsoulis *et al.*, 1999). Peak GH to insulin tolerance test (GH < 3 μg/L and IGF-1 SDS < 0) was found in 14% of slow-growing children with IBD, including those who were not treated with glucocorticoids (**Fig. 3**) (Wong *et al.*, 2010).

Binding protein abnormalities

IGF-binding protein abnormalities may reduce circulating IGF-1 leading to reduction of IGF-1 delivery to target organs. In children with CF, low IGFBP-3 and high IGFBP-1 levels in the setting of normal systemic IGF-1 may be responsible for growth failure (Ozen *et al.*, 2004; Street *et al.*, 2009). Low ALS levels during acute relapse of children with JIA and mild growth failure have recently been reported (Wong *et al.*, 2008). In adolescents with IBD, elevated IGFBP-3 and relatively normal IGF-1 may lead to low bioavailability of free IGF-1 (Mason *et al.*, 2015). IGFBP-2 may lead to a reduction in the formation of the ternary complex. Significantly higher IGFBP-2 levels have been documented in children with IBD (Hoeflich *et al.*, 1999; Street *et al.*, 2004) and CF (Street *et al.*, 2009), associated with IL-6.

Growth Plate Effects in Chronic Conditions

Effects of cytokines on growth plate

IL-1β and TNFα can impair growth plate chondrogenesis by decreasing both the width of the proliferating zone and rate of endochondral bone growth (Choukair *et al.*, 2014; Martensson *et al.*, 2004). Cytokines also lead to increased apoptosis and reduction of proteoglycan synthesis. Reduction in proliferation at the growth plate by cytokines also occurs by their effects on local IGF-1 signaling (MacRae *et al.*, 2007). Inflammatory cytokines act synergistically to affect longitudinal bone growth, and the extent of recovery following exposure to cytokines may be dependent on duration of exposure (MacRae *et al.*, 2006b).

Effects of glucocorticoid on growth plate

The mechanism of glucocorticoid effects on growth plate is very similar to the cytokine-driven effect. Glucocorticoid can block the activation of GH and IGF-1 receptors in chondrocytes. It can also impair IGF-1 signaling via the phosphatidylinositol-3-kinase pathway at the growth plate (Chrysis *et al.*, 2005; Giustina *et al.*, 1992; Giustina and Veldhuis, 1998; Klaus *et al.*, 2000), inhibiting chondrocyte proliferation and differentiation while stimulating chondrocyte apoptosis and autophagy (Chrysis *et al.*, 2003; Chrysis *et al.*, 2005; Zhao et al., 2014b). A crucial mechanism for glucocorticoid target at the level of the growth plate is its effect on increasing apoptosis (Chrysis *et al.*, 2005; Zaman *et al.*, 2012). New therapies targeting apoptosis may be potential new treatment for growth failure in chronic conditions.

Effects of poor nutrition on growth

In animal studies investigating the effects of malnutrition, reductions in all zones of the growth plate and decrease in chondrocyte numbers were observed (Kubicky *et al.*, 2012). Increased FGF21 levels during malnutrition lead to reduction in systemic GH binding to the GH receptor in chondrocytes with no effect on number of GH receptors (Kubicky *et al.*, 2012). The important role of FGF21 is further strengthened by the evidence of normal growth and the absence of GH insensitivity from a study in FGF21 knockout mice that were subjected to 4 weeks of food restriction (Wu *et al.*, 2013). Studies on the role of FGF21 and growth failure in chronic conditions are needed.

Growth in Conditions With Minimal or no Exposure to Glucocorticoids

Cystic Fibrosis

CF is an autosomal recessive condition with defect of the cystic fibrosis transmembrane conductance regulator (CFTR) gene (7q31.2), affecting primarily the lungs, as well as the pancreas, liver, intestine, and other organs. The CFTR gene defect leads to decreased chloride secretion and increased sodium absorption across the epithelial surface, resulting in chronic pulmonary infections, airway inflammation, and increased systemic inflammatory cytokines. Exocrine pancreatic insufficiency occurs in most individuals resulting in malnutrition and fat-soluble vitamin deficiency. Pancreatic islet cells may also become damaged over time, leading to cystic fibrosis-related diabetes (CFRD), often associated with further deterioration in growth failure.

Management involves addressing nutrition and minimizing and treating pulmonary infections with physiotherapy, antibiotic therapy, and therapies to reduce mucous viscosity. Systemic glucocorticoid is not often used in management of CF. However, allergic bronchopulmonary aspergillosis, seen in 4%–11% of individuals with CF, often requires prolonged oral glucocorticoid treatment to suppress the exaggerated immune response (Mahdavinia and Grammer, 2012).

Growth failure in *CF*

Short stature and growth failure are important complications in the CF population, although these problems have decreased in frequency over time. While 39% of children from an older study were below the fifth percentile for height, a contemporary cohort showed that only 1% of the cohort had short stature after adjustment for bone age and parental height (Lai *et al.*, 1999; Woestenenk *et al.*, 2011). Improvement in growth has been observed in those managed in specialist centers throughout their lifetime. Most published evidence suggests that height is associated with pulmonary and pancreatic function (Lucidi *et al.*, 2009; Woestenenk *et al.*, 2014; Zemel *et al.*, 2000).

Optimal nutrition is crucial for growth in CF with evidence that improvement in the nutritional status is associated with significant improvements in weight and height (Lai *et al.*, 1999). Furthermore, several studies have shown that benefits of long-term use of supplemental enteral feeding with gastrostomy on growth and lung function continue beyond cessation of therapy (Dalzell *et al.*, 1992; Levy *et al.*, 1985; Rosenfeld *et al.*, 1999; Shepherd *et al.*, 1986).

Infants with CF identified from neonatal screening are lighter and shorter and have smaller head circumference at birth than the general population, associated with lower systemic IGF-1 levels (Ghosal *et al.*, 1996; Haeusler *et al.*, 1994; Rogan *et al.*, 2010). Furthermore, children homozygous for the ΔF508 mutation were approximately 1 SDS below the mean for height from infancy to early adolescence (Keller *et al.*, 2003), highlighting a genotype impact on growth failure in CF.

Pubertal disorders in CF

Delayed puberty is not a common occurrence in contemporary cohorts of adolescents with CF; however, poor growth rate during puberty is still observed (Bournez *et al.*, 2012; Landon and Rosenfeld, 1987). Poor growth often precedes the onset of CFRD, usually diagnosed in mid-to-late adolescence. Therefore, increased awareness and screening are required in adolescents with CF, especially if growth and pubertal issues are encountered (Bizzarri *et al.*, 2015). Insulin therapy may improve lung function and weight gain in those with CFRD (O'Shea and O'Connell, 2014).

Adult height in CF

Evidence from studies shows that adult height in CF has improved in the last few decades with better surveillance and treatment regimens. Older studies showed that the average adult height in CF was at the twenty-fifth percentile and half the cohort had height below midparental height (Lai *et al.*, 1999; Zhang *et al.*, 2013). Early diagnosis and treatment via newborn screening may

have helped to improve adult height outcomes. An Australian study showed that those identified from newborn screening were significantly taller as adults than those diagnosed clinically (Dijk *et al.*, 2011).

Growth in Conditions Requiring Intermittent Systematic Glucocorticoid

Juvenile Idiopathic Arthritis

JIA is a group of conditions involving inflammatory arthritis beginning before the age of 16 years for >6 weeks. The management of JIA is dependent on the subtype and is focused on achieving optimal joint function, as no cure is currently available. While pain relief is generally achieved by nonsteroidal antiinflammatory drugs, intraarticular glucocorticoid injections may be required in those who do not respond. Previous management involves prolonged periods of systemic glucocorticoid. Currently, children with severe arthritis (systemic and polyarticular JIA) may require oral or intravenous glucocorticoid treatment for a short period until therapeutic immunomodulatory levels (e.g., methotrexate) are achieved. There is also increasing use of biological therapy targeting inflammatory cytokines, TNFα.

Growth failure in JIA

Poor growth is more common in children with polyarticular and systemic JIA (especially those with positive rheumatoid factor) compared with those with oligoarthritis (Liem and Rosenberg, 2003; Padeh *et al.*, 2011; Saha *et al.*, 1999; Simon *et al.*, 2002). In a study of 28 patients with JIA, significant reduction in height SDS by >2 standard deviations (SD) during the first 4 years of disease was observed despite normal height at diagnosis (**Fig. 4**) (Simon *et al.*, 2002). Growth failure is associated with glucocorticoid treatment in some studies (Haugen *et al.*, 1992; Zak *et al.*, 1999), although no association was found in others (Polito *et al.*, 1997; Wang *et al.*, 2002). Linear growth may also be associated with the inflammatory cytokine, IL-6, independent of glucocorticoid treatment (Souza *et al.*, 2008).

The use of modern therapies of JIA like methotrexate (Chedeville *et al.*, 2005) and biological therapy (Giannini *et al.*, 2010) has been shown to improve linear growth. However, in a large national study of almost 200 children with JIA treated with anti-TNF therapy (etanercept) for 2 years, height SDS increased significantly but only by approximately +0.2 SD (Kearsley-Fleet *et al.*, 2015).

Pubertal disorders in JIA

Delayed pubertal onset and reduced pubertal height velocity may further worsen growth failure in adolescents with JIA. Pubertal onset may be delayed by about 0.4–2.2 years compared with healthy adolescents (Aggarwal *et al.*, 2011b; Maher and Ali, 2013). Pubertal progression may be compromised, and pubertal growth spurt may be attenuated. Those with systemic JIA appear to be the most affected, with one study showing that height velocity during adolescence to be only 0.5 cm/year in the systemic group compared with 1.5 cm/year in the oligoarticular/polyarticular JIA (Aggarwal *et al.*, 2011a).

Adult height in JIA

Current published studies from over a decade ago report variable reductions in adult height, ranging from −0.3 to −2.0 SD (Gare and Fasth, 1995; Minden and Niewerth, 2008; Minden *et al.*, 2002; Packham and Hall, 2002; Simon *et al.*, 2002; Wang *et al.*, 2002;

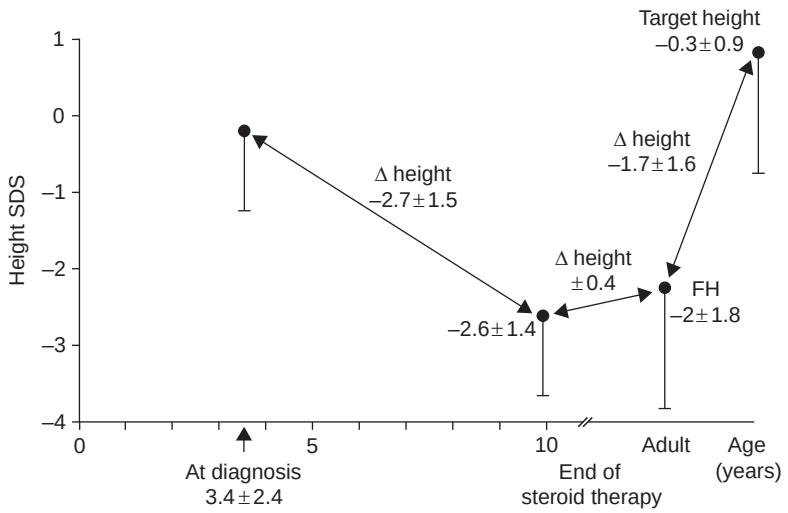

Fig. 4 Growth and adult height in children with systemic JIA. Reproduced from Simon, D., *et al.* (2002). Treatment of growth failure in juvenile chronic arthritis. *Hormone Research* **58** (Suppl. 1), 28–32, with permission © Karger.

Zak *et al.*, 1999). Different subtypes of JIA were included in these reports, which can explain the variation in adult height reported. Whereas approximately 12% of children with oligoarticular JIA had >1 standard deviation (SD) reduction in height at adulthood compared with diagnosis, 87% of patients with systemic JIA achieved adult height below their midparental height (Padeh *et al.*, 2011; Simon *et al.*, 2002). Studies with longer period of GC use resulted in significant larger loss of adult height (Simon *et al.*, 2002). Glucocorticoid-sparing therapies such as immunomodulators and biological therapy have only been part of routine management in the last 10–15 years. Currently, there are no studies of adult height in contemporary cohorts of children with JIA in the biological era, and such a study is needed.

Inflammatory Bowel Disease

IBD is a group of chronic inflammatory condition of the gastrointestinal tract, often relapsing and remitting in nature. The two principal types of IBD are Crohn's disease (CD) and ulcerative colitis (UC). While inflammation is usually limited to the mucosa of the large intestine in UC, inflammation in CD can be transmural and may involve any part of the gastrointestinal tract from the oropharynx to the perianal area. Glucocorticoid is an effective treatment for acute relapse of both conditions, although exclusive enteral nutrition (EEN) can also be used to induce remission in mild to moderate CD. Background maintenance therapy with aminosalicylates or immunomodulators (azathioprine and methotrexate) aims to reduce inflammation and prevent future acute relapse. Although surgical resection is curative in UC and can lead to dramatic improvement in those with localized CD, those with severe and widespread disease or glucocorticoid-dependent CD often require escalation to biological therapy such as infliximab or adalimumab, used much more frequently in the last decade.

Growth failure in IBD

Growth failure is more frequent and severe in children with CD than those with UC (Abraham *et al.*, 2012; Malik *et al.*, 2012b). For example, mean height SDS of children with CD of both sexes at diagnosis was −0.3 compared with −0.1 and +0.22 for boys and girls with UC, respectively (Newby *et al.*, 2008). At diagnosis, approximately 10% of children with CD had height SDS below −2.0 (Malik *et al.*, 2012b; Vasseur *et al.*, 2010). Furthermore, deteriorating height may occur in the absence of gastrointestinal symptoms prior to diagnosis of CD (Kanof *et al.*, 1988).

Compared with the use of glucocorticoid, the use of EEN during acute relapse has been shown to lead to better growth with concurrent improvement in the GH/IGF-1 axis independent of nutritional restitution (Bannerjee *et al.*, 2004). Despite modern glucocorticoid-sparing therapies, catch-up growth may still be inadequate. A contemporary study of children with CD managed mostly without oral glucocorticoid treatment showed that height SDS remained unchanged from diagnosis to 1 and 2 years follow-up at approximately −0.5 SDS (Malik *et al.*, 2012b). In adolescents with IBD, height velocity SDS adjusted for pubertal age is also reduced (Mason *et al.*, 2011a).

While the use of biological therapy can be successfully used for induction and maintenance of remission in moderate-to-severe CD associated with mucosal healing, studies of the effects of infliximab and adalimumab on growth in CD have yielded mixed results. Some studies showed significant improvement in growth rate (Church *et al.*, 2014; Malik *et al.*, 2011, 2012a), while some demonstrated no improvement (Sinitsky *et al.*, 2010; Wewer *et al.*, 2006). Improvement of growth following biological therapy can occur, independent of discontinuation of glucocorticoid therapy or progression of puberty (Malik *et al.*, 2011, 2012a). The persistence of poor growth in some of these children may be reflective of the fact that some are poor responders to modern therapies.

Pubertal disorders in IBD

Pubertal delay was a common occurrence in older cohorts of adolescents with CD. Data from the mid-1990s showed that the onset of breast development was delayed by 1.5 years in 75% of girls with CD (Brain and Savage, 1994; Ferguson and Sedgwick, 1994). Testicular enlargement was delayed by almost a year in CD and UC (Brain and Savage, 1994). A contemporary retrospective study found persisting pubertal delay in adolescents with CD, demonstrated by delay in age of peak height velocity (Mason *et al.*, 2011a). However, a more recent prospective study including clinical evaluation of puberty by a pediatric endocrinologist demonstrated that pubertal delay was not common but poor pubertal growth spurt was observed especially in adolescent males (Mason *et al.*, 2015).

Adult height in IBD

Only a modest reduction in adult height has been reported by most studies of adults with childhood-onset IBD. Most studies of adults with childhood-onset CD reported adult height of between −1.0 and +0.4 SD (Wong *et al.*, 2016). However, a subset will still fail to achieve their target height. A contemporary cohort of 123 CD individuals showed that 20% achieved adult height of ≥8 cm below midparental height and that the presence of jejunal disease was associated with lower adult height (Sawczenko *et al.*, 2006). There is a limited window of opportunity to improve growth in adolescents with chronic conditions prior to epiphyseal growth plate fusion upon completion of puberty. Given that the average age of presentation of CD is between 11 and 12 years, a more aggressive approach may be required in those with growth issues at diagnosis to optimize adult height.

Growth in Conditions Requiring Prolonged Systemic Glucocorticoid

Duchenne Muscular Dystrophy

DMD is an X-linked, life-limiting disease leading to progressive muscle weakness and eventual loss of ambulation by approximately 11–12 years (Mendell *et al.*, 2012). The dystrophin protein is reduced or lost in DMD causing increased muscle cell fragility, leading to a vicious cycle of degeneration, repair, and associated inflammatory changes, cumulating in replacement of muscle fibers with fat and fibrosis (Bushby *et al.*, 2010a). The only intervention proved to stabilize muscle strength is long-term glucocorticoid treatment, typically commenced from about 5 years of age. Previously, glucocorticoid is discontinued after loss of ambulation, but in the last 5–10 years, glucocorticoid is continued even after ambulation is lost for its protective effects on upper limb function and respiratory and cardiac function (Bushby *et al.*, 2010b). There are four main glucocorticoid regimen used in DMD: daily deflazacort, pulsed (10 days on and 10 days off) deflazacort, daily prednisolone, and pulsed prednisolone.

Growth failure in DMD

There is no doubt that prolonged glucocorticoid use in DMD is associated with profound growth failure. However, there is evidence that short stature and poor growth in DMD may already be present prior to commencement of glucocorticoid. Boys with DMD have slower than expected growth rate during the first few years of life and typically track along the lower percentiles during childhood and adolescence (Eiholzer *et al.*, 1988). Several factors may explain this including elevation of pro-inflammatory cytokines (De Paepe and De Bleecker, 2013) and increased metabolic requirements from extreme muscle necrosis and regeneration (Rapisarda *et al.*, 1995). The lack of physical activity and poor bone turnover may contribute to understimulation of bone growth. Genetic factors may play a role as boys with a distal deletion are more likely to be short (Sarrazin *et al.*, 2014). The short stature homeobox (SHOX) gene, located near Xp22, may be deleted as part of a contiguous gene syndrome in a minority of patients (Messina *et al.*, 2008).

Following glucocorticoid therapy in DMD, further deterioration of growth rate is observed. The Muscular Dystrophy Surveillance, Tracking, and Research Network analyzed data from 324 ambulatory boys with DMD aged 2–12 years and found that daily prednisolone use was associated with a height loss of 1.8 cm/year of prednisolone treatment and 0.6 cm/g of prednisolone use (Lamb *et al.*, 2016) (**Fig. 5**). Short stature was present in 72% of adolescent boys treated with daily deflazacort after a mean of 8.5 years (Wong *et al.*, 2017). At 15 years of age, boys treated with deflazacort were 21 cm shorter on average than untreated boys (Biggar *et al.*, 2006). Short stature is also more common in boys treated with daily glucocorticoid (Ricotti *et al.*, 2013), although the impact of the four common glucocorticoid regimens on growth is still unclear.

Pubertal disorders in DMD

While there is still little information on puberty in boys with DMD treated with prolonged periods of glucocorticoid, delayed puberty is likely to be very common if not universal. All but one of the 44 boys with DMD aged 13 years or above in one center

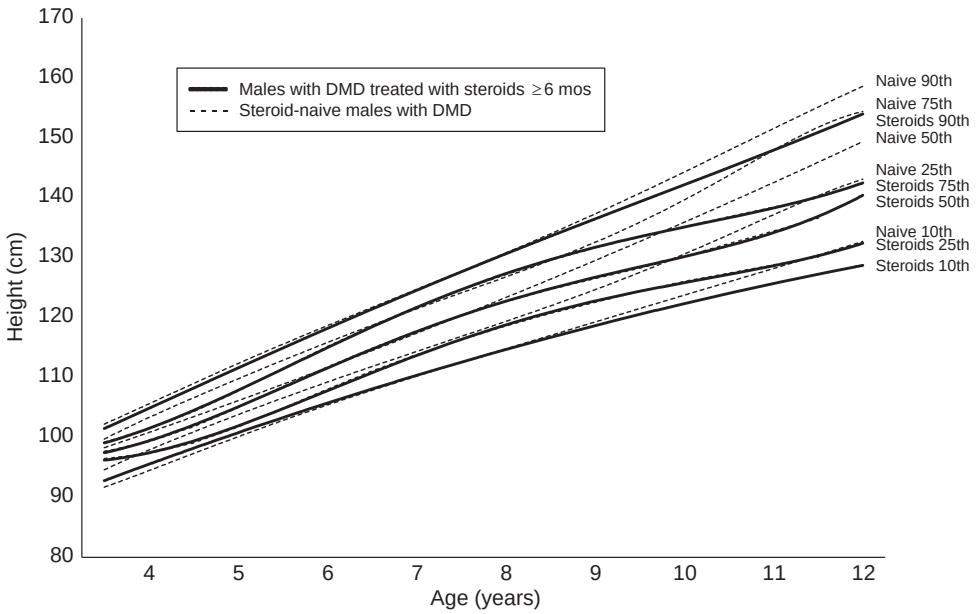

Fig. 5 Height trajectory in glucocorticoid-treated ambulatory boys with DMD in comparison with glucocorticoid naive boys. Reproduced from Lamb, M. M., *et al.* (2016). Corticosteroid treatment and growth patterns in ambulatory males with Duchenne Muscular Dystrophy. *Journal of Pediatrics* 173, 207–213, with permission © Elsevier.

treated with either deflazacort or prednisolone was prepubertal (Bonifati *et al.*, 2000). Boys with DMD who are not receiving glucocorticoid or are on low-dose pulsed therapy may show signs of puberty, although it is currently unclear if progression through puberty will happen normally. Suppression of the hypothalamic–pituitary–gonadal axis secondary to chronic high-dose glucocorticoid treatment is the most likely mechanism, although glucocorticoid may also impair androgen production at the level of the testes. It is possible that some DMD boys may have a contiguous gene deletion, which may be associated with hypogonadotrophic hypogonadism. The identification of low testosterone levels and small testes in young adults with DMD on glucocorticoid suggests that these individuals have persistent hypogonadotrophic hypogonadism, necessitating lifelong treatment with hormone replacement therapy (Wood *et al.*, 2015).

Adult height in DMD

Survival rates have improved significantly over the last few decades, with an improvement from 23% to 60% of boys with DMD reaching 20 years of age (Passamano *et al.*, 2012). There are currently no adult studies regarding adult height in boys with DMD. In an older study where prolonged glucocorticoid may not be used as frequently, most boys with DMD fell below the fifth percentile for height by 18 years of age (Bonifati *et al.*, 2000).

Management of Growth and Pubertal Disorders in Chronic Conditions

To effectively manage growth problems in these children and adolescents, it is important that height and weight are monitored in the clinic regularly. Obtaining height in nonambulatory children with chronic condition like DMD is challenging but important especially during monitoring of growth-promoting/sex steroid therapy. Alternatives include obtaining recumbent height or measuring ulnar length for estimation of height, although there are also challenges with these alternative methods of measurements. Height velocity in adolescents with chronic conditions must be interpreted in the context of pubertal staging. The use of pubertal self-assessment may be useful and may provide guidance for further endocrine evaluation, where clinical examination of puberty should be undertaken (Rollof and Elfving, 2012). However, in some adolescents, such as boys with DMD, testicular examination is mandatory, and this may require referral to the pediatric endocrinologists for clinical examination from 13 years of age. Other endocrine consequences in children with chronic conditions that may require consideration in the clinic include assessment of bone health, abnormalities of glucose homeostasis, and secondary adrenal insufficiency (especially those treated with prolonged glucocorticoid).

The first line management of growth issues in children in chronic inflammation involves optimization of the underlying condition, using the lowest possible dose of glucocorticoid and improving nutrition. In those where the underlying disease is managed and possible or those with limited window of opportunity for growth (i.e., already in puberty and progressing) but still growing slowly, endocrine growth-promoting therapies maybe considered. Pubertal induction should be considered for adolescents with delayed puberty. The use of recombinant human growth hormone (rhGH) in chronic conditions requires very careful consideration. There are still only a limited number of studies regarding its efficacy on growth in the chronic conditions, discussed in this article. A proposed pathway for growth monitoring and management in chronic condition is summarized in **Fig. 6**.

Pubertal Induction in Chronic Conditions

Treatment with sex steroids should be considered in adolescents with delayed puberty (i.e., breast stage 1 in girls $\geq$13 years and testicular volume $<$4 ml in boys $\geq$14 years) and growing slowly. Often, a short period of treatment (e.g., 3–6 months) will be sufficient, leading to improvement in virilization and increase in height velocity. This short period of treatment is often sufficient to prime the hypothalamus leading to appropriate progression through puberty. However, it is crucial that intervention with sex steroid therapy is introduced at an opportune time when disease is relatively well controlled. This may not be possible for some conditions, especially those with unremitting underlying causes (e.g., DMD). In those adolescents, a longer period of sex steroid treatment or maintenance of treatment until completion of pubertal should be considered. In boys with DMD where pubertal progression is unlikely and pathological fractures are very common, it is possible that an earlier age of intervention with sex steroid may be considered but this requires further research. Consideration of the use of transdermal estrogen should be given in girls with IBD given the issues with absorption.

Although pubertal induction with sex steroid is often recommended by pediatric endocrinologists for these adolescents, there is a paucity of studies examining the efficacy of sex steroid in chronic conditions. A study from the 1980s in five boys with CF and delayed puberty treated with 3 months of injectable testosterone showed that height velocity increased from 2.2 to 7.2 cm/year at 12 months (Landon and Rosenfeld, 1984). Another study of eight boys with IBD and delayed puberty treated with injectable and transdermal testosterone showed that only six boys increased their height velocity by $>$50% at 6-month follow-up despite adequate virilization in all (**Fig. 7**) (Mason *et al.*, 2011b). The growth response to pubertal induction is variable and may be related to disease activity (Mason *et al.*, 2011b). In boys with DMD, a retrospective study of 14 boys showed that neither growth nor pubertal response was optimal after testosterone treatment for a mean for 3 years (Wood *et al.*, 2015). This may be due to the longer insult to the hypothalamic–pituitary–gonadal axis in DMD compared with other conditions.

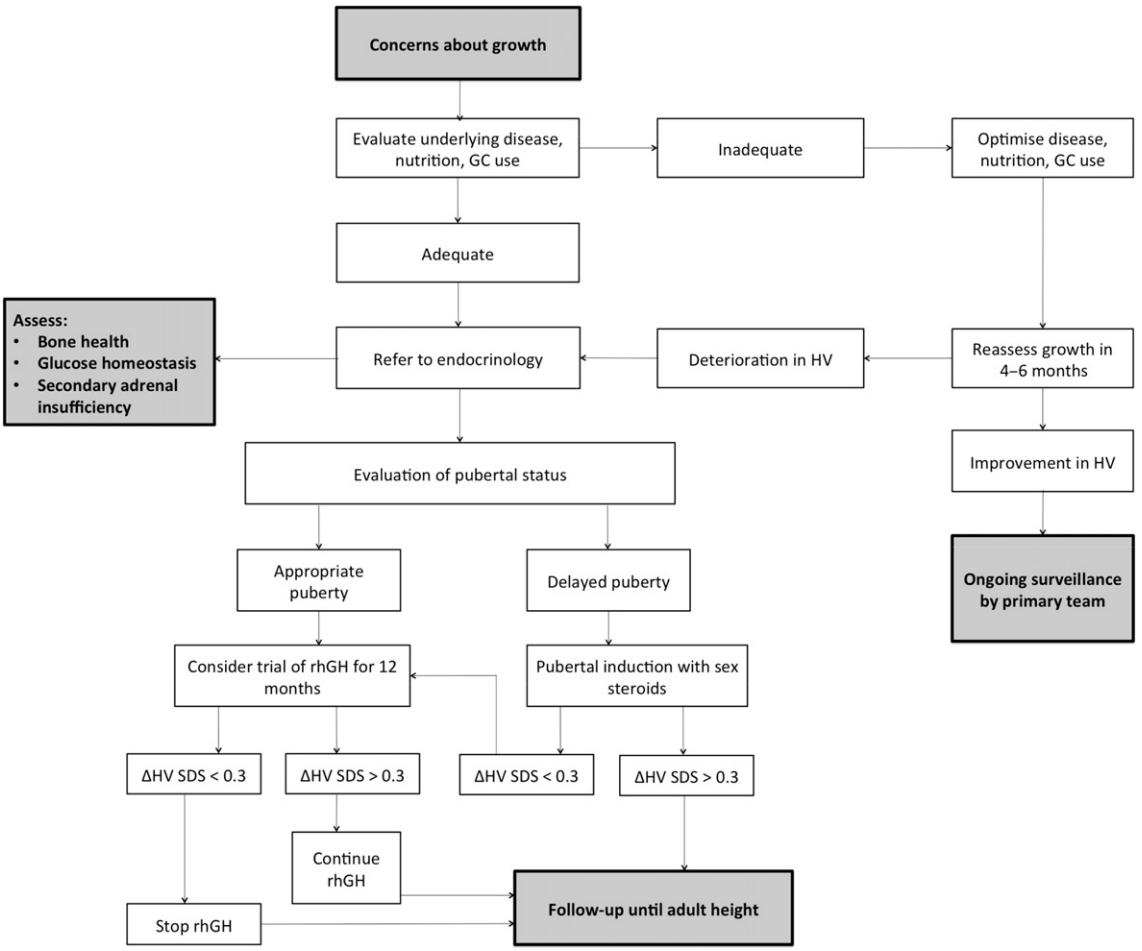

Fig. 6 Suggested pathway for monitoring and management of growth in chronic conditions.

Growth Hormone Therapy in Chronic Conditions

The availability of rhGH has led to its use in non-GH-deficient conditions (e.g., Turner's syndrome, Prader–Willi syndrome, and chronic kidney disease). rhGH at a higher dose may be able to overcome the relative GH insensitivity state seen in childhood chronic conditions (Hodson *et al.*, 2012). Most of the studies show an improvement of growth rate over the short to medium term but not normalization of height. A comprehensive review of the published studies of rhGH use in chronic conditions is summarized in a recent review (Wong *et al.*, 2016).

Six randomized trials of rhGH therapy with growth outcomes have been conducted in children with CF to date (Hardin *et al.*, 2001, 2005, 2006; Hutler *et al.*, 2002; Schnabel *et al.*, 2007; Stalvey *et al.*, 2012). Changes in height SDS in the rhGH treatment group over 12 months ranged from +0.2 to +0.6 SD, and height velocity is approximately 150% higher in the treatment group compared with placebo. However, exclusion criteria of these studies include those with abnormalities of glucose homeostasis or established CFRD and those who are colonized with *Burkholderia Cepacia*. These subgroups are usually more severely affected, may be less responsive to rhGH therapy, and are often the adolescents referred to be reviewed in the endocrine clinic.

In children with JIA, six randomized trials have been conducted demonstrating an improvement in growth (Bechtold *et al.*, 2001, 2003, 2007; Grote *et al.*, 2006; Saha *et al.*, 2004; Simon *et al.*, 2007). Only one trial using rhGH 0.33 mg/kg/week of rhGH included data on adult height. This study found that rhGH treatment over a mean duration of 8.4 years led to a net gain in height of +2.3 SD while the control group lost 0.7 SD from baseline to adult height (Bechtold *et al.*, 2007). However, mean adult height SDS was −1.6 SDS, suggesting incomplete catch-up growth. Another study suggested that early introduction of rhGH in JIA before the onset of severe growth failure may normalize growth rate; however, this requires further evaluation (Simon *et al.*, 2007). While there are insufficient data to support the use of rhGH before any evidence of growth failure, it is important to intervene before severe growth failure is present, especially those with limited growth potential.

In comparison with JIA, there is a paucity of data on rhGH trials in children with IBD. The only randomized trial in IBD conducted to date using rhGH at 0.45 mg/kg/week for improving linear growth found that height velocity increased by a median of 140% in the rhGH group compared with 8% reduction in the control group at 6 months, equivalent to a relative gain in height of +0.4 SD (**Fig. 8**) (Wong *et al.*, 2011). Another randomized trial of rhGH at 0.53 mg/kg/week in children with CD, designed to evaluate the role of rhGH in improving disease process, showed that height velocity improved by 60% in the treatment group at 12 weeks (Denson *et al.*, 2010).

There is currently only one published nonrandomized study of rhGH (0.3 mg/kg/week) in 39 DMD treated for a duration of 12 months (Rutter *et al.*, 2012). Following rhGH therapy, height velocity increased from 1.5 cm/year to 5.2 cm/year with concurrent improvement in lean body mass without deterioration of muscle or cardiopulmonary function. However, as severe short stature is common in these boys, with baseline mean height SDS of almost 3 SD below the mean in that study, the clinical significance of this to the growing child is unknown.

The use of relatively high-dose rhGH in chronic conditions, especially those concurrently treated with glucocorticoid, is associated with reduction in insulin sensitivity. Current short-term trials of rhGH in CF have not shown any adverse effects on glucose homeostasis, but as mentioned, current trials have excluded children with established CFRD or impaired glucose tolerance.

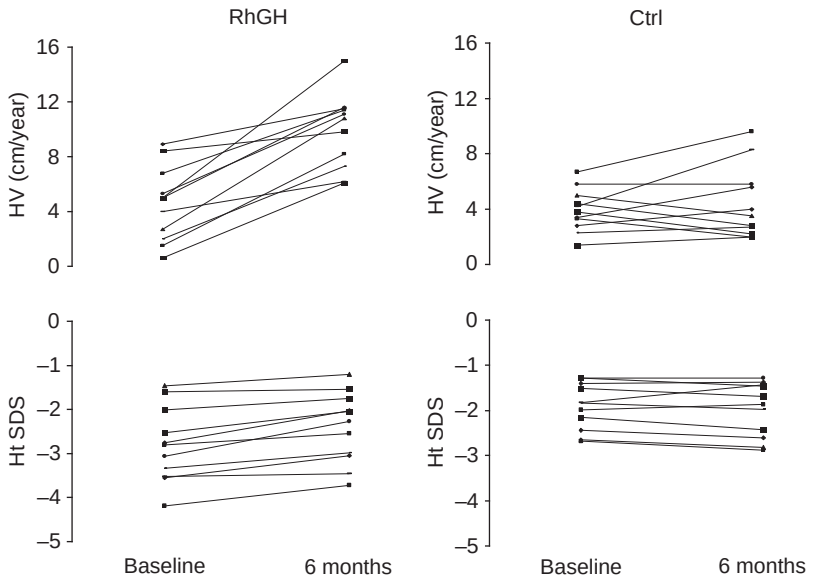

Fig. 8 Recombinant human growth hormone in children with IBD: Results from a preliminary randomized controlled trial. Reproduced from Wong, S. C., *et al.* (2011). A preliminary trial of the effect of recombinant human growth hormone on short-term linear growth and glucose homeostasis in children with Crohn's disease. *Clinical Endocrinology (Oxford)* 74, 599–607 (351), with permission © Wiley.

In rhGH trials of children with JIA treated with several years of glucocorticoid, almost 40% developed impaired glucose tolerance, and 5% developed type 2 diabetes (Bismuth *et al.*, 2010). The use of rhGH in IBD where the majority of the subjects were not treated with glucocorticoid led to a significant increase in fasting insulin levels but no abnormalities of glucose homeostasis (Wong *et al.*, 2011). Similarly, 5% of the subjects in the study of rhGH in DMD developed impaired glucose tolerance (Rutter *et al.*, 2012).

Given the limited evidence of rhGH in chronic conditions, its use should ideally be in the context of well-designed clinical trials. In exceptional circumstances, where clinicians may be able to prescribe rhGH under nonlicensed indication, careful discussion with the family needs to be conducted. A trial period of rhGH for 12 months can be considered in younger prepubertal children who are growing slowly or those who continue to grow slowly despite being in puberty. The decision to continue rhGH therapy beyond 12 months should be discussed with the family prior to the start of rhGH. Expert recommendations suggest that an increase of height SDS of greater than +0.3 SD with rhGH therapy in states of relative GH insensitivity may be acceptable (Bang *et al.*, 2012).

Insulin-Like Growth Factor Therapy in Chronic Inflammation

Given the state of functional GH insensitivity in chronic inflammation, there is biological rationale to consider the use of rhIGF-1 to promote growth in this setting. rhIGF-1 therapy in children with GH insensitivity due to GH receptor mutation leads to improvement in growth rate (Bright, 2016). Its use has also been investigated in children with idiopathic short stature (Midyett *et al.*, 2010). The only study of its efficacy in childhood chronic inflammation is in a crossover trial of seven children with CF using rhIGF-1 (80 μg/kg twice daily) compared with placebo (Bucuvalas *et al.*, 2001). This study failed to show an effect on linear growth despite normalization of serum IGF-1, but there was improvement in insulin sensitivity. A pharmacokinetic study of rhIGF-1 in eight children with CD using mathematical modeling allows appropriate dosing to ensure that systemic IGF-1 levels remain below +2.5 SD (Rao *et al.*, 2013). However, the effect of rhIGF-1 on linear growth in CD is currently unknown.

The potential adverse effect of hypoglycemia may preclude the use of a higher rhIGF-1 dose, observed in 14% of children with idiopathic short stature treated with 120 μg/kg twice daily of rhIGF-1 (Midyett *et al.*, 2010). There are also concerns that rhIGF-1 may accelerate skeletal maturation, which maybe disadvantageous for adult height prognosis (Bright, 2016). In contrast to the possibility of normalization of height with the use of rhGH in growth hormone deficiency, the use of rhIGF-1 in GH insensitivity syndrome fails to lead to complete catch-up growth with long-term follow-up (Fintini *et al.*, 2009). The possibility of combination therapy using rhGH and rhIGF-1 in these chronic conditions may be more physiological and deserves further exploration.

Conclusion

It is clear from clinical outcome studies that growth and pubertal development are affected in children with chronic inflammation despite contemporary treatment regimens. While pubertal delay may not be as common, timely induction of puberty is important. Although preliminary evidence suggests that rhGH treatment is effective for improving short-term linear growth, catch-up growth remains incomplete. Long-term treatment studies are required to assess adult height outcomes and other extended health benefits of promoting growth or manipulation of the GH/IGF-1 axis.

Normal Puberty: Somatic Characteristics

Dipesalema Joel, University of Botswana, Gaborone, Botswana
Ieuan Hughes, Addenbrooke's Hospital, Cambridge, United Kingdom

Abbreviation

BMI Body mass index
DHEA Dehydroepiandrosterone
DHEAS Dehydroepiandrosterone sulphate
FSH Follicle stimulating hormone
GnRH Gonadotrophin release hormone
GnRHa Gonadotrophin release hormone agonist
HPG Hypothalamic–pituitary–gonadal
HPV Human papilloma virus
LH Luteinizing hormone
MIH Mullerian inhibiting hormone

Glossary

Gonadarche Is the activation of the gonads by the pituitary hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH).
Gynaecomastia Is the enlargement of male breast tissue.
Menarche Is the time of first menstrual bleed. The first menstrual bleed is often not associated with ovulation; it typically is caused solely by the effects of estradiol on the endometrial lining.
Secondary sex characteristics Is any physical characteristic developing at puberty which distinguishes between the sexes but is not directly involved in reproduction, for example, development of breasts or beard, muscularity, distribution of fat tissue, and change of pitch in voice.
Spermarche Is the time of the first sperm production (heralded by nocturnal sperm emissions and appearance of sperm in the urine), which is due to the effects of FSH and LH, via testosterone.
Thelarche Is the appearance of breast tissue, which is primarily due to the action of estradiol from the ovaries.

Introduction

Physiology of Puberty

Puberty is a period of transition in the stage of development which is characterized by the occurrence of secondary sexual characteristics. During that transition period, there is a whole array of complex hormonal signals that bring about the changes from sexually immature to the sexually mature stage (**Table 1**). The general concept involved in the initiation of puberty was established in the mid-1960s (Donovan and Ten Bosch, 1965). Puberty is a complex, coordinated biological process with multiple levels of regulation. The timing of pubertal events is a heritable trait, although environmental factors can modulate such genetic influence (Banerjee and Clayton, 2007). At the start of puberty, through a complex neuro-signaling pathway, a hypothalamic neuronal peptide, kisspeptin, is secreted which in turn stimulates the release of gonadotropin release hormone (GnRH) from the GnRH neurons of the hypothalamus (Banerjee and Clayton, 2007). The GnRH is secreted into the blood vessels and subsequently stimulate the gonadotroph cells of the anterior pituitary gland to secrete the gonadotrophins, follicle stimulating hormone (FSH) and the luteinizing hormone (LH). The gonadotropins stimulate sex-steroidogenesis with the resultant production of testosterone and oestradiol from the testes and ovaries respectively. These in turn are responsible for the development of the secondary sex characteristics of puberty.

The Timing of Puberty

The age of normal pubertal onset is different for the boys and girls. These variations are due to genetic factors and a number of external factors such as adequate nutrition, the presence of chronic diseases and the level of physical exercise (Banerjee and Clayton, 2007, Gajdos *et al.*, 2010, Kaminski and Palmert, 2008). Over the last 100 years, there has been marked transgenerational decrease in the age of onset of puberty in both boys and girls due to improved condition of childhood nutrition world-wide (Zacharin, 2013). The hypothalamic–pituitary–gonadal (HPG) axis is active in early infancy. However, there is resistance to sex steroid action at that age and therefore in normal infants, there is no development of secondary sex characteristics. From 6 to 12 months of age, the HPG axis enters a period of quiescence that remains until the adolescent stage (Kurtoglu and Bastug, 2014).

Any time after age 8 years in girls and 9 years in boys, the HPG axis becomes reactivated to bring about normal pubertal development. The exact mechanism for the trigger of normal pubertal onset is has not been elucidated.

Table 1 A summary of Tanner stages of development and concomitant changes in boys and girls

Staging	Breast	Pubic hair staging	Concomitant changes	
Girls				
1	Prepubertal, papilla elevation	No pigmented hair		
2	Budding; larger areole; palpable and visible elevated contour	Pigmented hair, mainly labial	Accelerating growth rate	
3	Enlargement of the breast and areola	Coarser, spread of pigmented hair over mons	Peak growth rate, thicker vaginal mucosa, axillary hair	
4	Secondary mound of areola and papilla	Adult type but smaller area	Menarche (stage 3 or 4) decelerating growth rate	
5	Mature	Adult distribution		
Staging	Genital size	Pubic hair staging	Concomitant changes	Prader orchidometer (mL)
Boys				
1	Prepubertal	No pigmented hair	Long testis axis <1.5 cm	1–3
2	Early testicular, penile and scrotal growth	Minimal pigmented hair at base of penis	Early voice changes; testes length 2.5–3.3 cm	3–6
3	Increased penile length and width; scrotal and testes growth	Dark, coarse, curly hair extends midline above penis	Light hair on upper lip, acne, maximal growth, testes length 3.3–4.0 cm	8–12
4	Increased penis size including breadth; pigmented scrotum	Considerable, but less than adult distribution	Early sideburns; testes 4.0–4.5 cm	>12
5	Adult size and shape	Adult distribution, spread to medial thighs or beyond	Beard growth; testes >4.5 cm	>15

Somatic Characteristics of Normal Puberty in Clinical Setting

Normal Pubertal Changes for Girls

Pubertal onset in girls tend to occur at the age of 8–13 years (Zacharin, 2013). The onset of puberty in girls is affected by a numbers of factors including the variations in the ethnicity, the general community health and the nutritional status. The data suggest African American girls enter puberty earlier and reach menarche earlier than Caucasian and Hispanic girls (Ramnitz and Lodish, 2013, Herman-Giddens *et al.*, 1997, Morrison *et al.*, 1994). There is also evidence of an association between higher BMI in childhood or adolescence and earlier onset of puberty in girls suggesting that improved nutrition and socioeconomic conditions have contributed to that trend (Lundeen *et al.*, 2016). Relatively poor nutritional status in some communities may delay the onset of puberty to the late teens. The somatic variations in the pattern of pubertal changes in girls were described in the late 1960s and early 1970 by Marshall and Tanner. They are commonly referred as the Tanner Staging or Sexual Maturity Ratings (SMR). These consist of systematized descriptions of the development of secondary sexual characteristics, consisting of breast changes and pubic hair changes. The Tanner Staging for pubic hair and breast consists of five stages, with stage 1 representing prepuberty and stage 5 representing adult development. The first sign of true puberty in a girl is the development of the breast buds which is followed by pubic hair growth and rapid height spurt (Marshall and Tanner, 1969). The onset and progress of pubic hair differs markedly between genetically different communities (Oberfield *et al.*, 2011). The progress of puberty takes place in an ordered fashion with menarche occurring 2–2.5 years following the onset of thelarche (Zacharin, 2013). Menarche signal the end of growth, with only 5 cm of height gain remaining.

Hormonal changes during puberty

The mean LH, FSH, and oestradiol levels initially rise before the somatic characteristics of puberty become visible. The levels rises further as puberty progresses, accompanied by increases of both inhibin A and inhibin B. An unstimulated or GnRH/GnRHa stimulated LH level and an oestradiol level above the pre-pubertal range confirms gonadarche (Lee and Houk, 2007). Estrogen stimulated changes include onset and progression of breast maturity, genital growth, maturation of the vaginal mucosa, uterine/endometrial growth, and body composition changes resulting in the female pattern fat distribution (Lee and Houk, 2007). Breast growth, which may begin asymmetrically, progresses throughout puberty and is classified into one of five Tanner stages. Pubic hair is also Tanner staged (see below).

The pubertal breast changes in girls

The pubertal Tanner breast stages are as follows:

Stage 1 Pre-pubertal; elevation of papilla only with no palpable breast tissue.
Stage 2 Palpable breast bud with elevation of the papilla and enlargement of areola diameter.
Stage 3 Enlargement of breast, areola and the papilla forming a cone with no separation of their contours.
Stage 4 Projection of areola and papilla to form a secondary mound above the level of the breast.
Stage 5 Recession of the areola to the general contour of the breast and projection of the papilla only (**Fig. 1**).

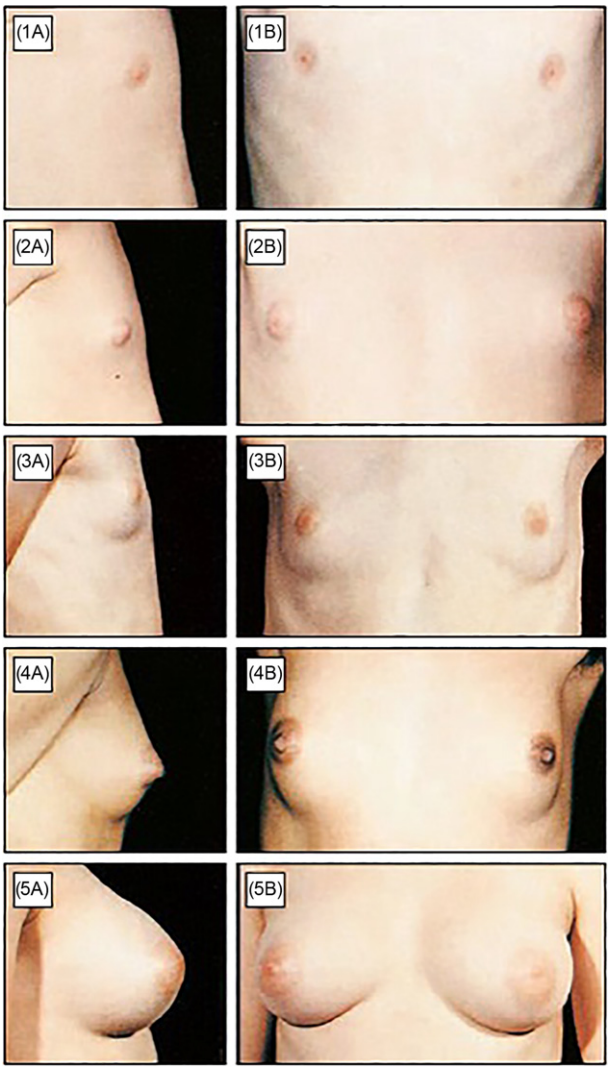

Fig. 1 Tanner staging of breast development in girls.

The pubertal pubic hair changes in girls

The pubertal Tanner pubic hair stages are as follows:

Stage 1 Prepubertal with no development of the no pubic hair.
Stage 2 Sparse growth of long, lightly pigmented, downy hair appearing chiefly along the labia majora.
Stage 3 The hair is considerably darker, coarser, and more curled, extending over the junction of the mid pubis.
Stage 4 Hair is adult-like in appearance and fills up the genital inverse triangle with no spread to the medial surface of the thighs.
Stage 5 Adult in quantity and type, it spread to the medial surface of the thighs (**Fig. 2**).

The growth spurt in puberty and bone maturation

The contribution of pubertal growth to the final height is approximately 27.5–29 cm in girls, accounting for 17% of the final height (Abbassi, 1998). The timing of the growth spurt (peak height velocity) occur approximately 2 years earlier in girls than in boys. Before puberty, the legs grew more rapidly than the trunk and during puberty, the growth spurt is truncal (Bass *et al.*, 1999). The height velocity can be plotted and compared with the norms using the growth velocity height charts (**Fig. 3**). The disparity in mean adult height between men and women results from the timing and magnitude of the growth spurt in boys and girls (Biro *et al.*, 2006). In girls, peak height velocity occurs, on average, 0.5 years prior to menarche (Biro *et al.*, 2006). The boys experience pubertal growth spurt approximately 2 years later than girls and hence the boys have an additional 2 years of prepubertal growth (at a rate of 3–8 cm per year) compared with girls (Kelly *et al.*, 2014). Additionally, the boys experience a greater peak height velocity than do girls (10.3 versus 9.0 cm/year) (Kelly *et al.*, 2014). The growth spurt typically lasts for about 2 years in both sexes.

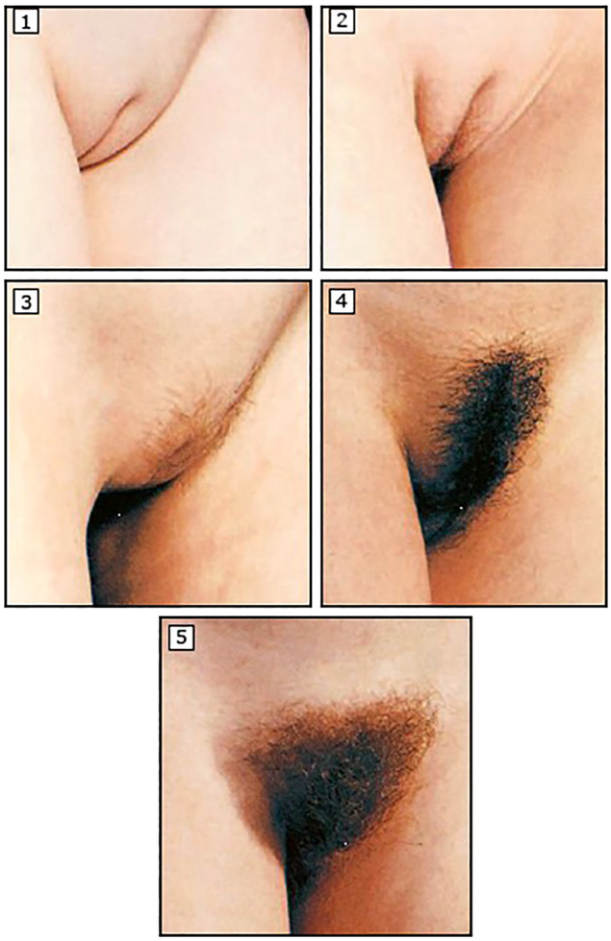

Fig. 2 Tanner staging of pubic hair development in girls.

Fig. 3 Prader orchidometre.

The bone growth accelerates during puberty, in concert with height velocity. Bone width and mineral content increase independently with age for each pubertal stage (Magarey *et al.*, 1999). Bone growth occurs first in length, followed by width, then mineral content and then bone density (Magarey *et al.*, 1999). The rate of bone mineral accrual peaks around the age of menarche in girls (McKay *et al.*, 1998, Taranger *et al.*, 1976). Approximately one-half of total body calcium is laid down during puberty in females, and one-half to two-thirds in males (Magarey *et al.*, 1999, Lloyd *et al.*, 1992).

Body shape and composition during puberty

Puberty is associated with changes in body weight and alterations in body composition of lean body mass and the proportion of body fat. There is an increase in the body mass index (BMI) during puberty. In early puberty, the annual increase in BMI is driven primarily by changes in lean body mass. Later, the increase in BMI tends to be driven by increases in fat mass. Unlike adults, annual increases in BMI during childhood are generally attributed to the lean rather than to the fat component of BMI (Maynard *et al.*, 2001). Girls tend to have a higher proportion of fat mass than boys at each phase, and after 16 years of age, the annual increase in BMI is largely because of increases in fat mass (Gasser *et al.*, 1993, Maynard *et al.*, 2001). Androgen stimulates pubic and axillary hair development, apocrine gland maturation resulting in adult-type body odor, and skin changes related to acne (Lee and Houk, 2007).

Normal Pubertal Changes for Boys

From the epidemiological data, the onset of puberty in boys occur at the age 9–14 years depending on the geographic location, nutrition and race. In a study involving over 4000 healthy boys, the mean age for entering puberty was 10.14 years for white boys, 10.04 years for Hispanic boys, and 9.14 years for African American boys (Herman-Giddens *et al.*, 2012). The average age at the initiation of puberty, assessed by age at the transition from Tanner Stage 1 to Tanner Stage 2 for genitalia or pubic hair development ranged between 9.8 and 10.5 years in South Africa (Jones *et al.*, 2009). These thresholds are 1.5–2 years earlier than historical norms. Similar trends have been reported from several countries around the world.

The first physical signs of puberty in boy is the testicular enlargement associated with increased folding of the scrotal rugae, followed by penile growth and the development of pubic hair. The testicular volume is often measured using the Prader orchidometer which is a series of three-dimensional ellipsoids with volumes ranging from 1 to 25 mL or more (**Fig. 3**). The testicular volume measuring more than 4 mL and a length greater 2.5 cm is pubertal. Testicular enlargement occur approximately 6 months prior to the appearance of penile growth and pubic hair. Puberty in boys is designated according to Tanner staging of genital development and pubic hair (**Fig. 4**). The Tanner staging does not include testicular volume but the correlation between the testicular volume and the stages of puberty have been established (Biro *et al.*, 1995, Dagli *et al.*, 2014) (**Fig. 5**).

Hormonal changes in puberty

As boys enter puberty, there is a gradual rise in the levels of LH and FSH. These consequently stimulate the leydig cells in the testes to produce testosterone which subsequently give rise to the development of male secondary sexual characteristics. That reflects an upregulation of the hypothalamic-pituitary-testicular axis (Andersson *et al.*, 1997). Other intermediate metabolites of adrenal and testicular origin also rise (oestrone, oestradiol, androstenedione, 17-hydroxyprogesterone) (Lee and Houk, 2007). An increase in the levels of adrenal hormones, dehydroepiandrosterone (DHEA) and DHEAS, indicate adrenarche. Inhibin B levels, a marker of Sertoli cell mass and function, rise progressively before the onset of puberty. Both testosterone and inhibin B appear to be related to the nocturnal release of LH seen in early puberty (Crofton *et al.*, 2004). Mullerian inhibiting hormone (MIH) levels in males rise rapidly during the first year of life, peak in late infancy and gradually decline to a nadir during puberty. Outside of the neonatal period, MIH levels are inversely related to testosterone.

The stages for the genitalia are as follows:

Stage 1 Prepubertal. Testes, scrotum, and penis are of about the same size and proportion as in early childhood. The testicular volume is less than 4 mL.

Stage 2 There is enlargement of the testes and scrotum; the scrotal skin changes in texture and reddens. The testicular volume at that pubertal stage ranges from 4 to 8 mL.

Stage 3 The penile growth occurred, mainly length first but with some increase in breadth. There is further growth of testes and scrotum. The testicular volume at that stage ranges from 9 to 12 mL.

Stage 4 There is further enlargement of the penis in length and breadth with development of glans. Testes and scrotum further enlarged. There is also further darkening of the scrotal skin. The testicular volume at that stage ranges from 13 to 15 mL.

Stage 5 Genitalia adult in size and shape. No further enlargement takes place after Stage 5 is reached. The testicular volume at that stage ranges is more than 16 mL.

The pubic hair stages are:

Stage 1 Prepubertal. The pubic area has no hair or it may have the vellus similar to those of the forearms.

Stage 2 Sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, appearing chiefly at the base of the penis.

Stage 3 Considerably darker, coarser, and more curled. The hair spreads sparsely over the junction of the pubes.

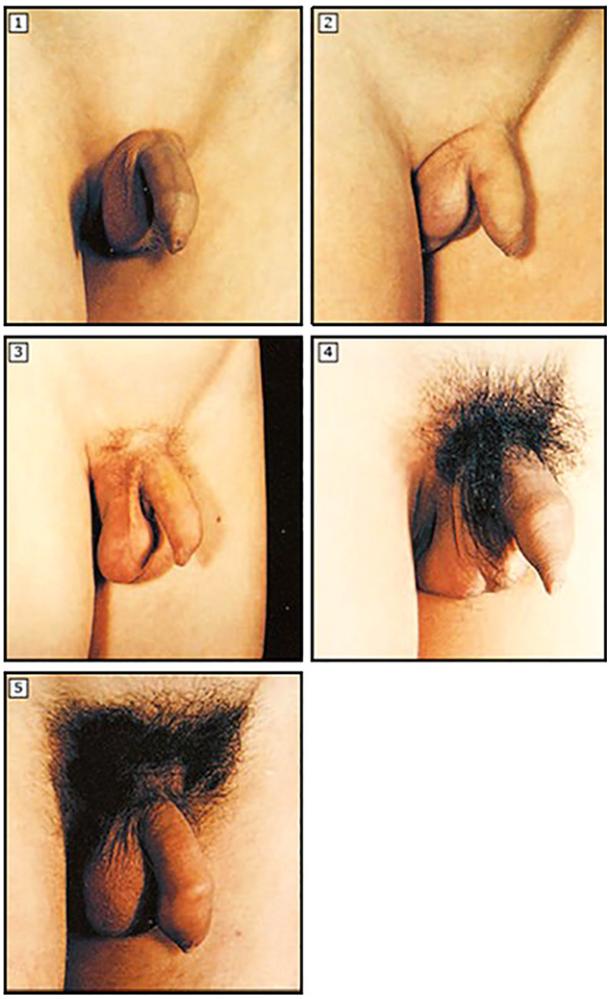

Fig. 4 Tanner staging of pubic hair and external genitalia development in boys.

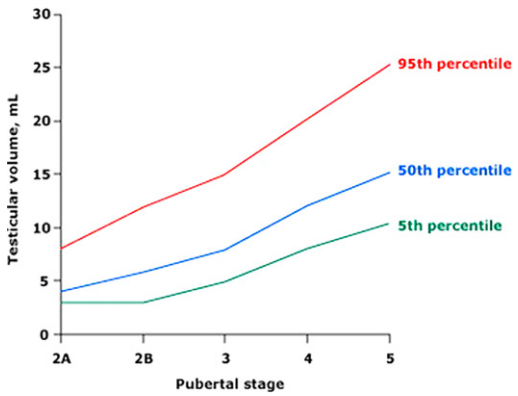

Fig. 5 Testicular volume in each pubertal stage.

Stage 4 Hair is now adult in type, but the area covered by it is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs.

Stage 5 Adult in quantity and type, distributed as an inverse triangle. Spread to the medial surface of the thighs and above the base of the inverse triangle.

The growth spurt in puberty and bone maturation

The changes in boys occur at mid puberty following prolonged exposure to testosterone. These include the peak growth velocity, cracking of the voice, acne, and the onset of axillary hair. There is also a gradual increase in total bone mineral content, lean body mass and a relative decline in body fat. These changes in body composition begins with the onset of puberty, but by comparison to the girls, a significant composition of the pubertal changes in boys do not occur until mid-puberty. Oestradiol is the main hormone which stimulate the skeletal maturation in both sexes. However, the oestradiol levels attained during mid-puberty in boys is similar to the levels in early pubertal girls. The growth velocity peaks in early puberty in females and it differs based on race. The disparity in mean adult height between male and females results from the timing and magnitude of the growth spurt in boys and girls. Spemarche, the onset of sperm production and the average male reaches spermarche at the age of 14 years or Tanner stage 3 for genital and pubic hair.

Other Somatic Characteristics of Normal Puberty

The transition from childhood to adulthood in puberty is associated with a number of somatic complications that present challenges to the patient, family and the society. These complications may include the development of acne, anemia, gynecomastia, dysfunctional uterine bleeding, myopia and scoliosis.

Acne—Acne is the inflammation of the pilosebaceous glands due to androgenic stimulation. During puberty, the androgen levels rise in both boys and girls. This rise in the androgen levels causes the number of acne lesions to develop (Lucky *et al.*, 1991). In girls, the severity of acne in later puberty is associated with higher serum levels of dehydroepiandrosterone sulphate (DHEAS) and a greater number of acne lesions in early puberty (Lucky *et al.*, 1997). Acne is common during puberty and it is part of normal somatic progression.

Anemia—Iron deficiency anemia is more common among adolescent girls as compared with adolescent boys due to menstrual bleeding and insufficient iron intake (Bergstrom *et al.*, 1995, Daniel, 1973). The levels of hemoglobin and ferritin increases with increasing pubertal stages in boys but not in girls. The testosterone increases erythropoiesis in boys, thus they are less prone to anemia.

Gynaecomastia—Pubertal gynecomastia affects roughly 50% of teenage boys at an average age of 13 years, and it persists for 6 to 18 months (Biro *et al.*, 1990). The larger the gynaecomastia, the more it is likely to persist longer. It has been found that boys with palpable breast tissue greater 2 cm during the first year of puberty are more likely to have persistent gynecomastia (Biro and Chan, 2017). The cause of pubertal gynaecomastia may reflect the imbalance in the effective estrogenic-to-androgenic stimulation. An increased production of estrogens and a decreased production of androgens results in pubertal gynaecomastia.

Musculoskeletal injuries—The pubertal adolescents are susceptible to musculoskeletal injuries and fractures during sport. The pubertal status maybe use to predict the specific type of musculoskeletal injuries that adolescents may encounter during participation in sports (Backous *et al.*, 1990). There is a greater risk to the epiphyseal growth plates damage during the peak of height velocity, which also is the time of greatest change in bone mineral content (McKay *et al.*, 1998). The incidence of distal radius fractures peak correspond with the age of peak height velocity in both boys and girls (Bailey *et al.*, 1989). The asynchronous growth of body parts may result in a limited range of motion of some joints. In pubertal adolescents, Osgood-Schlatter disease, which is caused by the inflammation of the tibial tubercle due to over, is quite common.

Gynaecologic outcomes—After reaching menarche, a girls' reproductive axis matures rapidly. Once a girl reaches menarche, rapid maturation of the reproductive axis ensues. By 1 year after menarche, 65% of girls have regular menstrual cycles, with 10 or more periods per year (Legro *et al.*, 2000). Pubertal adolescents suffer from excessive, prolonged endometrial bleeding, mainly due to anovulation. This phenomenon is called dysfunctional uterine bleeding and it is due to unopposed estrogen stimulating the endometrium resulting in proliferative phase. Estrogen levels ultimately cannot sustain the hyperplastic endometrial lining, resulting in irregular, heavy, menstrual bleeding.

Myopia—There is a high incidence of myopia during puberty. This is mainly caused by the growth in the axial diameter of the eye (Tanner, 1962).

Scoliosis—As a result of the pubertal growth spurt and the associated growth in the axial skeleton, there is accelerated progression of the degree of scoliosis.

Changes in the female genital tract—In the first year or two after menarche, there is persistence of columnar epithelial cells on the exocervix as well as the transformation zone of columnar to squamous epithelial cells on the exocervix. These factors may enhance infection with Chlamydia and genital human papillomavirus (HPV) (Harrison *et al.*, 1985, Moscicki *et al.*, 1989, Shew *et al.*, 1994).

Genetic and Epigenetic Control of Puberty

Ana Claudia Latronico, Universidade de São Paulo, São Paulo, Brazil
Leticia F Silveira, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

Abbreviations

AVPV Anteroventral periventricular
CPP Central precocious puberty
CHH Congenital isolated hypogonadotropic hypogonadism
GnRH Gonadotropin-releasing hormone

Introduction

In humans, the hypothalamic–pituitary–gonadal axis is fully active in the late gestational and neonatal periods, entering a phase of quiescence during infancy. Puberty is initiated upon the reactivation of this axis, marked by an increase in pulsatile gonadotropin-releasing hormone (GnRH) release leading to pituitary secretion of LH and FSH (Abreu and Kaiser, 2016). Traditionally, the normal age range of pubertal onset is between 8 and 13 years in girls and between 9.5 years and 13.5 years in boys according to cross-sectional data obtained in the 1960s (Carel and Leger, 2008; Marshall and Tanner, 1969; Marshall and Tanner, 1970). Pubertal timing can be influenced by complex interactions among genetic and environmental factors, such as socioeconomic status, general health, nutrition, and endocrine disruptors. Recently, it has been proposed that epigenetics plays a role in the complex interplay between genetics and environment (Abreu and Kaiser, 2016; Carel and Leger, 2008). Notably, timing of puberty is associated with risks of subsequent disease at adult age. It has been demonstrated that earlier age of menarche in girls is associated with increased risks of breast cancer, endometrial cancer, obesity, type 2 diabetes, and cardiovascular disease (Lakshman *et al.*, 2008, 2009). On the other hand, pubertal delay is associated with osteoporosis in both sexes.

Compelling evidence of the influence of genetic factors on pubertal timing has been provided by epidemiological and genetic studies. The role of genetic factors is illustrated by the similar age at menarche in mothers and daughters and among members of an ethnic group and by a greater concordance of pubertal timing in monozygotic than in dizygotic twins (Fischbein, 1977; Palmert and Hirschhorn, 2003). In the past decade, several genes have been identified in the complex network of inhibitory, stimulatory, and permissive neuroendocrine factors involved in the control of puberty onset. Definitely, the identification of genes mutated in congenital isolated hypogonadotropic hypogonadism (CHH) and central precocious puberty (CPP) has facilitated and improved the current understanding of the neuroendocrine control of reproduction.

Genetic Basis of CPP

Early activation of the hypothalamic–pituitary–gonadal axis results in gonadotropin-dependent precocious puberty, also known as CPP, which is clinically defined by the development of secondary sexual characteristics before the age of 8 years in girls and 9 years in boys (Carel and Leger, 2008; Latronico *et al.*, 2016). The estimated incidence of CPP in American girls is 1:5000–1:10,000. Among Danish girls, the prevalence of precocious puberty was 1:500, based on national registries over a 9-year period (Teilmann *et al.*, 2005). The prevalence is sexually dimorphic, being higher in girls than in boys (15–20 girls for every boy). Precocious puberty can result in short stature and psychological and behavioral disorders in untreated patients. Familial segregation analysis showed that 27.5% of cases of CPP are familial disorders with predominance of an autosomal dominant inheritance (Durand *et al.*, 2016; de Vries *et al.*, 2004). Recent studies have implicated gene mutations leading to activation and inactivation of hypothalamic expressed proteins in the pathogenesis of CPP (**Table 1**).

Kisspeptin System

Kisspeptin, encoded by the *KISS1* gene, is the most potent known stimulator of GnRH-dependent LH secretion. Kisspeptin acts through its cognate receptor, KISS1R, expressed in the surface of the GnRH secreting neurons. Hypothalamic *KISS1* expression is increased at the time of puberty onset, reaching maximum levels at the beginning of pubertal development. Activation of the kisspeptin complex plays a critical role in puberty initiation (Han *et al.*, 2005; Navarro *et al.*, 2007). *KISS1* and *KISS1R* were the first genes involved in the pathogenesis of CPP in humans. To date, only two activating mutations affecting the kisspeptin system —one in the gene encoding kisspeptin (p.Pro74Ser) and one in the gene encoding its receptor (p.Arg386Pro)—were associated with CPP, despite a relatively large cohort of patients have been screened, indicating that isolated mutations in these genes are uncommon causes of CPP (Silveira *et al.*, 2010b; Teles *et al.*, 2010). Although very rare, these prismatic cases contributed to the elucidation of the fundamental role of the kisspeptin pathway in the physiologic regulation of pubertal development (Ko *et al.*, 2010; Tommiska *et al.*, 2011).

 doi:10.1016/B978-0-12-801238-3.65226-1

Table 1 Genetic causes of nonsyndromic CPP

Gene	*Locus*	*Protein function*	*Pattern of inheritance*	*Type of mutation*	*Prevalence*
KISS1R (*or GPR54*)	19p13.3	Kisspeptin receptor	Adopted girl	Gain-of-function missense	Very rare
KISS1	1q32	Potent GnRH stimulator	Autosomal dominant with probably incomplete penetrance	Gain-of-function missense	Very rare
MKRN3 (maternal imprinted gene)	15q11.2 (Prader–Willi region)	Protein ubiquitination and RNA binding	Autosomal dominant with complete penetrance (paternal transmission)	Loss-of-function defects (missenses, frameshift, stop-codons mutations)	33%–46% of familial cases
DLK1 (maternal imprinted gene)	14q32 (Temple region)	Adipose tissue homeostasis and neurogenesis	Autosomal dominant with complete penetrance (paternal transmission)	Loss-of-function defect	Rare

MKRN3 Deficiency Causes CPP

In 2013, human mutations in *MKRN3*, a paternally expressed imprinted gene that encoding the makorin Ring-finger protein, were first described in a cohort of families with CPP (Abreu *et al.*, 2013). Whole exome sequencing revealed loss-of-function mutations in *MKRN3* in 5 of 15 families with CPP. These mutations were inherited from the father in all affected individuals, consistent with the maternal imprinting of *MKRN3*. Since then, other loss-of-function mutations of *MKRN3* have been reported in familial CPP (Grandone *et al.*, 2017; Macedo *et al.*, 2014; Simon *et al.*, 2016; de Vries *et al.*, 2014). The current frequency of *MKRN3* mutations in familial CPP is up to 46%, suggesting that these defects represent a common cause of premature sexual development in both sexes (Simon *et al.*, 2016).

MKRN3 is an intronless gene located on chromosome 15q11.2, in the Prader-Willi syndrome critical region. It encodes a protein with domains implicated in E3 ubiquitin ligase and RNA binding activity. MKRN3 function and the mechanism by which *MKRN3* mutations result in early activation of the central reproductive axis are not well understood. Studies in animal models demonstrated a high expression of *Mkrn3* in the arcuate nucleus prepubertally, which decreases before puberty initiation, reaching very low levels in adult life, suggesting an inhibitory role of MKRN3 on GnRH secretion (Abreu *et al.*, 2013; Abreu and Kaiser, 2016).

Macedo *et al.* (2014) studied 215 unrelated children (207 girls and 8 boys) from three university medical centers with a diagnosis of CPP. All but two of these patients (213 cases) reported no family history of premature sexual development. Novel heterozygous mutations in *MKRN3* were detected in eight unrelated girls with CPP. Four of them were frameshift mutations predicted to encode truncated proteins and one was a missense mutation, which was suggested to be deleterious by in silico analysis. All girls with *MKRN3* mutations had classical features of CPP with a median age of onset at 6 years. Segregation analysis revealed that these *MKRN3* mutations were inherited on the paternal allele, pointing out that inherited *MKRN3* defects were also recognized in children with apparently sporadic CPP.

More recently, a high frequency of MKRN3 mutations was demonstrated in boys with CPP, previously classified as idiopathic (Bessa *et al.*, 2017). The studied boys with CPP due to *MKRN3* mutations had also classical features of CPP, but with puberty initiation at a borderline age (median 8.2 years), suggesting that *MKRN3* deficiency has a smaller impact on puberty onset in boys than in girls. The median ages of pubertal onset of affected children with MKRN3 mutations from both sexes (girls: 6 years and boys: 8 years), suggest that MKRN3 is not crucial for GnRH suppression after the mini puberty of early infancy, but that its down-regulation plays a relevant role for the reemergence of GnRH pulses in the pubertal phase (Macedo *et al.*, 2014).

To date, >30 different MKRN3 mutations have been described. Notably, two indel mutations, p.Pro161Argfs*10 and p.Pro161Argfs*16, which affect a poly-C region of *MKRN3*, have been recurrent in girls and boys with CPP, suggesting a mutational hot spot codon (Grandone *et al.*, 2017; Macedo *et al.*, 2014). The identification of carriers of *MKRN3* mutations may contribute to early diagnosis of CPP, facilitating treatment decisions and guiding genetic counseling and prompt intervention in familial cases. The very early diagnosis (preclinical) was recently illustrated by the demonstration of a *MKRN3* defect in an asymptomatic 4 year-old girl in a family context who had lately developed premature sexual development (Stecchini *et al.*, 2016). The relative high prevalence of *MKRN3* mutations in familial CPP cases, previously considered idiopathic, has affected the clinical decision in the routine etiology investigation of premature central activation of reproductive axis. It has been suggested that in familial cases, *MKRN3* analysis could precede the brain MRI, which might be postponed in nonmutant cases or even avoided completely in patients with deleterious mutations (Latronico *et al.*, 2016).

Using multiplex ligation-dependent probe assays, no methylation abnormalities assays involving the *MKRN3* or delta-like 1 homolog gene (*DLK1*) loci were identified in CPP patients who were negative for coding region point mutations (Dauber *et al.*, 2017; Macedo *et al.*, 2014). However, defects located outside the target sequences of the methylation-specific probes cannot be ruled out due to technical limitations of the current methylation assays and the high complexity of imprinting center regulation of these two loci.

New Imprinted Gene Implicated with CPP

A very rare and complex genomic defect (~14-kb deletion and 269-bp duplication of *DLK1*) was identified in a large multigenerational family with five female members with CPP using a combination of linkage analysis and whole genome sequencing (Dauber *et al.*, 2017). The deletion included the 5′-untranslated region and the first exon of *DLK1*, including the translational start site. *DLK1* gene is located on the long arm of chromosome 14, within a locus associated with Temple syndrome, and similarly to *MKRN3*, it is a paternally expressed gene (da Rocha *et al.*, 2008). Temple syndrome is a rare genetic condition characterized by intrauterine growth retardation, postnatal short stature, truncal obesity, hypotonia, small hands, mild facial, dysmorphisms, and CPP (Kagami *et al.*, 2017). However, the female patients with CPP associated with isolated *DLK1* defect did not demonstrate any of these features apart from CPP, suggesting a nonsyndromic form (Dauber *et al.*, 2017). The inheritance pattern of the family with isolated CPP also follows that of a paternally expressed imprinted gene consistent with the known imprinting of *DLK1*. The complete loss of *DLK1* in this family affected by CPP was supported by undetectable serum DLK1 levels.

DLK1, also known as preadipocyte factor 1, is a transmembrane protein containing epidermal growth factor-like repeats in its extracellular domain. It is a noncanonical ligand in the Delta-Notch signaling pathway and plays a role in the inhibition of adipocytes differentiation. A neuroendocrine function for DLK1 was suggested by evidence of postnatal *Dlk1* expression in several hypothalamic nuclei and it increased progressively in mice postnatally (from day P6 to P20), correlating with increases in kisspeptin expression (Villanueva *et al.*, 2012). Furthermore, *Dlk1* expression was demonstrated in cell lines derived from kisspeptin neurons in the arcuate and anteroventral-periventricular (AVPV) hypothalamic nuclei (Dauber *et al.*, 2017).

Genome-wide association studies have identified multiple loci associated with pubertal timing. The important role of *MKRN3* and *DLK1* in human puberty initiation was reinforced by large genome-wide studies involving women of European descent. In this comprehensive study, menarche signals were found for paternal inheritance at the imprinted *MKRN3* and *DLK1* loci (Day *et al.*, 2017).

Familial CPP due to paternal *MKRN3* or *DLK1* copy alterations has been considered part of the group of imprinting disorder (Eggermann *et al.*, 2015). Interestingly, these congenital disorders are usually characterized by overlapping clinical features affecting growth, development, and metabolism. Indeed, Temple syndrome displays clinical features overlapping with Prader-Willi and Silver Russell syndromes (Dauber *et al.*, 2017; Kagami *et al.*, 2017). Early or precocious puberty has been described as part of the constellation of clinical features of these imprinted syndromes.

Genetic Basis of CHH

CHH is characterized by partial or complete lack of pubertal development, secondary to deficient GnRH-induced gonadotropin secretion (Boehm *et al.*, 2015). The underlying cause may be associated with developmental defects of GnRH neurons, deficient GnRH production or secretion, or resistance to GnRH action. The clinical diagnosis is confirmed by the presence of low levels of sex steroids associated with low or inappropriately normal LH and FSH serum levels, with no other pituitary hormone deficiencies and lack of an anatomical lesion in the hypothalamic–pituitary tract (Seminara *et al.*, 2000). The association of CHH with olfactory defects (anosmia or hyposmia) characterizes Kallmann syndrome, accounting for approximately 50%–60% of all CHH cases (Boehm *et al.*, 2015). The olfaction defects occur due to combined abnormal embryonic migration of GnRH neurons and olfactory fibers from their origin in the olfactory placode to the forebrain (Soussi-Yanicostas *et al.*, 1998; Wierman *et al.*, 2011). These patients usually present with hypoplasia or aplasia of the olfactory tract/bulbs associated with GnRH deficiency (Quinton *et al.*, 1996). In addition, a number of other developmental abnormalities may be associated with Kallmann syndrome, including cleft lip or palate, dental agenesis, ear anomalies, deafness, renal malformations, bimanual synkinesis, and skeletal anomalies (Mitchell *et al.*, 2011).

CHH is a rare, clinically and genetically heterogeneous condition, with a male predominance of 3–5 to 1. It occurs more commonly in the sporadic form or it may be familial, with X-linked, or autosomal recessive or dominant inheritance (Boehm *et al.*, 2015; Quinton *et al.*, 2001). Kallmann syndrome and normosmic CHH were once thought to be completely distinct conditions. However, in the last decade this paradigm has changed. The starting point for this change was the description of *FGFR1* mutations in both Kallmann syndrome and normosmic CHH patients since 2003 (Dode *et al.*, 2003; Pitteloud *et al.*, 2006a). Before that, only two genes were known to cause CHH: GnRH receptor (GnRHR) mutations in autosomic recessive normosmic CHH, and *KAL1* (recently renamed *ANOS1*) mutations, responsible for about 50% of X-linked Kallmann syndrome (Boehm *et al.*, 2015; de Castro *et al.*, 2017; Seminara *et al.*, 2000). Nevertheless, the majority of cases of CHH remained unexplained and these new findings opened the gates for a new era in the CHH research.

The molecular mechanisms involved in the central regulation of the gonadotropic axis are complex and still not completely understood. Studies of the molecular genetics of CHH and Kallmann syndrome have advanced tremendously in the past 20 years, greatly contributing to increase our knowledge on the mechanisms controlling the GnRH system. In the last few years, the advent of new sequencing techniques, such as parallel sequencing on a large scale, which enabled the study of candidate gene panels, and whole exome sequencing allowed an increase in the molecular diagnosis of patients with CHH from 30% to approximately 50% of cases (Boehm *et al.*, 2015). A growing list of genes has been implicated in the molecular pathogenesis of the CHH, pointing up the heterogeneity and complexity of the genetic basis of this condition. These genes encode neuropeptides and proteins involved in the development and migration of GnRH neurons, or in the control of different stages of GnRH function (**Table 2**).

Table 2 Genes implicated in CHH

Gene	*Locus*	*CHH phenotype*	*Associated clinical features*	*Inheritance*	*Prevalence*
GNRH1	8p21.2	nCHH		Autosomal recessive	Rare
GNRHR	4q13.2	nCHH		Autosomal recessive	6%–16%
KISS1	1q32.1	nCHH		Autosomal recessive	rare
KISS1R	19p13.3	nCHH		Autosomal recessive	2%–5%
TAC3	12q3	nCHH		Autosomal recessive	Rare
TACR3	4q24	nCHH		Autosomal recessive	rare
ANOS1	Xp22.31	KS	Bimanual synkinesia, renal agenesis	X-linked recessive	5%–8%
FGFR1	8p11.23	KS/nCHH	Cleft lip and/or palate, dental agenesis, bimanual synkinesia, skeletal anomalies, hand/foot malformation, septo-optic dysplasia, combined pituitary hormone deficiency, Hartsfield syndrome	Autosomal dominant	10%
FGF8	10q24.32	KS/nCHH	Cleft lip and/or palate, skeletal anomalies Bimanual synkinesia, combined pituitary hormone deficiency	Autosomal dominant	$<2\%$
PROK2	3p13	KS/nCHH		Autosomal recessive	3%–6%
PROKR2	20p12.3	KS/nCHH	Combined pituitary hormone deficiency	Autosomal recessive	3%–6%
CHD7	8q12.2	KS/nCHH	Congenital hearing impairment, semicircular canal hypoplasia CHARGE syndrome	Autosomal dominant	6%
SOX10	22q13.1	KS/nCHH	Congenital hearing impairment Waardenburg syndrome	Autosomal dominant	2%
SEMA3A	7q21.11	KS		Autosomal dominant	Rare
NELF	9q34.3	KS/nCHH		Autosomal dominant	Rare
IL17RD	3p14.3	KS	Congenital hearing impairment	Autosomal recessive	3%
FEZF1	7q31.32	KS		Autosomal recessive	Rare
CCDC141	2q31.2	nCHH		Autosomal recessive	3%
WDR11	10q26.12	KS/nCHH	Combined pituitary hormone deficiency	Autosomal dominant	Rare
FGF17	8p21.3	KS/nCHH	Dandy–Walker syndrome	Autosomal dominant	Rare
HS6ST1	2q14.3	KS/nCHH	Cleft lip and/or palate, skeletal anomalies	Autosomal dominant	Rare
AXL	19q13.2	KS/nCHH		Autosomal dominant	NR
LEP	7q32.1	nCHH	Early onset of morbid obesity	Autosomal recessive	$<2\%$
LEPR	1p31.3	nCHH	Early onset of morbid obesity	Autosomal recessive	$<2\%$
PCSK1	5q15	nCHH	Early onset of morbid obesity	Autosomal recessive	$<2\%$
OTUD4/ RNF216	4q31.21/ 7p22.1	nCHH	Cerebellar ataxia (Gordon–Holmes syndrome)	Autosomal recessive	Rare
PNPLA6	19p13.2	nCHH	Cerebellar ataxia (Gordon–Holmes syndrome) Boucher–Neuhöuser syndrome	Autosomal recessive	Rare
DMXL2	15q21.2	nCHH	Central hypothyroidism, diabetes mellitus, demyelinating polyneuropathy	Autosomal recessive	Rare
NR0B1 (DAX1)	Xp21.2	nCHH + AHC	Adrenal hypoplasia congênita (AHC)	X-linked recessive	Rare
HESX1	3p14.3	KS	Septo-optic dysplasia, combined pituitary hormone deficiency	Autosomal dominant	Rare

nCHH, normosmic congenital hypogonadotropic hypogonadism; KS, Kallmann syndrome.

The genetic causes of CHH have been categorized according to the stage of development of the gonadotrophic axis in which they participate (**Fig. 1**). Genes causing CHH can be broadly classified in genes involved in GnRH synthesis, secretion, or action, and genes implicated in the development and migration of GnRH neurons (Bianco and Kaiser, 2009). The first category includes basically neuropeptide hormones and their receptors, *GNRH1/GNRHR*, *KISS1/KISS1R*, and *TAC3/TACR3*, causing exclusively normosmic CHH (Bianco and Kaiser, 2009). The second category is more complex and includes a range of molecules, in some cases with interconnected functions, which are somehow involved in the GnRH neurons ontogeny and migration (Gonzalez-Martinez *et al.*, 2004b; Lima Amato *et al.*, 2017). The classical example of a gene with a definite role in GnRH and olfactory

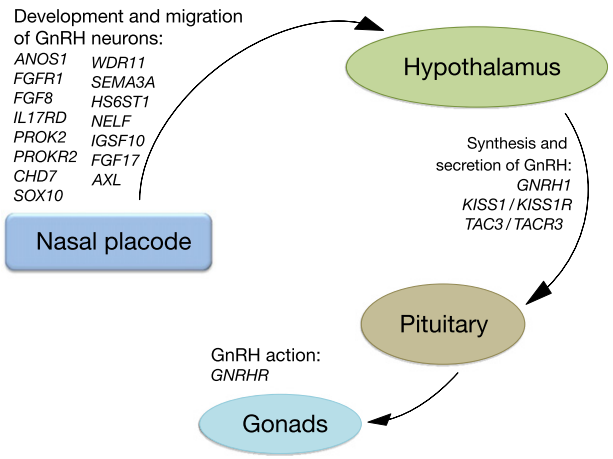

Fig. 1 Genes causing congenital hypogonadotropic hypogonadism (CHH).

neurons migration is *KAL1* (*ANOS1*), which encodes the extracellular matrix glycoprotein anosmin-1. *ANOS1* mutations cause exclusively X-linked Kallmann syndrome, usually with a severe reproductive phenotype (Boehm *et al.*, 2015; Mitchell *et al.*, 2011). This is not the case for other genes later found to influence GnRH neurons migration, which have been described both in normosmic CHH and Kallmann syndrome. These include fibroblast growth factors family and modulators (*FGFR1*, *FGF8*, *FGF17*, *IL17RD*, and *HS6ST1*), *PROK2*/*PROKR2* and other genes more rarely described in CHH (Lima Amato *et al.*, 2017). In addition, genes classically associated with complex syndromes, namely *CHD7* (CHARGE syndrome) and *SOX10* (Waardenburg syndrome), have recently been described in cases of CHH, usually associated with one other feature of the original syndrome, such as deafness, which is part of the Kallmann syndrome phenotypic constellation as well, suggesting an intersection between various clinical disorders and their causative genes (Boehm *et al.*, 2015; Kim *et al.*, 2008a; Pingault *et al.*, 2013).

Studies in large CHH cohorts in the last decade identified patients who harbor pathogenic rare variants in more than one gene, unraveling the concept of digenic or oligogenic inheritance in CHH. Currently, oligogenic cases account for 10%–20% of CHH patients, challenging the traditional Mendelian concept of CHH as a monogenic condition (Quaynor *et al.*, 2011; Sykiotis *et al.*, 2010). Genes more frequently associated with oligogenic inheritance include *FGFR1*, *FGF8*, *KAL1*, *PROKR2*, *PROK2*, *GNRHR*, *KISS1R*, and *NELF* (Quaynor *et al.*, 2011, Sykiotis *et al.*, 2010). Oligogenic inheritance is a possible explanation for the great phenotypic variability observed among some families. Indeed, the same family may present with cases of normosmic CHH, Kallmann syndrome, pubertal delay, or isolated abnormalities such as isolated anosmia or craniofacial malformations (Pitteloud *et al.*, 2007; Sykiotis *et al.*, 2010).

To date, >30 different genes have been associated with Kallmann syndrome and/or normosmic CHH, with different modes of inheritance, some of them with a relative high frequency and others very rarely described (**Table 1**). *ANOS1*, *GNRHR*, *FGFR1*, and *CHD7* are among the genes most commonly involved in the pathogenesis of GnRH deficiency (Costa-Barbosa *et al.*, 2013; Boehm *et al.*, 2015; Mitchell *et al.*, 2011). The main genetic causes of CHH will be explored with some more details in the following sections.

Genes Involved in GnRH Synthesis and Secretion and Action (*GNRH1/GNRHR*, *KISS1/KISS1R*, *TAC3/TACR3*)

This group is composed by hypothalamic–pituitary expressed G-protein coupled receptors and their cognate neuropeptides/hormones ligands, which have a role in GnRH synthesis, secretion, and function, causing exclusively normosmic CHH. Loss-of-function mutations in the receptors are far more common than in the ligands, which may reflect a compensatory effect of other endogenous ligands and all of them present as an autosomic recessive trait (Mitchell *et al.*, 2011). Some CHH patients were found to harbor heterozygous rare variants in some of these genes, but their role in the pathogenesis of GnRH deficiency is still uncertain (Chan *et al.*, 2011; Maione *et al.*, 2013). GnRH receptor (*GNRHR*) inactivating mutations were the first identified genetic cause of normosmic isolated hypogonadotropic hypogonadism (IHH) (de Roux *et al.*, 1997). Since the first description in 1997 (de Roux *et al.*, 1997), >20 different biallelic *GNRHR* mutations have been reported in cases of sporadic or familial normosmic IHH (Beneduzzi *et al.*, 2014; Chevrier *et al.*, 2011). *GNRHR* inactivating mutations are the most frequent cause of normosmic CHH, especially in familial cases (Beneduzzi *et al.*, 2014; Beranova *et al.*, 2001; Chevrier *et al.*, 2011). Conversely, mutations in the *GNRH1* gene, encoding the decapeptide hormone GnRH, which has always been an obvious candidate, are extremely rare (Bouligand *et al.*, 2009; Chan *et al.*, 2009; Mengen *et al.*, 2016).

Loss-of-function mutations of *KISS1R* were first reported in patients with normosmic CHH belonging to large consanguineous families by two independent researcher groups in 2003 (de Roux *et al.*, 2003; Seminara *et al.*, 2003). Since then, several different loss-of-function mutations have been described in the *KISS1R* gene in patients with partial or complete normosmic CHH (Silveira *et al.*, 2010a). These findings helped to elucidate the role of kisspeptin in the control of GnRH secretion, and posterior studies in

animal models confirmed kisspeptin as the main stimulator of GnRH-induced LH secretion (Colledge, 2009; Navarro *et al.*, 2009; Plant and Ramaswamy, 2009; Popa *et al.*, 2008). *KISS1R* mutations are responsible for about 5% of cases of normosmic CHH (Silveira *et al.*, 2010a). On the other hand, *KISS1* inactivating mutations are extremely rare, and were only reported once, in one consanguineous family with four affected women with normosmic CHH (Topaloglu *et al.*, 2012).

Homozygous inactivating mutations in the genes *TAC3* and *TACR3*, encoding neurokinin-B (NKB) and its receptor, respectively, were identified in four unrelated consanguineous families with normosmic CHH, as a fully penetrant autosomal recessive trait Topaloglu *et al.*, 2009). These findings provided compelling evidence that the NKB system is necessary for the activation of the hypothalamic–pituitary–gonadal axis in puberty. After the first description a number of mutations were described in both the homozygous and heterozygous state, but the role of the heterozygous variants is unknown (Gianetti *et al.*, 2010). NKB and dynorphin A (Dyn) are coexpressed in KISS1 neurons (so-called KNDy neurons), in the human mediobasal hypothalamus. Recent studies showed that the regulation of gonadotropin release by the tachykinins and their receptors seems to occur at least partly through actions on KISS1 neurons (Navarro, 2012).

Genes Involved in the Development and Migration of GnRH Neurons

ANOS1

ANOS1 (previously *KAL1*) encodes anosmin-1, an extracellular matrix glycoprotein essential for axonal guidance and migration of olfactory and GnRH neurons from the nasal placode to their final location in the brain (Ballabio and Camerino, 1992; Gonzalez-Martinez *et al.*, 2004a). Mutations in *KAL1* are reported to be present in approximately 5%–10% of all Kallmann syndrome patients and 15%–50% of the familial cases with an X-linked pattern of inheritance (Costa-Barbosa *et al.*, 2013; Mitchell *et al.*, 2011; Salenave *et al.*, 2008). Patients with *KAL1* mutations usually exhibit an almost uniformly severe and highly penetrant reproductive phenotype (Costa-Barbosa *et al.*, 2013, Mitchell *et al.*, 2011, Salenave *et al.*, 2008). Other anomalies frequently associated with X-linked Kallmann syndrome include high arched palate, cleft lip and/or palate, short metacarpals, unilateral renal agenesis, sensorineural hearing loss, bimanual synkinesia, and oculomotor abnormalities (Boehm *et al.*, 2015; Costa-Barbosa *et al.*, 2013).

Fibroblast growth factors family and modulators (FGFR1, FGF8, FGF17, IL17RD and HS6ST1)

Fibroblast growth factors (FGFs) and their cell surface receptors comprise a large and complex family of signaling molecules with a crucial role in embryonic development (Kim *et al.*, 2008b). FGF receptor 1 (FGFR1) signaling is required in normal GnRH neuronal migration, differentiation, and survival within the hypothalamus, and plays an essential role in the morphogenesis of the olfactory bulbs (Gonzalez-Martinez *et al.*, 2004a; Kim *et al.*, 2008b). *FGFR1* defects have been associated with both Kallmann syndrome and normosmic IHH, with an autosomal dominant mode of inheritance (Dode *et al.*, 2003; Pitteloud *et al.*, 2006a; Xu *et al.*, 2007). Currently, *FGFR1* mutations are one of the most common molecular causes of CHH, with or without olfactory defects. Mutations in FGF8, one of the various FGFR1 ligands, were also associated with both normosmic CHH and Kallmann syndrome, but with a much lower frequency than *FGFR1* (Falardeau *et al.*, 2008; Trarbach *et al.*, 2010). *FGFR1* and *FGF8* mutations are associated with marked phenotypic variability both within and among families and apparent incomplete penetrance (Pitteloud *et al.*, 2006b; Shaw *et al.*, 2011; Trarbach *et al.*, 2010; Villanueva *et al.*, 2015). Other phenotypic defects may be associated with mutations in the FGF system, including cleft lip-palate, dental agenesis, and bone defects, such as syndactyly and hand/foot malformation (Pitteloud *et al.*, 2006b; Shaw *et al.*, 2011; Villanueva *et al.*, 2015).

Variants in other genes that encode proteins acting as secondary ligands, cofactors or modulators for FGFR1 signaling were also associated with CHH in rare occasions, including *FGF17*, *IL17RD*, and *HS6ST1* (Miraoui *et al.*, 2013; Tornberg *et al.*, 2011). Particularly, *IL17RD* mutations were identified mainly in Kallmann syndrome patients with hearing loss. Variants in these genes were frequently identified in combination with additional variants in other CHH genes, suggesting synergic role in the pathogenesis of IHH, in an oligogenic trait (Boehm *et al.*, 2015).

PROK2/PROKR2

Prokineticins are cysteine-rich secreted proteins that promote diverse biological functions, including normal development of the olfactory bulb and sexual maturation (Martin *et al.*, 2011). Mutations in Prokineticin2 (PROK2) and its cognate receptor PROKR2, a G-protein-coupled receptor, were initially identified in Kallmann syndrome patients, but later described in normosmic CHH as well (Abreu *et al.*, 2008; Cole *et al.*, 2008; Dode and Rondard, 2013). Today, *PROK2/PROKR2* variants are identified in approximately 5% of all CHH patients in both a homozygous and heterozygous state with incomplete penetrance or variable expressivity frequently seen within and across pedigrees (Abreu *et al.*, 2010; Martin *et al.*, 2011).

Genes Associated with Complex Syndromes

A number of rare complex genetic syndromes, many of them comprising neurologic components, include CHH as one of their constellation of features. Mutations in *POLR3A* and *POLR3B* cause hypomyelinating leukodystrophies associated with dental abnormalities and CHH, with a variable phenotype (4H syndrome). *OTUD4*, *RNF216*, and *PNPLA6* mutations were identified in patients with Gordon Holmes syndrome, characterized by cerebellar ataxia/atrophy and normosmic CHH (Margolin *et al.*, 2013;

Synofzik *et al.*, 2014; Tarnutzer *et al.*, 2015; Topaloglu *et al.*, 2014). Recently, a complex homozygous mutation was identified in the *DMXL2* gene, in three siblings of a consanguineous family, presenting with a neurologic-endocrine syndrome characterized by demyelinating polyneuropathy, CHH, central hypothyroidism, mental retardation, and neonatal hypoglycemia progressing to insulin-dependent diabetes mellitus (Tata *et al.*, 2014). CHH may also be associated with early onset of severe obesity, a phenotype suggestive of loss-of-function mutations in *LEP*, *LEPR*, or *PCSK1* genes. Finally, defects in *DAX1* (*NROB1*) have long been known to cause X-linked adrenal hypoplasia and CHH (Boehm *et al.*, 2015).

Additionally, variants in the causative genes of complex syndromes were identified in cases of CHH alone or associated with only one additional phenotypic feature. This is the case of *CHD7* and *SOX10*.

CHD7 defects cause CHARGE syndrome, a multisystem disorder classically characterized by a variety of congenital anomalies including coloboma, heart defects, choanal atresia, delayed growth and development, genital hypoplasia, ear anomalies, and deafness (Jongmans *et al.*, 2006). Notably, GnRH deficiency and anosmia are consistent findings in this syndrome. In 2008, Kim *et al.* (2008a) reported CHD7 mutations in patients with Kallmann syndrome or normosmic CHH, most of them with hearing loss as the only additional feature. Currently, mutations in *CHD7* are identified in approximately 6% of all CHH patients, more commonly with Kallmann syndrome. However, if we consider only the cases of IHH associated with hearing loss, the prevalence of *CHD7* mutations rises to approximately 40% (Bergman *et al.*, 2012; Boehm *et al.*, 2015; Xu *et al.*, 2017).

Mutations in *SOX10* are a well-known cause of Waardenburg syndrome, characterized by deafness, skin/hair/iris hypopigmentation, Hirschsprung's disease, and neurological defects (Pingault *et al.*, 2013). A high frequency of olfactory-bulb agenesis was recently identified in patients with Waardenburg syndrome, raising the hypothesis that *SOX10* mutations might be involved in the Kallmann syndrome pathogenesis (Elmaleh-Berges *et al.*, 2013). Indeed, *SOX10* mutations were identified in individuals with Kallmann syndrome, almost exclusively associated with hearing loss (Izumi *et al.*, 2015; Maione *et al.*, 2016; Pingault *et al.*, 2013; Suzuki *et al.*, 2015; Vaaralahti *et al.*, 2014).

Other Genes

A growing list of genes has been associated with CHH, including *NELF*, *WDR11*, *SEMA3A*, *SEMA7A*, *AXL*, *FEZF1*, *CCDC141*, and *IGSF10* (Boehm *et al.*, 2015; Howard *et al.*, 2016; Hutchins *et al.*, 2016; Kansakoski *et al.*, 2014; Kim *et al.*, 2010; Kotan *et al.*, 2014; Quaynor *et al.*, 2011; Salian-Mehta *et al.*, 2014; Young *et al.*, 2012). Variants in these genes have been rarely reported in CHH, singly or in combination with defects in other genes.

Epigenetic Mechanisms and Pubertal Development

Epigenetics refers to mitotically heritable post-transcriptional modifications that affect chromatin structure and regulate gene expression, without changing the DNA sequence. These modifications are usually triggered by exposure to the environmental factors, enabling the integration between genetics and environment. Common epigenetic mechanisms include differential DNA methylation and histone post-translational modifications (Bird, 2002; Rzeczkowska *et al.*, 2014).

While monogenic or oligogenic genetic defects are involved in the molecular pathogenesis of rare conditions leading to extreme variations of pubertal development, such as CPP and CHH, the normal variation of pubertal timing may be influenced by more subtle genetic variations, environmental and epigenetic factors. The mechanisms involved in the reactivation of the gonadotropic axis, which triggers puberty initiation, are still poorly understood. The most accepted theories, corroborated by recent evidence, suggest that throughout the quiescent period in infancy, genes that stimulate the GnRH axis activity are repressed, while the inhibitory genes are fully expressed. There seems to be a programmed switch in gene expression involving transcriptional/posttranscriptional processes, allowing an increment in the expression and activity of stimulatory genes. It was only very recently that epigenetic mechanisms were implicated in the neuroendocrine regulation of puberty. Recent studies in animal models have demonstrated a role for epigenetics-mediated mechanisms in the CPP, through an inhibitory modulation of repressors that target kisspeptin pathways, and microRNAs (miRNAs) involved in the control of GnRH secretion (Leka-Emiri *et al.*, 2017; Lomniczi *et al.*, 2013; Rzeczkowska *et al.*, 2014; Tomikawa *et al.*, 2012; Semaan and Kauffman, 2013).

One of the best-studied epigenetic modifications is DNA methylation. It consists in the covalent addition of a methyl (–CH3) group to the fifth position of cytosines, predominantly in cytosine-phosphate-guanine (CpG) dinucleotides. Notably, the study of DNA methylation in the medial basal hypothalamus of male rhesus monkeys revealed an increase in GnRH mRNA levels across puberty that was paralleled by a decrease in CpG methylation status in the 5′ CpG island of *GnRH* gene (Kurian and Terasawa, 2013).

Histones acetylation leads to chromatin de-compactation, allowing the transcriptional machinery to access a gene, usually resulting in an increase in gene expression. Tomikawa *et al.* (2012) demonstrated that estrogen induces recruitment of estrogen receptor-α and histone acetylation in the Kiss1 promoter region of the AVPV, resulting in an increase in the AVPV-specific Kiss1 gene expression. These results indicate that epigenetic regulation of the Kiss1 gene is involved in estrogen-positive feedback to generate the GnRH/gonadotropin surge.

The study by Lomniczi *et al.* (2013) suggested that epigenetic repression of key inhibitory factors plays a fundamental role in the initiation of animal and human puberty. The researchers identified the Polycomb group (PcG) of transcriptional silencers as

major drivers of an epigenetic mechanism of transcriptional repression that regulate the timing of female puberty in rats. PcG proteins Eed and Cbx7 prevent the premature initiation of female puberty by silencing the *Kiss1* gene in kisspeptin neurons of the arcuate nucleus of the hypothalamus. Manipulations of DNA methylation were able to impact the onset of puberty. Inhibiting DNA methylation of PcG proteins promoters, allowing the continued expression of *Kiss1* repressors, resulted in pubertal delay (Lomniczi *et al.*, 2013). In a parallel study, the induction of DNA hypermethylation, inhibiting gene expression, led to earlier onset of puberty, corroborating the previous results (Messina *et al.*, 2016; Rzeczkowska *et al.*, 2014).

Epigenetic Regulation by Non-coding RNAs

Non-coding RNAs (ncRNAs) function to regulate gene expression at the transcriptional and post-transcriptional level. Some ncRNAs appear to be involved in epigenetic processes. They are shown to play a role in heterochromatin formation, histone modification, DNA methylation targeting, and gene silencing. miRNAs are one of the subtypes of ncRNAs related to epigenetic. miRNAs generally bind to a specific target messenger RNA with a complementary sequence to induce cleavage, or degradation or block translation. This may be done in the context of a feedback mechanism that involves chromosome methylation (Sato *et al.*, 2011).

New findings indicate that a miRNA-dependent mechanism regulates GnRH production to control puberty timing. Messina *et al.* (2016) demonstrated that increasing miRNAs that regulates the expression of *Zeb1* and *Cebpb*, two repressors of Gnrh transcriptional activators, and Gnrh itself in infantile mice lead to pubertal delay. Conversely, mice injected with target site blockers specific for these miRNA underwent early onset of puberty (Messina *et al.*, 2016).

Conclusion

Puberty is a major developmental stage. In the last two decades, several human genetic mutations have contributed to the unraveling of the complex networks implicated in the normal initiation of puberty. Genes involved in the abnormal hypothalamic–pituitary–gonadal axis development have been identified, leading to identification of inhibitory, stimulatory, and permissive factors acting upstream on GnRH neurons, integrating diverse hormonal and peripheral signals and acting as the "gate-keepers" of puberty initiation.

Hormonal Control of Puberty

Lindsey A Loomba-Albrecht and Dennis M Styne, University of California Davis, Davis, CA, United States

Introduction

The hormones that cause pubertal development and reproduction emanate from the adrenal glands and the hypothalamic–pituitary–gonadal axis. Adrenarche describes the pubertal increase in adrenal androgen production. Gonadarche refers to the pubertal increase in gonadal steroids, and results from the pubertal reactivation of the hypothalamic–pituitary–gonadal axis. Gonadarche typically follows adrenarche, though the two processes are controlled separately. Gonadotropin-releasing hormone (GnRH) is secreted in pulsatile fashion from the mediobasal hypothalamus into the hypophyseal portal vascular system to reach the anterior pituitary gland. There, it stimulates secretion of gonadotropins (luteinizing hormone (LH) and follicle-stimulating hormone (FSH)) from the pituitary gonadotrophs. The gonadotropins in turn stimulate the synthesis and secretion of gonadal steroids, leading ultimately to an increase in height velocity, the development of secondary sexual characteristics, and the other physical changes of puberty. The maturation of the hypothalamic–pituitary–gonadal axis and the process of puberty is part of an ongoing process that begins during fetal development and ends with the completion of sexual maturation.

Hypothalamic–Pituitary–Gonadal Axis

Fetal Development

GnRH secreting neurons within the arcuate nucleus of the hypothalamus act in a coordinated manner to transduce neural signals into pulsatile GnRH release (the GnRH pulse generator). These neurons demonstrate spontaneous autorhythmicity and function like an oscillator in the pulsatile release of GnRH. Increased cyclic AMP (cAMP) levels have been shown to stimulate GnRH release via activation of cAMP gated channels; channel activation is associated with calcium oscillations (Vitalis *et al.*, 2000; Weiner and Charles, 2001). The GnRH secreting neurons arise in the olfactory placode of the nose and migrate to the hypothalamus (Wray *et al.*, 1989). Abnormal migration of the GnRH neurons leads to delayed or absent pubertal development due to hypogonadotropic hypogonadism (for example type 1 Kallmann syndrome), with anosmia or hyposmia in various forms (Schwanzel-Fukuda *et al.*, 1989).

GnRH cells are detected in the olfactory placode by 5.5 weeks gestation and in the fetal hypothalamus by 9 weeks gestation (Schwanzel-Fukuda *et al.*, 1996; Verney *et al.*, 1996; Terasawa and Fernandez, 2001). The hypothalamic-hypophyseal portal system is functional by 12 weeks gestation. Overall functionality of the GnRH pulse generator occurs by at least the end of the first trimester (Terasawa and Fernandez, 2001). Prior to this, the fetal testes secrete testosterone under the stimulation of placental human chorionic gonadotropin (hCG), which shares a receptor with LH. Thereafter, Leydig cells in the fetal testes depend on LH as a stimulus to make testosterone.

The fetal pituitary gland begins secreting FSH and LH by 11–12 weeks of gestation; by midgestation, gonadotropin levels are high in both sexes. LH and FSH levels in the male fetus are lower than in the female, likely due to negative feedback from testosterone secreted from the fetal testes (Grumbach *et al.*, 1974). Gonadotropin levels decline in late gestation, likely due to the further development of the negative feedback mechanism (including the development of receptors for gonadal steroids in the hypothalamus and pituitary). In both male and female fetuses and at term, estrogen levels are high due to conversion of fetal and maternal adrenal androgens (DHEA and androstenedione) to estrogen by the placenta. The predominant estrogen produced by the placenta is estriol.

Infancy and Childhood

Estrogen levels drop sharply after birth. The newborn hypothalamic–pituitary axis is thus released from estrogen inhibition and gonadotropins increase in both amplitude and frequency. In infant boys, these LH pulses result in increased testosterone levels; in infant girls, the FSH pulses lead to increased estradiol. The striking sex difference in gonadotropin pulses (with infant females having much higher FSH pulses and infant males having much higher LH pulses) has been attributed to the in utero exposure to testicular testosterone in the male fetus, which may act to prime the hypothalamic–pituitary–gonadal axis according to some.

The resultant increase in gonadal steroid secretion represents what is called the postnatal surge or "mini-puberty of infancy." In infant boys, testosterone levels reach a peak approximating pubertal values around 3 months of age and then decline to prepubertal levels by 6–9 months (Grumbach and Kaplan, 1990; Andersson *et al.*, 1998; Forest, 1990). In girls, increased estrogen levels are seen intermittently during the 2 years of life. Though the purpose of the postnatal surge is incompletely understood, high gonadotropin levels are associated with a rapid expansion of the Sertoli cell population and increases in Leydig and germ cell

numbers. Infant boys may have testosterone levels in the mid-pubertal range during this time period. The decline in testosterone toward the end of the postnatal surge in males is associated with the decline in testicular cell populations (via apoptosis).

After the postnatal surge of increased LH and FSH secretion, there follows a long period (roughly 10 years) of quiescence of the pituitary gonadotropin–gonadal axis. During this time period, referred to as the prepubertal period or "juvenile pause," there is active inhibition of the hypothalamic pulse generator. Negative feedback from sex steroids and inhibin may contribute to this inhibition, but an intrinsic gonadal steroid independent CNS mechanism appears to play a greater role. Notably, gamma-amino butyric acid (GABA), the dominant CNS inhibitory neurotransmitter, has been shown to inhibit the hypothalamic pulse generator (Terasawa and Fernandez, 2001; Mitsushima *et al.*, 1994). As puberty approaches, this GABA inhibition diminishes and GnRH release increases. How various genes may affect GABA inhibition or further control the juvenile pause is not fully understood. However, the MKRN3 gene (encoding makorin RING-finger protein 3) has been identified as an important regulator of pubertal development. MKRN3 is an imprinted gene located on chromosome 15q11.2 which acts to inhibit GnRH secretion during the juvenile pause; the maternal allele is suppressed and only the paternal allele is expressed. A loss of function mutation of MKRN3 in the paternal allele leads to deficiency of MKRN3 and autosomal dominant central precocious puberty (Abreu *et al.*, 2013). More recently, defects in DLK1, a paternally expressed gene on chromosome 14, have also been associated with isolated central precocious puberty (Dauber *et al.*, 2017).

Endocrine activity of the hypothalamic–pituitary–gonadal axis begins increasing in the peripubertal period, before the physical changes of secondary sexual development are apparent. Increased amplitude of LH and FSH pulses (demonstrated by ultrasensitive gonadotropin assays) is demonstrated in most children in midchildhood (Mitamura et al., 1999, 2000). LH secretion in early pubertal boys exhibits diurnal rhythm with augmentation of pulse amplitude following nocturnal sleep onset (Wu et al., 1989, 1996; Boyar *et al.*, 1974; Jakacki *et al.*, 1982). Prior to puberty, these low amplitude and low frequency pulses are unable to activate gonadal function. As puberty progresses, there is continued augmentation of the LH pulses. The full adult pattern, whereby there is no sleep-wake difference in LH pulse amplitude, does not occur until adulthood (Wu *et al.*, 1996).

A diurnal rhythm of testosterone secretion also exists in peripubertal boys whereby testosterone declines gradually in the early part of the night, followed by a postmidnight increase reflecting the nocturnal onset of LH pulsatility (Crofton *et al.*, 2004). Peak levels of serum testosterone are reached in the early morning, with lowest values in the late evening. The lag time of 60 min between the peak of LH and the increase in testosterone is presumably due to time required for synthesis and secretion of the steroid hormone (Veldhuis *et al.*, 1987). In prepubertal girls, a diurnal rhythm of testosterone is also seen with augmentation in the early morning. Estradiol has a diurnal rhythm as well, with higher values in the early morning in late prepubertal and early pubertal girls (Mitamura *et al.*, 2000).

Puberty

The onset of puberty is marked by an increase in amplitude of secretory events. As puberty approaches, inhibition of the GnRH pulse generator wanes and GnRH pulses increase in amplitude. Though the "switch" that triggers the onset of puberty is unknown, neurostimulatory factors increase during early puberty, including glutamate and kisspeptin. Kisspeptin is a critical stimulatory factor for GnRH secretion and onset of pubertal development. Inactivating mutations in the kisspeptin receptor (KISS1R, previously GPR54) are associated with hypogonadotropic hypogonadism and pubertal delay (de Roux *et al.*, 2003; Seminara *et al.*, 2003). Alternately, a mutation in the gene encoding kisspeptin (KISS1) leading to prolonged kisspeptin effect has been found in a young male with central precocious puberty (CPP) (Silveira *et al.*, 2010). An autosomal dominant KISS1R mutation causing prolonged activation of intracellular signaling pathways in response to kisspeptin is also associated with CPP (Teles *et al.*, 2008).

In response to higher amplitude pulses of GnRH, the amplitude of gonadotropin pulses increases and increased daytime secretion of LH and FSH occurs. The frequency of pulses increases somewhat as well; this may contribute to the priming of the gonadotropes, making them more sensitive to pulses of GnRH (Wu *et al.*, 1996). Increasing pituitary responsiveness to GnRH can be demonstrated pharmacologically by administration of exogenous GnRH; exogenous GnRH is relatively ineffective in stimulating gonadotropin or gonadal steroid secretion prior to puberty but becomes effective after pubertal onset. If gonadotrophs are exposed to continuous rather than episodic GnRH, the GnRH receptors are downregulated with decreased responsiveness to GnRH. This phenomenon is utilized when GnRH agonists are employed to treat central precocious puberty.

During puberty, urinary FSH rises fivefold in both sexes. In girls, FSH rises in the early stages of puberty whereas LH rises in the later stages. Urinary LH rises 100-fold in girls and 50-fold in boys; the rise in first morning voided urinary luteinizing hormone levels precedes the physical onset of puberty (Demir *et al.*, 1996). Qualitative changes in gonadotropins occur in addition to these quantitative ones; FSH and LH variations affect biologic activity and half-life and provide an additional regulatory mechanism (Olivares *et al.*, 2004). Though secretion of FSH and LH are always pulsatile (due to pulsatility of the GnRH pulse generator), pulsatility of FSH secretion is less prominent than that of LH. This is attributed in part to the longer half-life of FSH compared with LH, to differences in the factors that modulate the action of GnRH on FSH and LH release by the gonadotrophs (especially gonadal steroids and regulatory proteins such as inhibin), and to intrinsic differences in the secretory pattern of the two gonadotropins.

In boys, circulating LH activates membrane-bound Leydig cell receptors to stimulate testosterone secretion. The enzyme 5-alpha reductase in certain tissues converts testosterone to dihydrotestosterone (DHT), which is a more potent activator of the androgen receptor. The testes additionally secrete other sex steroids, including androstenedione, delta-5-androstenediol, dihydrotestosterone and estradiol, in lesser amounts. Testosterone rises throughout puberty with the steepest increase in testosterone

levels occurring between pubertal stage 2 and 3. In boys, FSH supports spermatogenesis by binding to the FSH receptor on the cellular membrane of the seminiferous tubules. Estrogen in males is made from conversion of androgens (testicular and adrenal) by the enzyme aromatase. In all stages of puberty, boys have lower estrogen levels than girls. Males have higher concentrations of estrone (E1) than estradiol (E2); most of the circulating E1 is derived from peripheral aromatization of androstenedione (mainly originating from the adrenal gland).

In girls, extraglandular conversion of ovarian and adrenal androstenedione gives rise to nearly all of the circulating testosterone. FSH binds to cell-surface receptors on ovarian follicular cells to influence follicular development and stimulate secretion of estrogen. Nearly all estradiol in the female is produced by the ovary; a small fraction (less than 10%) of circulating estradiol arises from the extraglandular conversion of testosterone and androstenedione by aromatase. Girls have higher estradiol concentrations than boys prior to puberty, with a rise through puberty until the pubertal growth spurt and a decrease thereafter. The higher estrogen levels in girls may be an important factor in the more advanced levels of skeletal maturation in girls compared with boys.

In prepubertal girls, small amounts of estrogen will suppress gonadotropin secretion. Early in the menstrual cycle, estrogen has an inhibitory effect on FSH and LH secretion. After mid puberty, estrogen can either stimulate or suppress gonadotropin release, depending on the estrogen level and pattern. The onset of positive feedback (whereby higher amounts of estrogen can stimulate GnRH and gonadotropin release) occurs at midcycle once the ovarian follicle is of adequate size to produce sufficient estrogen and the pituitary has sufficient readily releasable LH to cause an LH surge. The LH surge stimulates prostaglandin, which causes an inflammatory response in the dominant follicle that leads to ovulation. The corpus luteum then forms from the remnants of the dominant follicle; it produces progesterone which prepares the endometrium for implantation and pregnancy. The increased estrogenic activity of the midcycle ovary stimulates growth of the endometrium, but the decrease in estrogen and progesterone toward the end of the menstrual cycle leaves the hyperplastic endometrium with no endocrine support. This, in addition to the local action of prostaglandins and constriction of arterioles, leads to necrosis of the endometrium and the onset of menses.

FSH Regulatory Proteins: Inhibin, Activin, and Follistatin

Inhibin, produced by multiple tissues including the ovarian granulosa cells and testicular Sertoli cells, suppresses FSH secretion from the pituitary gland. With gonadal failure, FSH is markedly elevated compared to LH due to the lack of FSH inhibition by inhibin and gonadal steroids. Inhibin is composed of an α-subunit and one of two β-subunits, β_A or β_B; production of inhibin is stimulated by FSH.

Inhibin B rises twice during male development, reflecting the two periods of Sertoli cell proliferation in infancy and in early puberty. In the early stages of puberty, inhibin B values have a close positive relationship to LH and testosterone levels and increase with pubertal progression. In stage G3, when inhibin B values peak, this relationship is lost, and inhibin B values become inversely related to FSH levels (Chada et al., 2003a; Crofton *et al.*, 2002). This relationship with FSH persists into adulthood. During childhood, inhibin B is a useful diagnostic marker for the presence and function of Sertoli cells. Undetectable or low inhibin B levels are observed in boys with absent testicular tissue whereas normal levels are seen with cryptorchidism. In adult men, inhibin B production is dependent on the presence of Sertoli cells and germ cells in the seminiferous tubules, and serum inhibin B levels are closely related to spermatogenesis. In girls, serum levels of inhibin A and B increase in early puberty and there is a strong positive correlation between inhibin B and FSH and estradiol early in puberty. After pubertal stage II, these relationships diminish (Chada et al., 2003b). Inhibin B is predominant in the follicular phase, and inhibin A is predominant during the luteal phase.

Activin is a closely related protein complex and acts in an opposing manner to inhibin to stimulate FSH synthesis and secretion from the pituitary. Like inhibin, follistatin also inhibits FSH expression and therefore is an additional regulator of FSH biosynthesis and secretion.

Serum values of FSH regulating proteins follow circadian patterns. Diurnal variation of inhibin B in peripubertal and early pubertal boys occurs with a decline in inhibin levels during the night as LH and testosterone levels rise, showing the negative feedback effect of testosterone on inhibin B secretion (Crofton *et al.*, 2004). Follistatin concentrations are greatest in the morning, and activin concentrations decline coincident with the nighttime increase in FSH levels in pubertal girls (Foster *et al.*, 2005).

Antimüllerian Hormone

Antimüllerian hormone (AMH), a glycoprotein produced by the Sertoli cells, acts ipsilaterally in a paracrine manner to cause regression of the Müllerian ducts in boys during early fetal development. AMH values rise from birth to relatively high levels during the first year of life in males. Levels remain stable in early childhood (with a modest late prepubertal peak), and then decline during puberty (Jeffery *et al.*, 2015). Newborn females have low or nondetectable serum levels of AMH, which rise only slightly thereafter. As with boys, there is a modest late prepubertal peak, (with a slight increase between ages 6 and 10 years), after which levels return to baseline low levels (Jeffery *et al.*, 2015). As with inhibin B, AMH can be used as a laboratory marker of Sertoli cell presence and function in young males. Boys with isolated cryptorchidism have normal values of AMH, whereas levels are absent in anorchia. Dysgenetic testes secrete only low serum AMH levels. Another indication of the presence of functional testicular tissue is a rise in testosterone in response to hCG, which only occurs if testicular tissue is present. AMH is additionally a

useful gonadal tumor marker because values are elevated in males with primitive Sertoli-like tumors and in girls and women with granulosa cell tumors.

Leptin

Leptin is a polypeptide hormone which acts to suppress appetite and regulate energy expenditure. It is secreted primarily by adipose cells and circulating leptin levels correlate with total fat mass. Leptin has additional importance in the function of the hypothalamic pituitary gonadal axis and is a permissive factor for the onset of puberty. Leptin is secreted in a pulsatile fashion, with peak levels seen at night. Leptin levels increase gradually during childhood; in prepubertal boys and girls, leptin levels are similar (Clayton *et al.*, 1997; Blum *et al.*, 1997). During puberty, leptin levels rise in females and decline in males and thus a sexual dimorphism arises in which in leptin levels reflect differential changes in body composition (Ahmed *et al.*, 1999).

Homozygous mutations in the leptin gene or leptin receptor lead to absent gonadotropin secretion and hypogonadotropic hypogonadism (as well as morbid obesity due to lack of satiety) (Ozata *et al.*, 1999; Clement *et al.*, 1998). Leptin replacement in an adolescent female with congenital leptin deficiency led to the onset of gonadotropin secretion and the onset of menses (von Schnurbein *et al.*, 2012). A critical level of leptin and a leptin signal is necessary for pubertal onset, but a rise in leptin is not required to trigger puberty and leptin administration alone will not cause a normal prepubertal individual to enter puberty. Women with hypothalamic amenorrhea are energy deficient and have low leptin levels and loss of leptin diurnal rhythm. Treatment with replacement doses of leptin results in increases in gonadotropins and estradiol and restoration of menses in these women (Chou *et al.*, 2011).

Laboratory Testing

In the past, baseline assays for LH and FSH were not sensitive enough to accurately predict the onset of puberty. However, modern assays are now reported to predict the onset of pubertal development as well as GnRH testing does. A value of serum LH greater than 4 mIU/mL measured by immunochemiluminometric (ICMA) assay is consistent with the onset of puberty. Likewise, older techniques for determination sex steroid levels in children have been shown to be inaccurate. This inaccuracy is primarily due to the presence of interfering substances and the relative insensitivity of antibodies used in assays. High performance liquid chromatography tandem mass spectrometry, or HPLC-MS/MS, allows the accurate measurement of extremely low values present in pediatric samples; it is now the preferred method to measure gonadal steroids in children (Wang *et al.*, 2004; Taieb *et al.*, 2003; Albrecht and Styne, 2007). A human cell bioassay measuring total estrogenic bioactivity (rather than estradiol alone) in children also has an extremely sensitive detection limit (of less than 1 pg/mL) (Paris *et al.*, 2002).

As previously discussed, both sex steroids and gonadotropins are secreted in a diurnal rhythm in early puberty. Because sex steroids are bound to sex hormone-binding globulin (SHBG), the half-life of sex steroids is longer than that of gonadotropins. Thus, random daytime measurement of serum sex steroids is more helpful in determining pubertal status than random measurements of serum gonadotropins.

The measurement of sex steroid levels in saliva has theoretical advantages over serum measurements, particularly in children. However, salivary levels are much lower than serum levels (roughly 2%–3%), raising concern that the salivary levels of sex steroids may be too low to accurately detect (particularly using standard assays and in patients with already low levels such as women and children). Furthermore, many factors have the potential to affect salivary levels of testosterone measured by immunoassay. Trauma such as tooth brushing that leads to blood in the specimen can influence the results, as can oral bacterial load and the presence of certain collection materials. Despite what is often claimed, the steroid level in saliva is not a direct representation of free steroid in the serum.

Adrenarche

Adrenarche denotes the pubertal increase in adrenal androgens and occurs prior to the onset of increased gonadotropin secretion. There is usually coordination between gonadarche and adrenarche, but control for each is distinct and the age at adrenarche does not significantly influence age at gonadarche. A continued rise in adrenal androgen secretion persists until early adulthood; levels then decline throughout adulthood to roughly 20% of peak levels. Physical signs of adrenarche include pubic and axillary hair development, axillary odor and acne. The appearance of pubic hair caused by adrenarche is referred to as pubarche.

Though the trigger for adrenarche is unknown, there is an increase in the size of the zona reticularis associated with an increase in the major adrenal androgens dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione. DHEAS is produced from DHEA by the action of the sulfotransferase enzyme SULT2A1, mainly in the adrenal glands and the liver. Adrenal androgens are relatively weak androgens that are converted to more potent ones such as testosterone and dihydrotestosterone (DHT) or to estrogens via aromatization. Plasma DHEA levels have a diurnal rhythm similar to that of cortisol, but plasma levels of DHEAS show less variation and are a useful biochemical marker of adrenarche.

Most patients with premature adrenarche, who secrete excessive amounts of adrenal androgens for their age, enter puberty and experience menarche within the normal age range. Moreover, prepubertal children who have congenital or acquired chronic

adrenal insufficiency (such as Addison's disease) and consequently have deficient or absent adrenal androgen secretion usually have a normal onset and normal progression through puberty.

Other Changes at Puberty

Prolactin

Prolactin is a peptide hormone released from the anterior pituitary gland which plays a critical role in stimulation of the mammary glands and lactation. The serum concentration of prolactin increases in normal female puberty but is not affected by male puberty. This sex difference is probably a consequence of the higher estradiol levels during puberty in girls and in women.

Growth Hormone

Rising levels of estradiol during puberty play a critical role in stimulating growth hormone production. Growth hormone is a major regulator of linear growth, and works primarily by increasing insulin like growth factor-1 (IGF-1) levels. IGF-1 has growth-promoting effects on many tissues throughout the body, including cartilage, bone, and skeletal muscle.

Sex Hormone-Binding Globulin

Between 97% and 99% of circulating testosterone and estradiol is reversibly bound to carrier proteins, including sex hormone-binding globulin (SHBG) (i.e., sex steroid–binding globulin or testosterone binding globulin, TeBG). These carrier proteins play an important role in regulating the transport and biological activity of the sex steroids. Only a small percentage (1%–2%) of circulating sex steroids are unbound; historically it has been assumed that only the unbound portion is biologically active, though this now appears to be an oversimplification (Goldman *et al.*, 2017).

Prepubertal levels of SHBG are approximately equal in boys and girls. At puberty, levels decline in both sexes but the decline is greater in males (Pinkney *et al.*, 2014). The difference between genders is likely due to differences in androgen levels as androgens are known to suppress SHBG levels (Garces *et al.*, 2010). The rise in adrenal androgen levels at adrenarche may explain the early drop in SHBG levels, which allows more circulating free hormone at a given concentration of testosterone. Estrogen has the opposing effect and leads to higher SHBG levels; SHBG values in adult woman are thus higher than in adult men. Although the plasma concentration of testosterone is 20 times greater in men than in women, the concentration of free testosterone is 40 times greater.

Prostate-Specific Antigen

Prostate-specific antigen (PSA) has been used as a biochemical marker in the diagnosis and monitoring of patients with prostate cancer. In children, PSA is produced by periurethral glands and by rectal glands (Diamandis and Yu, 1997; Frazier *et al.*, 1992); in adult men, the major source is prostatic epithelial cells. PSA values are measurable in prepubertal children by a highly sensitive assay; levels do not differ significantly between boys and girls until roughly the age of 12 years (Antoniou *et al.*, 2004). The significant increase of PSA in boys after this age likely reflects the increase in prostate gland volume caused by androgenic stimulation. PSA values are increased to the pubertal range in boys with idiopathic CPP, and decrease with GnRH agonist treatment.

Conclusion

The changes in gonadotropin secretion that occur at puberty do not arise de novo but are based upon preexisting patterns of endocrine secretion. In fetal life, GnRH secreting neurons in the hypothalamus develop function as an endogenous pulse generator. This pulse generator operates at a relatively low level in the prepubertal period (with the exception of a neonatal surge in activity), due to active inhibition. The inhibitory restraints are largely mediated by GABA, but steroid dependent factors also play a role. Prior to puberty, there is a waning of inhibition of the pulse generator and an increase in neuro-stimulatory factors, and GnRH pulses increase in amplitude. These pulses result in increasing amplitude of gonadotropin pulses, initially at night associated with sleep and then during both the night and day. As puberty progresses, increasing levels of gonadal steroids and their resulting effects are seen. Adrenarche is controlled separately from gonadarche and typically precedes it. A variety of other hormonal and metabolic changes, often resulting from the increasing levels of gonadal steroids, occur during the pubertal time period as well.

Abbreviations

AMH	Anti-Müllerian hormone
AR	Androgen receptor
BCERP	Breast Cancer and the Environment Research Program
BMI	Body mass index
EDC	Endocrine disrupting chemical
FSH	Follicle stimulating hormone
GnRH	Gonadotropin-releasing hormone
HPG-axis	Hypothalamic–pituitary–gonadal axis
LH	Luteinizing hormone
NHANESIII	Third National Health and Nutrition Examination Survey
PP	Precocious puberty
PROS	Pediatric Research in Office Settings

Glossary

Adrenarche Development of the inner zone in the adrenal cortex resulting in increased secretion of androgens.

Gaussian distribution Symmetrical, bell-shaped sample distribution about the mean.

Gonadarche The first gonadal changes in response to the onset of puberty. In boys, testicular enlargement is the first sign to appear. In girls thelarche is often the first sign of pubertal onset.

Menarche The occurrence of the first menstruation in a pubertal girl.

Pubarche Development of pubic hair.

Secular trend Changes over an extended period.

Spermarche Onset of the release of spermatozoa (spermarche) in boys.

Thelarche The onset of breast development.

Introduction

Puberty is a central milestone in human reproductive life marking the transition from childhood to adulthood. The physiological changes in this period lead to the attainment of full reproductive capacity. Secular changes in the timing of puberty have occurred virtually worldwide (Sørensen *et al.*, 2012). In both girls and boys, a gradual decline of age at pubertal onset has been reported throughout the last century (Aksglaede *et al.*, 2008).

Secular changes are important, not only from an individual point of view, but also at the population level, since early puberty is associated with adverse and potentially preventable long-term health outcomes, like type 2 diabetes and cardiovascular disease (Day *et al.*, 2015). Despite a strong genetic component behind the pubertal timing, other factors like nutritional status, socioeconomic status, stress, and environmental factors all seem to play a role for the timing of puberty. Apart from genetic factors, all the above-mentioned factors have been subject to changes during the 20th century and could therefore potentially be involved in the secular changes in timing of puberty.

Physiology of Normal Puberty and Variation in Timing

Puberty is the result of a complex process initiated by the hypothalamus integrating signals from different systems. It is linked to the development of secondary sexual characteristics, the pubertal growth spurt and results in the attainment of adult reproductive capacity.

The advent of puberty is marked by the re-emergence of hypothalamic–pituitary–gonadal (HPG) hormone activity axis after a period of relative quiescence during childhood. The pulsatile gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus stimulates the release of gonadotropins from the pituitary which in turn stimulates sex steroid production and initiates gonadal maturation (**Fig. 1**).

The development of the secondary sexual characteristics is induced by the activation and maturation of the gonads and subsequent sex steroid production (*gonadarche*) accompanied by an increase in the production of adrenal hormones (*adrenarche*). Follicle-stimulating hormone (FSH)-driven ovarian activation in girls results in estradiol production which stimulates the development of secondary sexual characteristics including growth of glandular breast tissue, uterus, and endometrial tissues. Testicular activation in boys results in maturation and enlargement of the testicles, which is primarily due to FSH-driven growth of the seminiferous tubules. Furthermore, Luteinizing hormone (LH)-driven testosterone secretion results in development of secondary sexual characteristics including penile enlargement and development. Gonadotropins affect differentiation and maturation

 doi:10.1016/B978-0-12-801238-3.66138-X

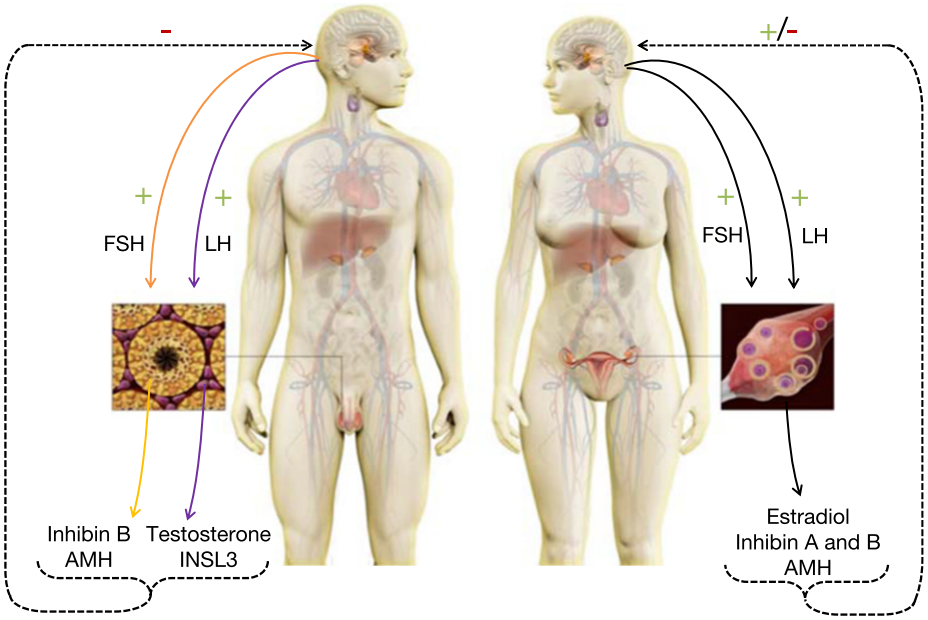

Fig. 1 At the onset puberty, the release of LH and FSH from the anterior pituitary gland stimulates the gonads to produce sex hormones in both male and female adolescents. In the male, FSH stimulates the Sertoli cells to produce Inhibin B, whereas AMH (Anti-Müllerian Hormone) secretion decreases with the onset of puberty (when Sertoli cells differentiate and start to express AR). LH stimulates the Leydig cells to produce testosterone and INSL3 (Insulin-Like Factor 3). The hormones produced in the testicles regulate the release of FSH and LH from the pituitary gland by negative feedback mechanism. In the females, FSH and LH stimulate the ovaries to produce Estradiol, Inhibin B, whereas Inhibin A is secreted following ovulation in the luteal phase of menses. AMH is secreted from small follicles and represent a marker of the follicle pool. These hormones regulate the release of FSH and LH from the pituitary gland by both positive and negative feedback mechanisms.

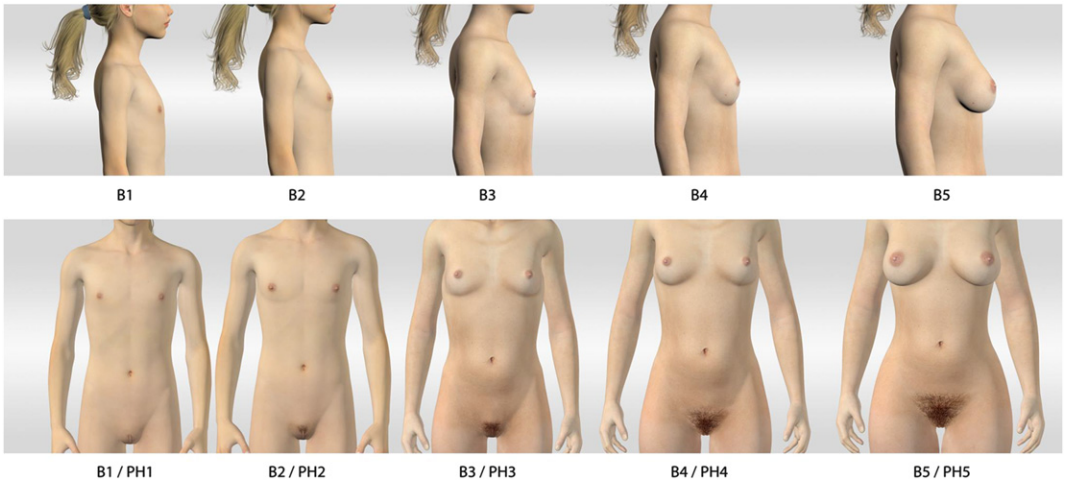

Fig. 2 Tanner scale, breast (B1–B5) and pubic hair scale (PH1–PH5) in girls (Copyright Claus Lunau A/S and Rigshospitalet, Copenhagen).

of spermatogonia and initiate spermatogenesis, which ultimately results in sperm production in boys. The first ejaculation of sperm, termed *spermarche*, occurs at an average age of 14 years, and is considered the male equivalent to the first menstruation (*menarche*) in girls.

With normal ranges from 8 to 13 years in girls and 9 to 14 years in boys for these clinical hallmarks, timing of puberty onset in the human exhibits a large variation between individuals (Parent *et al.*, 2003).

Pubertal stages are determined according to the *Tanner scale* (Marshall and Tanner, 1969, 1970). The scale defines five distinct developmental stages.

In girls, the important pubertal milestones, measured by the Tanner scale, are breast development (stages B1 (prepubertal) to B5) and pubic hair development (stages PH1 (no hair) to PH5) (**Fig. 2**). In girls, the initial pubertal milestone is thelarche (Tanner

scale, stage B2), whereas menarche is a late pubertal phenomenon that usually occurs 2–3 years after pubertal onset, while the attainment of a regular pattern of ovulatory cycles occurs even later.

In boys, signs of androgen action including penile growth and reddening of the scrotal sack are evaluated and grouped according to the Tanner scale, genital stages (stages G1 (prepubertal) to G5), and the development of pubic hair (stages PH1 (no hair) to PH5). Genital and pubic hair stages as well as testicular volume are the pubertal milestones evaluated in boys (**Fig. 3**). In boys, the first clinical sign of pubertal onset is the growth of testicles. The size of the testicles can be measured by using either a Prader orchidometer or ultrasonography. A ruler can also be used to measure the testicular size. A testicular volume enlargement of >3 mL measured by orchidometry defines pubertal onset in boys. The pubertal increase in testicular volume coincides with increasing penile size and other signs of androgenization. Voice break, peak height velocity and spermarche represent late pubertal phenomena in boys occurring approximately 3 years after pubertal onset.

In both sexes the production of adrenal androgens result in the development of pubic hair, which in addition is stimulated by the simultaneous gonadal testosterone production. Thus, the appearance of pubic hair is not exclusively dependent on the activation of the HPG-axis and can be observed in children without other signs of puberty.

Secular Trends in Puberty Timing in Girls

The change of age at puberty timing in girls over the past centuries is well documented. Historical data from Europe and the US have shown that *age at menarche* has drastically decreased from approximately 17 years around year 1850 to 13 years in 1970 (**Fig. 4**). In the period from the 1960s to 2010 the age at menarche appears to have only decreased slightly and then leveled off (Sørensen *et al.*, 2012).

Although much fewer studies exist on *age at thelarche* the studies to date show a marked decline in age at onset during the last 20–30 year period. This tendency is shown in **Fig. 5**, and highlighted by selected longitudinal studies from USA (red), Denmark (pink), and the Netherlands (brown-green). In Denmark, the age at onset of thelarche has decreased to about 10 years in the period 2005–06 when compared to the other temporally earlier data points, where the age was approximately 11 years (**Fig. 5**).

Given the dissociation of age at thelarche and age at menarche, the length of the pubertal transition (from thelarche to menarche) appears to have become longer (Aksglaede *et al.*, 2009).

Since the 1980s, different studies reporting ages at thelarche and menarche in the US, have indicated a new secular trend in puberty timing in girls (**Table 1**). In this article three selected large studies from the US and one from Denmark are included.

The first study from the US was based on data from the Third National Health and Nutrition Examination Survey (NHANES III) (Wu *et al.*, 2002) within the period 1988–94. The study included 1623 participants subdivided into three groups according to their ethnicity (White non-Hispanic, Black non-Hispanic or Mexican American). Whilst the second was based on the Pediatric Research in Office Settings network (PROS) (Herman-Giddens *et al.*, 1997) where data was collected on 17,077 participants within the period 1992–93 (**Table 1**). The PROS participants had White or African-American ethnic background. These studies assessed both age at onset of thelarche and menarche.

The most recent study from the US, The Breast Cancer and the Environment Research Program (BCERP), was collected from 2004 to 2011 in different geographic areas (Biro *et al.*, 2013). The study included 1239 participants divided into four groups according to their ethnicity (African-American, Hispanic, White non-Hispanic or Asian) and only used thelarche as an indicator of puberty onset (**Table 1**).

The results from the NHANES III study indicate a large variation in the timing of thelarche according to ethnicity, with an earlier age onset in the Black non-Hispanic and Mexican-American participants compared to the White non-Hispanic participants,

but with no evident difference in the timing of menarche according to ethnicity. This reflects the genetic component related to the pubertal onset. These results were replicated in the PROS study, reporting that girls with African-American ethnicity developed breast tissue at an earlier age compared to Caucasian girls, whilst the timing of menarche showed no trend according to ethnicity. The BCREP study also supported this trend in thelarche onset according to ethnicity but did not report on age at onset of menarche.

When assessing secular time trends in puberty onset, the studies from the US suggest a clear decline in the age of thelarche within the study period with no concurrent decline in the age of menarche (**Table 1**), albeit onset of menarche was not reported in the newest of the US studies. In Denmark, Northern Europe, two recent studies, following children from the same town, have been conducted. The Copenhagen Puberty Study included girls from two different cohorts collected from 1991 to 1993 and from 2006 to 2008 and used rigorous methods for pubertal assessment (breast tissue palpation, *thelarche*) and found that onset of thelarche in girls in the period 2006–08 was a full year earlier than among those included 15 years earlier (**Table 1**) (Aksglaede *et al.*, 2009). The downward changes in age at menarche onset was not as pronounced as the changes observed for breast development (*thelarche*), albeit the 4 month decrease in age at menarche is still a remarkable change within the 15-year period. The estradiol level was measured in all girls included in both of the abovementioned cohorts and data showed a decline in estradiol levels in the 2006–08 cohort compared to the 1991–93 cohort, despite the earlier age at onset of breast development. Additional, adjustment for body mass index (BMI) did not change the results. These findings indicate a decrease in age at thelarche with a lower concurrent decrease in menarche during the intervening period between the two Danish cohorts, which most likely was not caused by increased BMI or higher estradiol levels in the 2006–08 cohort.

In summary, different largescale studies, both in the US and Europe, indicate a worldwide secular trend towards earlier age at onset of breast development (*thelarche*) among otherwise healthy girls. However, age at menarche has not declined to the same extent as the age at thelarche onset within the same period, indicating that the overall pubertal period (thelarche to menarche) has increased. Additionally, a clear variation in timing of thelarche, in relation to ethnicity, is pronounced in all the US studies.

Secular Trends in Puberty Timing in Boys

Pubertal onset in boys has received less attention and fewer, mainly smaller studies, are available. Based on the available studies on pubertal onset in boys, defined as Tanner, genital stage 2 (G2) or a testicular volume enlargement over 3 mL, there are indications of a secular trend towards earlier onset within the last 30 years. In 1980, the age at onset of puberty (G2) in boys was approximately 12.0 years while the age at onset has declined to about 11.5 years in 2000 (**Fig. 6**) (Sørensen *et al.*, 2012).

Of the few more comprehensive studies that have been performed in boys, are the NHANES III study (Karpati *et al.*, 2002) and The Copenhagen Puberty Study (**Table 2**). The NHANES III study collected data on 2481 boys and in line with results from girls show puberty G2 onset variation according to different ethnical backgrounds. White non-Hispanic boys developed Tanner, G2 stage at 10.1 years, Black non-Hispanic at 9.3 years and Mexican American at 10.4 years. The Copenhagen Puberty Study from Northern Europe examined white Caucasian boys from two different cohorts collected from 1991 to 1993 and from 2006 to 2008. In the 1991–93 cohort, the age of onset of testicular enlargement over 3 mL was 11.92 years, whilst in the 2006–08 cohort this age had decreased to 11.66. Along with this Tanner, G2 onset decreased from 11.83 to 11.59 years between the two Danish puberty cohorts of boys (**Table 2**).

The data from NHANES III has never been compared with earlier US studies because of the insufficient quality of the earlier US studies (Sørensen *et al.*, 2010); and although the decline in age in The Copenhagen Puberty Study was borderline significant, this was not robust after adjustment for BMI (no longer significant) (Sørensen *et al.*, 2010). These limited data on pubertal onset in boys makes it difficult to conclude on the magnitude of any potential secular trend in pubertal timing.

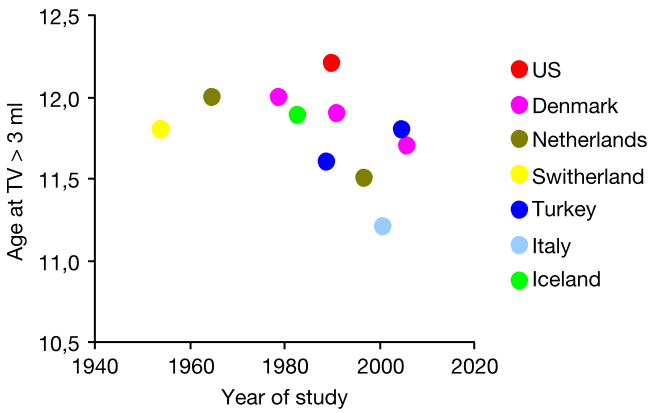

Fig. 6 Secular changes with reference to age of a testicular enlargement over 3 mL (Sørensen *et al.*, 2012).

Precocious Puberty

Assuming a Gaussian distribution of age of pubertal onset in the population, the normal range of puberty is defined as two times the standard deviation above and below the mean age of pubertal onset. In the European population, precocious puberty (PP) is defined as thelarche before the age of 8 in girls and a testicular volume enlargement over 3 mL in boys before the age of 9 (Teilmann *et al.*, 2005).

Incidence and Prevalence of Precocious Puberty

Different studies have examined the incidence of PP during the last decades. In Denmark, *Thamdrup* determined the incidence of early puberty to be 3–5 new cases per year in 1950 (Thamdrup, 1961). However, Thamdrup's study was performed before uniform registration of diagnosis in the national registry was introduced in Denmark, and may have underestimated the incidence. A more recent nationwide register based study in Denmark also analyzed the incidence of PP in Denmark in the period 1993 to 2001 using comprehensive national patient registries of PP based on International Classifications of Disease (ICD-10: E30.1 or E22). The study reported 50–70 new cases of PP (both sexes) per year in Denmark in that period and that incidence was constant within the study period. The incidence of new cases of PP within the study period according to sex was 8 cases per 10,000 girls aged 5–9 years and <0.5 per 10,000 girls aged 0–4 years; for boys the incidence was lower: (<1 per 10,000) for boys younger than 8 years and 1–2 per 10,000 boys aged 8–10 years. The prevalence of PP according to sex within the study period was 20–23 cases per 10,000 girls and under 5 per 10,000 boys (Teilmann *et al.*, 2005).

Another single-center study performed in the Capital Region of Denmark reported a marked increase in the number of referrals of girls with signs of early puberty, increasing from 6 new referrals in 1993 to approximately 80 new referrals in 2008 (Mogensen *et al.*, 2011). In 2016 the number of referrals in that center had increased even further to >200 girls with signs of early puberty (personal communication, A. Juul, 2018). Another Danish study performed in a different Center included 191 girls referred with early puberty from 1998 to 2012. The incidence of early puberty onset had increased from approximately 1 per 10,000 in 1998 to 4 per 10,000 in 2012 (Sømod *et al.*, 2016).

The reviewed studies from Denmark vary in methodology, and registration of precocious puberty and its variants (premature thelarche, premature adrenarche) are not uniformly evaluated between studies. Nevertheless, we suggest that the incidence of girls with signs of early puberty referred to Danish hospitals appears to have increased during the last decades.

Studies from other parts of the world indicate a similar rise in the number of cases who present signs of early puberty. A Korean group reviewed data on the use of GnRH analogues in children with PP based on data from the Korean Health Insurance Review Agency from 2004 to 2010 (Kim *et al.*, 2015). The study found the annual incidence of early puberty in girls had increased from 0.3 to 5 per 10,000 girls during the study period. The incidence in boys increased from 0.03 to 0.12 per 10,000 boys. Both the Danish and the Korean studies found the increase in incidence of PP to be more pronounced in girls compared to boys. In France, a nationwide study was performed from 2011 to 2013. Data from that study determined the incidence of early onset of puberty to be 2.7 per 10,000 girls and 0.24 per 10,000 boys (Le Moal *et al.*, 2018). This supports the trend observed in Denmark during the last decades.

It is likely that the possible changes in the incidences of PP are caused by a secular trend towards a lower mean age at pubertal onset. As age at pubertal onset approximates a Gaussian distribution, a lower mean age at pubertal onset results in an increase in the proportion of the distribution below the lower bound of the 95% confidence interval. Alternatively, the increase of PP cases could be due to an increase in the skewness of the distribution towards the lower bound. The Copenhagen Puberty Study did not

find any differences between the data where a Gaussian distribution was applied compared to data where skewedness was taken into account (Aksglaede *et al.*, 2009). The findings from The Copenhagen Puberty Study have been applied to illustrate the increase in the number of healthy girls from 1991 to 1993 and from 2006 to 2008, respectively, who would meet the diagnostic criteria of PP (early onset of Tanner, B2) (**Fig. 7**).

Data concerning boys from The Copenhagen Puberty Study were used to construct **Fig. 8**, illustrating the change in the number of healthy boys who would meet the diagnostic criteria of PP.

The increase in the PP incidence in boys illustrated in **Fig. 8** seems to be much lower compared to that of girls in accordance with well-known clinical observations.

These considerations based on data from The Copenhagen Puberty Study illustrate the potential problems with the current diagnostic criteria for PP when considering the secular trend towards earlier onset of thelarche. The causes of PP are numerous and they may be either non-pathological or pathological. Because of this, examination of the girls, with early pubertal development, is very important. Revision of the diagnostic criteria for PP has been debated (Sørensen *et al.*, 2012), including a lowering of the appropriate age below which a brain Magnetic Resonance Image (MRI) should be performed. With a lowering of the lower limit of

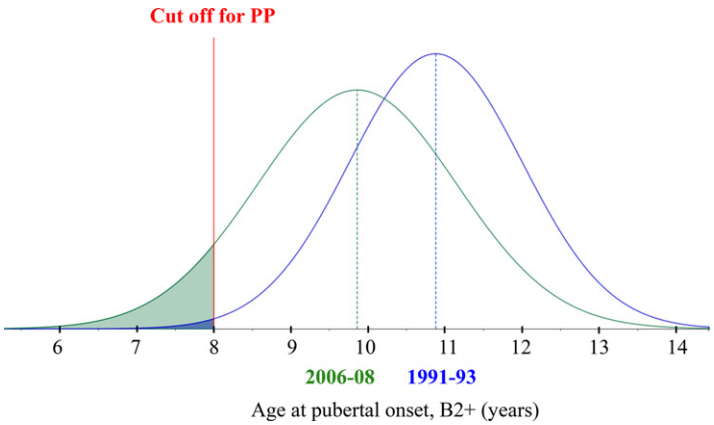

Fig. 7 Gaussian distribution curves for the two examination periods in The Copenhagen Puberty Study in girls: the blue curve depicts the distribution of pubertal onset (Tanner, B2) from the 1991 to 1993 examination period and the green curve depicts the distribution of pubertal onset from the 2006 to 2008 examination period. The mean ages at B2 onset from the different examination periods are shown by the dotted lines. The PP diagnosis criteria, that is, thelarche before the age of 8, are visualized by the red line, and the shaded area, under the left side of the curves, represents the number of girls falling into the PP category. Following data have been used: examination period 1991–93: mean 10.88 years and 2SD 8.66–13.11 and examination period 2006–08: mean 9.86 years and 2SD 7.28–12.44 (Aksglaede *et al.*, 2009).

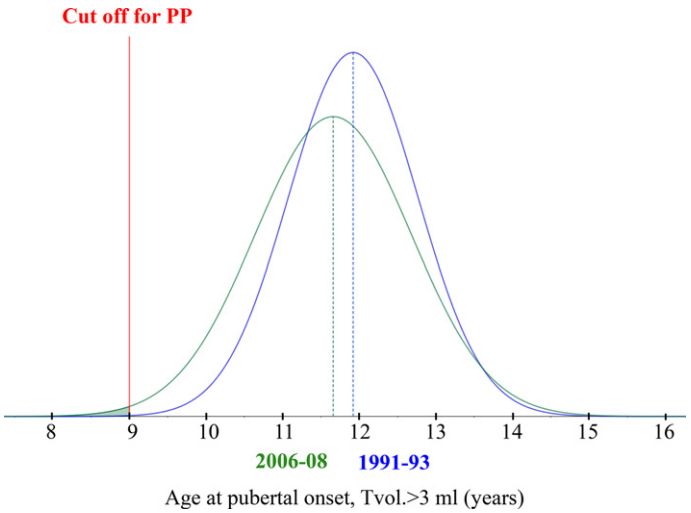

Fig. 8 Gaussian distribution curves for the two examination periods in The Copenhagen Puberty Study in boys: the blue curve represents the 1991–93 examination period and the green curve represents the 2006–08 examination period. The estimated mean ages for the two examination periods are marked by the dotted line. The shaded area under the left side of the curves represents the number of boys falling into the PP category. Following data have been used: examination period 1991–93: mean 11.92 years and 2SD 10.25–13.59 and examination period 2006–08: mean 11.66 years and 2SD 9.62–13.70 (Sørensen *et al.*, 2010).

normal puberty, an increasing number of children would be eligible for brain imaging. The main argument against revising the definition of PP is the potential of missing pathological cases (Sørensen *et al.*, 2012). Due to the significant secular changes in the norm on the one hand, and this concern of overlooking pathologies, the diagnostic criteria and ages below which a brain MRI should be performed remain controversial.

Possible Mechanisms for the Secular Trends in Pubertal Timing

As discussed earlier in this article, puberty timing and subsequent reproductive capacity are determined by changes in the secretion of the pituitary gonadotropins, LH and FSH, which are dependent on the frequency and amplitude of GnRH secretion from the hypothalamus. Genetic factors play an important role in the timing of these signals. Additionally, signals linked to the environment such as nutrition, stressors, and endocrine disruptors might interfere with the hypothalamic signaling system, directly or indirectly, via peripheral signaling. Knowledge about the precise mechanisms of action is not fully understood, but possible mechanisms are presented in this section.

Genetic Factors

Pubertal timing is a highly polygenic trait and different genetic variants have been shown to influence pubertal timing. The heritability has been found to variate from 0.50 to 0.68 in boys (Silventoinen *et al.*, 2008) and 0.57 (in relation to the age at menarche) in girls (Anderson *et al.*, 2007). The significance of genetic factors is also highlighted by the wide variation in pubertal onset between different ethnic groups. In the NHANES III study, the age at pubertal onset in girls varied 0.8 years between the white non-Hispanic and the Black non-Hispanic participants. The knowledge about genetic factors is still scarce, however, presumably genetic factors per se cannot account for the recent secular trends, but potential susceptibility genes may be indirectly involved in gene-environment interactions that could account for the secular trend.

Body Mass Index, Nutrition and Socioeconomic Status

BMI has a very important positive association to pubertal timing in girls; high BMI being associated with early breast development and low BMI being associated with pubertal delay. In boys a similar association between BMI and pubertal timing has been shown, although a U shaped association has been suggested within the normal BMI range, where very obese boys appear to enter puberty later. Thus secular trends in BMI/obesity have been suggested as likely explanations for the US puberty epidemic, whereas BMI did not explain the trend towards earlier breast development among girls in Denmark (Aksglaede *et al.*, 2009). Thus, individual fat mass play an indisputable important role for activation of the HPG axis and pubertal onset in girls, but may not entirely explain the secular trend in pubertal timing.

Environmental Causes Including Endocrine Disruptors

Endocrine disrupting chemicals (EDC) are ubiquitous in our environment and numerous have been identified. In this section only manmade EDC will be considered. EDCs can originate from different kind of sources released to the environment intentionally, such as insecticides, plastic, lacquer, paint, pest-controllers or unintentionally by either degradation of industrial products and building materials or by leakage of packing materials into food items. All people are therefore exposed to EDCs to some extent because of its presence in the daily life. EDCs can potentially interfere with the sex hormone actions in many different ways; estrogenic actions, anti-androgenic actions, or by affecting aromatase activity. Thus, EDCs can potentially both accelerate as well as delay puberty in both boys and girls, respectively. The chemicals can act at different levels for instance direct on the central parts of HPG-axis, the gonads, peripheral target organs for example the breast tissue and cause early maturation by direct estrogenic actions. By contrast, other EDCs can act as anti-androgens and delay androgen-dependent signs of puberty like pubic hair development.

Persistent EDCs like DDT and DDE have been banned for decades but still exist in the environment and bioaccumulate in humans. Exposure to DDT and DDE have been associated with earlier puberty, and similarly higher levels of DDT/DDE associated with earlier age at menarche (Ouyang *et al.*, 2005). Studies have indicated a correlation between high levels of PCB exposure and delayed pubertal development in boys (Den Hond *et al.*, 2002).

Flame retardants like PBB was evaluated in pregnant women (Özen and Darcan, 2011), and high PBB levels were associated with earlier menarche in the offspring.

Non-persistent EDCs like phthalates which can be found in many different everyday products for instance plastics, food packaging, cosmetics and medical devices have been shown to correlate with PP (Srilanchakon *et al.*, 2017), although controversy exist. Two different studies have reported on an association between phthalate exposure, a non-significant tendency towards earlier breast development, and a significant delay in the age at getting pubic hair (Frederiksen *et al.*, 2012; Wolff *et al.*, 2014), in accordance with their anti-androgenic actions. Other non-persistent EDCs like benzophenones have also been associated with delayed puberty in a large cross sectional study among contemporary US girls (Wolff *et al.*, 2015). The possible association

between pubertal timing and human exposure to a cocktail of hundreds of different EDCs at the same time, with estrogenic and anti-androgenic actions remain a difficult task to evaluate.

Conclusion

The age at pubertal onset in girls and boys has declined during the last decades, and an increase in the incidence and prevalence of precocious puberty particularly in girls has been documented. Potential reasons for this development could be related to changes in BMI, nutrition, socioeconomic status and exposure to endocrine disrupting chemicals.

Delayed Puberty; Male☆

Alan D Rogol, University of Virginia, Charlottesville, VA, United States

Introduction

Puberty is a unique and integrated transition from childhood to emerging adulthood and then to young adulthood. It includes major physical, emotional, and psychological changes, for which the attainment of fertility signals its completion; however, in none of these three spheres is maturation or development complete at the attainment of fertility. Puberty marks the time of greatest growth and sexual maturation since fetal life, and it is marked externally by the development of the secondary sexual characteristics for each gender and by major alterations in linear growth, body composition, and the regional distribution of body fat. All are subserved by qualitative and quantitative alterations in multiple hypothalamic–pituitary–end-organ axes, especially those for the gonad and for growth hormone (GH)/insulin-like growth factor I (IGF-I).

Growth at Puberty

Normally growing children have a relatively constant annual growth rate of 5–6 cm after 4–5 years of age until the onset of the pubertal process. The pubertal growth spurt may be divided into three phases: the first phase involving minimal velocity just before the spurt ("takeoff" velocity), the phase of rapid acceleration to peak height velocity (PHV), and the phase of diminished velocity and cessation of growth at the time of epiphyseal closure of the long bones. The individual pattern depends on the timing and tempo of the developmental process. Those with a significant delay often have a peripubertal decrement in height velocity (to a so-called preadolescent "dip") before the accelerated velocity of the growth spurt phase.

The sequence of pubertal alterations in linear growth and body composition is more tightly aligned to changes in the hypothalamic–pituitary–gonadal (HPG) and GH/IGF-I axes than to chronological age. In most Western populations, the age at initiation of the accelerated phase in boys averages ~11.0 years, and the age at PHV averages ~13.5–14.0 years, with a growth rate of 10–11 cm year^{-1}. This biological "anchor" occurs at mid- to late pubertal development. Maximal growth in body weight during adolescence usually occurs after PHV. It is composed mainly of an increase in fat-free mass (muscle) with a minimal increment in fat mass, leading to a decrease in the percentage of body fat during the later stages of pubertal development.

Secondary Sexual Characteristics

The timing and tempo of pubertal maturation are linked to alterations in the HPG and GH/IGF-I axes. There may be great variability in the onset of pubertal development, but once entrained, there is less variability in progress through the pubertal stages. However, there is still significant variability in the progression of puberty (tempo) that may be very relevant to boys with delayed adolescent maturation. The external signs of pubertal development have been summarized into relatively easily discernible stages. In general, scrotal thinning and reddening occur concomitantly with an increase in testicular volume to 4 mL or greater. As testis size increases and the levels of the male hormone testosterone increase, there is lengthening of the phallus followed by an increase in its circumference as it further lengthens. Pubic hair increases in area from just above the phallus to growth in all directions, including the medial thigh. The quality of the hair becomes more coarse and curly. With delayed pubertal maturation, the chronological age differs from the "biological" age. The various stages of growth noted previously—takeoff and PHV—and the hormonal changes noted in what follows are more tightly correlated to biological age than to chronological age.

The Endocrine System and Pubertal Development

Gonadotropins

After peaks of activity during fetal life and within the first few months of extrauterine life, the HPG axis becomes quiescent, only to reawaken at puberty. Gonadotropin release is pulsatile at all ages. Puberty is anticipated by an increase in the amplitude of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion that may be detected several years before the external signs of pubertal development are present. Initially, biologically relevant surges ("pulses") of LH occur only after the onset of deep

☆*Change History*: December 2017. Alan D Rogol added a new section concerning two hormones, anti-Mullerian (AMH) and inhibin B (IN b). References to support the data for these new hormones have been added and more recent review articles to justify other material added.

This chapter is an update of Alan D. Rogol, Delayed Puberty, Male, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 635-638.

sleep. These permit the testes to increase the production of the potent androgen testosterone. However, the hypothalamic–pituitary axis for LH remains exquisitely sensitive to the negative feedback actions of testosterone or one of its metabolites, estradiol, such that the minor increases in testosterone are able to dampen LH release. As puberty unfolds, the small increments in testosterone levels are no longer able to maintain suppressed levels of LH. The increases in LH continue for longer and longer periods during the day, pushing testosterone levels even higher. Concomitantly, the feedback sensitivity of the HPG axis diminishes and the ambient levels of testosterone are no longer sufficient to suppress the surges of LH. At the end of the pubertal process, the pulsatile release of LH occurs every 1 or 2 h during the day and night.

Anti-Mullerian Hormone and Inhibin B

Anti-Mullerian hormone (AMH) is a marker for (immature) Sertoli cell function. It is low in early infancy, peaks several years later, and remains high as pubertal maturation begins. Its levels then decrease from early mid-puberty to steady low levels characteristic of the adult. Androgens themselves are potent inhibitors of AMH production, and high levels in late puberty may be useful in narrowing the differential diagnosis of hypogonadism.

Inhibin B is also a gonadal glycoprotein produced by the Sertoli cell. It is a specific inhibitor of FSH (and spermatic function). Its levels also peak in infancy, decrease during childhood, and again increase at early to mid-puberty. It may serve as a marker for spermatic function. As inhibin B levels fail to rise, the levels of FSH increase in an attempt to stimulate the testicular tubules to drive spermatogenesis.

Gonadal Steroid Hormones

Nighttime increases in circulating levels of testosterone are often detectable even before the external signs of puberty develop. The daytime levels rise later as the testis volume increases. The circulating levels of testosterone are substrate for at least two important enzymes, 5α-reductase (which converts testosterone to dihydrotestosterone) and aromatase (which converts testosterone to estradiol). The effects on the lean body mass are in part due directly to testosterone and indirectly to estradiol, because the latter leads to the marked increases in GH and IGF-I due to an action of estradiol on the hypothalamus and pituitary. Circulating estradiol levels cause maturation and eventually closure of the epiphyses of the long bones, signaling the virtual cessation of linear growth. Diminished bone mass is present in boys with delayed pubertal development, including severe constitutional delay in growth and puberty (CDGP).

Growth Hormone and Insulin-Like Growth Factor I

GH levels increase throughout the first stages of pubertal development to reach a maximum at the time of PHV. The levels of IGF-I also rise, denoting a switch to positive feedback or at least an absence of negative feedback action of IGF-I on GH release. Although serum testosterone levels increase markedly by PHV, it is likely that the conversion to estradiol is responsible for the alteration in pulsatile GH release.

Summary and Integration

During pubertal development, there is an intricate interplay between the increased activation of the HPG and the GH/IGF-I axes. Both contribute to the pubertal spurt in linear growth and to the marked alterations in body composition and the regional distribution of body fat. They have independent and at least additive, if not synergistic, actions at puberty.

Causes of Delayed Pubertal Development in Boys

Delayed pubertal development has many causes, both physiological (functional) and pathological. It usually occurs because of inadequate secretion of the gonadal steroid hormones, especially that of testosterone in boys. The causes may be conveniently separated into hypogonadotropic (central) and hypergonadotropic causes, depending on primary hypothalamic–pituitary dysfunction or primary gonadal failure.

Of these categories, the physiological causes are by far the most common, especially in 14- to 16-year-old boys. As the second decade of life ends, the likelihood of finding a pathological cause rises sharply (see **Table 1**).

Evaluation of Delayed Puberty in Boys

As with any evaluation that includes growth and maturation, one begins with the growth curve. Normal growth over an extended period of time speaks to the overall general good health and well-being of the individual. The childhood growth rate is relatively constant, usually between 5 and 7 cm year^{-1}. In boys who undergo puberty at the usual time, there is an almost imperceptible

Table 1 Causes of delayed pubertal development in boys

Hypergonadotropic (primary) hypogonadism
Congenital
Chromosomal abnormality
Klinefelter syndrome 47 XXY and variants
Anorchia (vanishing testis syndrome)
Acquired
Trauma (or surgery)
Chemotherapy or radiation therapy for childhood neoplasia
Postinfectious (e.g., mumps and orchitis)
Hypogonadotropic (secondary) hypogonadism
Congenital
Various forms of hypothalamic–pituitary disease
Gonadotropin-releasing hormone deficiency
Multiple pituitary hormone deficiencies
Congenital malformations as part of holoprosencephalic anomalies
Acquired
Tumors, particularly craniopharyngioma
Pituitary apoplexy
Malnutrition and acute and chronic systemic disease
Endocrine deficiencies
Hypothyroidism
Hyperprolactinemia
Head trauma
Physiological
Constitutional delay of growth and puberty

slowing of growth (the takeoff point). This is followed by rapid acceleration to PHV and then deceleration toward zero velocity as the epiphyses of the long bones close. The greater the delay in pubertal development, the greater the slowing of growth before takeoff—often called the preadolescent "dip." This occurs at the time that one's peers are undergoing their most rapid growth, highlighting the differences among likely normal individuals. With quite delayed puberty, the rate may dip as low as 4.0–4.5 cm in the year before the pubertal spurt. However, this knowledge does not mitigate the distress of the smaller, often slighter, immature individual.

The evaluation is no different from any other medical evaluation in that the history can often give clues as to what to look for in the physical examination, or what laboratory tests to perform to integrate the information to produce a differential diagnosis. Of particular importance in the history is the pattern of growth, not only of the child but also of his siblings and parents. The pubertal development of the siblings and parents can be of help as well, because there is some familial patterning in the timing and tempo of pubertal maturation.

Although it is not often emphasized, one should take a detailed dietary history because delayed pubertal development may be related to a total energy deficit—caloric deprivation and/or excessive expenditure. Prior medical conditions and some of the mediations used to treat them can delay growth and pubertal maturation. There are many individual organ systems that may be disordered and cause delayed growth and pubertal development. Many are related to the gastrointestinal (GI) system—decreased intake and/or excessive caloric losses. The other major organ systems that can be affected are the endocrine system and central nervous system (CNS). Disorders of the HPG, GH/IGF-I, thyroid, and adrenal axes can lead to delayed growth and sexual maturation. CNS disease may be heralded by headaches, visual disturbance, seizures, and nausea and vomiting.

The general physical examination might not be too rewarding unless there are congenital (or acquired) anomalies. The typical boy with delayed pubertal development has a relatively normal physical examination—but for that of a younger child. The key elements are the measurements of height and weight and the genitalia, including pubic hair. There are convenient stages to mark pubertal progression; noting the Tanner stages can integrate not only the timing but also the tempo of pubertal development.

Laboratory testing that may help to define the diagnosis includes the hemogram and tests of liver, kidney, and GI function. From the endocrine point of view, one seeks evidence for low IGF-I and IGF binding proteins-3, low thyroxine level, low testosterone level, or high prolactin or cortisol level. The detailed endocrine evaluation is beyond the scope of this article.

Imaging studies may help; an X-ray of the left hand and wrist can indicate a bone age (biological age). That is critical as one tries to determine whether the delay is significantly outside the normal variation. Other imaging, whether CNS or GI or the like, should follow from clues gathered in the history, physical examination, and laboratory evaluations. A karyotype is indicated if Klinefelter syndrome is considered. Boys with this condition often have delayed tempo of puberty, but are of normal or slightly increased stature.

The younger the child during his teenage years, the more likely that physiologically delayed puberty (CDGP) is the correct "diagnosis." Treatment depends on the specific diagnosis.

Treatment of Delayed Pubertal Development in Boys

For most causes of delayed puberty, testosterone administration will form part of the therapeutic plan. It may be exogenous (usual) or may involve merely waiting for the endogenous testosterone to be secreted. By the time most boys with CDGP arrive in the specialist's office, testosterone therapy has already been considered. It is critical to start slowly and increase the dose gradually, so as not to cause epiphyseal closure that is too rapid and, subsequently, shortened adult height. Testosterone therapy can be halted as the testes increase in size (to ~8–10 mL), in concert with increasing endogenous testosterone secretion. Testosterone comes in many forms: gel, nasal gel, buccal, injectable, and implantable (pellets). The vast majority of use in pubertal boys is "off label" and beyond the scope of this report. An additional concern with the use of cutaneous forms of testosterone is the transference to others, especially children and women.

For pathological conditions, the treatment of the individual obviously depends on the diagnosis. It may be as simple as adding calories or dampening the activity of inflammatory bowel disease, or it may be as complex as removing a CNS tumor or correcting significant renal failure. Many of the hormonal deficits can be replaced (e.g., GH, thyroxine, and testosterone), and some of the excesses can be dampened (e.g., hyperprolactinemia and Cushing's syndrome).

Whatever the cause, it is critical to follow the growth and maturation status over time (trajectory). The amount of testosterone given should escalate over time to mimic the natural evolution of puberty. Physiologically delayed puberty is very common in 12- to 15-year-old boys. As they become older adolescents, it is less likely that a physiological cause for delayed pubertal development will be found. Often, it is the disease and distress that are the most prominent symptoms, and discussions with the patient and his parents along with short-term therapy with testosterone may be all that is required to help the boy through pubertal maturation and toward emerging adulthood. In addition to growth and genital development, there are remarkable alterations in body composition, including bone mass and fat distribution. Dissatisfaction with his body image is often a cardinal feature of the adolescent boy's distress, and therapy with testosterone has major salutary effects.

Delayed Puberty and Hypogonadism; Female☆

Sasha Howard and Leo Dunkel, Queen Mary University of London, London, United Kingdom

Self-Limited Delayed Puberty

Self-limited delayed puberty (DP), also known as constitutional delay of growth and puberty (CDGP), represents the extreme end of normal pubertal timing, and is defined as the absence of breast development in girls at an age that is 2–2.5 standard deviations (SD) later than the population mean (Palmert and Dunkel, 2012). 50%–75% of subjects with self-limited DP have a family history of delayed pubertal onset (Sedlmeyer, 2002). Familial self-limited DP has a clear genetic basis. It is a highly heritable condition, which segregates in an autosomal dominant pattern (with or without complete penetrance) in the majority of families. Autosomal recessive, bilineal and X-linked (Sedlmeyer, 2002), as well as sporadic cases are also observed. However, the underlying neuroendocrine pathophysiology and genetic regulation has been largely unknown.

Some insights into the genetic mutations that lead to familial self-limited DP have come from sequencing genes known to cause GnRH deficiency, most recently via next generation sequencing. Linkage analysis and targeted sequencing strategies that have provided initial insights in this field (Cousminer *et al.*, 2015; Wehkalampi *et al.*, 2008) have been mostly superseded by whole exome and genome sequencing strategies to identify novel candidate genes. Recently, whole exome and targeted resequencing methods have implicated two pathogenic mutations in *IGSF10* as the causal factor for late puberty in six unrelated families from a large Finnish cohort with familial DP (Howard *et al.*, 2016). Mutations in *IGSF10* appear to cause a dysregulation of GnRH neuronal migration during embryonic development, which presents in adolescence as DP without previous constitutional delay in growth.

In view of the possible overlap between the pathophysiology of DP and conditions of GnRH deficiency, a few studies have specifically examined the contribution of mutations in CHH genes to the phenotype of self-limited DP. Mutations in *HS6ST1*, *FGFR1*, *GNRHR* and newly in *KLB* have been found in a small number of kindreds of CHH patients and their relatives with DP (Tornberg *et al.*, 2011; Pitteloud *et al.*, 2006; Xu *et al.*, 2017; Lin *et al.*, 2006). Variants in several HH genes including *GNRHR*, *TAC3*, *TACR3*, *IL17RD* and *SEMA3A* have been identified by whole exome sequencing in some cases of DP, including self-limited DP (Zhu *et al.*, 2015). However, these variants have not been tested in vitro or in vivo for pathogenicity and thus may be an overestimation. Mutations of the β-subunits genes of LH or FSH are extremely rare causes of pubertal abnormalities (Themmen and Huhtaniemi, 2000). Females with inactivating mutations of *LHB* present with onset of normal puberty, but with normal or late menarche followed by infertility due to lack of ovulation (Themmen and Huhtaniemi, 2000). Individuals with inactivating *FSHB* mutations present with incomplete pubertal development and primary amenorrhea in females (Layman *et al.*, 1997). Despite a large body of evidence for kisspeptin as one of the most important elements of the neural network responsible for GnRH pulse generation, only very rarely have human mutations in *KISS1* been found in patients with delayed or absent puberty (Topaloglu *et al.*, 2012). The excitatory neuropeptide, neurokinin b, also plays a role in the upstream control of GnRH secretion. Of 50 self-limited DP patients investigated for mutations in *TAC3* and *TAC3R*, only one mutation in a single patient was found in the latter gene (Tusset *et al.*, 2012). Overall, the current picture indicates that the genetic background of HH and DP may be largely different, or shared by as yet undiscovered genes (Vaaralahti *et al.*, 2011). Very recently, rare heterozygous variants in *FTO* have been identified in pedigrees with self-limited DP associated with extreme low BMI and maturational delay in growth in early childhood (Howard *et al.*, 2017).

The absence of pathological medical history, signs and symptoms, and positive family history of DP in one or both of the parents suggests a diagnosis of self-limited or constitutional DP, but before making the diagnosis, significant pathological conditions (e.g., central nervous system [CNS] tumors) should be excluded. Girls with constitutional delay usually have delayed maturation during early childhood, and consequently they are shorter than their peers (Crowne *et al.*, 1991). Adrenarche may also occur later than usual, in contrast to the normal age of adrenarche in patients with isolated hypogonadotropic hypogonadism. Bone age is retarded compared to chronological age, but the developmental milestones are achieved at a normal bone age; that is, onset of signs of pubertal development by the bone age of 12 years and menarche at the bone age of 13 years (Palmert and Dunkel, 2012). Gonadotropin and estradiol concentrations increase in concert with the development of the bone age. Thus, all stages of pubertal development occur at an age later than usual. However, it appears that about half of girls with CDGP do not reach their target height, based on parental heights (Bramswig *et al.*, 1990). Probably because of low estrogen concentration for chronological age (but not for bone age), growth hormone (GH) secretion is functionally and temporally impaired for age, and when this functional GH deficiency lasts for a

☆*Change History*: January 2018. Sasha Howard and Leo Dunkel added the section on Self-limited delayed puberty and updated the text throughout. New references have been added.

sufficiently long period of time, it may also have an impact on adult height. After the onset of puberty or the initiation of appropriate estrogen treatment, growth velocity and GH secretion return to normal. Final height cannot be increased with GH treatment, although GH treatment may temporarily increase growth velocity in some girls. Self-limited DP is associated with adverse health outcomes including short stature, reduced bone mineral density and compromised psychosocial health (Zhu and Chan, 2017).

There are three main groups of differential diagnoses of self-limited DP (**Table 1**): functional hypogonadism, GnRH deficiency leading to hypogonadotropic hypogonadism (HH), and disorders causing primary hypogonadism (Sedlmeyer and Palmert, 2002; Palmert and Dunkel, 2012), although up to 30 different etiologies underlying DP have been identified (Varimo *et al.*, 2017).

Hypogonadotropic Hypogonadism

Gonadotropin-releasing hormone (GnRH) and gonadotropin deficiency can be caused by various genetic or developmental defects of the hypothalamic–pituitary axis, or by destructive lesions such as tumors, inflammatory processes, vascular lesions, and trauma (Silveira and Latronico, 2013). Usually, patients with isolated gonadotropin deficiency have normal height for their age during the prepubertal period, in contrast to patients with constitutional delay, who are often short. In hypogonadotropic hypogonadism, gonadotropin responses to GnRH stimulation may be subnormal, but because of the functional hypogonadotropism in constitutional delay, the differential diagnosis between these two conditions may be difficult.

Functional Gonadotropin Deficiencies

Anorexia Nervosa

Anorexia nervosa is usually associated with severe or even fatal weight loss, which is due to distorted body image, obsessive fear of obesity, and avoidance of food (Munoz-Calvo and Argente, 2016). Virtually all patients have primary or secondary amenorrhea. Functional hypogonadotropic hypogonadism is at least partly due to severe weight loss, but amenorrhea may also precede the onset of weight loss (Frisch and McArthur, 1974). The underlying pathophysiology of amenorrhea is due to GnRH deficiency because the luteinizing hormone (LH) secretory pattern in pubertal-aged girls with anorexia is similar to that seen in girls during pre-puberty: low or absent LH pulses and blunted LH response to exogenous GnRH (Munoz and Argente, 2002). Long term pulsatile administration of GnRH has been shown to restore a pubertal pattern of LH secretion, confirming the hypothalamic location of the defect. Recovery of normal weight will normalize most endocrine and metabolic functions, but amenorrhea may persist for years (Miller, 2013).

Athletic training

Overly intensive exercise may inhibit GnRH secretion, arrest pubertal development, and cause amenorrhea. These disorders are common especially among long-distance runners, gymnasts, and ballerinas (Barrack *et al.*, 2013). Hypogonadotropic hypogonadism may develop even when the female athletes have normal weight but have less fat and more muscle compared to non-athletic girls. In female athletes with delayed or arrested pubertal development, adrenarche usually takes place at the normal age. The mechanism of delayed puberty is unclear, but interruption of intensive training advances puberty and menarche before any change in body composition or weight, suggesting a direct effect of physical activity on GnRH secretion.

Malnutrition and chronic diseases

In malnutrition and chronic diseases, weight loss below the level of 80% of ideal body weight can cause delayed or arrested pubertal development (Pozo and Argente, 2002). Nutrition plays an important yet uncharacterized role in the control of GnRH secretion. For example, in regional enteritis, gonadotropin secretion remains normal if nutrition is optimally

balanced, but a non-optimal nutritional status will result in a hypogonadotropic state and arrested pubertal maturation. Chronic renal insufficiency delays pubertal development, but after successful renal transplantation, gonadotropin secretion is usually restored.

Central Nervous System Tumors

Tumors causing delayed puberty most commonly interfere with GnRH synthesis or secretion. Deficiency of other pituitary hormones is common. Associated posterior pituitary hormone deficiencies are often manifested by diabetes insipidus.

Craniopharyngioma

The most common neoplasm causing hypothalamic–pituitary dysfunction and hypogonadism is craniopharyngioma (Tan *et al.*, 2017). It is actually a congenital tumor that most commonly becomes symptomatic between 6 and 14 years of age. At presentation, the most common symptoms are headache, visual disturbances, short stature, delayed puberty, polyuria, and polydipsia. The structure of the tumor varies from solid to cystic. MRI, both with and without contrast enhancement, is the imaging modality of choice. Whilst the characteristic calcifications and size of the tumor can be visualized with CT, the size and extent of the tumor, involvement of the third ventricle and cystic features of the tumor can be confirmed with MRI. Treatment consists of surgery and radiotherapy, but the recurrence rate is high even when complete surgical removal is attempted (Karavitaki *et al.*, 2005).

Langerhans' cell histiocytosis

Langerhans' cell histiocytosis (LCH), also called Hand–Schuüller–Christian disease or histiocytosis X, is characterized by infiltration of lipid-containing histiocytic cells in the skin, bone, and viscera. CNS involvement and, in particular, hypothalamic–pituitary involvement are well-described features of LCH. The precise incidence of CNS–LCH disease is unknown, and the natural history is poorly understood. Diabetes insipidus (DI) is reported to be the most common and well-described manifestation of hypothalamic–pituitary involvement (up to 50%). Anterior pituitary dysfunction has been reported in up to 20% of patients with LCH and occurs almost exclusively concurrently with DI (Montefusco *et al.*, 2017). The natural course of the disease is fluctuating, making evaluation of treatment effect difficult. Endocrine function is not improved following medical treatment of LCH with chemotherapy and glucocorticoids. All LCH patients should undergo a thorough endocrine evaluation periodically.

Germinomas

Germinomas are the most common extrasellar tumors to cause delayed puberty, although these tumors are a rarity among primary CNS tumors (Sato *et al.*, 2009). Polydipsia, polyuria, and visual disturbances are the most common symptoms associated with these tumors, followed by arrested growth and delayed puberty. Germinomas are commonly located in the pituitary stalk, in the suprasellar region of the hypothalamus, or in the proximity of the pineal gland. Seeding of the tumor to the cerebrospinal fluid is common, and this can also be used in the diagnosis, where examination of tumor markers (hCGß and alphafetoprotein) or germ cells (with positive placental alkaline phosphatase staining) in the cerebrospinal fluid may be helpful. These laboratory findings, together with clinical features and an excellent response to radiation therapy, are so characteristic that surgery is rarely indicated except for biopsy to establish histological diagnosis (Shibamoto, 2009).

Other Central Nervous System Disorders

Defects in development

Various malformations affecting the development of the prosencephalon may cause DP combined with deficiency of any or all other pituitary hormones (Kelberman *et al.*, 2009). Midline malformations are often associated with optic dysplasia, and an absent septum pellucidum is often found by imaging techniques (septo-optic dysplasia). Other congenital midline defects, which may range from holoprosencephaly to cleft lip and palate, may also be associated with variable hypothalamic–pituitary dysfunction.

Genetic defects affecting development of the anterior pituitary cause hypopituitarism, including hypogonadotropic hypogonadism, in some cases. During fetal development of the anterior pituitary gland, a number of sequential processes occur that affect cell differentiation and proliferation. Recent advances in molecular biology have revealed several steps that are required for pituitary cell line specification, and several genes have been identified to play a role in control of these steps. The pituitary transcription factors, HESX-1, LHX-3 and SOX2 are vital for early patterning of the forebrain and pituitary, and mutations in these developmental genes result in syndromic hypopituitarism with gonadotropin deficiency in humans (Kelberman *et al.*, 2009). PROP-1 is important for the development of gonadotropin-secreting cells and

mutations in this gene are the most common cause of combined pituitary hormone deficiency in humans (Parks *et al.*, 1999). PITX2 is also vital for survival of gonadotrope cell lineage and is required for expression of the gonadotrope-specific transcription factors GATA2, EGR1 and SF1.

The DAX-1 orphan nuclear receptor gene (DAX1) and steroidogenic factor-1 (SF1) are important for the development of the adrenal gland, gonads, ventromedial hypothalamus and pituitary gonadotrope cells. Mutations in DAX1 cause X-linked adrenal hypoplasia congenita, with associated hypogonadotropic hypogonadism, whilst mutations in SF1 are associated with 46XY sex reversal or gonadal dysgenesis, and 46XX premature ovarian insufficiency (Achermann *et al.*, 1999). Leptin and prohormone convertase-1 may also influence GnRH release and processing of the GnRH receptor, with mutations resulting in a phenotype of hypogonadotropic hypogonadism (Farooqi *et al.*, 2007). Depending on the condition, different approaches for counseling are needed.

Iatrogenic gonadotropin deficiencies

Treatment of CNS tumors, leukemia, or neoplasms with cranial irradiation may result in gradual development of hypothalamic–pituitary failure. GH deficiency is the most common component of the radiation-induced hormone disorder, but gonadotropin deficiency also occurs when the radiation dose is high enough (Shalitin *et al.*, 2011). Development of radiation-induced hypothalamic–pituitary failure usually takes from 1 year to several years to ensue.

Hypergonadotropic Hypogonadism

Gonadal Dysgenesis Syndromes

Turner syndrome

The syndrome of gonadal dysgenesis (Turner syndrome) is the most common form of hypergonadotropic hypogonadism, affecting about 1 in 2500 live-born girls. About half of girls with Turner syndrome have the 45,X karyotype, but about 99% of fetuses with this karyotype abort spontaneously, and in 1 of 15 spontaneous abortions the fetus has the 45,X karyotype (Saenger *et al.*, 2001). Chromosomal mosaicism and structural abnormalities of the sex chromosomes modify the clinical features. Typical features include short stature (which may be apparent already at birth), lymphedema of the extremities and loose posterior cervical skinfolds during the newborn period, low-set or deformed ears, epicanthal folds, ptosis, micrognathia, high arched palate, dental abnormalities, wide-spaced nipples caused by shield-like chest, hypoplastic areolae, short neck with low hairline, and cubitus valgus. Abnormalities of the left side of the heart include coarctation of the aorta, aortic stenosis, and bicuspid aortic valves. Renal anomalies include abnormal position or alignment (horseshoe kidney) and various anomalies on the collecting system. Patients with Turner syndrome have increased incidence of

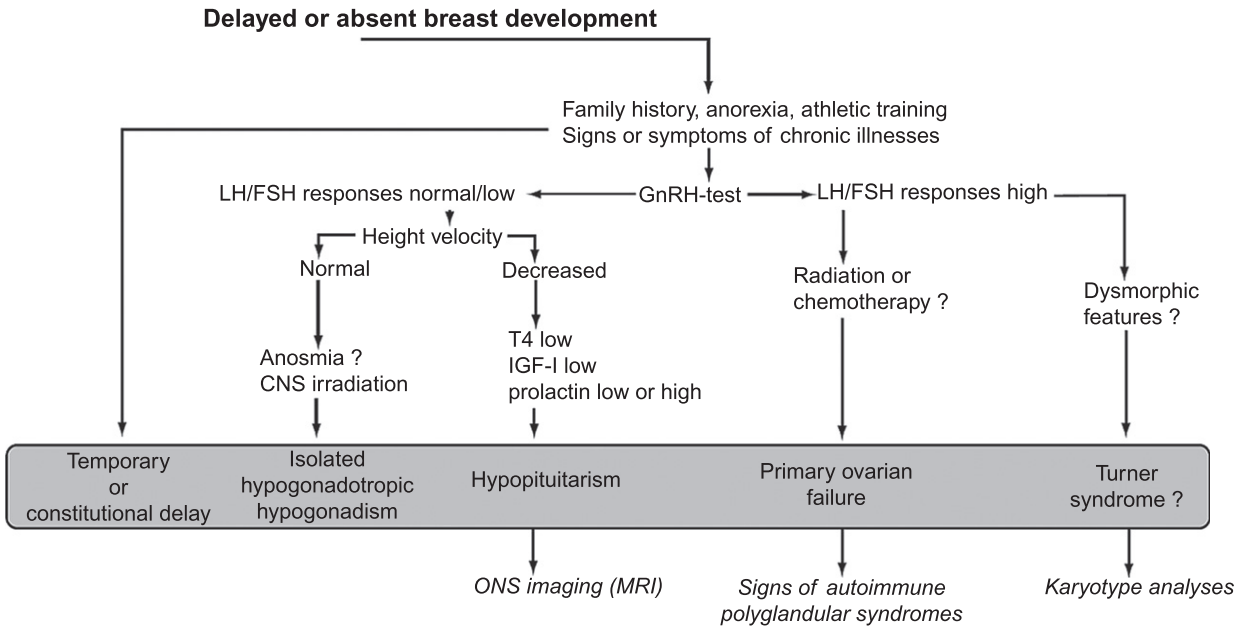

Fig. 1 Differential diagnosis of delayed puberty in females.

inflammatory bowel disease, autoimmune thyroiditis, Graves' disease, and insulin resistance. Intelligence is usually normal, but spatiotemporal processing, visuomotor coordination, and mathematical skills performance may be impaired (Sybert and McCauley, 2004).

Ovarian insufficiency is also apparent at birth, as evidenced by high gonadotropin concentrations during the neonatal period. During childhood, with the development of the CNS-mediated inhibition of GnRH secretion, gonadotropin levels decrease to near normal levels, but by 10 years of age they usually are elevated again. The Müllerian structures (uterus and fallopian tubes) are present but remain infantile if the ovarian failure is not adequately treated with hormone replacement therapy. Histologically, the ovaries are streaks of connective tissue, with a decreased number of primordial follicles and oocytes for age. Spontaneous oocyte death is accelerated, resulting in premature loss of the oocyte pool.

Sexual infantilism is one of the most common clinical findings in girls with Turner syndrome. More than 90% have gonadal failure. It is important to remember, however, that up to 30% of girls will undergo spontaneous pubertal development and that 2%–5% will have spontaneous menses and may have the potential to achieve pregnancy without medical intervention. Pubertal development may be delayed and, in most patients, is followed by progressive ovarian failure.

Most patients are small for their gestational age at birth, and the slow growth rate is apparent after 3 years of age. Most girls fail to have a pubertal growth spurt due to insufficient estrogen production in the ovaries. The mean adult height is approximately 143–146 cm, depending on both parental heights and the overall height of the same genetic population.

46,XX and 46,XY gonadal dysgenesis

The term "pure gonadal dysgenesis" refers to phenotypic females with no pubertal development and the 46,XX or 46,XY karyotype without detectable chromosomal abnormalities (Hughes, 2008; Weinberg-Shukron *et al.*, 2015). Patients with 46,XX gonadal dysgenesis have normal stature, bilateral streak gonads, normal female internal and external genitalia, and (sometimes) sensorineural deafness. Malignant transformation of the streak gonad is rare. Most cases are sporadic, but autosomal-recessive form has also been described; however, few casual genes have been identified in these patients. Patients with familial or sporadic 46,XY gonadal dysgenesis have normal female internal and external genitals with occasional clitoral enlargement due to increased testosterone production by the gonad, bilateral streak gonads, and normal or tall stature with eunuchoid body proportions. The dysgenetic gonads may undergo neoplastic transformation, so gonadectomy may be indicated (McCann-Crosby *et al.*, 2014).

Other Causes of Gonadal Dysgenesis

XX gonadal dysgenesis can occur in combination with cerebellar ataxia and learning difficulties, or with multiple malformation syndromes with a range of associated features including microcephaly, limb abnormalities, facial and cardiac defects. Other causes of ovarian dysgenesis include X isochromosome, where abnormal chromosome division results in duplication of identical chromosome arms, most commonly of the long (q) arm (Cox and Liu, 2014). These patients have streak gonads and a similar phenotype to Turner syndrome.

Other Causes of Primary Ovarian Insufficiency

Irradiation and chemotherapies

Damage to the gonads by irradiation or chemotherapy depends on the patient's gender, age at the time of treatment, radiation dose and fractionation schedule, and total dose and nature of chemotherapy delivered (Johnston and Wallace, 2009). Most chemotherapy protocols use multiple agents whose effects may be synergistic. Biochemical detection of gonadal damage is rarely possible before puberty, so treatment-induced gonadal damage during childhood may present with infertility or premature menopause during adulthood. Abdominal, pelvic, and total body irradiation may result in ovarian and uterine damage. The human oocyte is sensitive to radiation, with an estimated LD50 of less than 4 Gy (Wallace *et al.*, 1989). Less than 2% of children receiving total body irradiation subsequently became pregnant, although there may be some protection of ovarian function in prepubertal girls. Uterine radiation increases the incidence of nulliparity, fetal loss, and small-for-dates infants, and it reduces the success of assisted reproduction. Suppression of the pituitary–gonadal axis with gonadal steroids or GnRH agonists does not protect the ovary from the damage induced by irradiation or chemotherapy. AMH has been shown to be a clear marker of damage to the ovarian reserve of girls receiving chemotherapeutics for cancer (Lunsford *et al.*, 2014).

Premature ovarian failure

The term premature ovarian failure (POF) comprises a heterogeneous spectrum of disorders, from ovarian follicular dysfunction to ovarian dysgenesis (Cox and Liu, 2014). In most cases the etiology is unknown. Discovered first in the Finnish population, point mutations in the extra-cellular domain of the FSH receptor with subsequent inactivation of the receptor function result in raised FSH levels, variable development of secondary sex characteristics and primary or secondary amenorrhea (Aittomaki *et al.*, 1995). Whilst up to 40% of Finnish patients have such a mutation, these appear to be

rare in other populations. Post-receptor defects in the gonadotropin receptor signaling pathways have also been described, with a similar phenotype to FSH receptor mutations. Various microdeletions on the short and long arm of the X chromosome are also found in women with POF, with several genes implicated including POF1, POF2, DIAPH2, FOXL2, BMF15 and most recently STAG3 (Le Quesne Stabej *et al.*, 2016).

Histological examinations of ovarian biopsies show the presence of follicles in all patients with FSH receptor defects, whereas only one in four of those with unknown etiology have follicles. Hence, whereas the receptor defect causes a specific arrest in follicular maturation, many patients with hypergonadotropic ovarian failure have true ovarian dysgenesis. The ovarian phenotype in patients with inactivating FSH receptor mutation is informative in regard to the role of FSH in the regulation of follicular development: the early phases of follicular maturation (up to the preantral stage) are independent of FSH, but for the final maturation of the follicle, this gonadotropin is absolutely necessary.

Autoimmune ovarian insufficiency

Autoimmune ovarian insufficiency is often one of the components of autoimmune polyendocrinopathies. Autoimmune polyglandular syndrome type I is an autosomal recessive disorder caused by mutation in the autoimmune regulator (AIRE) gene, which maps to 21q22.3. It is characterized by two of the three major clinical symptoms that may be present: Addison disease, hypoparathyroidism, and chronic mucocutaneous candidiasis. Moniliasis often precedes symptoms and signs of endocrinopathy. Furthermore, hypoparathyroidism usually reveals itself before adrenal insufficiency.

Ahonen *et al.* (1990) reported data from a 10-month to 31-year follow-up of 68 patients from 54 families, ages 10 months to 53 years at the time of report. Hypoplasia of the dental enamel and keratopathy were frequent and were not attributable to hypoparathyroidism. Some of the manifestations of the disorder did not appear until the fifth decade. Thus, all patients need lifelong follow-up for the detection of new components of the disease. Candidiasis was the initial manifestation in 60% of the patients and was present in all patients at some time. Hypoparathyroidism was present in 79%, adrenocortical failure in 72%, and gonadal failure in 60% of female patients over 13 years of age. Other autoimmune diseases associated with primary ovarian insufficiency include myasthenia gravis, systemic lupus erythematosus and rheumatoid arthritis.

Diagnosis

The cutoff age for identifying girls who need evaluation for delayed puberty may vary in different ethnic groups, but in most populations early signs of secondary sexual development should be present by 13 years of age (Palmert and Dunkel, 2012).

A thorough history should note evidence of chronic disease, anorexia, the intensity of athletic training, and the timing of puberty of both parents (**Fig. 1**). In self-limited DP, often either one of the parents developed late. A history of chronic illnesses, such as celiac disease and inflammatory bowel disease, will suggest a temporary or secondary delay of puberty. Stature and height velocity should be evaluated using appropriate growth charts. Height velocity is usually slow in patients with constitutional delay and is usually normal in patients with hypogonadotropic hypogonadism; however, hypogonadotropic states cannot be ruled out by short stature and slow growth rate. Likewise, bone age (X-ray film of left hand and wrist read according to standards such as Greulich and Pyle) delay provides useful information in the growth analysis, but it contributes little to the differential diagnosis.

Gonadotropin levels assessed by basal LH and FSH determination are often increased in primary ovarian insufficiency or in Turner syndrome, but the basal gonadotropin values are not useful in the differential diagnosis of self-limited delay and hypogonadotropic hypogonadism (Harrington and Palmert, 2012). Dynamic testing, such as administration of synthetic GnRH, may provide information for the differential diagnosis (Binder *et al.*, 2015). In some girls with self-limited DP, a pubertal pattern of response (post-GnRH maximum LH higher than maximum FSH) may be observed, but although a low prepubertal response to GnRH is typical of hypogonadotropic hypogonadism, it can be found in some girls with self-limited DP. Investigation of the differential diagnosis of the two conditions may involve a number of other physiological and stimulation tests, including assessment of LH pulsatility by frequent sampling and first morning-voided urine FSH and LH (Demir *et al.*, 1996; Harrington and Palmert, 2012). In boys, a single measurement of inhibin B < 35 pg/mL in boys has shown to help discriminate HH from self-limited DP with high sensitivity (Coutant *et al.*, 2010), but this has not been demonstrated in girls. Follow-up is often warranted before a definitive diagnosis can be made.

A karyotype is important to confirm or exclude the diagnosis of Turner's syndrome. Autoantibody screening may be informative particularly in cases of hypergonadotropic hypogonadism. Measurement of AMH is valuable in gonadal failure to assess ovarian reserve. An MRI brain is warranted in cases of suspected hypogonadotropic hypogonadism.

Management of Delayed Puberty

When estrogen therapy is required to induce pubertal development, the dosing and timing should be aimed at mimicking normal pubertal development, taking account of the individual's desire to begin puberty and also of the family history of age at onset of puberty. Doses should be adjusted to the responses of individual patients, who may be monitored in terms of the development of secondary sex characteristics, bone maturation, and/or uterine volume.

Before initiation of estrogen therapy in girls with Turner syndrome, serum gonadotropin levels should be determined to exclude the possibility of delayed spontaneous pubertal development. If gonadotropin levels are normal, a sonographic examination should be undertaken to determine the status of the gonads. Hormonal induction of feminization should be initiated and carried out in a manner that simulates the normal growth and development of secondary sex characteristics as closely as possible. Estrogen therapy needs to be initiated and adjusted according to the needs and priorities of the individual.

In hypopituitary girls and in girls with Turner syndrome, estrogen therapy should be coordinated with the use of GH. Previous practice in Turner's syndrome tended towards delaying estrogen therapy until the mid-teens in order to optimize growth promotion with GH. However, more recent studies point to potential benefits from treatment with combined very low-dose estrogen and GH from an early age, in terms of final height and potentially other areas including cognitive development and uterine maturation (Saenger *et al.*, 2001; Ross *et al.*, 2011). Whilst it remains unclear as to the best timing to initiate estrogen therapy in Turner's girls, the current consensus is that induction of puberty should not be delayed in order to promote linear growth (Bondy and Turner Syndrome Study, 2007). Additionally, whilst ethinylestradiol has traditionally been the estrogen of choice for pediatric patients, 17β-estradiol in transdermal, gel or oral form has a better risk profile in terms of growth restriction, liver toxicity and vascular side-effects. Data from hypopituitary females receiving combined estrogen and GH treatment indicate a markedly greater impairment of GH-mediated IGF1 synthesis with ethinylestradiol than with 17β-estradiol. Uterine development may also be impaired with the use of ethinylestradiol as compared to 17β-estradiol (Bakalov *et al.*, 2007; Doerr *et al.*, 2005).

Estrogen therapy should be initiated at a low dose (one-eighth to one-quarter of the adult dose) and increased gradually (at intervals of 6–12 months) (Matthews *et al.*, 2017). Doses can then be adjusted to the response (Tanner stage, bone age, and uterine growth), with the aim of completing feminization gradually over a period of 2–3 years.

A progestin such as oral medroxyprogesterone acetate should be added either if one than one episode of significant breakthrough bleeding occurs or after 24–36 months of estrogen therapy to establish menstrual cycles, at least every 2–3 months to prevent endometrial hypertrophy.

Individuals with Turner syndrome who have functioning ovaries and who progress through puberty spontaneously should receive contraceptive and genetic counseling. However, ovulatory function should be documented (FSH and LH measurements) because a perimenopausal pattern of anovulation can lead to endometrial hyperplasia.

Glossary

Gonadotropin-releasing hormone agonist Synthetic analog of native gonadotropin releasing hormone in which amino acid substitution causes an agonistic effect and prolonged exposure results in inhibition of gonadotropin release.

Gonadotropin-releasing hormone stimulation test Diagnostic test to assess the presence and origin of the onset of puberty. It is also used to monitor treatment in children with central precocious puberty.

Hypothalamus Cerebral structure involved in the onset of puberty by pulsatile secretion of gonadotropin-releasing hormone.

Pituitary Endocrine gland located in the brain involved in the regulation of the reproductive organs by secretion of luteinizing hormone and follicle-stimulating hormone.

Precocious puberty Early onset of puberty before certain age limits in girls or boys.

Introduction

Gonadotropin-dependent precocious puberty (GDPP) is defined as the onset of puberty at an age younger than normal as a result of precocious activation of the hypothalamic–pituitary–gonadal axis. This form of premature activation needs to be distinguished from gonadotropin independent forms caused by autonomous secretion of sex steroids by the gonads or the adrenal gland.

The term gonadotropin-dependent precocious puberty is composed of the following elements:

Gonadotropin-dependent: Means that pubertal development is driven by activation of the cerebral (central) structures that are responsible for normal puberty. Peripheral causes of physical pubertal development (resulting from sex hormone production by, e.g., adrenal or ovarian tumors are per definition excluded).

Precocious: The definition of precocity depends on the normal age of onset of puberty in a certain population. In general, the age limit is defined as 2 or 2.5 standard deviations (SD) below the mean or median of the population. In recent years several observations indicated that in some populations the normal age of onset of puberty has decreased. This resulted in discussions on the age limit that would demand further medical investigation for detection of underlying disease. Nevertheless, precocity is defined as the occurrence of pubertal development in girls younger than 8 years of age and in boys younger than 9 years of age (Kaplowitz *et al.*, 2016).

Puberty

Female: The onset of puberty in girls is primarily defined by the onset of breast development. In the pubertal staging of Tanner, this is stage B2. Other signs helpful in assessing pubertal development are an increase in growth velocity, an acceleration of bone age development, and an increase in ovarian and uterine size on ultrasound.

Male: The onset of puberty in boys is primarily defined by an increase in testicular volume and subsequent enlargement of penis and scrotum. In the pubertal staging of Tanner, this is stage G2, with a testicular volume of four or more milliliters.

Physiology of Normal Puberty

Normal puberty is characterized by the "awakening" of the gonadotropin-releasing hormone (GnRH) pulse generator in the hypothalamus. In early embryonic development, hypothalamic GnRH cells migrate from the olfactory placode to the hypothalamic region. From birth until puberty, GnRH activity appears to be suppressed or compromised, except during the early neonatal period. Particularly in boys during this phase, termed "mini-puberty," serum values of gonadal steroids can be measured in the pubertal range (Contreras *et al.*, 2017; Quinton *et al.*, 2017).

☆*Change History*: January 2018. D. Mul, W. Oostdijk and S.L.S Drop updated text and references. The articles has extended from girls only to boys and girls in separate sections where appropriate. The paragraph distribution has been changed. Fig. 1 is new, Fig. 2 is enriched with a second photograph (now figure 3b); a previous Table 3 has been replaced by text. Literature references were updated, and now extensively listed. Further reading section has been shortened.

This article is an update of Dick Mul, Wilma Oostdijk and Stenvert L.S. Drop, Precocious Puberty, Central (Female), In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 40-45.

 doi:10.1016/B978-0-12-801238-3.03912-X

Studies of the neuronal mechanisms involved in the onset of puberty suggest that changes in the balance between inhibitory and stimulating neurotransmitters initiate puberty. Recent findings draw attention to the possibility that transcriptional repression might be a central mechanism in controlling the initiation of puberty. It is now well proven that the secretion of GnRH is regulated by kisspeptin as well as by permissive or opposing signals mediated by neurokinin B and dynorphin. These three supra-GnRH regulators compose the kisspeptin-neurokinin B-dynorphin neuronal (KNDy) system, a key player in pubertal onset and progression. Moreover, an ongoing increasing number of inhibitory, stimulatory and permissive networks acting upstream on GnRH neurons (such as GABA, NPY, LIN28B, MKRN3) integrate diverse hormonal and peripheral signals and have been proposed as the "gate-keepers" of puberty (Livadas and Chrousos, 2016) (**Fig. 1**).

Environmental influences probably affect normal regulatory mechanisms, emphasizing that the onset of puberty is also dependent on peripheral signals, like sexsteroids and leptin (derived from adipose tissue). Endocrine disruptors may also affect timing of pubertal onset by influencing GnRH pulse generation (reviewed in Livadas and Chrousos, 2016).

Biochemically, the onset of puberty can be demonstrated by pulsatile luteinizing hormone (LH) release, initially at night and later during the day (**Fig. 2**; Schroor *et al.*, 1999).

Pulse frequency and amplitude increase with progression of puberty. Gonadotropin production stimulates the end organs to sex steroid production, resulting in sexual maturation. Sex steroids, mainly estrogens, also influence bone age progression.

Etiology

The estimated incidence of GDPP in girls is 2–3 in 10,000, the prevalence in a Danish national registry was estimated to be 0.2% of girls. In boys, an incidence of 0.24 per 10,000 was suggested (Le Moal *et al.*, 2018).

The etiology of GDPP can be classified as idiopathic or organic. It has been shown that in 70%–90% of girls with GDPP the etiology is idiopathic. However in boys this figure is substantially less: 35%. In idiopathic GDPP, no organic cause for the precocious onset of puberty is found. The number of organic causes will likely increase with the refinement of central nervous system imaging by magnetic resonance imaging (MRI), revealing, for example, hypothalamic hamartoma in children formerly diagnosed as idiopathic CPP. In recent years, in idiopathic forms of precocious puberty, potential causative abnormalities have been found. Several *genetic* variants were found, such as mutations of the imprinted gene MKRN3 in boys (Abreu *et al.*, 2013, 2015; Bessa *et al.*, 2017; paradoxical gain-of-function mutant of the G-Protein receptor PROKR2 (Fukami *et al.*, 2017) and paternally inherited DLK 1 deletion (Dauber *et al.*, 2017). But also environmental factors such as *endocrine disruptors* are thought to play an important role (Leonardi *et al.*, 2017; Le Moal *et al.*, 2018).

It is of interest that LIN28B SNPs are associated with normal puberty timing; however variations of this gene are not commonly involved in molecular pathogenesis of GDPP (Silveira-Neto *et al.*, 2012).

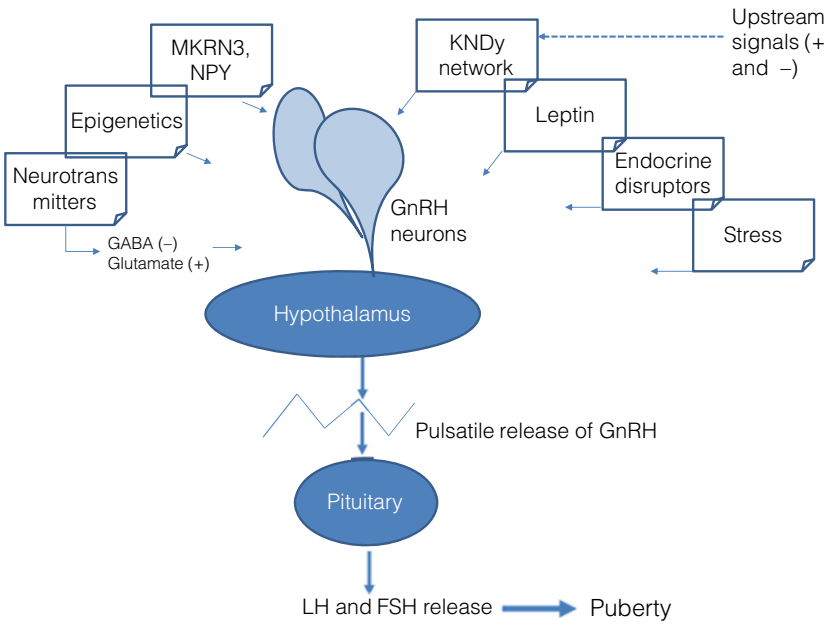

Fig. 1 Schematic representation of proposed mechanism of pubertal onset (after Livadas, S. and Chrousos, G. (2016). Control of the onset of puberty. *Current Opinion in Pediatrics* 28, 551–558). KNDy: kisspeptin-neurokinin B-dynorphin.

Children with neurodevelopmental disabilities such as cerebral palsy or brain trauma have an increased chance of developing GDPP (Bruzzi *et al.*, 2017; De Sanctis *et al.*, 2015).

Functional gonadotropin producing pituitary adenoma present during childhood with central precocious puberty, but are extremely rare (Ntali *et al.*, 2014).

In general, the younger the girl at the onset of CPP, the higher the chance of organic pathology. However, significant pathology was less often seen in girls with signs of puberty before age 3 compared to those >3 years. and progression from premature thelarche to CPP is very rare. In young girls, CPP must be differentiated from premature thelarche without central activation (Kaplowitz and Mehra, 2015).

In organic GDPP, a cerebral organic lesion causes the premature onset of puberty. Local pressure on GnRH neurons or disruption of inhibitory fibers may cause GnRH release. **Table 1** lists possible causes of organic GDPP. Treatment of GDPP in children with organic lesions is primarily aimed at the underlying pathology. However, the progression of puberty is not always halted by this treatment.

Arachnoid cyst
Gonadotropin producing pituitary adenoma
Following peripheral precocious puberty
Meningitis/encephalitis sequelae

Clinical Presentation

Girls

Girls with GDPP usually present with breast development as the initial sign of puberty (Fig. 3A). Frequently, this is accompanied by acceleration of growth, and, sometimes, behavioral changes. In some girls—in contrast to normal puberty—menarche occurs soon after the onset of breast development due to rapid progression of puberty. Less visible changes occur in bones and internal genitalia. Girls that present with only pubic or axillary hair should further be analyzed for causes of premature adrenal activity, not for problems in the pituitary–gonadal axis.

Boys

Boys with GDPP present with acceleration of growth, pubic hair development and growth of penis and scrotal maturation (Fig. 3B); during physical examination testicular enlargement can be established. Behavioral changes are not uncommon. As in girls, these symptoms are accompanied by accelerated maturation of bone structures.

Diagnostic Procedures

Bone Age Assessment

Bone age accelerates as a result of estrogenic stimulation and may cause premature closure of the growth plate, resulting in compromised final height. The method of bone age assessment in GDPP is not uniform. In most studies, the Greulich–Pyle method is used. It has been shown that final height predictions for GDPP in girls using the tables of Bayley and Pinneau for accelerated bone age significantly overestimate the achieved final height, and it is more appropriate to use the "average" tables for prediction (Kauli *et al.*, 1997).

Pelvic Ultrasonography (Girls Only)

Pelvic ultrasonography reveals the changes in aspect and volume of the ovaries and uterus. The ovaries increase in volume, and the number and the diameter of follicles as well as the diameter of the ovaries increase. Uterine findings include changes in shape and the presence of endometrium.

Brain Imaging

In young girls presenting with CPP, MRI of the brain (especially the pituitary region) is mandatory to exclude central nervous system (CNS) abnormalities. The role of MRI in girls with signs of puberty at age 6 or 7 is under discussion. Some studies indicate that in these cases the search for pathology should not be performed. On the other hand, MRI in girls with CPP at age 6 or 7 has shown CNS abnormalities. A decision tree was developed showing that, in girls, higher estrogen levels and younger age (<6 years)

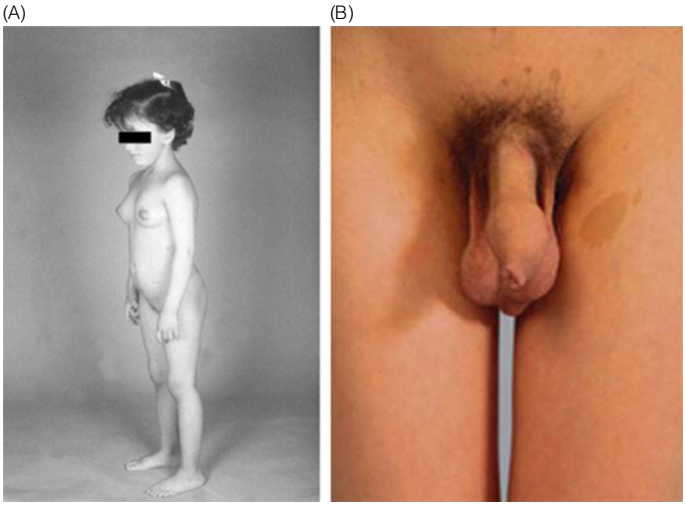

Fig. 3 (A) A 7-year-old girl with clinical presentation of CPP. (B) An 8 year old boy with an organic cause of GDPP. Note testicular enlargement and café au lait spots typical for neurofibromatosis.

at diagnosis increased the probability of the detection of a CNS abnormality on MRI (Chalumeau *et al.*, 2002) In another study the same was observed for higher basal LH levels at diagnosis (Pedicelli *et al.*, 2014; Kaplowitz and Mehra, 2015).

As a rule of thumb, the literature suggests that brain MRI should still be done in girls with onset of puberty younger than age 6 and in (all) boys. Girls with neurologic findings and rapid pubertal progression are more likely to have intracranial pathology and require an MRI examination above the age of 6 years (Carel *et al.*, 2009).

Laboratory

An essential part of the diagnosis of GDPP is the biochemical confirmation of the central (hypothalamo–pituitary) stimulation of the gonads by gonadotropins. In premature thelarche, for example, no central activation is present. The demonstration of central activation is a prerequisite for treatment with GnRH agonists. Basal values of LH or follicle-stimulation hormone (FSH) have limited value in view of limited sensitivity of many assays. Therefore, stimulation tests with native GnRH or a short-acting GnRH agonist (GnRHa) should be used in the diagnostic workup.

The increasing sensitivity of the pituitary for GnRH stimulation in normal puberty is the basis of the test. Depending on the assay, the peak value of serum LH should exceed a particular threshold. Early studies used thresholds >10 IU/L using radioimmunoassay methods, whereas the use of the more sensitive immunofluorometric assay allows cutoff values of approximately 6 IU/L. A prepubertal response in a GnRH stimulation test does not completely rule out the presence of CPP since it has been demonstrated that the more potent GnRH agonists, are able to produce pubertal LH peaks in children with prepubertal LH peaks in the standard GnRH stimulation test. Mainly children with recent onset of puberty demonstrate these varying results in the different stimulation tests. The use of urinary LH in diagnosing and follow-up of pubertal disorders has recently been proposed (Kolby *et al.*, 2017).

The use of sex steroid serum levels in the diagnosis of GDPP is limited because of the circadian variation of these levels. However, they may be used in the evaluation of pubertal suppression during treatment. **Table 2** provides a summary of the current diagnostics in GDPP. In the future, AMH and inhibin B (ovarian products) may be a promising method to differentiate progressive forms of GDPP from slowly progressive forms (Chen *et al.*, 2017).

Treatment

Gonadotropin-Releasing Hormone Agonists

Synthetic agonists of GnRH in depot form are the treatment of choice for GDPP. Basically, the native GnRH molecule is modified at least at the glycine-6 position, where it is substituted by another amino acid resulting in a super-agonistic effect. Prolonged exposure of the pituitary to a GnRHa paradoxically results in inhibition of gonadotropin secretion (**Fig. 4**).

The mechanism of this inhibitory effect is not completely understood. For example, it seems that the frequency of the GnRH pulses is not altered after GnRHa exposure and that down-regulation of GnRH receptors occurs to only a limited extent. The depot formulations of GnRHa have been shown to be able to effectively suppress the endogenous pubertal activity in GDPP. The clinical representation of this inhibition is arrest of pubertal development, sometimes even regression of physical signs of puberty, decreasing volume of uterus/ovaries, and deceleration of bone age maturation.

Based on decades of experience monthly administration of GnRHa is currently considered standard care for children with GDPP. Long acting preparations have been developed to allow quarterly of even yearly administration. In Europe, triptorelin and leuprolide acetate are most frequently used as GnRHa depot preparations. The recommended monthly dose is 3.75 mg intramuscularly or subcutaneously. In general, in the United States 7.5 mg is the recommended dose. In the United States a Histrelin implant that delivers pubertal suppression during more than a year has been approved. The optimal dose should be the lowest

Table 2 Important elements in the diagnosis of gonadotropin-dependent precocious puberty

History
Girls: Onset of breast development, growth acceleration, menarche, behavioral changes, concomitant disease or complaints, family history
Boys: Penile and testicular growth, genital hair, growth acceleration, behavioral changes, concomitant disease or complaints, family history
Physical examination

Laboratory
GnRH stimulation test: Luteinizing hormone and follicle-stimulating hormone response to GnRH (agonist) administration; sex hormone assessment

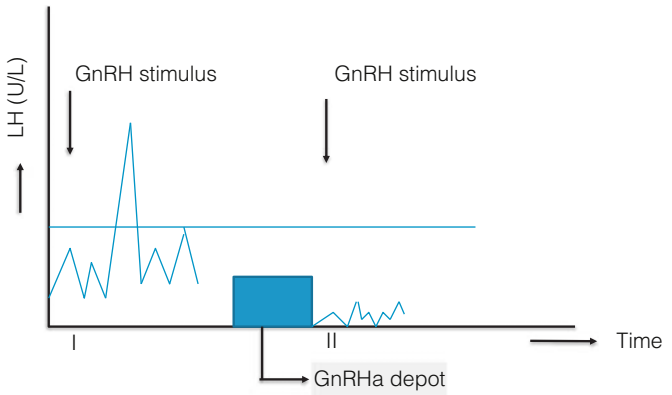

Fig. 4 Schematic representation of the inhibiting effect of gonadotropin-releasing hormone agonist (GnRHa) exposure. (I) GnRH stimulation before GnRHa treatment. Luteinizing hormone (LH) increases considerably in reaction to GnRH stimulus. (II) GnRH stimulation during GnRHa treatment. There is no increase in LH after GnRH stimulus due to the inhibitory effect of prolonged GnRHa exposure.

with which optimal suppression can be achieved. Only a few side effects have been described, mainly sterile abscesses at the injection sites (Lee *et al.*, 2014a).

The 3-months leuprolide depot 11.25 mg not always results in sufficient suppression. Better results are noticed with of the 3 months depot leuprolide 22.5 or 30 mg (Lee *et al.*, 2014b). The 3 months triptorelin 11.25 depot results in a better suppression, especially after 3 months of treatment (Durand *et al.*, 2017). Limited data about final height with these 3-months depots are available (Bertelloni *et al.*, 2015).

Data on a once-yearly histrelin implant showed adequate hormonal suppression and increase of predicted adult height after 60 months of treatment (Silverman *et al.*, 2015; Eugster, 2016).

Anaphylactic reactions to GnRH agonists have only rarely been reported (Ökdemir *et al.*, 2015).

Indications

In 2009 an international consensus statement on the use of GnRH analogs in children was published (Carel *et al.*, 2009). Indications for treatment are either auxological or psychological. The aim of treatment concerning growth is to attain a final height in accordance with parental height and thus to prevent height loss due to the early onset of puberty. It should be noted that positive height outcomes are to be expected in the younger age group, especially in girls with pubertal onset before the age of 6. Psychological issues include reduction of psychological stress resulting from development of puberty or occurrence of menarche inappropriately early for age (Menk *et al.*, 2017). However, psychological distress as such is not a definitive indication for GnRHa therapy in girls with GDPP (Schoelwer *et al.*, 2015). Sexual abuse and early pregnancy appear to be rare. However, early menarche and early sexual activity of patients with mental retardation provide special concern of families and peer groups (school). In these patients, GnRHa treatment may be indicated. Before initiation of treatment, central activation of the pituitary has to be demonstrated.

In boys, auxological reasons for treatment prevail. There is not enough data on psychological issues.

Monitoring

Several parameters should be used to monitor the suppressive effect of treatment. As mentioned previously, clinical progression of puberty must stop or even regress, and—in girls—menstrual bleeding should not occur. However, withdrawal bleeding soon after the initiation of treatment is frequently observed. Furthermore, the pubertal growth velocity should decrease to normal pre-pubertal values. Bone age progression will slow, especially after 6 months of treatment. On ultrasound, uterine and ovarian volume decrease to pre-pubertal values.

In boys, comparable monitoring of physical changes should be initiated. Growth velocity should decrease, and regression of testicular volume and change to soft, unstimulated tissue at palpation are important markers.

Biochemically, baseline sex steroid levels will become pre-pubertal in effectively suppressed patients (Freire *et al.*, 2016). Suppression of hypothalamic–pituitary–gonadal axis activity is determined during treatment by intravenously GnRH testing. Alternative methods include taking a blood sample after subcutaneous GnRHa or after injection of the GnRHa depot. Measurements of LH in urine samples seems to be promising (Kolby *et al.*, 2017). Some children show behavioral changes after the injection interval, which may indicate ineffective suppression during the final days of the injection interval. In clinical practice, meticulous clinical observation of growth and puberty during treatment is sufficient to assess effectiveness of GnRHa treatment.

Results of Treatment

Girls

Numerous studies have addressed the effect of GnRHa treatment for GDPP, and final height data have become available. However, none of these studies used randomized controlled study designs (Guaraldi *et al.*, 2016). Most studies have used the difference between height prediction at the start of treatment and attained final height as the most important outcome parameter. It is well-known that there is a wide variation in bone age assessment between observers; thus, height predictions may lack reliability. Study designs should include an assessment of bone age by only one observer. Furthermore, as noted previously, height predictions vary depending on the method and the prediction tables used. Another way to evaluate the effect of treatment is to compare attained final height with mid-parental height or genetic target height.

It can convincingly be concluded from the available data on GnRHa treatment that an increase in final height ranging from 8 to 10 cm can be obtained in girls with onset of puberty younger than 6 years. Girls with onset of puberty between 6 and 8 years, a more heterogeneous group, may have a moderate benefit ranging from 4.5 to 7.2 cm (according to the accelerated tables of Bayley Pinneau), or 3.4 to 9.5 cm when the average tables of Bayley Pinneau were used. When compared to parental height, final height is 0.5–1.0 SD below target height or midparental height.

Multivariate analyses of the results of treatment are probably most appropriate for the development of guidelines for start and/or discontinuation of treatment. The factors shown in **Table 3** have been shown to influence the results of treatment (height gain) in multivariate analysis. Several studies show better results in girls with GDPP when treatment is initiated before age 6. In contrast, in univariate analysis, chronological age at the start of treatment is negatively correlated with height gain. These contradictory results emphasize the need for proper analysis of the results of treatment.

The optimal timing with respect to chronological age and bone age for discontinuation of treatment cannot be determined from the literature. Possibly the best indication to discontinue treatment is a decrease of height velocity below pre-pubertal values during GnRHa treatment Alternatively, one may assess height prognosis every 6 months and discontinue treatment whenever a decrease in height prognosis is calculated.

Boys

Data on boys treated with GnRHa are sparse. They allow for the conclusion that GnRHa treatment improves AH in comparison with untreated boys, albeit with a large variability (1.8–11.1 cm). In the largest study of 26 boys, mean height gain was 6.2 cm, and most boys reached an AH close to target height (TH). Younger boys and those with idiopathic GDPP were likely to receive greater benefit from treatment, whereas in boys with organic forms, including neurofibromatosis, the long-term height prognosis was worse (Bertelloni and Mul, 2008).

Other Outcome Variables

Concerning other outcome variables after GnRHa treatment in GnPP, endocrine investigation after discontinuation of treatment showed prompt and complete reversibility of gonadal suppression. Menarche occurred within 1 year after discontinuation of treatment. Available, but limited data on fertility showed no adverse outcome (Guaraldi *et al.*, 2016). There is, however, apparent need for more studies in this field because there is conflicting data that PCOS may occur more often in GnRHa treated girls. One long term study concluded that the health status of former CPP women is similar to that of the general population. By now, no conclusions can be drawn on timing of menopause or health of offspring (Guaraldi *et al.*, 2016).

Studies on bone mineral density (BMD) during GnRHa treatment in girls showed normal BMD for chronological age and low BMD when corrected for bone age. At final height, BMD appeared to be normal (Thornton *et al.*, 2014).

In some children, body mass index (BMI) increases during GnRHa treatment. Pretreatment BMI SD is the strongest predictor of increased BMI SD at final height. GnRHa treatment does not lead to obesity Lazar *et al.* (2015).

Table 3 Factors that influence final height after GnRHa treatment in girls

At start of treatment
Bone age at start of treatment: more advanced bone age → better final height
Chronological age at start of treatment: younger chronological age → better final height
At discontinuation of treatment
Bone age at end of treatment: the higher the bone age, the less positive effect on final height
Chronological age at end of treatment: the higher the chronological age, the less positive effect on final height
Bone age advance at discontinuation of treatment
The more advanced bone age over chronological age, the less positive effect on final height

GnRHa and Growth Hormone

During treatment with GnRHa, it is frequently observed that height velocity decreases, even below pre-pubertal levels. The effects of GnRHa treatment on the growth hormone (GH)–IGF axis remain controversial. However, several groups have studied the effect of the addition of GH to GnRHa in children with precocious puberty. Results suggest the importance of maintaining adequate height velocity during treatment to achieve height gain. In short-term studies, the addition of GH resulted in increased predicted adult height compared to treatment with GnRHa alone. Only one study provides data for final height, confirming the results of the short-term studies (Liu *et al.*, 2016).

Conclusion

Effective suppression of pituitary gonadal function is achieved with depot GnRHa treatment in girls and boys with GDPP. Hormonal suppression is fully reversed after treatment is discontinued. Further studies should be performed to determine the final indications of treatment and long-term outcome on reproductive function.

Gonadotrophin-Independent Precocious Puberty; Female and Male

Stenvert LS Drop, Erasmus Medical Center - Sophia Children's Hospital, Rotterdam, the Netherlands
Hedi L Claahsen van de Grinten, Radboud University Medical Center, Nijmegen, the Netherlands

Glossary

Gonad A gonad is a gland that produces gametes (sex cells) and sex hormones. In the female the reproductive cells are the egg cells, and in the male the reproductive cells are the sperm. The male gonad, the testicle, produces the male hormone testosterone, AMH and inhibin B; the female gonad, the ovary, produces the female hormones progesterone and estrogens and AMH.

Gonadotropin-releasing hormone stimulation test Diagnostic test to assess the presence and origin of the onset of puberty by stimulating the gonadotrophine producing cells.

Precocious puberty Early onset of puberty before certain age limits in girls or boys.

Introduction

GnRH-independent precocious puberty (GIPP) or peripheral (pseudo-) precocious puberty is defined as pubertal signs at an age younger than the reference range that is not the result of central activation of the hypothalamic–pituitary–gonadal axis. Rather it is mainly caused by autonomous secretion of sex steroids by the gonads or the adrenal gland. The etiology of GIPP may vary by the gender of the child and can be categorized into either congenital/genetic or acquired disorders. Furthermore, based on the clinical presentation the etiology can be categorized in isosexual (i.e., androgen production in males and estrogen production in females) or contrasexual (i.e., increased androgen production in females leading to virilisation and inappropriate estrogen production in males leading to feminizaton/breast development in males) **Table 1**.

Besides pathological conditions also physiological variations of pubertal development have to be considered such as premature thelarche and premature adrenarche.

Table 1 Differential diagnosis gonadotropin independent precocious puberty (GIPP)

Isosexual	*Girls (estrogen production)*	*Boys (androgen production)*
	Ovarian cysts	Leydig cell tumor
	Ovarian Tumor	HCG secreting tumors (such as germinoma, teratoma, hepatoma, choriocarcinoma)
	Peutz–Jaeger syndrome	Testotoxicosis
	Aromatase excess syndrome	Adrenal neoplasm
		CAH (CYP21, CYP11B1 deficiency)
		Cushing syndrome
		Cortisol resistance syndrome (Chrousos syndrome)
	McCune–Albright Syndrome	McCune–Albright Syndrome
	Juvenile hypothyroidism	Juvenile hypothyroidism
	Endocrine disrupting chemicals	Endocrine disrupting chemicals
	Iatrogenic	Iatrogenic
Contrasexual	*Girls (androgen production)*	*Boys (estrogen production)*
	CAH (CYP21, CYP11B1, 3 beta HSD deficiency)	Klinefelter syndrome
	Virilising adrenal or ovarian neoplasm	Aromatase excess syndrome
	Cushing syndrome	
	Aromatase deficiency	
	Cortisol resistance syndrome (Chrousos syndrome)	
	Iatrogenic	Iatrogenic
Physiological variations of puberty	*Girls*	*Boys*
	Premature adrenarche	Premature adrenarche
	Premature thelarche	Pubertal gynaecomastia
	Premature menarche	
		Macroorchidism

Whereas GnRH dependent precocious puberty is estimated to occur in approximately 1:5000–10,000 (Partsch and Sippell, 2002) overall incidence figures for GIPP are lacking and depends on the underlying cause. For some rare disorders estimated prevalences have been reported, for instance for McCune–Albright syndrome ranging between 1/100,000 and 1/1,000,000 (Dumitrescu and Collins, 2008). Ovarian cysts are prevalent in 2%–5% of prepubertal girls and of those 5% are found to produce estrogens, giving an estimated risk of GIPP of 1:400 (0.25%) (Papanikolaou and Michala, 2015). Adrenocortical tumors are very rare neoplasms in children with an estimated annual incidence of 0.3 per 10^6 children under the age of 15 years.

Main Causes of Isosexual Precocious Puberty in Females

Ovarian Cyst

Etiology: Autonomous estrogen producing ovarian cysts can develop at any age and may regress spontaneously after a few weeks or months. They are the most common cause of precocious puberty in girls and consist of enlarged antral follicles or cysts. Cysts developed in the antenatal period under the influence of maternal and placental hormones may persist or enlarge because of high gonadotropin levels during minipuberty (Aydin *et al.*, 2017; Papanikolaou and Michala, 2015). Antral follicles in the ovary are a common finding on ultrasound in prepubertal girls (up to 8 mm) but occasionally they secrete estrogens.

Clinical features: The main symptoms are breast development (Tanner stage 2–3) and vaginal discharge or bleeding as a result of estradiol withdrawal after cyst resolution. Girls >8 years. may complain of abdominal pain or menstrual irregularity. Abdominal pain may be due to ovarian torsion particularly when cysts are large. Late diagnosis can cause loss of an ovary, peritonitis or even death.

Diagnostic work up: Laboratory studies will reveal increased estrogen levels and suppressed gonadotropin levels. Tumor markers as AMH or inhibin B are low. Pelvic sonography will show a unilateral simple cyst varying in diameter (average 2 cm; up to 4–6 cm). It is of particular interest that ovarian microcysts are a common ultrasonographic finding in non-classical CAH.

Treatment: Treatment may be conservative with or without anti-estrogens/aromatase inhibitors to reduce estrogen production or ultimately surgical (cystectomy; oophorectomy). Recurrences may occur more frequently in patients managed conservatively. Periodic pelvic sonography is recommended to monitor the size of the cysts.

Ovarian Tumor

Etiology: Ovarian tumors are rare before the onset of puberty. Most of them are benign but malignant tumors have been described. The three main types are epithelial cell tumors (70%), germ cell tumors (20%) and sex-cord-stromal tumors. Examples of sex-cord stromal tumors are granulosa cell tumors and Sertoli-Leydig cell tumors; the latter may occur in association with the Peutz-Jeghers Syndrome which is characterized by mucocutaneous pigmentation and intestinal polyposis (Bellfield and Alemzadeh, 2016). An overview of tumor markers is given in **Table 2**.

Clinical features: Clinical manifestations of sex steroid producing ovarian tumors include isosexual precocious puberty but also may include virilisation, abdominal pain. An abdominal mass that can be palpated is uncommon.

Diagnostic work up: Laboratory investigations will reveal elevated levels of ovarian derived steroids and suppressed gonadotropin levels. Ultrasonography will show unilateral ovarian mass but does not lead to a clear classification. Size can vary between 2.5 and 25 cm. Elevated levels of tumor markers will be very helpful to classify the tumor and for follow up after surgery. **Table 2**.

Treatment: Treatment is surgical (Haroon *et al.*, 2013). Staging should include peritoneal cytology, exploratory laparotomy and unilateral salpingo-oophorectomy (Fleming *et al.*, 2010) (**Fig. 1**).

Peutz–Jeghers Syndrome (PJS)

Etiology: PJS is a rare syndrome inherited by an autosomal dominant pattern. It is due to a mutation in the *STK11/LKB1* gene but also spontaneous mutations are described (Bellfield and Alemzadeh, 2016). PJS is characterized by mucocutaneous pigmentation

Table 2 Ovarian tumor markers

Histology	*AFP*	*Beta-HCG*	*LDH*	*CA-125*	*CEA*	*CA 19.19*	*Inh B*
Endodermal sinus tumor	+	−	+	+	−	+	−
Teratoma (immature)	+	−	−	+	−	+	−
Dysgerminoma	−	+	+	+	−	+	−
Embryonal CA	+	+	−	−	−	+	−
Chorio CA	−	+	−	−		+	−
Epithelial cell tumors	+	+	+	+	+	+	−
Sex stromal cell tumors	+	−	+	+	−	−	+

AFP = alpha fetoprotein; beta-HCG = beta-human chorionic gonadotropin; LDH = lactate dehydrogenase; CA-125 = cancer antigen 125; CEA = carcinoembryonal antigen; CA 19.19 = cancer antigen 19.19; Inh B = Inhibin B.

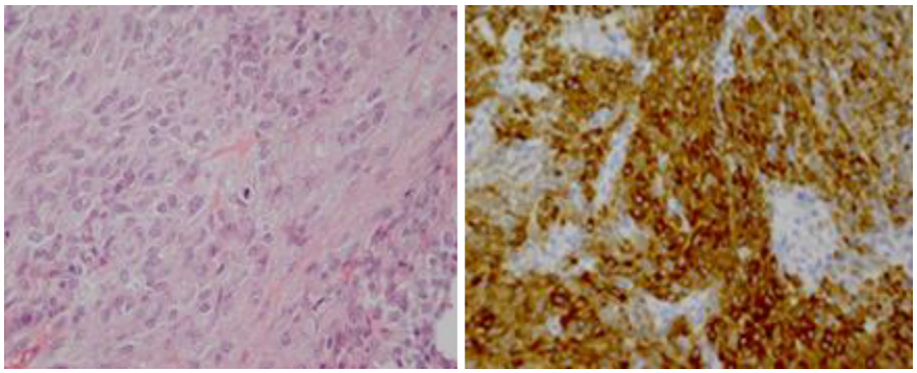

Fig. 1 Histology of juvenile granulosa tumor. Left: the nuclei are lacking atypical features; an occasional mitotic figure can be demonstrated lacking atypical features (× 200). *Right*: The tumor is staining positive for inhibin B (× 200). Source: www.espe-elearning.org.

of the lips, buccal mucosa and fingers/toes, gastrointestinal polyposis and a predisposition to malignancy. Women are at risk of developing malignancies such as breast cancer or estrogen secreting ovarian tumors.

Clinical features: Patients have the typical facial features of pigmentation. They should be screened regularly with specific screening programs to detect tumors at an early stage. Breast development indicates autonomous estrogen production. As the tumors may produce androgens also pubic hair can occur.

Diagnostic work up: Pelvic ultrasound may reveal often small and multiple lesions within the ovary and contain calcifications. Most tumors produce inhibin A and B and AMH.

Treatment: Treatment consists of surgical removal of the tumor.

Main Causes of Isosexual Precocious Puberty in Males

In boys isosexual peripheral precocious puberty has to differentiated from physiological premature adrenarche (PA). The main clinical manifestation of PA is the precocious appearance (before the age of 9 years) of pubic and/or axillary hair and the presence of adult type body odor without any other signs of excessive androgen production such as increased height velocity or advanced bone age (Voutilainen and Jääskeläinen, 2015). The etiology is multifactorial with polygenic contribution, overweight and obesity being important factors. Serum or urine levels of adrenal androgens, such as DHEA(S), may be elevated for age, but do not always correlate with clinical signs of androgen action. Importantly, in contrast to central PP there is no evidence of gonadarche (testicular enlargement) and progression of puberty.

Leydig Cell Tumor (LCT)

Etiology: Leydig cell tumors are rare during childhood and are rarely malignant but because of the androgen production the consequences are serious. They derive from primordial mesenchyme and occur commonly between the age of 5–10 years. Histological it can be difficult to distinguish Leydig cell hyperplasia from Leydig cell tumors. One of the hallmarks of LCT is the presence of Reinke Crystals in about 40% of the cases. LCT have to be distinguished from other scrotal tumors such as teratomas or cystic lesions (dermoid cyst, epidermoid cyst) (Friend *et al.*, 2016).

LCT secrete androgens, notably testosterone and more rarely estrogens. The D578H-LHR mutation, which has been found only as a somatic mutation, is specifically responsible for Leydig cell adenomas and nodular Leydig cell hyperplasia. Histology will show an encapsulated adenoma consisting of homogeneous Leydig cells without evidence of malignant transformation. In nodular Leydig cell hyperplasia nests of Leydig cells will be found (Boot *et al.*, 2011) (**Fig. 2**).

Clinical features: Most boys with androgen producing LCT present with a painless scrotal mass and premature pubarche (sometimes unilateral), penile enlargement and an asymmetrical testis volume. Also gynaecomastia can occur.

Diagnostic work up: Laboratory studies will reveal elevated levels of androgens, notably testosterone, and suppressed levels of gonadotropins. Levels of tumor markers such as alpha-fetoprotein an beta-human chorionic gonadotropin are notably low and can help to differentiate form other tumors such as teratomas in which alpha fetoprotein (AFP) may be elevated. Ultrasound including Doppler sonography may reveal a small hypoechoic mass in the testis.

Treatment: Treatment is surgical. In benign lesions a testis sparing approach may be considered and have to be performed by experienced surgeons (Emre *et al.*, 2017).

Human Chorionic Gonadotropin (HCG) Producing Tumors

Etiology: Testicular and extragonadal germ cell tumors (germinoma) and other embryonal tumors such as hepatoblastoma or chorioncarcinoma may secrete HCG. The production of beta-HCG generates hyperplasia of Leydig cells resulting in elevated levels of testosterone as well as estrogens through aromatization of androgens. The histology depend on the tumor localization and the

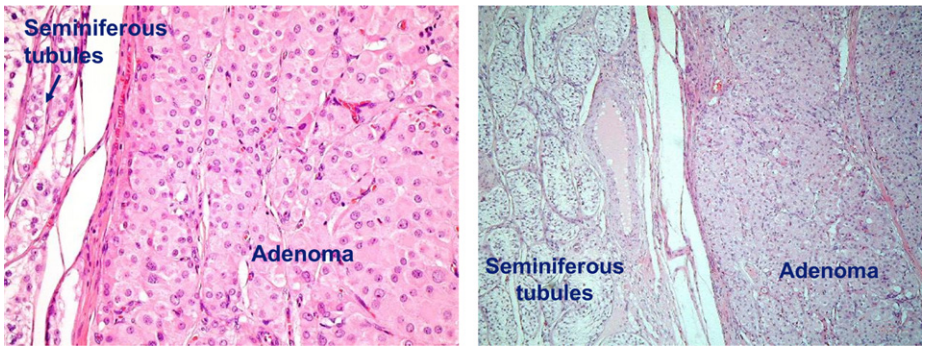

Fig. 2 *Left*: Encapsulated Leydig cell adenoma (× 100); *right*: homogeneous Leydig cells without evidence of malignant transformation (× 400). Source: www.espe-elearning.org.

origin of the tumor. Intracranial germ cell tumors account for 3%–11% of malignant CNS tumors in childhood and are located in the hypothalamus, pinealis region, thalamus or basal ganglia.

Clinical features: Symptoms depend on the location of the tumor. Intracranial germ cell tumpurs often present with diabetes insipidus. In addition to signs of isosexual precocious puberty boys may present with gynecomastia. The testes are not or only minimally increased in size.

Diagnostic work up: Laboratory studies reveal elevated levels of testosterone and suppressed levels of gonadotropins but Beta-HCG levels are markedly increased. As HCG producing tumors are mostly located in the CNS, retroperitoneum or mediastinum MRI studies are indicated.

Treatment: Chemotherapy (cisplatin; etoposide; bleiomycin) has a high rate of inducing remission. (Nascimento *et al.*, 2012; Bravo-Balado *et al.*, 2017). Serum tumor markers are not only beta-HCG but also alpha-fetoprotein (AFP) and testosterone levels (Eren *et al.*, 2009).

Familial Male-Limited Precocious Puberty or Testotoxicosis

Etiology: Familial male-limited precocious puberty (FMPP) or testotoxicosis results from heterozygous constitutively activating mutations of the *LHCGR* gene encoding the luteinizing hormone/choriogonadotropin receptor (LH/HCG), a member of the large G protein-coupled receptors with 7 transmembrane segments. Several *LHCGR* mutations have been described in the 6th or rarely in the 7th transmembrane segment (Nagasaki *et al.*, 2010). The mutation can occur de novo or may be inherited in an autosomal dominant fashion. Premature maturation of Leydig cells and Sertoli cells can occur due to chronic exposure of testosterone. The Leydig cells in affected boys produce Inhibin B and testosterone.

Clinical features: Boys present with very early pubertal development typically before the age of 4 with rapid growth, tall stature, an enlarged penis, pubic hair but only minimal testicular enlargement. (Schoelwer and Eugster, 2016). If left untreated short stature will result due to early closure of the epiphyses. Also muscular development is prominent.

Diagnostic work up: High intra-testicular testosterone concentrations may be sufficient for spermatogenesis and even allow fatherhood (Juel Mortensen *et al.*, 2017). Prepubertal gonadotropin levels and low levels of GnRH stimulated gonadotrophines are found. There is a lack of suppression of testosterone levels by GnRH agonists.

Treatment: Various treatment options are listed in **Table 3**. Cyproterone acetate (CPA) and medroxyprogesterone acetate (MPA) have been used for their antiandrogen properties but ketoconazole has been found more effective due to its ability to inhibit adrenal and testicular androgen biosynthesis. However there are safety issues in view of hepatotoxicity and adrenal suppression. Ketokonazole, Spironolactone or Bicalutamide can also be used in combination with aromatase inhibitors. (Kang *et al.*, 2016).

Causes of Iso—and Contrasexual Precocious Puberty in Both Sexes

Familial Glucocorticoid Resistance (Chrousos Syndrome)

Etiology: Glucocorticoid resistance syndrome is caused by mutations in the human glucocorticoid receptor (hGR) gene encoded by the *NR3C1* gene (chromosome 5). As the negative feedback by glucocorticoids at the level of hypothalamus is impaired ACTH production is increased. Thus the adrenal glands overproduce not only glucocorticoids but also mineralocorticoids and androgens.

Clinical features: The clinical spectrum of the condition is broad ranging from severe signs of adrenal insufficiency to mild or even asymptomatic forms. In boys and girls the increased levels of androgens lead to precocious puberty and hyperandrogenism (Nicolaides and Charmandari, 2017; Malchoff *et al.*, 1994). One of the hallmarks of this condition is the presence of hypertension and a hypokalemic alkalosis.

Diagnostic work up: Laboratory investigations will reveal increased levels of adrenal steroids and ACTH and renin activity. Ultrasonography will show adrenal hyperplasia. A 24 h blood pressure measurement will reveal hypertension.

Table 3 Anti-androgens, anti-estrogens and aromatase inhibitors

Drug name	*Mechanism of action*
Cyproterone acetate (CPA)	Antiandrogen
Medroxyprogesterone acetate(MPA)	Antiandrogen
Ketokonazole	Inhibits P450 enzymes
Spironolactone	Weak antiandrogen agent
Testolactone	First generation aromatase inhibitor
Anastrozole	Third-generation aromatase inhibitor
Letrozole	Third generation aromatase inhibitor
Bicalutamide	Nonsteroidal antiandrogen
Tamoxifen	Selective estrogen receptor inhibitor
Fulvestrant	Estrogen receptor inhibitor

Treatment: The treatment consist of dexamethasone in a dose carefully titrated according to the clinical manifestations and biochemical profile. (Charmandari *et al.*, 2013; Malchoff *et al.*, 1994).

Aromatase Excess Syndrome (AEXS)

Etiology: Aromatase excess syndrome (formerly known as familial gynecomastia) is a very rare genetic disease characterized by symptoms related to estrogen excess notably pre-or peripubertal onset of gynecomastia. Aberrant aromatase expression is the result of subchromosomal inversion of the *CYP19A1* gene encoding for the enzyme aromatase that converses (adrenal) androgens to estrogens.

Clinical features: AEXS is characterized by premature thelarche and early menarche that is accompanied by accelerated growth and bone maturation. Also sparse facial hair and high pitched voice has been described. In pubertal boys testicular volume is lower but normal in post-pubertal males.

Diagnostic work up: Laboratory investigations will reveal elevated levels of estrogens and suppressed FSH, but in the GnRH test LH and testosterone will increase. There is an increased aromatase activity in skin fibroblasts. Gene mutation analysis will be confirmatory.

Treatment: Treatment consist of aromatase inhibitors (see **Table 3**). (Shozu *et al.* (2014)).

McCune–Albright Syndrome (MAS)

Etiology: McCune–Albright Syndrome (MAS) is characterized by the triad polyostotic fibrous dysplasia, hyperpigmented macules (café-au-lait spots) and precocious puberty (see **Figs. 3–5**). The cafe au lait spots have a characteristic pattern with irregular borders ("coast of Maine") in contrast to the smooth borders in neurofibromatosis.

The clinical presentation of MAS is the result of constitutive activation of cells affected by a postzygotic gain of function somatic mutation in the *GNAS1* gene (Lumbroso *et al.*, 2004). It should be noted the individual phenotype may be very heterogeneous depending on the number and types of tissues involved. MAS in boys is very rare and precocious puberty occurs less frequently and later in life than in girls. Gene mutation analysis in peripheral blood cells have a low yield, whereas the likelihood of detecting a mutation is increased in affected tissue.

Girls

Clinical features: Girls present with painless vaginal bleeding and minimal breast enlargement as a result of estrogen secretion by autonomously functioning ovarian cysts.

Diagnostic work up: Laboratory studies will reveal an elevated level of estradiol and suppressed levels of gonadotropins, confirmed by suppressed levels of gonadotropins in the GnRH test. Typically, unilateral ovarian cysts are seen on pelvic sonography. Other endocrine organs can be involved such as thyroid, adrenal, parathyroid and pituitary gland. Careful follow up is indicated. Hyperphosphaturia may occur due to intrinsic renal abnormality or due to overproduction of phosphatonin (Boyce *et al.*, 2017). A bone scan is in order to evaluate for fibrous dysplasia (see **Fig. 4**).

Treatment: Treatment options are listed in **Table 3**. Cyproterone-acetate (CPA) and medroxyprogesterone (MPA) are two of the first agents historically used. However long-term treatment has proven unsatisfactory. Several first- and second-generation aromatase inhibitors have been studied, however with insufficient long-term effectiveness, perhaps with the exception of letrozole. More recently estrogen receptor modulators such as tamoxifen or fulvestrant have been shown to be more promising. Ultimately, surgical options may be considered such as cystectomy or even oophorectomy.

Boys

Clinical features: Boys present with penile growth and slight bilateral enlargement of the testes. Sometimes even macroorchidism. On ultrasound hypo-or hyperechoic lesions are found with microlithiasis and focal calcifications.

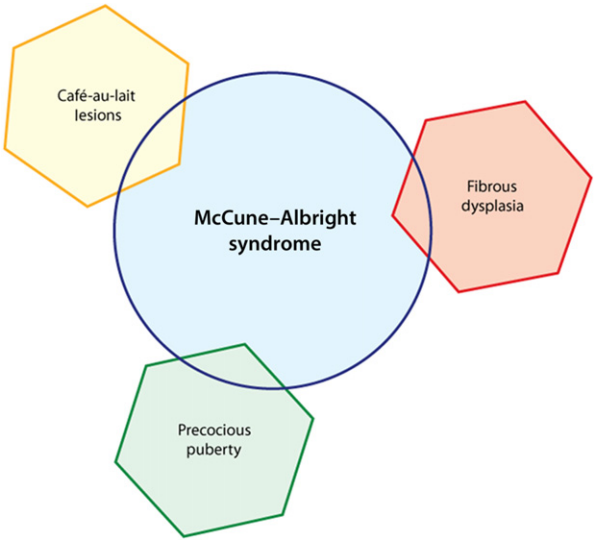

Fig. 3 The McCune–Albright trias.

Fig. 4 Fibrous dysplasia; in view of spontaneous fractures a stabilizing rod has been inserted.

Diagnostic work up: Laboratory studies will reveal elevated levels of testosterone and suppressed levels of gonadotropins.

Treatment: A combination therapy consisting of an androgen receptor blocker and an aromatase inhibitor are most often used (see **Table 3**).

Adrenal Tumors

Etiology: As adrenocortical tumors are often hormone secreting tumors the clinical presentation may be the result of the combined overproduction of gluco- and mineralocorticoids as well as androgens or estrogens. But also pure androgen or estrogen producing

Fig. 5 Café-au-lait pigmentation in case of McCune–Albright syndrome; the lesion having a jagged border does not cross midline, which is very characteristic of MAS.

adenoma have been described. The cause of isosexual precocious puberty in a girl with an adrenal adenoma has been shown to be the result of markedly increased adrenal estrogen production caused by aromatase P450 activity due to abnormal enhancement of transcriptional activity of parts of the promotor of the aromatase gene.

Diagnostic work up: Laboratory investigations will reveal elevated levels of adrenal steroids and suppressed levels of gonadotropins. Imaging studies such as ultrasonography, CT and MRI will establish an adrenal mass.

Pathology Adrenal Tumors

Adrenocortical tumors are very rare neoplasms in children. In recent studies several recurrent chromosomal alterations were identified, the most frequent being $-4q34$, $+9q33\text{-}q34$, $+19p$, loss of heterozygosity of chromosome 17 and 11p15. In addition several focal amplifications and homozygous deletions comprising well-known oncogenes (MYC, MDM2, PDGFRA, KIT, MCL1, BCL2L1) and tumor suppressors (TP53, RB1, RPH3AL) have been identified. In addition a strong DAX1 protein expression, correlating with SF1 gene expression was demonstrated in adrenocortical tumors of pediatric patients (de Sousa *et al.*, 2015). Thus potential driver genes and cellular pathways as well as the existence of different oncogenic routes are implicated in childhood adrenocortical tumors (Letouzé *et al.*, 2012).

Adrenocortical carcinoma has its peak incidence in children <4 years of age, and is associated with the Li-Fraumeni and Beckwith-Wiedemann syndromes.

The distinction adenoma versus carcinoma may be difficult and requires careful staging of the tumor in accordance with criteria specifically developed for childhood adrenal tumors (Wieneke *et al.*, 2003). See **Fig. 6** and **Table 4**.

Treatment: The treatment is surgical.

Primary Hypothyroidism (VanWyk–Grumbach Syndrome)

Etiology: The Van Wyk–Grumbach syndrome (or the "overlap" syndrome) is characterized by a long-standing history of primary hypothyroidism usually due to acquired thyreoiditis (Hashimoto). The pathophysiology of VWGS is not yet clear, but the most accepted theory states that the high concentrations of TSH are sufficient to cause activation of the FSH receptor (since they share the same α subunit) and produce gonadal enlargement and isosexual puberty in boys and girls. Also bioactive FSH but no LH has

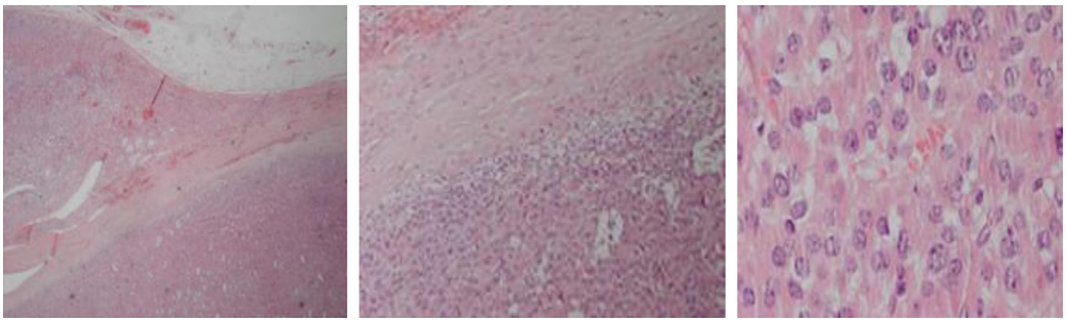

Fig. 6 *Left*: The adrenal tumor is surrounded by a fibrous capsule, which is not at any point invaded by the tumor (× 12.5). *Middle*: Same area; polygonal epitheloid cells with eosinophilic cytoplasm, arranged in solid sheets with micro-cysts, and rich in thin-walled blood vessels. Bland nuclei; no mitotic figures (× 100); *right*: same area showing the intimate relationship between the tumor cells and thin-walled blood vessels characteristic of endocrine tumors, and consistent with the morphology of an adreno-cortical adenoma (× 400). Source: www.espe-eleaarning.org.

Table 4 Macroscopic and microscopic criteria for malignancy of adrenal cortical neoplasms in pediatric patients

Tumor weight of > 400 g
Tumor size > 10.5 cm
Extension into peri-adrenal soft tissues and/or adjacent organs
Invasion into vena cava
Venous invasion
Capsular invasion
Presence of tumor necrosis
15 mitoses per 20 high power field (400 ×)
Presence of atypical mitotic figures

After Wieneke, J.A., Thompson, L.D. and Heffess, C.S. (2003). Adrenal cortical neoplasms in the pediatric population: A clinicopathologic and immunophenotypic analysis of 83 patients. *The American Journal of Surgical Pathology* **27**, 867–881.

been detected. A pituitary MRI may reveal an enlarged pituitary size (due to increase size of the thyrotrophs) which could be miss-interpreted as a tumor.

Clinical features: Pre-pubertal girls present with breast development and vaginal bleeding, with a lack of pubic and axillary hair growth.

Diagnostic work up: Decreased bone age (to different degrees) and elevated prolactin level are often seen sometimes combined with galactorrhoea.

Treatment: Early recognition and initiation of thyroid hormone replacement therapy will avoid further diagnostic procedures, fear of malignancy and unnecessary surgery. Ovarian cysts or a pituitary mass will resolve. Boys present with testes enlargement in 80% of the cases due to an increased size of the seminiferous tubules but without Leydig cell stimulation and low testosterone concentrations. Thyroid replacement therapy results in resolution of all signs and symptoms and final height prediction will improve. (Christens *et al.*, 2014).

Exogenous Sex Steroid Exposure

Premature or excessive sex steroid exposure is clinically obvious in younger children but can be easily missed or "rationalized" as "normal" in peri-pubertal aged children. In the prepubertal child (boys and girls) androgen excess will manifest with acne, adult-type body odor, sexual hair and diffuse hirsutism and clitoral and penile growth. Estrogen exposure will cause breast development. Unintentional secondary exposure to testosterone and estrogen containing transdermal products may occur directly through skin-to-skin contact. Testosterone and estrogen preparations are widely available for adults as part of hormone replacement therapy or contraception. Treatment consists of identification of the source. Following withdrawal of the androgen exposure most symptoms will regress; however clitoral and penile length may not regress completely (Cabrera and Rogol, 2013; De Pinho *et al.*, 2016).

Endocrine Disrupting Chemicals (EDC)

Endocrine disrupting chemicals are substances that may interfere with the endocrine system mimicking natural hormones such as estrogens and androgens. They may also produce overstimulation or alter the metabolism of endogenous hormones. They may bind to a cellular receptor and block functions of endogenous hormones and thus acting as anti-estrogens or anti-androgens. These

substances include polychlorinated biphenyls (PCB), dichlorodiphenyltrichloroethane, pesticides, plasticizers (such as phthalates). Plasma levels of di(2-ethylhexyl)phthalate (DEHP) were found significantly higher in patients with peripheral PP when compared to control (Buluş *et al.*, 2016). In a recent review of the clinical and epidemiological literature it was concluded that currently available data is inconclusive necessitating further study to understand the role of EDC in pubertal development (Leonardi *et al.*, 2017).

Congenital Adrenal Hyperplasia (CAH)

Etiology: Isosexual precocious puberty in boys and contrasexual puberty in girls may result from increased androgen secretion by the adrenal cortex particularly with undiagnosed classic simple virilising (SV) form or non classic (NC) form of 21 hydroxylase deficiency or the more rare form of 11beta-hydroxylase deficiency. Due to the enzymatic defect there is a lack of negative feedback of cortisol to the pituitary gland with consequently increased production of ACTH that lead to hyperplasia of the adrenal cortex with increased production of adrenal androgens.

Clinical features: Androgen excess depends on the severity of the enzymatic defect and will manifest with a variation of signs as acne, adult-type body odor, sexual hair and diffuse hirsutism and penile growth. In the more severe forms (SV forms) there is also an increased height velocity with a increased bone age. In NC CAH patients the height velocity is generally not increased with still an advancement in bone age. Typically in boys the testes have a prepubertal volume. Untreated elevated androgens may lead to activation of hypothalamic–pituitary–gonadal axis resulting in GnRH dependent puberty (see below).

Diagnostic work up: increase levels of serum or saliva 17 hydroxyprogesteone and androstenedione (in the morning) are the hallmarks of 21 hydroxylase deficiency. A urinary steroid profile will show increase steroid metabolites. Furthermore, a bone age has to be done. An ACTH stimulation test can help to diagnose milder forms of CAH. The diagnosis can be confirmed by gene mutation analysis. With the introduction of the neonatal screening programs in many countries the classic simple virilising forms are mostly diagnosed and treated already in the neonatal period.

Treatment: Corticosteroid treatment will result in suppression of adrenal androgens and in regression of the symptoms. However, parents have to be counseled for the positive and negative effects of glucocorticoid treatment.

Gonadotrophin-Dependent Precocious Puberty

It should be noted that the treatment of Gn-independent PP may be complicated by activation of the hypothalamic–pituitary–gonadal axis resulting in GnRH dependent or central PP. Therefore frequently GnRH analog treatment is necessary as adjuvant therapy (Santos-Silva *et al.*, 2014). In patients with CAH is has been shown to have an augmenting effect on linear growth (Güven *et al.*, 2015).

Conclusions

Whereas the prevalence of GnRH-independent precocious puberty (GIPP) is low and the etiology heterogeneous it is of paramount importance to establish a definitive diagnosis as in case of adrenal or gonadal sex hormone producing tumors surgical treatment is required.

Abbreviations

AXIN2	Axin-like protein (Axil) or axis inhibition protein 2
BRAF	B-Raf (gene that encodes protein B-Raf)
CP	Craniopharyngioma
CSF	Cerebrospinal fluid
CT	Computed tomography
CTNNB1	β-Catenin gene
GLI2	GLI family zinc finger 2
IFN-α	Interferon alpha
LEF1	Lymphoid enhancer-binding factor 1
MRI	Magnetic resonance imaging
PTCH1	Protein-patched homologue 1
SHH	Sonic hedgehog
TSH	Thyroid-stimulating hormone

Introduction

Craniopharyngioma (CP) is defined by the World Health Organization (WHO) as "a benign, partially cystic epithelial tumor of the sellar region, presumably derived from Rathke's pouch epithelium" (Rushing *et al.*, 2007). The two clinicopathological subtypes typically observed are adamantinomatous and papillary. In childhood and adolescence, adamantinomatous CP with cyst formation is most common. Papillary CP occurs almost exclusively in adults. While this article is predominantly about adamantinomatous CP, some features that distinguish it from the papillary will be presented.

CP is extremely heterogenous in their location, rate of growth, size, shape, gross structure, propensity to invade adjacent tissue, histology, and functional impact. As they originate from cells along the path of the primitive craniopharyngeal duct and adenohypophysis, they can be located above and/or within the sella or rarely below and around the sella. Although metastasis is exceedingly rare and CP is typically categorized as benign WHO grade I, they invariably impact on adjacent vital structures such as the optic nerves and chiasm, pituitary stalk and gland, hypothalamus, third ventricle, and internal carotid artery. This results in potential visual, endocrine, metabolic, and neurological morbidity. Location, size, local extension, and adherence can make CPs difficult to resect. Local tumor growth and invasion and definitive treatment can compromise such nearby structures with further significant impact on morbidity and quality of life. Their unpredictable potential to recur regardless of initial treatment modality poses further challenges for achieving control and cure.

The two main modalities of treatment currently available are surgery and radiotherapy. However, the optimal treatment of CP remains controversial. Radical surgery with complete resection aimed at long-term cure for childhood-onset CP has been favored historically. However, partial resection has been reported to have equivalent tumor-control rates as complete resection (Tan *et al.*, 2017). In the past two decades, there has been a greater preference toward individual risk-based interventions, incorporating more conservative surgery using advanced neurosurgical devices and techniques and improved precision radiotherapy to control the disease. More recently, reports on long-term prognosis, novel neurosurgical and radio-oncological treatment approaches, and molecular genetics have provided new insight into further risk-adapted treatment of CP to prevent severe sequelae such as hypothalamic syndrome and obesity.

Epidemiology

The incidence of CPs ranges between 0.5 and 2 cases per million persons per year (Bunin *et al.*, 1998). Although diagnosed at any age, a bimodal age distribution is demonstrated with peak incidence rates at 5–15 and 50–75 years. CPs constitute approximately 5%–10% of pediatric brain tumors. It remains the most common neuroepithelial intracranial tumor in the pediatric population, constituting about 56% of all sellar and suprasellar tumors in children (Miller, 1994).

Pathology

Etiology

The two subtypes of CP are thought to arise from different processes involving the development of the anterior pituitary (pars anterior or adenohypophysis) and its intermediate lobe (pars intermedia). In the fourth week of gestation, these lobes of the

 doi:10.1016/B978-0-12-801238-3.65241-8

pituitary develop from an ectodermal evagination, called Rathke's pouch. It grows upward from the roof of the stomodeum (oral cavity) toward the infundibulum. During the sixth week of gestation, the connection between Rathke's pouch and the oral cavity (the craniopharyngeal/pharyngohypophyseal duct) disappears. Subsequently, cells in the anterior wall of Rathke's pouch develop into the anterior lobe and pars tuberalis (extension of the anterior lobe along the pituitary stalk), and those in the posterior wall form the intermediate lobe (Miller, 1994).

Adamantinomatous CPs are theorized to develop from embryonic squamous-cell rests found along the path of Rathke's pouch and the primitive craniopharyngeal duct. For the papillary subtype of CP, a metaplastic origin from cells in the pars tuberalis has been proposed (Larkin and Ansorge, 2013).

Histopathology

The adamantinomatous and papillary subtypes are based on histopathologic appearances. The cystic adamantinomatous subtype, which is the most predominant in childhood, resembles tumors of tooth-forming tissues of the jaw or ameloblastomas known as adamantinomas. Microscopically, the tumor is made up of many cell types. At the border are dense areas of columnar epithelial cells. These palisading areas blend with squamous epithelial cells arranged loosely and termed stellate reticulum. Keratinization of these epithelial cells can result in anuclear areas of "wet keratin" in both compact and loose zones. Cyst cavities are lined by flat epithelium and contain desquamated flat keratin plates. Therefore, the cyst fluid is rich in membrane lipids such as cholesterol and keratin and has a typical dark "motor oil" appearance. It can contribute to chronic inflammation within the cyst walls. The desquamated cells can also calcify, but metaplastic bone formation is unusual (Miller, 1994).

Squamous papillary CPs, which occur almost exclusively in adults, are composed of stratified squamous epithelium with papillary projections of epithelial cords into the surrounding tissues. They rarely calcify or desquamate, with the cell layers being solid and compact and with no stellate regions. Mixed CPs contain features of both adamantinomatous and papillary types (**Fig. 1**).

Molecular Pathology

In the majority of adamantinomatous CPs, activating mutations in *CTNNB1*, the gene encoding β-catenin on chromosome 3, have been identified (Sekine *et al.*, 2002). In the papillary subtype, *BRAF* p.V600E mutations are described instead (Brastianos *et al.*, 2014). Thus, adamantinomatous and papillary CP are distinct molecular entities. Recently, the coexistence of *BRAF* p.V600E and *CTNNB1* mutations was reported in one case of adamantinomatous CP (Larkin *et al.*, 2014). Whether other mutations are present in human adamantinomatous CPs in addition to those in *CTNNB1* remains to be explored. Most identified mutations in adamantinomatous CP affect regulatory amino acids encoded by exon 3 of *CTNNB1* (Martinez-Barbera and Buslei, 2015). Normally, β-catenin is degraded in the proteasome and does not accumulate in the nucleus. In CP, the mutant form of β-catenin is resistant to degradation, accumulates in the cytoplasm and nucleus, and activates the canonical WNT signaling pathway (Hölsken *et al.*, 2009). This occurs in nests or clusters of CP cells and not throughout the tumor (Gaston-Massuet *et al.*, 2011). Nuclear localization of β-catenin in the cell clusters can be seen with immunostaining of tumor tissue. These clusters are a histological hallmark of human adamantinomatous CP and are not present in any other pituitary tumors.

Whole-genome methylation and microarray gene expression studies in a large cohort of patients have revealed different gene expressions and methylation patterns in adamantinomatous compared with papillary CP (Hölsken *et al.*, 2016). In the adamantinomatous subtype, genes in the WNT (such as *LEF1* and *AXIN2*) and hedgehog (such as *GLI2*, *PTCH1* and *SHH*) pathways are upregulated (Hölsken *et al.*, 2016). Overactivation and suppression of a number of target genes and signaling cascades

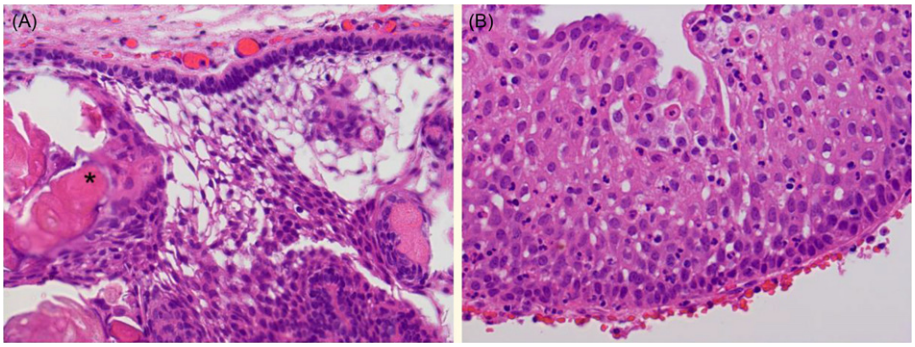

Fig. 1 Histological appearances of adamantinomatous (A) and papillary (B) craniopharyngioma (hematoxylin and eosinophil, 400 ×). (A) Demonstrates typical features of an adamantinomatous craniopharyngioma with nuclear palisading of columnar squamous epithelial cells that blend into central, looser areas of stellate reticulum. Pearls of wet keratin can be also appreciated (*asterisk*). In contrast, a papillary craniopharyngioma in (B) demonstrates undulating sheets of well-differentiated, nonkeratinizing squamous epithelium. There is an associated acute inflammatory infiltrate in this case.

downstream from the WNT–β-catenin pathway have also been reported (Hölsken *et al.*, 2009; Gump *et al.*, 2015). These are involved in embryogenesis and oncogenesis and likely to contribute to tumor initiation, growth, adhesion, and migration. Investigating whether a particular pathway has antitumorigenic or protumorigenic effects presents opportunities for designing targeted biological treatments for CP.

Clinical Presentation

Initial Presentation

The clinical features of a CP are due to its space-occupying effect and compression of adjacent vital structures. The diagnosis of CP in children is frequently delayed due to the nature of symptomatology. In a large cohort of childhood-onset CP, the median duration of symptoms before diagnosis was 6 months (range, 0.1–108 months) (Hoffmann et al., 2015a). Headache was the most common symptom before diagnosis (50%) and often the first (38%). In isolation and without the characteristic red flags of raised intracranial pressure, it can be attributed to other common causes of headache. The prediagnosis symptom interval was shorter in children under age 7 years than older patients. It did not correlate with tumor size, hypothalamic involvement, or visual impairment. Hydrocephalus, nausea, visual impairment, and neurological deficits prompted earlier diagnosis. Growth failure, endocrinopathies, and weight gain at diagnosis often forebode a longer duration of history.

Spectrum of Clinical Manifestations

Tumor location and size influence the clinical presentation (**Table 1**). Compression or destruction of the third ventricle, optic chiasm, nerves and/or tracts, other cranial nerves, hypothalamus, pituitary stalk, or adjacent vascular structures by CPs results in the typical presenting clinical features, which include hydrocephalus, headache, progressive visual loss, neurological deficits, and/or endocrine abnormalities. Retrochiasmatic tumors can extend posteriorly and compress the chiasm anteriorly against the tuberculum sella. These tumors tend to fill the third ventricle and cause hydrocephalus. Raised intracranial pressure results from either obstructive hydrocephalus or mass effect. At presentation, 20% of children have papilledema. Approximately, 10%–20% of children present with acute neurological deterioration, which requires urgent cyst decompression or tumor resection (Sughrue *et al.*, 2010). Although a midline suprasellar mass typically causes a superior temporal quadrantanopia by compression of the overlying optic chiasm, eccentric growth of a CP can lead to patterns of visual loss that vary in type and severity. Lateral extension of the tumor can cause displacement of internal carotid arteries and posterior communicating arteries. Posterior extension of the tumor can displace the tip of the basilar artery, posterior cerebral arteries, oculomotor nerves, and rostral brainstem.

Endocrine Morbidity

CPs can compress or destroy the hypothalamus, anterior pituitary, pituitary stalk, and posterior pituitary, resulting in varying patterns of endocrinopathy. Virtually, all of the pituitary hormones can be affected, but the commonest is growth hormone deficiency presenting as growth failure, followed by deficiencies of thyrotrophin-releasing hormone (TSH) and gonadotrophins. Adrenocorticotropic hormone deficiency is less common at presentation but is potentially life-threatening. At diagnosis, at least one pituitary hormone deficiency is common. Pituitary dysfunction tends to worsen after surgery and rarely recovers.

Central diabetes insipidus is unusual at presentation but is extremely common in the immediate postoperative period (albeit transient) and later postoperatively. CP impinging on the pituitary stalk suppresses prolactin inhibitory factor (mainly dopamine) reaching the lactotrophs of the anterior pituitary. Thus, prolactin levels can be raised (Sughrue *et al.*, 2010).

Table 1 Spectrum of manifestations and morbidity from craniopharyngioma

Structures affected	*Manifestations*
Third ventricle and CSF flow	Raised intracranial pressure, hydrocephalus, headache, vomiting, papilledema, acute neurological deterioration
Optic chiasm, nerves, and/or tracts	Defects in visual fields and acuity
Anterior pituitary	Growth hormone deficiency and growth failure Deficiency of TSH, gonadotrophins (i.e., follicle-stimulating hormone and luteinizing hormone), and adrenocorticotropic hormone
Posterior pituitary	Antidiuretic hormone and central diabetes insipidus
Hypothalamus	Imbalances in regulation of appetite, thirst, body temperature, heart rate, blood pressure, and circadian rhythm; hypothalamic syndrome including obesity, behavioral changes, and daytime sleepiness

Hypothalamic Morbidity

In approximately 35% of patients with CP, symptoms of hypothalamic syndrome, such as obesity, behavioral changes, disturbed circadian rhythm, daytime sleepiness, and imbalances in regulation of thirst, heart rate, blood pressure, and body temperature, have been found at diagnosis (Müller, 2016). Despite adequate replacement of pituitary deficiencies, weight gain and the development of obesity can still occur. The hypothalamic imbalances in energy regulation contribute to obesity and are exacerbated by factors limiting physical activity such as visual impairment, neurological deficits, psychosocial difficulties, and increased daytime sleepiness (Müller, 2010, 2011; Prieto *et al.*, 2015).

The rate of hypothalamic dysfunction dramatically worsens after treatment of CP. In approximately half of patients, the severity of obesity often worsens early after initial surgical treatment with rapid weight gain in the first 6–12 months and reaching a plateau during the long-term course of disease (Müller, 2011). Patients with CP and hypothalamic obesity typically develop morbid obesity that is unresponsive to conventional lifestyle modification (Müller, 2016). It can result in increased risks of cardiovascular disease, sequelae due to metabolic syndrome (Erfurth, 2015), and nonalcoholic fatty-liver disease (Hoffmann et al., 2015b). Hence, appropriate surgical strategies aimed at preserving the hypothalamic integrity are mandatory for the prevention of morbid obesity resulting from hypothalamic damage.

Investigations for CP

Imaging

CP can comprise of cystic, solid, or mixed components. Pediatric lesions are predominantly cystic. Based on anatomical relationship of the tumor to the optic chiasm, CPs can also be categorized into prechiasmatic, retrochiasmatic, subchiasmatic, and laterally expansile (Sughrue *et al.*, 2010). About 75% of CPs are suprasellar with intrasellar extension; some are entirely suprasellar (20%) and occasionally intrasellar (5%). Intraventricular CPs are rare, arising within the third ventricle and extending downward through the sphenoid bone into the nasopharynx (Harwood-Nash, 1994).

Plain radiographs are rarely used for diagnosis. However, they can demonstrate abnormalities in the sella, including sellar enlargement (65%), erosion of the clinoid processes or dorsum sella (44%), or calcifications (80%) (Donovan and Nesbit, 1996; Moore and Couldwell, 2000).

On computed tomography (CT) imaging, the tumor appears as a lobulated, heterogeneous, suprasellar mass. Associated cyst fluid is either isodense or hypodense. The solid portion and cyst capsule enhance with contrast. Calcifications, particularly in the suprasellar region, are best demonstrated on plain CT. The presence of abundant suprasellar calcification is clinically significant, as it is associated with tumors that adhere to surrounding brain tissue, thereby making resection difficult. The calcification can be seen as large confluent areas or small punctate or curvilinear areas (Donovan and Nesbit, 1996; Moore and Couldwell, 2000). Calcification is more difficult to detect on magnetic resonance imaging (MRI).

High-resolution MRI sequences of the sellar region, with and without contrast enhancement, are the images of choice (**Fig. 2**). The signal characteristics of CPs on MRI scans are typically heterogeneous and vary with the amount of cystic and solid components and the amount of cholesterol, keratin, hemorrhage, and calcification. On T1-weighted images, the cystic component is hypointense unless proteinaceous when hyperintensity may be observed, while the cyst rim enhances following contrast administration. The solid component is isointense but demonstrates contrast enhancement. The tumor is usually hyperintense on T2-weighted images.

MRI provides in-depth detail regarding the relationship of the tumor to adjacent anatomical (particularly the hypothalamus, optic chiasm and nerves, third ventricle, and pituitary) and vascular structures. Preoperative identification of the location and distortion of the solid mammillary bodies can aid in predicting the relative position and adherence of the CP to the hypothalamus. Another important feature on MRI is the position of the anterior communicating artery, which is invariably closely related to the optic chiasm. The anterior communicating artery can still be seen with large tumors even when the chiasm is exceptionally thin and cannot be distinguished from the solid tumor or capsule. The position of the anterior communicating artery and the chiasm relative to the tumor strongly influences the choice of surgical approach (Sughrue *et al.*, 2010). The use of T2-weighted MRI and fast imaging employing steady-state acquisition MRI sequences also allows the brain–CP interface and the relative position of the hypothalamus to be identified (Xie *et al.*, 2011). This can aid in the planning of surgical resection and radiotherapy fields. Likewise, imaging may also demonstrate hydrocephalus that, in turn, may influence surgical approaches.

Differential Diagnoses

The imaging differential diagnosis of a CP includes Rathke's cleft cysts, pituitary adenomas, optic pathway and hypothalamic gliomas, germinoma, meningiomas, Langerhans cell histiocytosis, and giant aneurysms. Radiologically, subtle differences exist to aid the diagnosis. Rathke's cleft cysts usually do not have a solid component, are not lobulated, are nonenhancing, and are more homogeneous. Pituitary adenomas enlarge the sella, are more homogeneous, and are usually less cystic. Gliomas are usually not calcified. Meningiomas are rarely cystic, uniformly enhance significantly, and are isointense on T1- and T2-weighted images. Giant aneurysms usually contain a laminated thrombus (Donovan and Nesbit, 1996).

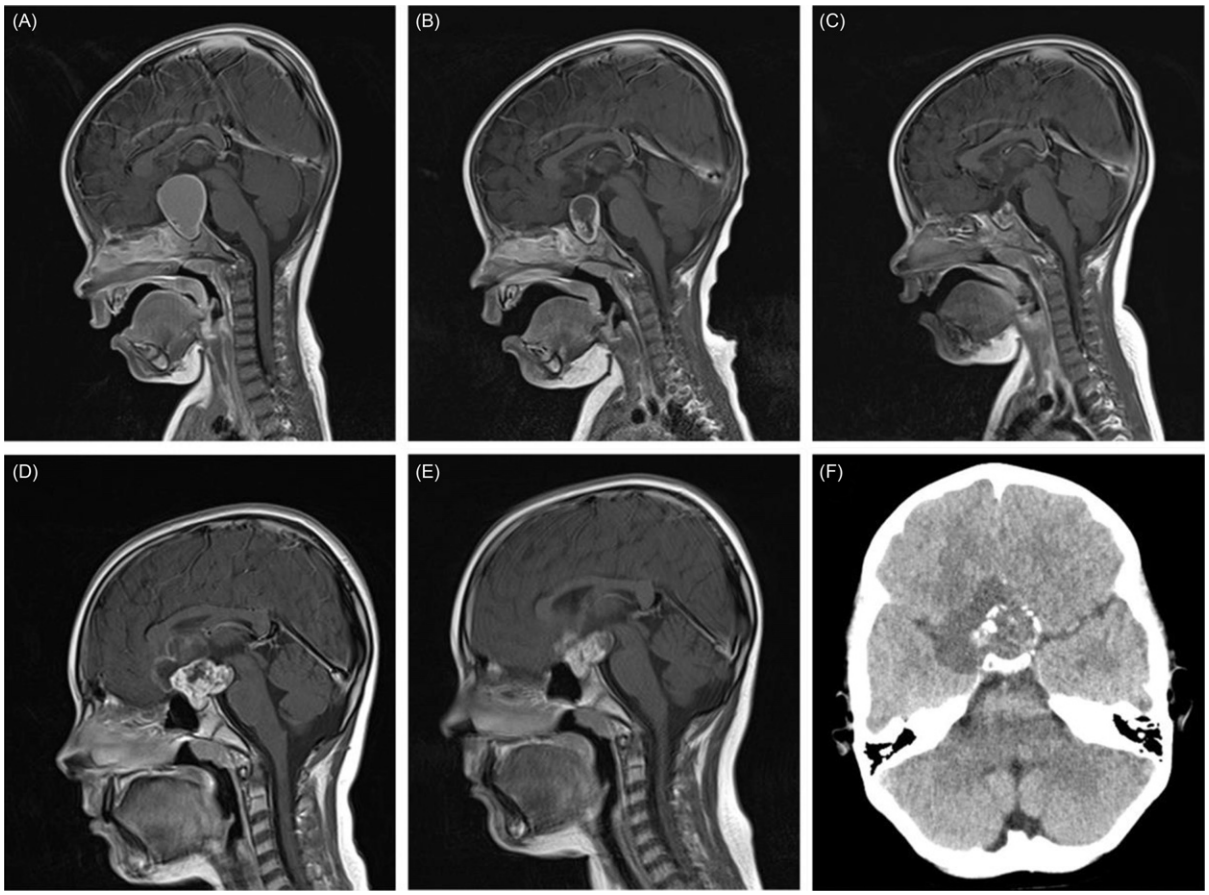

Fig. 2 Imaging of craniopharyngiomas. Figs.(A)–(C) demonstrate sagittal T1-weighted, gadolinium-enhanced MR images of cystic adamantinomatous craniopharyngioma in a 1-year-old male. The preoperative image (A) demonstrates the suprasellar cyst clearly and avidly enhancing cyst wall. The hyperintense signal characteristics of the intracystic fluid are different to surrounding CSF, suggesting a proteinaceous consistency. Image (B) demonstrates a reduction in cyst size following Ommaya reservoir insertion and aspiration. Cystic reaccumulation despite intracystic therapy resulted in open debulking surgery. The postoperative scan (C) shows significant reduction in lesion size. By contrast, the preoperative (D) and postoperative (E) sagittal T1-weighted, gadolinium-enhanced MR images from another child are of solid/cystic adamantinomatous craniopharyngioma. While a differential diagnosis of this lesion could include a low-grade glioma, the calcium deposits around the periphery of the lesion on CT imaging (F) are in keeping with a craniopharyngioma. Given the degree of postoperative residual tumor involving the hypothalamus (E), the patient subsequently received focal proton beam radiotherapy.

Clinical and Laboratory Evaluation

Except when immediate neurosurgical intervention is indicated, patients should have an ophthalmology assessment (including fundoscopy, visual acuity, and visual field examination) and endocrine assessment (including growth, pubertal status, clinical evaluation, and biochemical tests for hypothalamic–pituitary function) before treatment. The tumor markers alpha-fetoprotein and beta-HCG contribute to excluding nongerminomatous germ cell tumor (suprasellar common location).

Management

Young patients with CP should be managed at a specialist center with expertise that includes pediatric neurosurgery, oncology, endocrinology, ophthalmology, neuroradiology, histopathology, psychology, and neurorehabilitation. The aims and main modalities of management are presented in **Table 2**. The definitive modes of management are surgery with or without radiotherapy for the primary tumor and for recurrence.

Surgery

Surgery, with endoscopic or microsurgical techniques, is the initial treatment of choice for the primary tumor. The two main strategies based on extent of resection are radical or total/gross/complete resection and partial or limited/subtotal resection. Both

Table 2 Aims and main modalities of management of craniopharyngioma

Aims of management	*Management modalities and comments*
Relieving significant compression on vital structures by solid and cystic tumor components	Emergency surgery is indicated Large cystic component requires surgical drainage, catheter, and Ommaya reservoir to allow repeated aspiration (Müller *et al.*, 2017). The risks of these procedures are spillage of cyst fluid and aseptic meningitis Raised intracranial pressure, ventriculomegaly, and hydrocephalus warrant CSF diversion procedures. Dexamethasone contributes to reducing cerebral edema in patients with large tumors Visual impairment requires timely surgical resection
Prevent progression and recurrence Preserve function of vital structures especially optic apparatus, hypothalamus, and pituitary Minimize long-term morbidity and mortality	Surgical resection of tumor with the extent ranging from total/complete/radical to subtotal/partial and influenced by size and location of CP
Correct pituitary hormone deficiencies	Hormone replacement for glucocorticoid and ADH deficiencies should be started before surgery

have pros and cons. Radical resection with complete tumor removal is intended to achieve long-term cure. Theoretically, the benign histology implies that complete removal should suffice in providing cure. In reality, the rate of recurrence (up to 50% in some series) and injury to vital structures is high despite apparent surgical clearance (De Vile *et al.*, 1996; Müller *et al.*, 2005a,b; Puget *et al.*, 2007). Nevertheless, it is still considered a favorable approach for smaller lesions without hypothalamic involvement (Mallucci *et al.*, 2012). Partial resection is aimed at decompressing the space-occupying impact of the tumor, halting progression of residual tumor, minimizing damage to adjacent structures, and reducing the target for radiotherapy. Currently, optimal surgical management of CP is deemed to involve risk-adapted multimodal treatment strategies, combining surgery and radiotherapy, aiming to limit morbidity.

The surgical route to access the CP is determined by the anatomical location, size, consistency of the tumor (cystic, solid, or mixed), and degree of neurosurgical expertise. It can be broadly classified into transcranial for predominantly suprasellar CP, transphenoidal (transnasal) for predominantly intrasellar tumors, and skull base approaches for both locations. Large lesions involving the suprasellar, intrasellar, and intraventricular sites may require combinations.

Occasionally, the cystic component of a CP requires immediate reduction, either alone or prior to more definitive surgery. Aspiration of the cyst is generally performed either endoscopically, transphenoidally, or stereotactically. Cysts that frequently reaccumulate may require fenestration. However, spillage of intracystic contents into surrounding cerebrospinal fluid (CSF) spaces from such a technique has resulted in a preference for the insertion of a subcutaneous drainage device. For obstructive hydrocephalus, various CSF diversion options are available until definitive tumor intervention is performed. The techniques for removal or drainage of CPs are evolving, and long-term follow-up is necessary to compare their outcomes (Sughrue *et al.*, 2010).

Radiotherapy

CP is extremely radiosensitive. Radiation therapy has been proved effective in shrinking the tumor, preventing recurrence and long-term disease control. It is used as adjunct to partial resection and also for tumor recurrence. As yet, there is uncertainty whether radiotherapy should be administered early to any residual tumor or deferred until signs of progression. The postoperative tumor bed and the residual tumor are targeted and monitored with serial imaging. The radiotherapy technique used is influenced by the age of the patient, the previous management, the size and location of the CP, and its proximity to vital structures (Müller, 2017; Müller *et al.*, 2017).

External beam radiation therapy

The radiotherapy techniques used for CP can be broadly classified as external beam radiation therapy and internal radiation. In the former category, conventional fractionated electromagnetic radiation has been used most widely, but proton beam therapy is emerging as a more favorable option. Fractionated radiation therapy delivers a high dose of 54 Gy to the target by dividing the treatment into multiple fractions. It is typically administered each day, so as to allow normal tissue repair between fractions. In most retrospective external beam series, excellent local control has been reported. Doses less than and >54 Gy have been associated with recurrence rates in children of 50% and 15%, respectively (Regine *et al.*, 1993). Factors predictive of local control include age of the patient, large tumor size (>5 cm), extent of resection, use of modern imaging, era of radiation treatment, and radiation technique. Modern techniques incorporating three-dimensional serial imaging enable clearer delineation of the tumor from normal tissue and improve targeting treatment more precisely at the tumor, minimizing risk to normal tissue and thus widening the therapeutic ratio (Kiehna and Merchant, 2010). These modern electromagnetic techniques include intensity-modulated radiation therapy (IMRT), stereotactic radiosurgery, and fractionated stereotactic radiotherapy. With IMRT, the dose delivered to different parts of a CP and adjacent tissues is tailored by modifying the intensity and shape of radiation beams. Stereotactic radiosurgery or gamma knife is a nonsurgical intervention with a single radiotherapy fraction. It is considered for well-

delineated solid tumors <3 cm diameter and located >3 mm from vital structures. In contrast, stereotactic radiotherapy includes multiple fractions and can be used to treat larger tumors >3 cm (Müller, 2014).

Proton beam therapy exhibits maximum dose deposition terminally (Bragg peak effect) with less risk to tissue along the radiotherapy path. This allows for higher dose delivery to the tumor. Initial results of the use of proton beam therapy in the treatment of CPs are encouraging, and use of this modality is expected to increase as more proton facilities open (Beltran *et al.*, 2012).

Internal radiation therapy

Intracavitary radiotherapy of cystic CPs has been used both as a primary and an adjunctive therapy for recurrence (Leksell and Liden, 1952; Tian, 1997). It involves the instillation of a radioisotope such as ^{90}yttrium, ^{32}phosphorus, or ^{186}rhenium via an indwelling catheter into the tumor-cyst cavity so that a high dose of radiation can be delivered to the surrounding secretory epithelial layer. Although sustained cyst regression and obliteration have been reported (Blackburn *et al.*, 1999), the impact of intracavitary irradiation on visual and endocrine function varies widely (Hasegawa *et al.*, 2004; Julow *et al.*, 2007). Intracavitary therapy has not been widely adopted owing to these drawbacks and the difficulties in handling radioactive compounds.

Chemotherapy

Chemotherapy for the treatment of CP is still experimental. A range of systemic agents have failed to produce benefit. Nevertheless, the immunomodulatory agent interferon-alpha (IFN-α) has been shown to potentially be effective after demonstrating efficacy in treating squamous-cell carcinoma (Jakacki *et al.*, 2000). The similar epithelial origin of CP provided the rational for trials with this agent. For CP with a cystic component, intracystic IFN-α can delay disease progression and the timing of further intervention with surgery or radiotherapy by median 5.8 years (Kilday *et al.*, 2017). Intracystic bleomycin has not been found to be superior to other available treatment modalities (Zhang *et al.*, 2016).

Risk-Adapted Treatment Strategies

In recent years, various risk-adapted individualized treatment strategies have been adopted for the primary management of CP (Müller, 2017; Müller *et al.*, 2017). They are aimed at managing raised intracranial pressure; relieving compression on optic nerves/chiasm, pituitary, and hypothalamus; preventing tumor regrowth and/or progression; minimizing further damage to vital structures; and acute and long-term mortality and morbidity (Puget *et al.*, 2007; Mallucci *et al.*, 2012; Fjalldal *et al.*, 2013; Müller *et al.*, 2017). A wide range of grading methods have been reported to evaluate hypothalamic involvement, including preoperative MRI (Elowe-Gruau *et al.*, 2013), pre- and postsurgical assessment (Müller *et al.*, 2012), and risk-grade adjustment after initial cyst decompression (Mallucci *et al.*, 2012). The general consensus from all these grading and treatment strategies is that limited surgical approaches and postoperative external irradiation are recommended for CP with hypothalamic involvement, and the management should be undertaken by experienced multidisciplinary teams. Monitoring with serial clinical and radiological evaluation is initially frequent (e.g., every 3 months in the first year after radiotherapy), becomes less intense over time, and can be discontinued after a progression-free period of 10 years. The rate of progression, its impact, and the age of the patient are among the factors that influence further intervention.

Treatment Complications

Surgical

The most common complication from surgery is transient diabetes insipidus in the immediate postoperative period (Sughrue *et al.*, 2010). Permanent diabetes insipidus further compromises in preexisting anterior pituitary hormone deficiencies, and additional dysfunction is also frequent. Although visual impairment at initial diagnosis can recover after surgery, it can also emerge postsurgery and especially with CP closely related to the optic chiasm. The risks of surgical trauma to the hypothalamus are significantly high especially with radical surgery.

Radiotherapy

Radiation therapy results in pituitary dysfunction and visual defects similar to that observed after surgery, but the severity of these complications, particularly diabetes insipidus, appears to be reduced. Late adverse effects of radiotherapy include vascular damage and stroke, especially Moyamoya disease (Sanford, 1994), and impaired cognition (Merchant *et al.*, 2006). The latter is especially concerning for the developing brain of preschool-age children.

Other complications of radiation therapy include treatment-induced cyst expansion, radiation-induced neoplasms (glioblastoma, sarcoma, and meningioma), radiation necrosis, optic neuritis, calcification of basal ganglia, and hypothalamic injury.

Outcomes

Recurrence of CP appears not to be influenced by the extent of surgical resection nor hypothalamic involvement. In the multicenter HIT study of a large cohort of patients with childhood-onset CP, the progression-free survival at 20 years was 58% (Sterkenburg *et al.*, 2015). However, it varied from 57% to 83% for patients who had radiotherapy to those who did not and was considerably lower for children diagnosed under 5 years compared with above age 10 years, 39% versus 77% (Sterkenburg *et al.*, 2015).

Malignant transformation is extremely rare and has been reported in a small number of children and adults with CP (Sofela *et al.*, 2014). The majority of patients had adamantinomatous CP; the most common malignancy was squamous-cell carcinoma, and an association with multiple benign recurrences and radiotherapy was identified (Sofela *et al.*, 2014).

Mortality rates from CP have improved over time and are now generally low, with survival influenced by factors including associated raised intracranial pressure, postoperative infections, endocrinopathies, or secondary effects of radiotherapy. Overall survival for childhood-onset CP is good. A recent comprehensive review of the literature since 1994 reported survival rates of 83%–96% at 5 years, 65%–100% at 10 years, and 62% at 20 years (Müller, 2017). In the HIT study, the 20-year survival was considerably higher at 85% and was not influenced by initial and subsequent management (Sterkenburg *et al.*, 2015). However, morbidities associated with hypothalamic, visual, pituitary, neurocognitive, and psychosocial defects had a significant impact on the quality of life of patients with CP (Sterkenburg *et al.*, 2015).

Conclusion

Adamantinomatous CP, which is the predominant subtype in children and adolescents, has distinct characteristics, histopathology, and molecular pathogenesis compared with the papillary subtype. Its location deep in the brain, close proximity to vital structures, unpredictable growth behavior, and chronic incurable nature can cause considerable life-long morbidity. Thus, the benign classification of CP and the overall high long-term survival of affected patients are deceptive. Manifestations at diagnosis arise from the mass effect of CP on intracranial structures. Impairment in vision, pituitary hormones, hypothalamic integrity, and neurological function vary but can be profound and progressive despite intervention. High-resolution MRI sequences enable evaluation of the tumor and its relationship to vital structures.

Definitive management for the primary tumor and recurrences comprises surgery with or without radiotherapy. Patients with CP should be managed by multidisciplinary experienced teams and ideally in the context of national and international multicenter studies. Hypothalamic-sparing, risk-adapted multimodal treatment strategies aimed at achieving good disease control, minimizing damage to vital structures, and improving outcomes are recommended. As a rule of thumb, tumors that do not impinge on the hypothalamus are treated by gross total resection. However, partial resection with radiation therapy is preferred when there is hypothalamic involvement. Modern electromagnetic (photon) radiation therapy techniques provide superior delineation of the CP and precision in targeting the tumor. However, proton therapy is deemed to be safer and more effective than photon as the radiation dose is concentrated at the tumor itself while sparing normal tissue along its path. Intracavitary irradiation, radiosurgery, and intracavitary chemotherapy with IFN-α are options for some CP. For CP with a cystic component, intracystic IFN-α may potentially delay disease progression and the timing of further intervention with surgery or radiotherapy but requires validation in a randomized clinical trial. Recent identification of activating mutations in the β-catenin gene and novel insights into the molecular pathogenesis of adamantinomatous CP offer hope for developing effective treatments.

Glossary

Gelastic seizures Brief, repetitive, stereotyped episodes of pleasant laughter or giggling lasting a few seconds, associated or not to loss of awareness, facial myoclones and/or abnormal eye movements. Onset in infancy, high frequency and gelastic-type attacks are strongly related to the presence of hypothalamic hamartomas.

Hamartoma Congenital, non-neoplastic, pedunculated or sessile lesion consisting of heterotopic nervous tissue with no growth potential, mostly arising from the hypothalamus between the tuber cinereum and the mammillary bodies.

Precocious puberty Generally defined as the onset of secondary sexual characteristics before 8 year of age in girls and 9 years in boys; this definition is arbitrary, however, because of the marked variation in age when puberty begins in normal children, particularly if they belong to different ethnic groups.

Introduction

Hypothalamic hamartomas are rare, congenital, non-neoplastic tumor-like lesions of varying size (diameter ranging from less than 1 m to 6.5 cm) made up of heterotopic grey matter, neurons, glial cells, and fibre bundles. They usually originate in the posterior hypothalamus, the tuber cinereum or the mamillary bodies, have a sessile or pedunculated attachment, extend postero-inferiorly into the interpeduncular space and sometimes bulge into the floor of the third ventricle. Most hamartomas have a spherical shape below the tuber cinereum.

In rare cases, they may be prechiasmatic in location or may lie free in the interpeduncular fossa. They are often associated with single or combined cerebral and extracerebral congenital abnormalities, including polymicrogyria and/or heterotopia, arachnoid cyst, callosal defects, polydactyly, facial anomalies and heart malformations. An inheritance factor has been observed in individual patients.

Hypothalamic hamartomas may be asymptomatic but they generally present with central precocious puberty (CPP), gelastic seizures, generalized seizures, mental retardation, behavioral disturbances and memory difficulties. The hallmark of the epileptic syndrome is the gelastic seizure — a brief, repetitive, stereotyped attack of laughter — which begins in early childhood, often in the neonatal period. Later, in the first decade, a generalized epileptic encephalopathy develops, characterized by tonic, atonic, and other seizure types in association with a slow spike-and-wave discharge and cognitive deterioration. Hamartomas of the central nervous system do not usually grow or grow very slowly; they generally lack malignant characteristics.

Hypothalamic hamartoma is part of the Pallister-Hall syndrome, though it has exceptionally been reported in association with oral, facial, digital syndrome (OFD), Laurence-Moon-Biedl syndrome and other conditions.

Classification

Different classifications of hypothalamic hamartoma have been proposed according to the topographic and clinical data available. Hypothalamic hamartoma can be classified into two types:

- pedunculated, which is more likely to be associated with precocious puberty;
- sessile, often associated with seizures.

Another classification has been suggested based on topography and associated surgical risks:

- Type Ia and Ib are generally small pedunculated hamartomas that are attached to the tuber cinereum (Ia) or to the mamillary bodies (Ib) and are usually associated with precocious puberty.
- Type IIa and IIb are relatively large lesions that displace the hypothalamus slightly (IIa) or markedly (IIb) and are usually associated with gelastic or other types of seizures. Surgery has been recommended for types Ia, Ib, and IIa, especially when epileptic activity and behavioural abnormalities are severe and difficult to control.

A further classification has been proposed based on magnetic resonance (MR) imaging:

- The parahypothalamic type (PHH) is attached to the floor of the third ventricle or suspended from the floor by a peduncle. PHH is generally associated with precocious puberty but without seizures or development delay

☆*Change History*: January 2016. G. Patti, G. Morana, N. Di Iorgi, and M. Maghnie updated the text and reference.

This article is an update of Mohamad Maghnie, Stefano Ghirardello, Giulia Meloni, Hamartoma, Pituitary, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 427-433.

 doi:10.1016/B978-0-12-801238-3.95988-9

- The intrahypothalamic type (IHH), enveloped by the hypothalamus to displace the third ventricle, is more likely to be associated with medically intractable seizures. Two thirds of IHH patients suffers from severe developmental delay, cognitive impairment and have a poor quality of life

Histology and Pathophysiology

Hypothalamic hamartoma is thought to be a developmental aberration, but its origin is unclear. Remnants of brain tissue left along the floor of the third ventricle when chorda withdraws may account for its origin in the central nervous system (CNS). Histologically, it consists mainly of normal brain elements: neurons, glial cells, and fiber bundles that are frequently myelinated and connected to surrounding hypothalamic structures. Frequently, however, hamartomas do not reproduce the normal architecture of neighbouring tissue.

The hypothalamic hamartoma functions as an ectopic luteinizing hormone-releasing hormone (LHRH) pulse generator that escapes the intrinsic CNS inhibitory mechanism. In the mouse, monkey and human, LHRH neurons originate in the medial olfactory placode of the developing nose, migrate across the nasal septum, and enter the forebrain with the nervus terminalis, arching into the septal-preoptic area and hypothalamus. In hypothalamic hamartoma a significant number of LHRH neurons migrate beyond the medial basal hypothalamus to the region of the mammillary bodies and tuber cinereum and form one of the constituents of the heterotopic mass of CNS tissue. The defect in migration could be related to an imbalance of diffusible chemotrophic factors that are secreted by restricted cell populations within the brain or to neural cell adhesion molecules, which play an important role in axonal pathfinding.

Since the number of LHRH neurons is limited, it is possible that a majority of the LHRH neurosecretory neurons may migrate into the hamartomas during CNS development. On the other hand, hypothalamic hamartoma may be related to aberrant differentiation among other cell types of neural primordia, including progenitor cells with the capacity to form LHRH neurosecretory neurons.

Histological specimens observed after surgery reveal hamartomas of low cell density containing irregularly structured groups of ganglionoid cells with variably sized unipolar and bipolar neurons interspersed among glial cells with myelinated and unmyelinated fibres connected to sorrounding hypothalamic structures. The tissue is highly vascular and many of the vessels have fenestrated endothelium and double basement membranes. Each vessel is almost totally sorrounded by axons. There is no or very little tendency to proliferation.

Immunohistochemical studies confirm the neuronal origin of hypothalamic hamartoma showing positive staining for neuron-specific enolase, synaptophysin and neurofilament protein.

Different immunohystochemical studies demonstrate the presence of membrane-bound, electron-dense granules (100 nm in diameter) which contain LHRH within the perikarya, the axons and the axons terminals and which are the elements of an independent neuroendocrine unit.

The examination of two hypothalamic hamartomas associated with sexual precocity revealed that they contained astroglial cells expressing TGFα, but not LHRH neurons. These findings imply that some hypothalamic hamartomas induce sexual precocious puberty by activating endogenous LHRH secretion via astroglial-derived factors such as TGFα and/or TGFβ. This activation appears to require a close proximity of hypothalamic hamartoma to either LHRH neurons or their axonal processes in the median eminence. In some cases, the hamartoma itself does not initiate precocious sexual maturation due to its location, but rather a lesion of the adjacent hypothalamic tissue resulting from surgery may cause activation of astroglial cells which may then lead to increased LHRH secretion from hypothalamic LHRH neurons.

A number of findings suggest that hamartomas are themselves epileptogenic. Electroencephalography (EEG) recordings revealed focal spikes arising from the depth contacts within hypothalamic hamartomas, while electrical stimulation studies reliably reproduce gelastic episodes, suggesting a close relationship between hamartomas and the generation of laughing attacks. The most fascinating studies based on ictal single-photon emission-computed-tomography demonstrated marked blood flow in the hypothalamus and thalamic structures during gelastic events. Improvement in intractable epilepsy has been reported in some cases after the resection of hamartoma.

Clinical and experimental evidence suggest that the hypothalamus and adjacent structures, in particular the mamillary bodies and its immediate connections, may comprise an important sub-cortical pathway for seizure propagation. Sessile hypothalamic hamartomas with displacement of the hypothalamus are associated with seizures.

Recent evidence shows that, unlike laughing and focal seizures, slow spike-and-wave discharges and associated tonic and atonic seizures do not arise directly from hamartoma. Indeed, postoperatively, these seizures may progressively "run down" after removal of the hamartoma, suggesting that they are the result of secondary epileptogenesis. Most HH cases are sporadic. Approximately 5% of HH cases are associated with Pallister-Hall syndrome, which is caused by haploinsufficiency of GLI3. Craig et al have identified somatic GLI3 mutations in sporadic HH cases, suggesting a role in the etiology of HH lesions.

Clinical Presentation

Endocrine Aspects

Hypothalamic hamartoma is considered the most common *organic cause* associated with CPP. The incidence of hypothalamic hamartoma in determining CPP varies widely ranging from 2% to 28%.

The age of onset of the first signs of CPP has been reported between 0 and 4 years (frequently before 2 years) while CNS lesions (gliomas, germinomas, arachnoid cysts) tend to occur in association with CPP later in life.

CPP associated with hypothalamic hamartoma has all of the hormonal hallmarks of puberty, including plasma estradiol levels, a pubertal pattern of pulsatile LH and a pubertal LH response after gonadotopin-releasing factor administration. Higher levels of peak LH response and peak LH/FSH ratio after LHRH have been reported in girls with CPP associated with hypothalamic hamartoma compared to idiopathic precocious puberty.

Neurological and Behavioral Aspects

Epilepsy is the main neurologic manifestation of hypothalamic hamartoma (HH). Gelastic seizures beginning in infancy, often in the neonatal period, are the classic epileptic presentation of HH. In a proportion of patients, there is a progression through other partial seizure types to a generalized epileptic encephalopathy.

Gelastic seizures associated with HH are refractory to medical treatment. Generalized seizures are reported in approximately 70% of patients. Generalized seizures most often appear after a period of gelastic and complex partial seizures manifestations. The development of generalized seizures is usually paralleled by the development of behavioral disturbances.

Several studies reported a characteristic, recognizable epileptic syndrome that shows a typical evolution over time. The syndrome begins with laughing attacks; the resemblance to normal laughter is so close in some patients that delayed diagnosis is possible. The pattern is quite stereotyped, with some variations over time. After a few years, the laughing attacks are associated with momentary loss of awareness, facial myoclonus and/or abnormal eye movements. Autonomic phenomena are common. In the later childhood, typically between the ages of 4 and 10 years, features of secondary generalized epilepsy appear with multiple seizure patterns including tonic, atonic, and tonic-clonic seizures and progressive cognitive impairment.

Behavioral disturbances, including attention deficit hyperactivity disorder like symptoms in patients with HH is generally associated with intractable seizures.The recurrence of these seizures promotes cognitive deterioration and behavioral disturbance. In a review of all reported patients with HH, 49% manifested cognitive disturbance and 31% had behavioral problems, while all patients had seizures. Children with gelastic seizures and HH are often emotionally unstable, easily irritated restless and agitated, aggressive and antisocial. HH patients with CPP but without evidence of seizure activity rarely have cognitive defects.

In a study with a large cohort of patients, it has been demonstrated that patients with hamartomas display a statistically significant increase in co-morbid psychiatric conditions, including oppositional defiant disorders, attention-deficit/hyperactivity disorder, high rates of conduct disorders, speech retardation/learning impairment and anxiety and mood disorders. At the present time, there are no definitive data to indicate exactly how the epileptic pathology interferes with a patient's development and behaviour and why a majority of patients have a cognitive-behavioural deficit which often worsens with age.

Brief infantile attacks are not associated with any significant change in EEG. However in later childhood, with the progression of the epileptic syndrome, EEG abnormalities develop with generalized suppression of background rhythm, generalized low-voltage fast activity or both. Interictally, there are generalized slow spike-and-wave discharges and background activity that is abnormally slow for the child's age as hallmarks of secondary generalized epilepsy.

Magnetic Resonance Imaging

MR imaging is the diagnostic method of choice for the evaluation of hypothalamic hamartomas. They appear as well defined round to oval masses, generally isointense to grey matter on both T1- and T2-weighted images. Following gadolinium injection they never enhance (**Fig. 1**). However, hypothalamic hamartomas may sometimes be slightly hyperintense on T2-weighted (**Fig. 2**) and FLAIR images. The variance in myelinated axons and the presence of gliosis can affect the variability of the T2 signal. Proton MR spectroscopy (**Fig. 2**) can show decreased N-acetylaspartate and increased myoinositol. These findings correlate with the proportion of glial cells within the hamartoma.

Another characteristic feature of hypothalamic hamartomas is their relative stability in size, shape and signal in long-term MR follow-up during and after medical treatment. Signal or cystic changes have occasionally been observed: in these cases, the differential diagnosis should include low grade gliomas.

Overall the MR findings which commonly indicate hypothalamic hamartomas are: an isointense mass with a pedunculated or sessile attachment to the hypothalamus without contrast enhancement, stable in size and shape during follow-up, associated with endocrinological and clinical features of CPP, mostly before 2 years of life and associated with gelastic seizures.

Treatment

Precocious Puberty

The aims of treatment are to arrest physical maturation, to prevent early menarche or sexual adult psycho-physical maturation and to improve adult height to within the range of target height combined with normal body proportions. GnRH agonists are the therapy of choice to halt premature sexual development in patients with a HH if precocious puberty is its only manifestation.

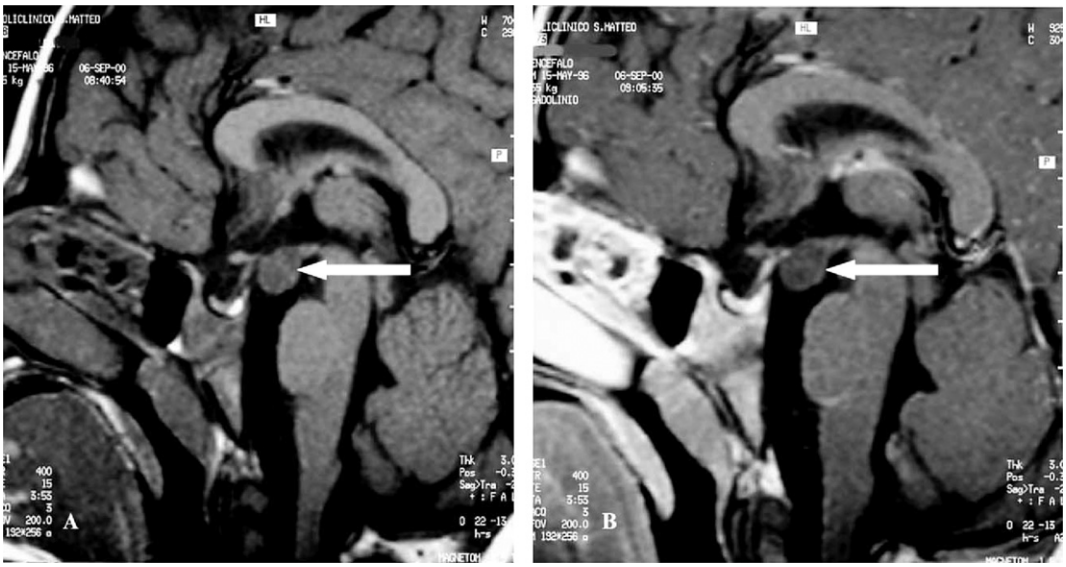

Fig. 1 (A) Sagittal T1-weighted image; (B) Gd-enhanced sagittal T1-weighted image. Sessile hamartoma in typical third ventricular location, isointense to gray matter before (A) and after (B) gadolinium administration (*white arrow*).

Successful suppression treatment with GnRH analog preparations has been reported by several groups for a duration of up to 8 years with homogeneous endocrinological response characterized, after an initial phase of increased serum LH and FSH levels (flare-up), by a reduction to prepubertal ranges of basal LH, FSH, testosterone and E2, a prepubertal peak LH and FSH-response to GnRH stimulation test and prepubertal LH/FSH ratio with improvement of adult height towards predicted final height and close to target height; no adverse events have been reported. A variety of GnRH formulations are available and efficacious. The depot preparations are preferred because of improved compliance. In most children, monthly injections adequately suppress the gonadotropic axis, but some children require more frequent injections.

A controversial outcome of precocious puberty has been reported after surgical resection of hamartomas. It has been suggested that surgery is safe and it can be considered an option when compared to the cost of medical treatment, monthly treatment administration up until puberty (sometimes poorly tolerated), painful injections in some cases, the psychological implications, and in some rare cases an intolerance to treatment. Total resection, however, cannot be achieved in all hamartomas.

Females with hypothalamic hamartoma have a higher incidence of irregular menses, obesity, neurological and behavioural problems with a normal reproductive axis within 4–5 years after discontinuation of GnRH analog therapy; pregnancies resulted in normal, live infants.

Seizures

Treatment options for intractable gelastic seizures in HH patients include direct open surgery with craniotomy, endoscopic surgery, radiosurgery with gamma knife (GKS) and stereotactic radiofrequency thermocoagulation.

In the last few years, it has become clear that epileptic encephalopathy associated with hypothalamic hamartoma is a treatable condition. Strong evidence now exists that removal, destruction or disconnection of the hamartoma leads to remarkable control of the seizures, as well as to an improvement in behaviour and probable cessation of cognitive decline.

Gelastic seizures are resistant to all currently available medications. Rarely, treatment of the focal seizures and of tonic and atonic attacks can be moderately successful with conventional anti-epileptic drugs. However, recent and sufficient experience suggests that long-lasting control of these seizures can be effected by complete removal, destruction, or disconnection of the hamartoma, thanks to important improvements in imaging and surgical techniques. There now exist various possible surgical approaches to the lesion and the debate is currently focused on the best technique to use (i.e., it must be tailored to the specific surgical anatomy of the hamartoma) in order to guarantee, in each single case, the possibility of total removal or disconnection of the lesion. The transcallosal approach (suited for intraventricular lesions) presently appears the technique with the highest rate of success, with 90% of cases free or virtually free of all seizures at one year post-surgery follow-up. Prolonged follow-up is necessary to evaluate the real effects on cognitive impairment, whereas behavioural abnormalities tend to show marked improvement in many patients.The pterional approach is useful for targeting peduncolated HHs, which are relatively easy to be completely resected.

Open and endoscopic disconnection surgery is a safe and effective option for small, sessile HHs.

Described secondary effects of surgery are small strokes with good recovery, encephalomalacia, third-nerve palsy, memory impairment, and transient diabetes insipidus. Postoperative mortality has also been reported.

Stereotactic radiosurgery (SRS) is increasingly being utilised. The major attractions of stereotactic radiotherapy involve the avoidance of mortality and morbidity risks associated with invasive neurosurgery. Stereotactic localisation allows attainment of a high degree of accuracy

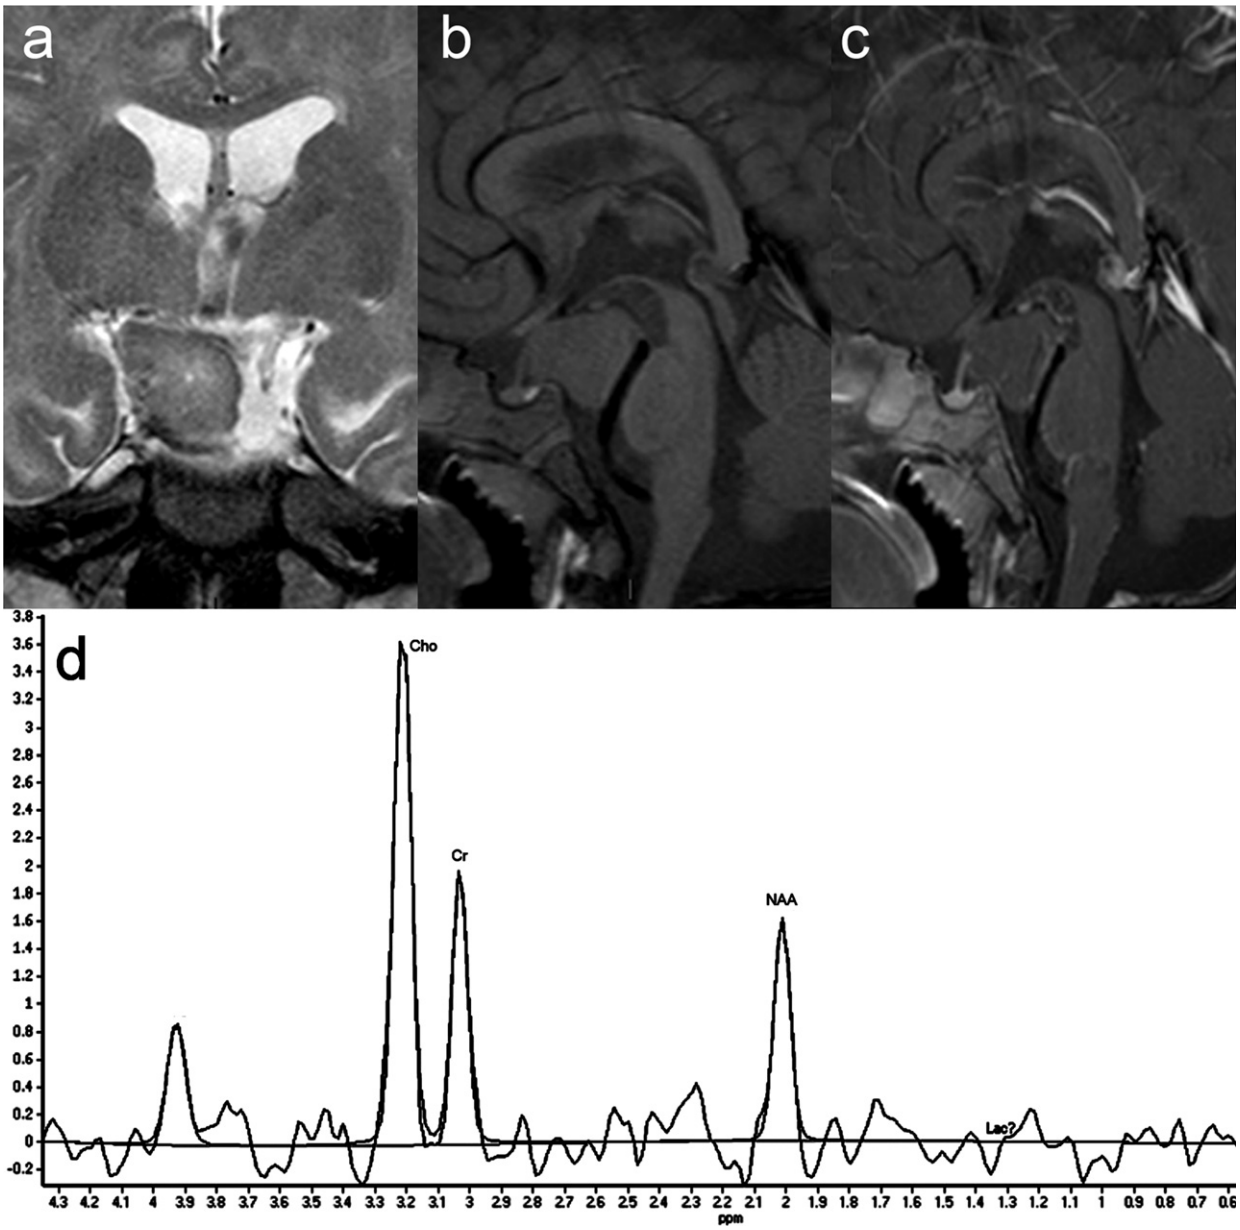

Fig. 2 (A) Coronal T2-weighted image; (B) Sagittal T1-weighted image; (C) Gd-enhanced sagittal T1-weighted image; (D) Single voxel MR spectroscopy (144 ms echo time). Retrosellar median-right paramedian solid mass lesion attached to the floor of the third ventricle and projecting into the interpeduncolar fossa. The lesion is slightly hyperintense on T2 (A), isointense on T1 (B), without contrast enhancement (C). Proton MRS shows mild increase of Cho/NAA and Cho/Cr ratios (D).

and precision, enough to deliver a dose of radiation high enough to affect epileptogenesis while sparing critical normal structures at the same time. Regis at al have reported excellent result in 60% of children with complete seizure cessation in 40% and rare nondisabling seizures in 20%, often in association with dramatic behavioural and cognitive improvement.

Some reports emphasize the importance of the margin dose of radiation. Patients treated with doses exceeding 17 Gy to the margin of the HH have greater rates of seizure remission than those receiving less than 13 Gy. Duration since onset has been reported to be another factor predictive of outcomes with SRS. Patients with short durations are likely to enjoy better responses, whereas patients with long histories are likely to receive modest benefits even with high doses. The disadvantage of SRS is its delayed action, with maximal effect usually experienced after a period of about 6 months post treatment. Surgery may be preferred over radiosurgery among patients with very large lesions that could be causing symptoms do to mass effect, since surgery can accomplish immediate decompression. Overall, when the lesion is sufficiently small SRS offers a rate of seizure control comparable to microsurgery but with much lower risk.

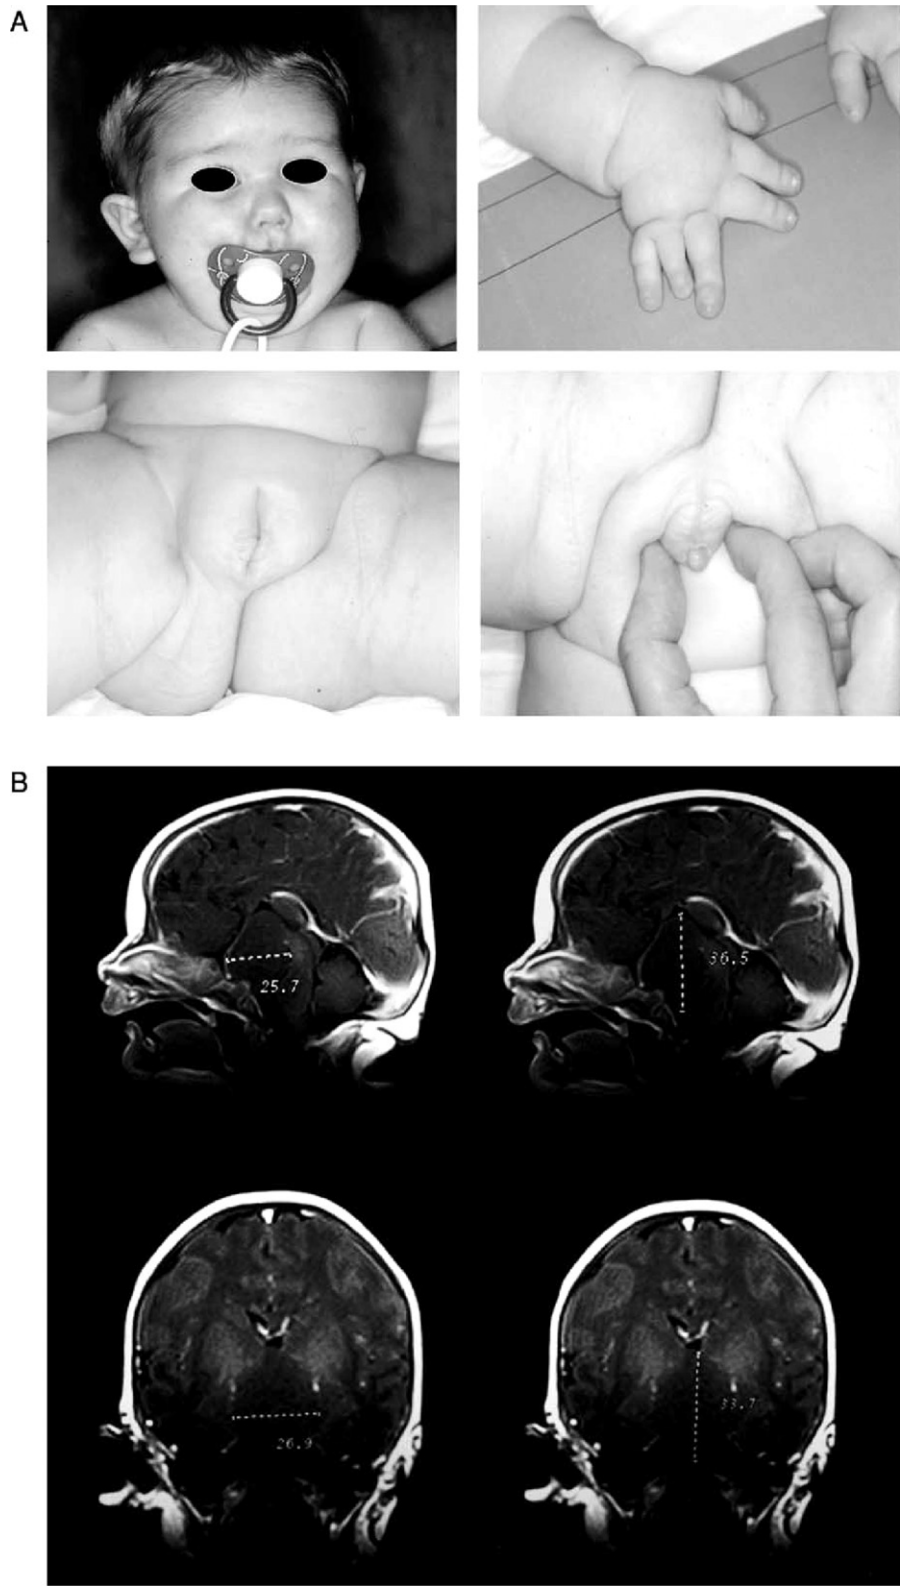

Fig. 3 (A) Frontal view showing a phenotype suggestive of congenital hypopituitarism. Note the hands with polydactyly; micropenis and cryptorchidism are associated with panhypopituitarism. (B) Sagittal and coronal T1-weighted MR images demonstrating the mass (dotted lines) compatible with hamartoblastoma and the absence of pituitary tissue.

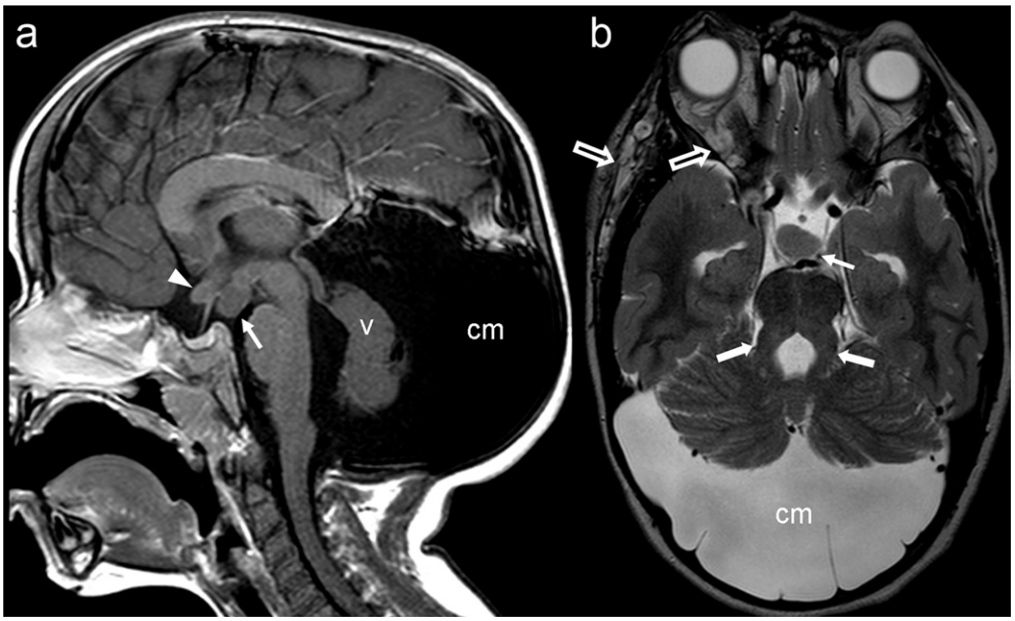

Fig. 4 Varadi–Papp syndrome and coexistent Neurofibromatosis type 1. (A) Gd-enhanced sagittal T1-weighted image; (B) Axial T2-weighted image. Hypothalamic hamartoma attached to the floor of the third ventricle and projecting into the interpeduncolar fossa (*thin arrow*, A, B). Pathologic thickening of the optic chiasm (*arrowhead*, A), without contrast enhancement, and small neurofibromas in the right orbit and temporal subcutaneous region (*open arrows*, B). Vermian hypoplasia (v), huge cystic dilatation of the cistern magna (cm) and molar tooth malformation (*thick arrows*, B).

Stereotactic radiofrequency thermocoagulation has also been used. It is a procedure during which a monopolar needle, under stereotactic guidance, is inserted into the surgical target. Current at high frequency (above 250 Khz) is injected, resulting in heating of the tissue at the electrode tip. The effectiveness of stereotactic radiofrequency thermocoagulation in the treatment of epilepsy has been reported in small case series of HH. Kameyama et al. reported the largest group, consisting of 25 patients of whom 19 (76%) had seizure remission; improvement in behaviour also occurred. Complications in this group included evidence of hypothalamic dysfunction in more than 50% of patients (hyperphagia, hyponatremia, Horner's syndrome, all transient). Stereotactic radiofrequency thermocoagulation has the advantage over SRS of earlier postoperative treatment effects.

Associated Conditions

Pallister–Hall Syndrome

Pallisteral–Hall syndrome (PHS) was first described in 1980 as a lethal congenital malformation syndrome associated with hypothalamic hamartoblastomas, postaxial polydactyly, craniofacial malformations and imperforated anus. Additional abnormalities include developmental and postnatal retardation, holoprosencephaly, pituitary agenesis/dysgenesis with hormone dysfunction leading to micropenis, cryptorchidism, hypopituitarism or panhypopituitarism, laryngeal clefts, bifid epiglottis, buccal frenula, small nose/anteverted nares, low-set/posteriorly angulated ears and microphtalmia, limb/skeletal malformations such as short fourth metacarpals and nail dysplasia, involvement of other organs with abnormal lung lobulation, renal agenesis and/or dysplasia, and congenital heart defects (**Fig. 3**). The syndrome is now considered a clinical, variable "iceberg" disorder with wide phenotypic variability where adrenal insufficiency is the most common cause of perinatal death.

This disorder is inherited as an autosomal dominant trait and has been reported in association with unbalanced chromosome translocation between chromosomes 3 p and 7q and later mapped to chromosome 7p13. Mutations in the transcription regulator gene GLI3 have been identified in patients with PHS, but also in four other different autosomal dominant phenotypes: the Greig cephalopolysyndactyly syndrome, preaxial polydactyly type IV, postaxial polydactyly type A and postaxial polydactyly type A/B.

Consensus guidelines in 1996 developed diagnostic criteria for the delineation of familial Pallister–Hall syndrome, which include the presence of hypothalamic hamartoma, central polydactyly most commonly affecting the third or fourth digit, and, in the first degree relatives of an index case, hypothalamic hamartoma or similar digital abnormalities associated with an autosomal dominant. An association with endocrine dysfunction requires hormone substitutive treatment. Adult height above the target height has been reported in a patient treated with growth hormone for up to 7 years. Surgical correction of visceral abnormalities is mandatory.

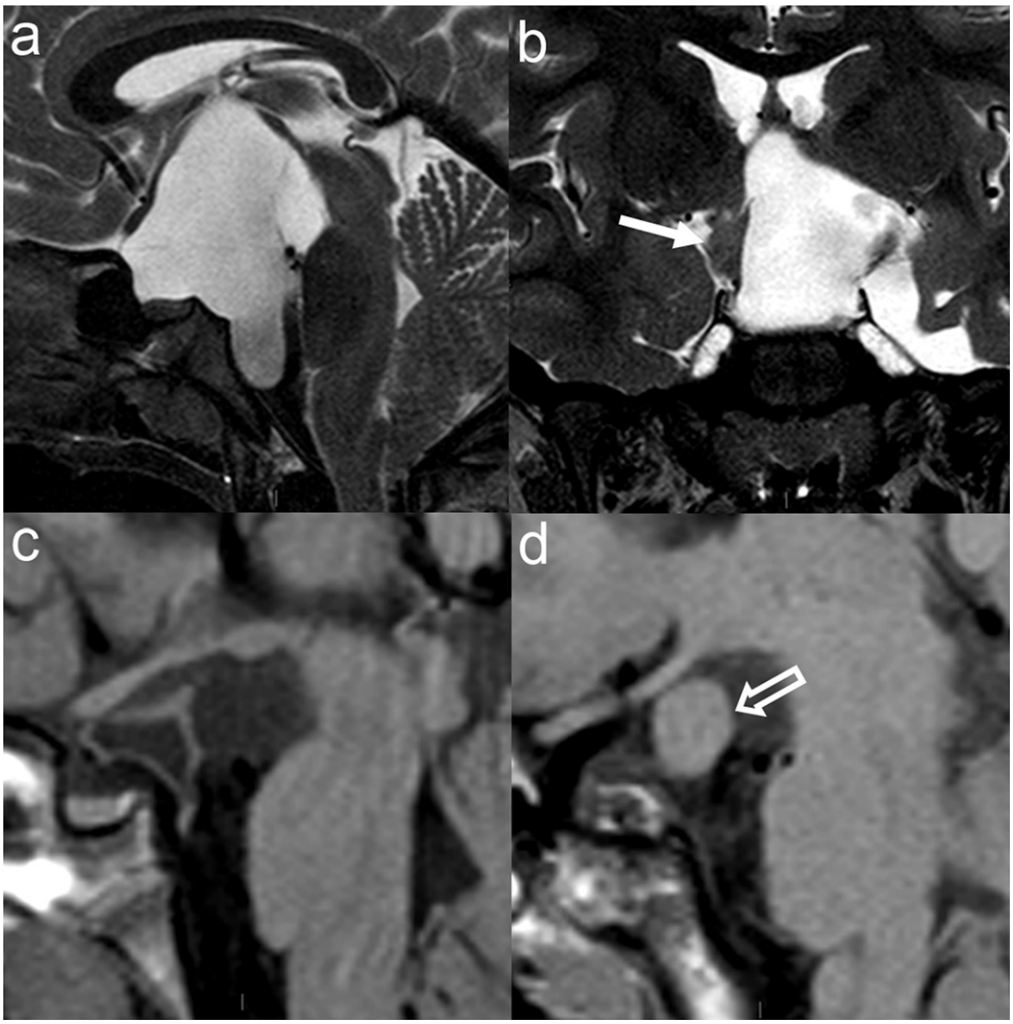

Fig. 5 Coexistent suprasellar arachnoid cyst and hypothalamic hamartoma in a 8-year-old boy with precocious puberty. (A) Sagittal T2-weighted image; (B) Coronal T2-weighted image; (C, D) Sagittal T1-weighted images. (A, B) Brain MRI at admission shows a huge suprasellar arachnoid cyst. Along the right wall of the cyst a solid mass, isointense to brain parenchyma, is demonstrated (*arrow*, B). (C, D) Brain MRI performed following surgical fenestration of the cyst better shows the peduncolated hamartoma, projecting into the interpeduncolar fossa (*open arrow*, D).

PHS patients usually have well controlled seizures and endocrine disturbances other than precocious puberty. Only a few PHS patients (those with the most frequent and difficult to control seizures) have marked behavioural or developmental problems. These data support previous reports of a strong effect of seizures on cognitive and behavioural problems in patients with HH.

Other Conditions

Hamartomas may be found in syndromes of midline defects such as oral-facial-digital syndrome type 6 (Varadi–Papp syndrome) (Fig. 4), Smith–Lemli–Opitz syndrome, solitary maxillary incisor, or in association with CNS malformations including agenesis of corpus callosum or holoprosencephaly. They have also been described in Laurence–Moon–Biedl syndrome, McKusick–Kaufman syndrome and Waardenburg syndrome. Syndromic HH have milder symptoms than isolated HH, but likely arise from similar pathogenic mechanisms.

HH have also been reported in association with a spectrum of cystic abnormalities (Fig. 5) which include intrahamartomatous cysts, arachnoid cysts that extend within the hamartoma, and arachnoid cysts that are adjacent to or remote from the hypothalamic hamartomas. The mechanism behind this association is not known. Different hypotheses advocate disruption of the prenatal subarachnoid space formation by the hamartoma, or inclusion of meningeal tissue within the hamartoma.

Acknowledgment

We thank Dr Luigi Gargantini (Clinica Pediatrica, Ospedale di Treviglio) for providing the case of Pallister–Hall syndrome illustrated in Fig. 2.

Glossary

Amenorrhea The absence of menstruation during a minimum period of 3–6 months in women who have previously experienced menstruation (secondary amenorrhea) or the lack of menarche at 16 years of age (primary amenorrhea).

Bone mass Total quantity of bone tissue, including the total volume of bone tissue and the total quantity of mineralized extracellular matrix.

Malnutrition A pathological condition occurring when energy and nutrient requirements are not met by dietary intake. There is a wide spectrum of clinical forms, depending on the severity and duration of the deficit, the age of the subject, and the cause of the condition. *Alterations in bone mass in adolescents*: Decreased bone mineral density: Significant diminution of bone mass per unit volume in relation to what is considered normal for the age, pubertal stage, and sex of the subject. BMD below -2 SD (Z score) + two criteria: Two or more fractures of low impact in long bones before 10 years; three or more fractures in the same bones before 19 years; one or more vertebral fracture at whatever age. *Alterations in bone mass in adults*: osteopenia: BMD between -1 and -2.5 SD; osteoporosis: BMD -2.5 SD; severe osteoporosis: BMD $>$ -2.5 DE, presence of one or more fractures.

Introduction

Anorexia nervosa (AN) is a psychiatric disorder with childhood and adolescent onset characterized by excessive dieting, some compensatory behaviors (excessive exercise, vomiting, and use of laxatives) and specific psychopathological symptoms (disturbance of experience of body weight and/or image, and fear of becoming fat) that lead to severe and maintained weight loss, which results in progressive malnutrition. The American Academy of Psychiatry suggested, in the fifth addition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), that other forms exist, such as avoidance/restrictive food intake disorder (ARFID), that present no specific psychopathological symptoms, and less severe forms renamed "other specified feeding or eating disorder" (OSFED). The latter includes five former disorders: atypical anorexia, purging disorder, subthreshold bulimia, subthreshold binge eating disorder, and night eating disorder. The new category of ARFID is intended to capture not only individuals who meet the criteria for the Feeding Disorder of Infancy and Early Childhood DSM-IV category, but also other individuals with clinically significant eating problems who are not included in DSM-IV categories, and therefore must be assigned a diagnosis of eating disorder not otherwise specified (EDNOS), such as selective eating and/or dysphagia.

Prevalence

The lifetime prevalence of DSM-5 AN among women is up to 4% and of bulimia nervosa and binge eating disorder 2%, respectively, with a bimodal age distribution including peak ages of 14 and 18 years, respectively. However, an increasing number of cases in girls during the initial stages of puberty (12–15 years), as well as at the onset of puberty, have been observed in recent decades. The female/male ratio ranges from 5:1 to 10:1. The more inclusive DSM-5 criteria reduce the proportion of EDNOS diagnoses regarding DSM-IV and increase the proportion of anorexia and bulimia nervosa, with the new cases tending to have a higher minimum body mass index (BMI) and a more benign course (Muñoz and Argente, 2004). The eating patterns and compensatory behaviors (e.g., reduced food intake, exercise to reduce weight) is a continuum in the population; furthermore, up to 50%–67% of adolescent females are dissatisfied with their weight and body shape, and most adolescents have been on a diet at least once in their life. Many of these teens use unhealthy weight control methods, including fasting, diet pills, excessive exercise, and vomiting.

☆*Change History*: December 2017. M. Teresa Muñoz, Monserrat Graell and Jesús Argente updated the text and added new references.

This chapter is an update of Jesús Argente, Mara Teresa Muñoz, Anorexia Nervosa, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 237-248.

Etiopathogenesis

The etiology of AN is multifactorial, including genetic, biological, psychological, and cultural factors. The coexistence of various risk factors increases the possibility of developing this disease (Fig. 1 and Table 1).

Individual Factors

Patients with AN frequently present some specific temperamental features considered risk factors to develop some mental disorders, including eating disorders. These include introversion, obsession, perfectionism, persistence, low self-esteem, avoidance behavior, and high anxiety. In addition, patients who use purgative methods have a marked tendency to impulsive behaviors and often present self-injuries and suicidal attempts, and have problems with alcohol and drugs. The consequent malnutrition elicits several alterations, both physical and mental (obsession, depression), and alterations in their ability to maintain social relationships that is often manifested as isolation. All of this results in a new decrease in self-esteem and sense of effectiveness (Mayhew *et al.*, 2017).

Some high-level athletes develop AN, but others present incomplete or subclinical forms with a more difficult diagnosis. A form called Female Athlete Triad includes low energy availability with or without disordered eating, menstrual dysfunction, and low bone mineral density (BMD) (Fig. 1).

Genetic Factors

Independent of the type of TCA, the majority of the candidate genes are related to the homeostatic control and reward systems (Hinney *et al.*, 2017). The principal genes include the following:

1. Homeostatic pathway: the genes for leptin, leptin receptor, proopiomelanocortin, Agouti-related peptide, melanocortin 4 receptor, brain derived neurotrophic factor, and FTO.

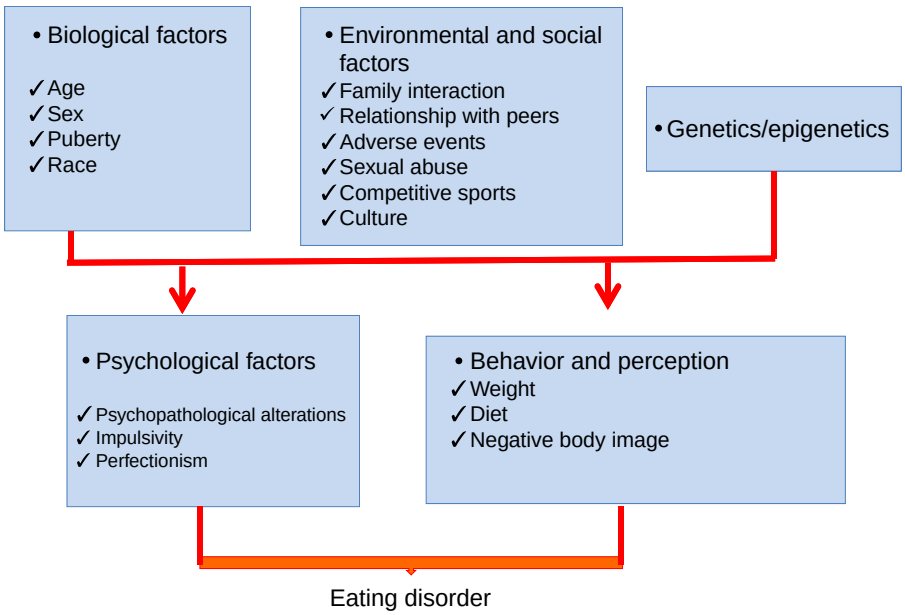

Fig. 1 Risk factors increasing the possibility of developing eating disorders.

Table 1 DSM-5 diagnostic criteria for anorexia nervosa (American Psychiatric Association, 2013)

Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. Significantly low weight is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected
Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight
Disturbance in the way one's body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight

Source: American Psychiatric Association (2013) Diagnostic and statistical manual of mental disorders (5th edn.). Arlington, VA: American Psychiatric Association.

2. Reward-related pathways, including central neurotransmitters such as serotonin and its receptors and transporters (HTR1D, HTR2A, HTR2C, SLC6A4), dopamine and its receptors and signaling (DRD2, DRD4, ANKK1), noradrenaline (COMT), opioids (genes *OPRD1*, *OPRM*), and the cannabinoid system.
3. Two AN loci have been identified by GWAS. The gene Early B-Cell Factor 1, when inactivated in AN, results in a reduction in leptin levels.
4. In a recent whole-exome/genome sequencing study of TCA, the following genes were identified: estrogen-elated receptor α (ESRRA) and histone deacetylase 4 (HDAC4) that induce the expression of monoamino oxidase A and B, suggesting a potential role in the metabolism of neurotransmissors such as serotonin and dopamine.

Familial Factors

Some studies find that families are overprotective, strict, and have low levels of warmth in their rearing practices in comparison to other families without eating disorders. In addition, an inability to solve family conflicts can occur (Mayhew *et al.*, 2017). In some families in conflict (i.e., conjugal), the adolescent is often recognized as an individual with their own needs only after the onset of the illness; consequently, the patient tends to maintain the illness in order to keep the family's attention (**Fig. 1**).

Sociocultural Factors

Adolescents are often very vulnerable, receiving a large quantity of information that they cannot assimilate, which creates tension regarding problems normal for their age, including sexuality, competitiveness, individuality, and independence within the family (**Fig. 1**).

The adolescent is constantly bombarded with information regarding the ideal weight and figure, how to have the perfect body, what type of exercise one must practice to achieve this perfect body, and miracle diets. The cultural image model barely tolerates diversity in body forms, identifying thinness as a value of success (Mayhew *et al.*, 2017).

Evaluation

Multiple organ system complications are seen, including those involving the cardiovascular and peripheral vascular systems and gastrointestinal, hematological, renal, skeletal, endocrine, and metabolic disorders. These alterations are related not only to the state of malnutrition, but also to the conduct of these patients to control their weight.

The psychopathological and familial evaluation realized by a mental health professional (psychologist and/or psychiatrist) is crucial to diagnose and decide the therapeutic approach.

Medical Complications

The clinical manifestations of AN are broad, affecting all systems of the organism, and depend largely on whether the form is restrictive or purgative. About 10%–20% of anorexic patients have bulimic tendencies, which mainly include provocation of vomiting, the use of laxatives, and a compulsive increase in physical activity.

Cardiovascular problems occur in up to 80% of patients, including bradycardia and hypotension, due to autonomic nervous system imbalances (Muñoz and Argente, 2004). Electrocardiographic abnormalities may include atrial and ventricular arrhythmias and QTc abnormalities. In addition, changes in myocardial function have been reported with decreases in myocardial tissue mass, mitral valve prolapse, and pericardial effusions.

Gastrointestinal complications are also common. AN can cause a decrease in gastrointestinal motility, resulting in chronic constipation. Laxative abuse can lead to cathartic colon syndrome and chronic constipation that is sometimes refractory to treatment. Cases of acute gastric dilatation have been described during the phase of realimentation of extremely affected anorexia patients since gastric emptying of solids is retarded, with emptying of liquids being retarded in some patients. Esophageal problems include severe esophagitis and even ruptures of the esophagus, associated with induced vomiting (Muñoz and Argente, 2004).

Neurological consequences result from severe malnutrition. Computed tomography and magnetic resonance imaging have demonstrated cortical atrophy and ventricular dilatation. Malnourished patients have greater cerebrospinal fluid volumes and reduced white and gray matter volumes (Muñoz and Argente, 2004). Abnormalities on computed tomography scans are reversible with refeeding and nutritional recovery.

Biochemical Abnormalities

Hematological findings include anemia, leucopenia (relative neutropenia and lymphocytosis), thrombocytopenia, low erythrocyte sedimentation rate, and decreased fibrinogen levels in plasma (Muñoz-Calvo, 2005). The anemia and occasional pancytopenia appear to be due to hypoplasia of the bone marrow, which is filled with a gelatinous mucopolysaccharide.

Vomiting results in the loss of sodium, hydrogen, and potassium, causing metabolic alkalosis. The use of laxatives provokes the loss of potassium and bicarbonate, which can result in metabolic acidosis (Muñoz-Calvo, 2005). Finally, the use of diuretics can cause increased loss of sodium, potassium, and calcium in the urine, depending on the dose and drug used.

Renal complications are present in 7% of these patients and can include a decrease in glomerular filtration, an increase in plasma urea and creatinine levels, electrolyte alterations, edema, and hypokalemic nephropathy.

Cellular immune functions are also altered because of poor nutrition. These include modifications in some immunoglobulin fractions (IgG and IgA and complement factors C3 and C4), low response in the cutaneous delayed hypersensitivity test, and alterations in the lymphocyte subpopulations CD3, CD4, and CD57. However, infections are infrequent in these patients.

Plasma protein levels are usually normal, although in some cases hypoalbuminemia is present. Elevated amylase has been observed in the absence of clinical signals of pancreatitis.

Mild hypercholesterolemia is frequent in AN, with the elevation occurring in the low-density lipoprotein fraction, whereas both high-density lipoprotein and very low-density lipoprotein levels are normal. The cause of the hypercholesterolemia is a result of a reduced bile acid requirement is also characteristic (Muñoz-Calvo, 2005).

Differential Diagnosis

A differential diagnosis must be made in situations characterized by loss of weight in young persons, such as brain tumors and lymphomas, and in cases with gastrointestinal symptoms, such as chronic inflammatory disease (Muñoz and Argente, 2004). In addition, different endocrine pathologies, such as Addison's disease, hyperthyroidism, and uncontrolled diabetes mellitus, must be taken into consideration. Depending on the predominant psychopathological symptoms, depression, obsessive-compulsive alterations, social phobia, and schizophrenia must be ruled out.

Complications

Endocrine and Neurotransmitter Disturbances

Hypothalamic–pituitary–gonadal axis

Patients with AN exhibit isolated hypogonadotropic–hypogonadism of hypothalamic origin. The etiology is uncertain, although multiple factors may play a role, including hypothalamic dysfunction, reduction of weight, sex steroids, and neurotransmitters alterations, as well as physical exercise (Schorr and Miller, 2017).

Adolescents with AN exhibit low basal levels of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) as well as low estradiol and testosterone levels, indicating the abnormal function of the hypothalamic–pituitary–gonadal axis (Schorr and Miller, 2017). These hormonal alterations result in a prolonged follicular phase and an insufficient luteal phase. In addition, spontaneous secretion of LH during a 24-h period is decreased in both frequency and amplitude of the secretory bursts. With weight gain, serum levels of both LH and FSH are increased, suggesting that malnutrition may play a role in the regulation of gonadotropin secretion (Muñoz-Calvo, 2005). Disturbances in neurotransmitters have been described, including the dopaminergic system and endogenous opioids, which are both peptides involved in gonadotrophin-releasing hormone (GnRH) regulation.

Malnutrition may be responsible for the delayed puberty and reduction in growth seen in these patients. This phenomenon has been interpreted as a mechanism of adaptation to the reduction in nutrients. Delayed puberty is present when symptoms appear in prepubertal patients; in contrast, if the disease begins after development has begun, puberty is detained, and the growth spurt is delayed and reduced. Finally, if symptoms appear after puberty, secondary amenorrhea is present. One of the indications that the process of adaptation to malnutrition has begun is hypoinsulinemia, present as a consequence of low glucose and amino acid levels. Furthermore, growth hormone (GH) abnormalities and low IGF-1 levels contribute to poor growth in prepubertal patients, leading to a reduction in their final height (Schorr and Miller, 2017).

Leptin is a fat-derived anorexigenic hormone. In subjects with reduced fat stores, problems with reproductive system functioning are frequent, including a reduction in serum sex steroid levels. A similar phenomenon, the shutdown of the hypothalamic–pituitary–gonadal axis, occurs in patients with AN after the loss of fat stores. In both cases, it is speculated that the problems with gonadal function could be related to the decreased basal serum leptin levels and pulsatile secretion as a result of the loss of fat tissue (**Fig. 2**). The degree of weight recovery after nutritional therapy in AN patients is correlated with the increase in their serum leptin levels. Furthermore, this rise in leptin correlates substantially with increasing gonadotropin levels, suggesting that the increase in circulating leptin associated to nutritional recovery could be involved in the activation of the hypothalamic–pituitary–gonadal axis. However, the increase in free leptin index after nutritional therapy in AN patients has been associated with the resumption of menses, thus reinforcing the importance of the increase in leptin bioavailability on the hypothalamic–pituitary–gonadal axis reactivation (Argente *et al.*, 1997).

Kisspeptin is a neuropeptide that acts directly on hypothalamic GnRH neurons, which in turn stimulate the secretion of FSH and LH. Kisspeptin levels are reduced and negatively correlated with BMI in adolescents with AN (Schorr and Miller, 2017).

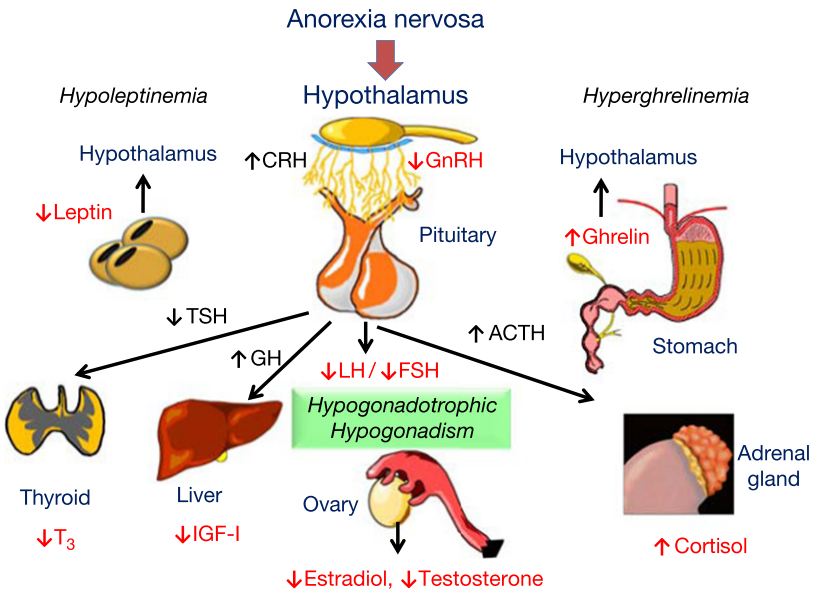

Fig. 2 Hormonal changes in patients with AN and hypothalamic amenorrhea.

One study reported that 85% of patients reached 90% of their ideal weight, restarting menstruation within the following 6 months. However, amenorrhea persisted in 15% even though they regained their weight. It therefore follows that one of the decisive factors for the normalization of gonadal function is the recuperation of the nutritional state (Baskaran *et al.*, 2017).

Hypothalamic–pituitary–GH axis

AN is associated with a nutritionally acquired resistance to GH, with decreased liver production of IGF-1 and elevated GH levels. Multiple mechanisms have been proposed to explain the hepatic GH resistance, including low IGF-1 levels and elevated levels of fibroblast growth factor 21, produced in hepatocytes and white adipose tissue (Baskaran *et al.*, 2017).

Few studies have analyzed spontaneous GH secretion (SGHS) in patients with AN. We studied SGHS in a group of anorexic patients at diagnosis and at two different time-points during weight recovery, and found that at diagnosis SGHS is heterogeneous (Muñoz-Calvo, 2005). In 40% of subjects, the mean 24-h GH secretion was >3 ng/mL (lower limit of normality), and the remaining 60% had levels below the normal range. The difference between these groups and the controls was due to modification in the amplitude of the GH peaks and not as a result of pulse frequency. In both groups, recovery of at least 10% of initial weight resulted in the normalization of the parameters of SGHS. These observations suggest that alterations in GH secretion in these patients are due to modifications in its neuroendocrine control, with a possible increase in growth hormone-releasing hormone (GHRH) release and decreased somatostatin tone.

The GH pattern in conjunction with the negative correlation between basal and pulsatile GH secretion and BMI suggests that the observed alterations in GH secretion are directly related to malnutrition. One possible mechanism could involve the reduced IGF-1 levels caused by malnutrition. This would reduce the negative feedback action that IGF-1 exerts on GH secretion at the level of the hypothalamus and pituitary. Another variable that may be involved is the hypoestrogenism that accompanies amenorrhea. It has been suggested that malnutrition underlies the increase in the amount of GH secreted in each pulse and that hypoestrogenism is responsible for the increased pulse frequency. Definite conclusions, however, cannot be drawn from these studies (Muñoz-Calvo, 2005).

Serum GH-binding protein (GHBP) levels in patients with AN are dramatically reduced and tend to normalize with weight recovery. The reduction in GH receptors is most likely one of the principal causes of GH resistance. In malnutrition, the low GHBP levels may be related to hypoinsulinemia, alterations in thyroid function, or hypoestrogenism. On the other hand, many studies have demonstrated a correlation between serum GHBP levels and BMI or the percentage of body fat or, more specifically, visceral fat. Given that it has not been demonstrated that circulating GHBP is uniquely or even preferentially derived from liver GH receptors, it is possible that other tissues, such as adipose tissue, may contribute to plasma GHBP levels. If this is the case, the extreme reduction in adipose tissue in patients with AN may cause the observed decrease in serum GHBP levels (Muñoz and Argente, 2004).

Patients with AN have extremely reduced serum IGF-1 levels that tend to normalize with weight recovery; however, as observed for other forms of malnutrition, the time necessary for this to occur may be prolonged. Circulating IGF-1 is largely dependent on GH, but it is also very sensitive to nutritional changes. In AN patients, serum IGF-1 levels do not correlate with GH secretion, which suggests that the decrease in IGF-1 is independent of GH and probably directly due to the state of malnutrition (Muñoz and Argente, 2004).

Patients with AN have elevated serum IGFBP-1 and IGFBP-2 levels that tend to normalize with weight recovery. Both are reported to be GH-independent and very sensitive to nutritional regulation. The increase in IGFBP-1 in these patients is most likely related to hypoinsulinism (Muñoz and Argente, 2004).

Serum IGFBP-3 levels are decreased in AN patients as a consequence of GH resistance and tend to normalize after weight recovery. Indeed, all components of the trimolecular complex formed by the union between IGFBP-3, IGF, and the acid-labile subunit are decreased. Given that these proteins are all GH-dependent and regulated by the nutritional state, this is not unexpected. IGFBP-3 decreases significantly with caloric restriction, but in adults it decreases only with protein restriction. In contrast to other catabolic situations, in AN increased proteolysis of IGFBP-3 has not been observed (Muñoz-Calvo, 2005).

Alterations in the GH-IGF-1 axis have been well documented, but with respect to the recuperation of growth, the results are not conclusive. Some authors observe delayed growth, while others report total recuperation of this parameter. One recent retrospective study in adolescents with AN, delayed puberty, and reduced growth velocity (<2.5 cm/year) reported that nutritional rehabilitation and administration of recombinant GH at high doses resulted in an increase in growth velocity during the 3 years of treatment (Léger *et al.*, 2017). However, more controlled studies are necessary to determine the long-term effect of GH in these patients. The delay in bone age and ponderal gain during treatment would be the main predictors of growth recuperation.

Hypothalamic–pituitary–thyroid axis

Thyroid function is affected by malnutrition in AN (**Fig. 2**). Clinically, patients appear to be in a relative hypothyroid state, sometimes called euthyroid sick syndrome. Clinical manifestations include hair loss, dry skin, hypothermia, and bradycardia. All these findings are reversible with appropriate refeeding and successful treatment. Laboratory findings include low-normal levels of thyroxine (T_4) and thyroid-stimulating hormone, below-normal levels of triiodothyronine (T_3), and elevated levels of reverse T_3. All these findings are the result of malnutrition and weight loss. In fact, the low T_3 level correlates with the amount of weight loss. The extremely reduced T_3 levels in these patients are due to altered peripheral deiodination that preferentially transforms T_4 into the inactive metabolite, reverse T_3. These alterations normalize with weight recovery, and thyroid hormone replacement is usually not indicated (Muñoz and Argente, 2004).

Hypothalamic–pituitary–adrenal axis

In AN, plasma cortisol levels are often elevated due to an increase in the frequency of secretory bursts of cortisol (**Fig. 2**). The circadian rhythm is conserved. Dexamethasone can partially suppress this hypercortisolemia, which is similar to that observed in patients with depression and Cushing's disease. In acute situations of AN, the dexamethasone test has no medical significance; however, in patients who are gaining weight, it may have prognostic value (Muñoz and Argente, 2004). Refeeding studies of anorexic patients have shown that, irrespective of the individual's initial weight, weight gains as low as 10% are associated with the normalization of cortisol secretion. The mean plasma half-life of cortisol is prolonged and ACTH levels are within the normal range, but the ACTH response to CRH is lower than that of control patients. This hypercortisolemia may indicate a defect at the level of the hypothalamus, or even higher, that results in hypersecretion of CRF (Muñoz-Calvo, 2005). Taken together, these observations suggest CRH hypersecretion more than cortisol resistance.

Adipokines and appetite-regulating hormones

Long-term energy balance is regulated via a system composed of different hormones secreted in proportion to corporal adiposity, which act at the level of the central nervous system. These respond to changes in body fat and activate anabolic or catabolic pathways, the first through production of NPY, which stimulates food intake, and the second via the hypothalamic melanocortin system, which reduces food intake and stimulates weight loss.

Leptin, a hormone synthesized by adipose tissue, plays an important role in the regulation of food intake and energy expenditure. Plasma leptin levels and secretory pattern vary during the night and day, and are influenced by food intake (Argente *et al.*, 1997). Leptin acts at the level of the hypothalamus to decrease appetite, resulting in weight loss. Moreover, leptin has other functions, such as regulation of bone metabolism, neuronal and cognitive functions, as well as its more recently described function in the immune system. In different studies, low levels of leptin have been reported in AN subjects compared to controls, and this could contribute to the development of hypothalamic amenorrhea, as well as the compulsive physical exercise that these patients perform (**Fig. 2**). A recent study observed that the changes in circulating leptin could be related not only to the changes in adipose tissue, but also to psychological symptoms such as depression, anxiety, and stress, which will depend on the severity of the malnutrition (Stroe-Kunold *et al.*, 2016).

The ghrelin (gastrointestinal peptide hormone) levels are regulated by acute and chronic changes in energy balance (e.g., fasting increases, whereas feeding decreases, circulating ghrelin concentrations). Ghrelin levels are high in AN, presumably as an adaptive response to the low energy state, with levels inversely correlating with BMI and fat mass (Muñoz-Calvo, 2005).

Serum adiponectin levels have been reported to be elevated, unchanged, or low in AN. Levels of this adipokine are an inverse predictor of bone density in adolescents with AN, with high adiponectin levels possibly contributing to the low BMD in AN by increasing osteoclast activity.

PYY is an anorexigenic peptide primarily produced in the L-cells of the colon in proportion to caloric intake, with levels increasing after food intake. High serum PYY levels might contribute to reduced food intake and decreased bone formation in AN.

Bone mineral density and bone microarchitecture

Adolescents with AN show a decrease in bone mass, with the pathogeny being not completely known, but several studies have highlighted a number of factors, including low caloric intake with low serum IGF-1 levels, increased serum cortisol and PYY levels, low body weight, and reduced levels of adipose tissue with low serum leptin levels (Stroe-Kunold *et al.*, 2016).

It is well known than more than 50% of adolescents girls and 70% of males with AN present a BMD of -1 (Z score) in at least one or two areas. After 1 year of follow-up, the reduction in BMD at the level of the lumbar spine is reported not to improve significantly in these patients even with weight recuperation, indicating suboptimal bone accrual rates. Approximately 11% have a BMD of -2 Z scores at diagnosis and approximately 30% of adolescents with AN have an increased risk of fractures. Likewise, adolescents with BN have a reduction in bone mass at the lumbar level, suggesting that weight loss does not explain the deleterious effect of TCA in bone (Singhal *et al.*, 2018).

Bone loss in AN occurs in both the trabecular and cortical bones, although it is more evident in the former. We studied a group of girls with restrictive AN with moderate malnutrition and secondary amenorrhea of more than 1 year of evolution, and found loss of bone mass at the lumbar and femoral levels. Weight gain and resumption of menses increased bone mass, especially in the lumbar spine (Stroe-Kunold *et al.*, 2016).

It is clear that AN has negative effects on BMD and on the size and structure of the bone, and that these alterations could explain the increased fracture risk. Advances in imaging techniques, such as quantitative computed tomography (QCT) and more recently high-resolution peripheral QCT (HR-pQCT), provide estimations of bone geometry and cortical and trabecular volumetric BMD (vBMD), that directly correlate with fracture load (Singhal *et al.*, 2018). Baskaran et al. (2017) observed a reduction in the area and cortical thickness, and an increase in the cortical porosity in the distal radial (a non-weight bearing site) of adolescents with AN by using QCT.

HR-pQCT allows the evaluation of the bone microarchitecture, estimating bone stiffness and load failure (strength), which are both diminished in adolescents with AN, which contributes to the fracture risk. Recently, using HR-PQCT, Singhal et al. observed alterations in the trabecular and cortical zones of the tibia (weight-bearing site) associated with increases in marrow adipose tissue and reduced strength estimates in adolescents and young women with AN (Frølich *et al.*, 2017).

The degree of osteopenia possibly depends on the age at which the amenorrhea began, as well as its duration. Indeed, patients with primary amenorrhea have a more severe reduction in bone mass than those that present with secondary amenorrhea. There are significant concerns about the lasting impact and irreversibility of bone mass loss. Evaluation of bone density is recommended in patients who have been amenorrheic for 6 months to 1 year (Muñoz and Argente, 2004).

Sex hormones

Administration of estrogens and gestagens to adolescents with reduced bone mass and amenorrhea for at least 1 year indicated that the reduction in bone mass could not be reversed. In contrast, in patients with weight gain, femoral neck BMD was found to improve. The resumption of menses also improves spinal vertebral BMD and bone mass compared to that seen at diagnosis (Muñoz *et al.*, 2007). These findings demonstrate the effect of estrogen on trabecular bone density.

The effects of estrogens on bone metabolism include inhibition of the resorption process, although direct effects on osteoblast activity have also been described. It has been reported that AN occurring during adolescence impairs both mineral accrual and bone size.

Although reduced vBMD may be related to estrogen deficiency, no reduction in bone size after adjusting for fat and lean mass has been reported. Weight, but not estrogen use, is a significant predictor of BMD at all skeletal sites in anorexic women (Chou and Mantzoros, 2017).

Female AN patients exhibit androgen deficiency, with both low free testosterone levels and dehydroepiandrosterone sulphate (DHEAS) levels being reported in women with AN. Androgen deficiency could contribute to a loss of bone mass in these patients.

IGF-1

IGF-1 is one of the most important regulators of bone metabolism. Circulating levels of IGF-1 correlate with BMD in the normal population. IGF-1 exerts a double effect on bone metabolism by stimulating osteoblastic activity and the resorption process. Deficiency in growth factors, especially IGF-1, which is most likely due to the state of malnutrition, as well as the slow recuperation of their plasma levels with weight gain, is known to occur in these patients. Improvement in nutritional status in AN patients via intravenous hyperalimentation therapy results in a rapid increase in serum IGF-1 levels, followed by a progressive increase in osteocalcin, a specific marker of osteoblast function (Muñoz-Calvo, 2005). This indicates that bone formation begins immediately. Nevertheless, increased bone resorption appears to continue for at least 5 weeks.

Leptin

Leptin is effective in reducing trabecular bone loss, trabecular architectural changes, and periosteal bone formation. These findings suggest that leptin may regulate bone remodeling, and this effect may be, at least in part, mediated by the osteoprotegerin (OPG)/RANK (receptor for activation of nuclear factor kappa B) ligand pathway. The RANK and RANK ligand (RANKL) are members of the tumor necrosis factor (TNF) and TNF receptor superfamilies, which are essential for osteoclast differentiation. In the bone microenvironment, the stimulatory effects of RANKL are neutralized by the secreted decoy receptor, OPG. It follows that the balance between OPG and RANKL secretion by stroma cells is critical for the regulation of osteoclast formation (Stroe-Kunold *et al.*, 2016). The dramatic decline in leptin levels observed in AN may be one of the major hormonal factors involved in the pathogenesis of the associated bone fragility through diminishing cortical bone formation rates and skeletal growth. Leptin may also play an important protective role in bone metabolism by inhibitory bone resorption.

Other hormones

Insulin levels are low in girls with AN compared with normal-weight controls, and are positively associated with levels of bone turnover markers. Omentin-1 levels are increased in adolescents with AN and are reported to be an independent predictor of BMD, being negatively correlated with bone turnover markers and possibly exerting negative effects on bone mass. Oxytocin has anorexigenic and bone anabolic effects, and its levels are reduced in adolescents with AN and associated with the decline in bone mass (Muñoz-Calvo, 2005).

Bone

In adolescents with AN, it is clear that markers of bone formation are decreased and markers of bone mineral resorption are increased. The bone isoenzyme alkaline phosphatase (bAP) and the amino-terminal pro-peptide of procollagen I (PNIP) have the greatest diagnostic sensitivity in detecting anomalies in bone remodeling, at least in osteoporetic women (Chou and Mantzoros, 2017).

Levels of PNIP, a marker of bone formation, and of N-telopeptide (NTX), a marker of bone resorption, are reduced in adolescents with AN, indicating a low level of bone turnover during a period of active growth when the level of bone turnover is elevated in healthy adolescents (García de Álvaro *et al.*, 2007).

OPG, which inhibits osteoclastogenesis and osteoclast activity, and RANKL, which increases osteoclastogenesis and osteoclastic activity, are key factors in the modifications in bone remodeling and diminution of bone mass in patients with AN. Hence, the greater the reduction in the ratio OPG/RANKL, the greater is the drive for bone resorption. We studied a group of AN patients with malnutrition and secondary amenorrhea with an evolution of more than 1 year at the beginning of the study who received oral estrogen treatment throughout the follow-up period. The OPG/RANKL ratio was significantly decreased after 1 year, due to an increase in serum RANKL values. These patients showed lower BMD values, both at diagnosis and at the end of the study. The decrease in the OPG/RANKL ratio in girls with AN could partly explain the increase in bone loss that occurs in these patients (De la Piedra *et al.*, 1999). Different studies have demonstrated that during undernutrition and amenorrhea, with low IGF-1 and extremely low circulating estradiol, bone formation markers correlated positively with IGF-1 and bone resorption markers negatively with estradiol. This indicates that IGF-1 stimulates bone formation, whereas estradiol's actions predominately inhibits bone resorption (De la Piedra *et al.*, 1999).

Treatment

An integral treatment program (addressing all alterations in the patient) should be instituted and carried out by a multidisciplinary and coordinated team, including a pediatrician, endocrinologist, psychiatrist, psychologist, nurse, and others such as teachers and family. It is fundamental that an accurate evaluation and diagnosis are made and that the patient and family are aware of the importance and nature of the disease and of each aspect of the treatment (Muñoz and Argente, 2004).

Treatment objectives should have a strict priority: prevent the death of the patient; prevent the disease from becoming chronic; and attainment of physical and mental recuperation.

Nutritional Treatment

Refeeding

To begin refeeding successfully, it is fundamental that a therapeutic alliance with the patient be established in which the patient understands and accepts (at least partially) that he or she has a disease. This can be accomplished by asking the patient if he or she has the various signs and symptoms of AN so that, little by little, the patient can identify with this condition (Baskaran *et al.*, 2017).

The physician should use height and weight graphs to explain what percentile the patient is currently in and what the patient's weight should be for his or her age and height. A target weight, acceptable to both the patient and the physician, should be agreed upon. The patient's understanding of caloric requirements to maintain a normal weight should be explored because very few possess knowledge of the appropriate requirements for their height, age, and sex. Patients must understand that their growth and physical activity depend on the adequate intake of calories, including proteins, fats, carbohydrates, and vitamins and minerals (Muñoz-Calvo, 2005).

Obtaining and maintaining an adequate weight

After the target weight has been achieved, a maintenance diet must be prescribed, and foods not on the diet and eating between meals must be prohibited for a time, which will help the patient to overcome the fear of losing control or gaining weight. Afterwards it will become necessary progressively to schedule meals out of the diet (e.g., in summer camps, restaurants) to achieve eating without a prescribed diet during approximately the second year of treatment (Baskaran *et al.*, 2017).

Nutritional supplementation

Calcium: Different meta-analyses observed no increase in BMD in adolescents with AN after receiving calcium supplements.

Vitamin D: Correlations between supplementation with calcium and vitamin D and BMD have not been found in these patients (Robinson *et al.*, 2017).

Table 2 Therapeutic options for improving bone mass in AN

Therapy options	
Weight recovery	Maintain the recovery and maintenance of weight should be a goal
Calcium and vitamin D	1300 mg of calcium and 600 IU of vitamin D daily (maintain vitamin D levels between 30 and 50 ng/mL)
Estrogens	100 μg 17 β estradiol transdermally with cyclic medroxyprogesterone acetate (2.5 mg/day during 10 days) or oral micronized progesterone (100–200 μg during 10–12 days)
Testosterone	150 μg transdermally
DHEA	50 mg of micronized DHEA orally per day, with an oral contraceptive (20 μg of EE and 0.1 mg of levonogestrel)
rhIGF-1	30 μg/kg of rhIGF-1, twice daily with an oral contraceptive (35 μg of EE and 0.4 mg norethindrone)
Biphosphonates	35 mg of risedronate orally/weekly 10 mg of alendronate orally/day
TPT	20 μg/day, subcutaneously

DHEA, dehydroepiandrosterone; *rhIGF-1*, recombinant IGF-1; *TPT*, teriparatide.

Gonadal steroid replacement

Different controlled studies have demonstrated that oral estrogens are not effective in increasing bone mass in adolescents with AN. Estrogen–progesterone combination pills that provide doses of 20–35 mg of ethinyl estradiol may further decrease the levels of IGF-1, an important bone trophic hormone. Thus, oral contraceptives may have an IGF-1 suppressive effect, which could potentially explain the small-to-negligible effectiveness of this therapy. In contrast, the utilization of transdermal patches of 100 mcg of 17 β estradiol with cyclic progesterone, a modality which has been shown to exert little to no suppression on IGF-1 as compared with oral contraceptives, causes in girls with AN a significant increase in BMD over an 18-month period (**Table 2**). These differential effects could be related to the type of estrogen (17 β estradiol vs. EE) and/or the method of administration (transdermal vs. oral) (Robinson *et al.*, 2017).

IGF-1 replacement

Administration of recombinant human IGF-1 (rhIGF-1) to adolescents with AN causes an increase in levels of bone formation markers, but not bone resorption markers (**Table 2**). Additionally, rhIGF-1 in conjunction with an estrogen-progesterone combination pill causes a significant increase in spinal vertebrae BMD and serum levels of bone formation markers, and decreases bone resorption markers in adult women with AN compared with a placebo (De la Piedra *et al.*, 1999).

Biphosphonates

Bisphosphonates, having a long half-life and strong affinity for bone as demonstrated by their absorption into its matrix, inhibit osteoclastic bone resorption. In adult women with AN, oral intake of bisphosphonates for a year increased BMD of the posterioanterior spine by 3% and of the hip by 2%. One placebo-controlled study in girls with AN who received alendronate found no increase in spine BMD and minimal increases in femoral neck BMD. Another study showed that treatment with risedronate and testosterone produced a 3% increase in bone mass in the lumbar area and a 2% increase in the femoral neck (Miller *et al.*, 2011). Testosterone increased muscular mass, without improving bone mass (**Table 2**). Biphosphonates pass through the placenta and have a long half-life. They have not been approved by the Food and Drug Administration (FDA) for use in women during fertile ages with AN due to the limited knowledge of their long-term efficacy.

DHEA

There is no evidence of an improvement in BMD after the administration of DHEA. If it is associated with oral anticontraceptives, BMD at the level of the femoral neck increases (Robinson *et al.*, 2017) (**Table 2**).

Teriparatide

Administration of 1.34 pH (teriparatide, or TPT), an anabolic agent, to older women with reduced bone mass for 6 months resulted in an increase of 6%–10% in the lumbar spine (**Table 2**). However, the safety of this drug has not been established due to an increase in osteosarcoma in rodent studies. This suggests that TPT should not be used in adolescents and young women (Robinson *et al.*, 2017).

Other alternative drugs

Leptin: Interventional studies evaluating the effect of recombinant leptin in patients with hypothalamic amenorrhea have shown improved LH pulse frequency and increased serum LH levels, as well as overall improvement in ovarian parameters and markers of bone formation, suggesting that leptin is required for normal reproductive and neuroendocrine function. However, recombinant leptin also produced a 4.3% decline in fat mass, a finding that is a potential limitation for its use in individuals with AN (Robinson *et al.*, 2017).

Exercise activity

Exercise is important for bone health in individuals with AN, as it increases BMD. The recommendations for physical activity in those with AN is controversial. Increased physical activity in combination with malnutrition can exacerbate weight loss (Baskaran *et al.*, 2017).

Psychiatric treatment

Psychiatric (psychotherapeutic) treatment is imperative in the AN patients. Psychological intervention should start as early as possible, together with and favoring nutritional rehabilitation, and must continue sufficiently to assure maintenance of the achieved improvements and prevent relapses. Psychoeducational techniques are highly useful during the early stages of treatment. They are focused on parents and adolescents in order to give them a deep understanding of nutritional aspects, symptoms of the disorder, and treatment aspects (Herpertz-Dahlmann, 2017).

The family based treatment is usually combined with cognitive-behavioral therapy, which is an effective psychotherapeutic intervention for eating disorders and consists of modification of disturbed behaviors and thoughts underlying the disorder.

Pharmacological Treatment

Pharmacological therapy is not an essential treatment in patients with AN because the specific psychopathology is unresponsive to this treatment. Therefore, it should not be used as the unique or principal treatment. The use of drugs is especially controversial in adolescent patients. However, some general symptoms such as obsessions, compulsivity, hyperactivity, and extreme anxiety could improve with some pharmacological agents such as low doses of olanzapine (atypical antipsychotic) or clorazepam (benzodiacepines). Limited studies, not replicated, have also suggested the use of fluoxetine as a prevention of relapse in recovered patients (Rienecke, 2017).

It is important to take into account that the use of psychoactive drugs is not recommended in patients with very low bodyweight due to their secondary effects and lower efficacy in these conditions.

Prognosis and Evolution

The clinical course of AN is marked by episodes of remission and relapse even in the best-controlled cases. The first episode in adolescents is long, and rarely lasts <4 or 5 years. On a community level, 5-year recovery rates for DSM-5 AN are 60%–70%, whereas 20% have partial remission. However, 20%–25% of anorexic patients could become chronic. The transition to bulimia nervosa is frequent, occurring in 30%–40% in 6–8 years of follow-up (Muñoz and Argente, 2004).

The mortality rate is between 0.5% and 1% per year of observation. The most frequent causes of death are cardiovascular problems due to severe undernutrition, gastrointestinal complications, infections, and suicide. The mortality rate increases slightly (up to 20% for 20 years of follow-up) in longer follow-ups (Baskaran *et al.*, 2017).

Some factors are associated with poor prognosis: long-term disorder, very low weight at the onset of treatment, compulsive physical exercise, purging behavior, drug abuse, previous obesity, poor family relationship, child abuse, and comorbid psychiatric disorders. Otherwise, some factors are related with good prognosis: early diagnosis and treatment, recovery of most of the lost weight (90%–92% of ideal weight), and specialized treatment.

Conclusion

AN is a psychiatric disease. Evidence suggests that there is hypothalamic dysfunction that in general normalizes with weight recovery.

The most relevant factors contributing to the loss of bone mass include: low caloric intake with low serum IGF-1 levels, excessive exercise patterns despite malnutrition, hypogonadism, increased serum cortisol and PYY levels, low body weight, and small amounts of adipose tissue with low serum leptin levels. These in turn result in a high risk of fractures.

Analysis of the genetic mechanisms underlying weight regulation is progressing rapidly. The genetic analysis of AN may help to define new drug targets and therefore lead to new treatment strategies.

An integral treatment program should be instituted and carried out by a multidisciplinary and coordinated team, including a pediatrician, endocrinologist, psychiatrist, psychologist, and nutritionist. The prognosis for adolescents with eating disorders is currently more favorable than in past decades; however, 20%–25% of patients remain chronic.

Endocrine Late Effects in Childhood Cancer Survivors

Wassim Chemaitilly, St. Jude Children's Research Hospital, Memphis, TN, United States
Laurie E Cohen, Harvard Medical School, Boston, MA, United States and Dana-Farber/Boston Children's Hospital Cancer and Blood Disorders Center, Boston, MA, United States

Glossary

Alkylating agents A group of chemotherapy drugs that impair cell multiplication by adding an alkyl group to DNA. Rapidly proliferating cancer cells are particularly vulnerable to alkylating agents. However, normally multiplying non-malignant cells may also be affected. This phenomenon explains the gonadal toxicity of these medications. The most commonly used alkylating agents are: busulfan, carmustine (BCNU), chlorambucil, cyclophosphamide, dacarbazine, ifosfamide, lomustine (CCNU), mechlorethamine, melphalan, procarbazine, temozolomide, and thiothepa.

ACTH deficiency (ACTHD) Deficiency in adrenocorticotropic hormone (ACTH). ACTHD refers to the same condition as central adrenal insufficiency or secondary adrenal insufficiency; these are terms intended to distinguish this entity from adrenal insufficiency due to a disorder originating from the adrenal glands (primary adrenal insufficiency).

Hematopoietic stem cell transplant (HSCT) Treatment procedure that involves repopulating a patient's previously depleted bone marrow by infusing hematopoietic stem cells. Bone marrow transplantation (BMT) is the term used when the source of the grafted hematopoietic stem cells is the bone marrow. Autologous HSCT involves infusing the patient's own, previously collected, stem cells as a rescue procedure following high-dose chemotherapy to treat non-hematological cancers (such as brain tumors). Allogeneic HSCT uses stem cells from a distinct, preferably matched and related, donor to treat hematologic malignancies such as leukemia or lymphoma.

Hematopoietic stem cell transplant conditioning Treatment that purposefully depletes a patient's bone marrow (myeloablative treatment) prior to repopulating it with donor stem cells. Conditioning regimens include myeloablative chemotherapy with or without total body irradiation (TBI) or total lymphoid irradiation (TLI; a regimen that spares the brain).

Immunotherapy for cancer Medications that utilize the immune system's response to attack cancer cells and target tumor growth. Strategies include cellular therapy (e.g., use of chimeric antigen receptor CAR-T cells), immune checkpoint inhibitors such as monoclonal antibodies (e.g., anti-CTLA4 such as ipilimumab), or non-specific immunotherapy agents (e.g., interferon).

LH/FSH deficiency (LH/FSHD) Deficiency in luteinizing hormone (LH) and follicle stimulating hormone (FSH). LH and FSH are also known as the gonadotropic hormones (or gonadotropins). LH/FSHD refers to the same condition as hypogonadotropic hypogonadism.

Premature ovarian insufficiency (POI) Refers to female hypogonadism and infertility due to disorder originating from the ovaries (and not as a consequence of LH/FSHD). POI refers to the same condition as primary ovarian insufficiency or primary ovarian failure.

Primary hypothyroidism Hypothyroidism due to a disorder originating from the thyroid gland itself (and not as a consequence of TSHD).

Targeted chemotherapy agents Medications that target molecular pathways that are deemed specifically responsible of tumor growth. Tyrosine kinase inhibitors (TKI) such as sorafenib, imatinib, and sunitinib are among the most commonly used targeted chemotherapy agents. Differences to conventional chemotherapy include the necessity of prolonged "maintenance" use to maintain tumor growth suppression.

TSH deficiency (TSHD) Deficiency in thyroid stimulating hormone (TSH, also known as thyrotropin). TSHD refers to the same condition as central hypothyroidism or secondary hypothyroidism, which are terms intended to distinguish this entity from primary hypothyroidism.

Introduction

Strides in cancer cure rates have allowed an increasing number of individuals to survive a wide range of childhood onset tumors and malignancies. Childhood cancer survivors (CCS) are estimated to represent 1 out of 530 individuals aged 20–40 years in the United States of America (Ward *et al.*, 2014). However, life-saving treatments such as multi-agent chemotherapy and radiotherapy have been shown to expose patients to a variety of late-onset chronic health conditions, referred to as "late effects," with repercussions on quality of life and longevity (Diller *et al.*, 2009). The endocrine system seems to be particularly vulnerable to disruptions from cancer treatments, especially radiotherapy and/or alkylating chemotherapy agents; endocrine late effects are indeed among the most commonly observed complications in CCS, with up to 50% of individuals affected (Brignardello *et al.*, 2013). This article offers an overview of the most frequently described endocrine late effects in CCS: hypothalamic/pituitary (HP) dysfunction, primary thyroid disease, primary gonadal insufficiency, bone mineral density (BMD) deficit, obesity, and diabetes mellitus. **Tables 1** and **2** propose a summary of the screening approach of patients who are at risk of developing each of these late

effects in order to facilitate early diagnosis and treatment and hopefully improve patient outcomes (Hudson *et al.*, 2013). The tables were adapted from the Children's Oncology Group Long-Term Follow-Up Guidelines (www.survivorshipguidelines.org), supplemented by brief diagnosis and management suggestions.

Hypothalamic/Pituitary Dysfunction

HP dysfunction encompasses the following entities: growth hormone (GH) deficiency (GHD), central precocious puberty (CPP), luteinizing and follicle stimulating hormones deficiency (LH/FSHD), thyroid stimulating hormone deficiency (TSHD), and adrenocorticotropic hormone deficiency (ACTHD). Central diabetes insipidus, a frequent and challenging acute complication of HP tumors and surgery, will not be discussed in the present overview, as it does not occur as a late effect (Clement *et al.*, 2016).

Survivors of childhood cancer or central nervous system (CNS) tumors may develop various components of HP dysfunction as sequelae from local tumor growth, surgical resection, or radiotherapy (Clement *et al.*, 2016). The role of conventional chemotherapy in inducing permanent HP damage is not well established (Rose *et al.*, 2004; Gurney *et al.*, 2006; Bakker *et al.*, 2004). Emerging data on novel chemotherapy agents such as tyrosine kinase inhibitors (TKI) (Lodish, 2013; Rastogi *et al.*, 2012) and immune system modulators (Corsello *et al.*, 2013) support some effect on the HP axis.

Individuals with HP dysfunction due to local tumor growth or surgery frequently present with multiple HP disorders from the outset. Radiation-induced HP dysfunction tends to appear as a late effect a few months to several years after CNS irradiation, with multiple HP disorders appearing sequentially rather than simultaneously in affected patients (Laughton *et al.*, 2008; Chemaitilly *et al.*, 2015; Clement *et al.*, 2016). **Fig. 1** highlights the relative overlap between GHD, LH/FSHD, TSHD, and ACTHD in a study where data from 748 CCS exposed to cranial radiotherapy and followed for a mean of 27.3 years were reported (Chemaitilly *et al.*, 2015). It is important to note that continuous improvements in the delivery of radiotherapy may modify the risk of HP

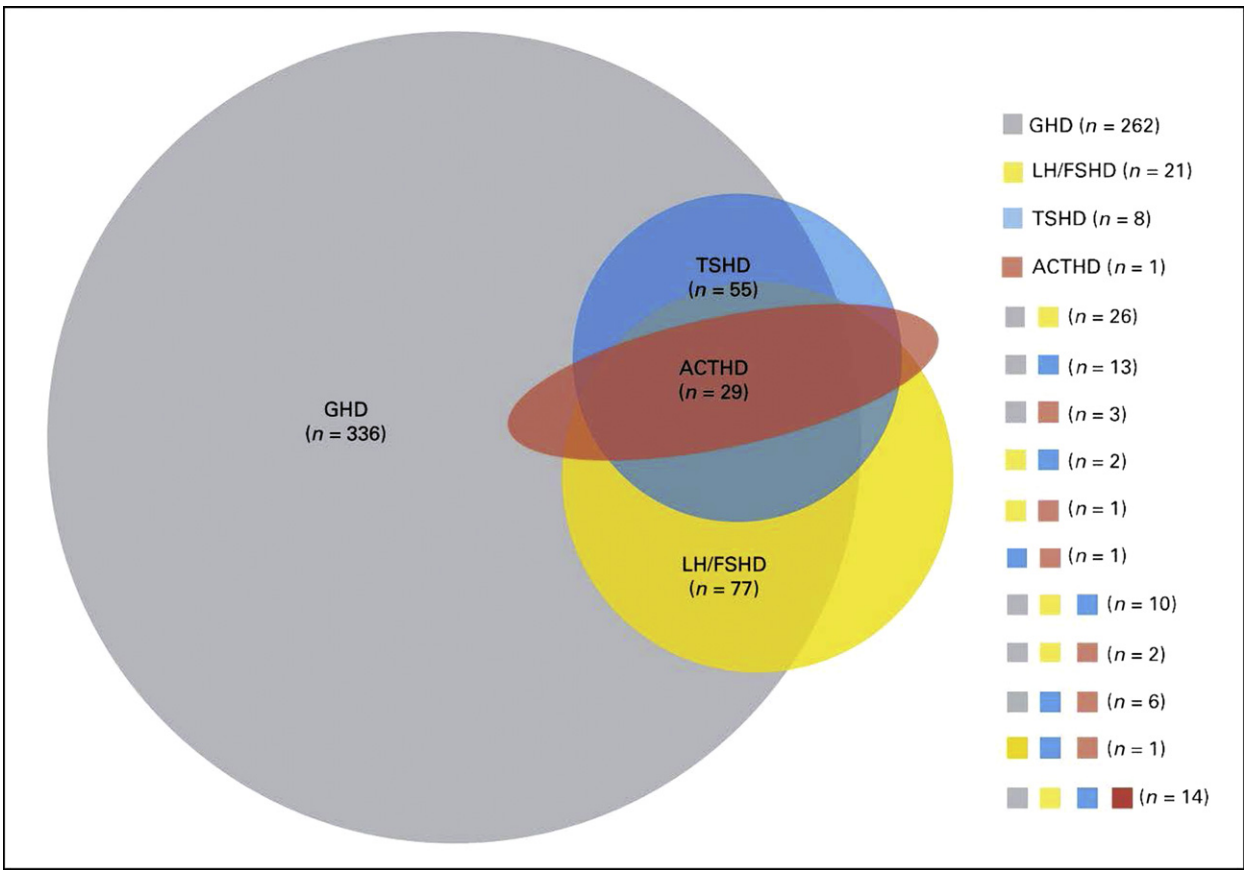

Fig. 1 Proportions and overlap among anterior pituitary hormone deficiencies following cranial radiotherapy. *ACTHD*, adrenocorticotropic hormone deficiency; *GHD*, growth hormone deficiency; *LH/FSHD*, luteinizing hormone/follicle-stimulating hormone deficiency; *TSHD*, thyroid-stimulating hormone deficiency. dysfunction in individuals treated under more recent protocols, such as those using protons rather than photons to generate energy (Eaton *et al.*, 2016).

Growth Hormone Deficiency

Prevalence and risk factors

The prevalence of GHD has been reported at 12.5% in short- to medium-term survivors of CNS tumors (Clement *et al.*, 2016) and 46.5% in long-term CCS exposed to HP radiotherapy (Chemaitilly *et al.*, 2015). It is the most prevalent and frequently only HP disorder in this population (**Fig. 1**) (Chemaitilly *et al.*, 2015; Laughton *et al.*, 2008). The risk is highest in patients with tumors developing within or near the hypothalamus/pituitary and those treated with radiotherapy HP doses $\geq$18 Gy (Chemaitilly *et al.*, 2015; Mostoufi-Moab *et al.*, 2016; Clement *et al.*, 2016). The risk of GHD in relation to radiotherapy increases in a dose- and time-dependent fashion; treatment at doses 10–18 Gy may still result in GHD in CCS monitored over an extended period of time (Merchant *et al.*, 2011). Increased risk of GHD is not limited to survivors of CNS tumors; it extends to all individuals treated with radiation fields that include the HP region regardless of the etiology. This includes survivors of acute lymphoblastic leukemia (ALL) exposed to cranial radiotherapy (Wilson *et al.*, 2016; Brauner *et al.*, 1986), pediatric hematopoietic stem cell transplant (HSCT) recipients conditioned with total body irradiation (TBI) (Brauner *et al.*, 1997; Chemaitilly *et al.*, 2007; Papadimitriou *et al.*, 1991), and CCS treated with radiotherapy for non-brain solid tumors of the head such as retinoblastoma (Pomarede *et al.*, 1984; Friedman *et al.*, 2013), nasopharyngeal carcinoma (Cheuk *et al.*, 2011), and a variety of sarcomas (Punyko *et al.*, 2005). The risk may be higher in individuals exposed to HP radiotherapy at a younger age (Clement *et al.*, 2015; Chemaitilly *et al.*, 2015; Brauner *et al.*, 1986). The risk association with conventional chemotherapy agents is not as well established as with HP radiotherapy (Rose *et al.*, 2004; Gurney *et al.*, 2006; Bakker *et al.*, 2004). Treatment with imatinib mesylate, a TKI that represents the first-line therapy for chronic myelogenous leukemia, has been reported to result in skeletal growth impairment, possibly due to GHD or decreased sensitivity to GH (Narayanan *et al.*, 2013; Rastogi *et al.*, 2012; Tauer *et al.*, 2015).

Diagnosis and management

Children and adolescents with GHD usually experience a decrease in linear growth velocity, with growth chart plots yielding a height curve that gradually crosses to lower percentiles. Patients may present with short stature (height < -2SD) if left untreated for an extended period of time, and referrals for evaluation should not be delayed until that advanced stage (Growth Hormone Research Society, 2000). Medical providers should seek and identify other factors that alter linear growth in CCS, including direct growth plate damage due to spinal radiotherapy or chemotherapy (Hobbie *et al.*, 2011), abnormally timed puberty, undernutrition, and poorly controlled chronic health conditions. Sitting height or arms span measurements can help identify the contribution of spinal radiotherapy or scoliosis to poor growth in affected patients (Clayton and Shalet, 1991). The importance of a careful assessment of pubertal development cannot be understated, as seemingly normal growth velocity due to stimulation from sex hormones in patients simultaneously experiencing CPP may delay the diagnosis of GHD with consequences on final adult height (Sklar and Constine, 1995; Chemaitilly *et al.*, 2016b). Obesity is an additional confounder that is known to influence skeletal maturation and GH secretion (Geffner, 1996).

Diagnosing GHD in CCS follows the same steps as in the general non-CCS population (Grimberg *et al.*, 2016; Fleseriu *et al.*, 2016) with the understanding that providers cannot rely on screening with insulin-like growth factor I (IGF)-I and IGF-binding protein 3 (IGFBP-3) levels as these have been shown not to be reliable in individuals exposed to HP radiotherapy (Sklar *et al.*, 1993; Weinzimer *et al.*, 1999). Failing one dynamic test may suffice for the diagnosis of GHD in CCS with high pre-test probability for GHD such as those with known other HP disorders or patients exposed to high-dose HP radiation who manifest signs of growth failure (Growth Hormone Research Society, 2000). Testing patients with GH-releasing hormone is discouraged because of false negative results related to the likely hypothalamic (rather than pituitary) site of radiation-induced injury (Ham *et al.*, 2005; Schriock *et al.*, 1984; Constine *et al.*, 1993). Given frequent confounders related to pubertal stage, patients should have their skeletal maturation assessed via bone age X-ray (Pyle *et al.*, 1971).

The treatment of GHD in CCS relies on the same principles as in the general non-CCS population (Fleseriu *et al.*, 2016; Grimberg *et al.*, 2016; Growth Hormone Research Society, 2000). Patients and their families should be informed that full recovery of the pre-cancer growth potential may not be achievable given non-GH-related factors (Brownstein *et al.*, 2004; Chemaitilly *et al.*, 2016a). The safety of GH replacement in CCS has been the subject of multiple studies because of concerns related to the in vitro effects of GH and IGF-I on cell cycle and multiplication, and whether treatment with human recombinant GH (hGH) could increase the risk for cancer recurrence, secondary malignancies, or mortality (Chemaitilly and Robison, 2012; Raman *et al.*, 2015). Data from CCS followed in the long term did not support associations between treatment with hGH and increased odds of cancer recurrence or mortality (Ergun-Longmire *et al.*, 2006; Sklar *et al.*, 2002). A higher risk of second neoplasms in individuals treated with hGH was reported in a large cohort of CCS, and this risk seems mostly to be due to a higher incidence of radiation-induced meningioma (Sklar *et al.*, 2002; Ergun-Longmire *et al.*, 2006). These associations were, however, not supported by a more recent report from the same cohort focusing on CNS neoplasms (Patterson *et al.*, 2014), nor by data from other cohorts (Mackenzie *et al.*, 2011). Initiation of hGH in the absence of active neoplasia after a 1-year observation time is a generally accepted practice in CCS (Raman *et al.*, 2015). Guidelines are lacking regarding the optimal observation time for survivors of non-malignant brain tumors such as craniopharyngioma (Raman *et al.*, 2015). Possible benefits of hGH on quality of life, bone health, and cardiovascular risk

factors in GH-deficient adult survivors of childhood cancers and brain tumors may be inferred from studies conducted in the non-CCS population (Elbornsson *et al.*, 2012, 2013); however, there are no data specific to CCS and this remains an active area for research (Chemaitilly *et al.*, 2015).

Central Precocious Puberty

Prevalence and risk factors

CPP is diagnosed in girls and boys experiencing puberty before the ages of 8 or 9 years, respectively, as a result of the early activation of the HP gonadal axis (Chemaitilly *et al.*, 2001; Carel and Leger, 2008). The prevalence of CPP in CNS tumor survivors has been reported at 12.2%–15.2% (Chemaitilly *et al.*, 2016a; Clement *et al.*, 2016) and is even higher in patients with tumors located in the HP region (26%–29%) (Chemaitilly *et al.*, 2016a; Gan *et al.*, 2015). Tumors located near the hypothalamus and optic pathways such as low-grade gliomas, HP radiotherapy at a wide range of doses (18–50 Gy), hydrocephalus, age <5 years at radiotherapy, female sex, and increased BMI have been reported as risk factors for CPP (Chemaitilly *et al.*, 2016a; Gan *et al.*, 2015; Trivin *et al.*, 2006; Oberfield *et al.*, 1996; Armstrong *et al.*, 2009).

Diagnosis and management

Diagnosing CPP follows a similar approach as in the general pediatric population (Carel and Leger, 2008; Carel *et al.*, 2009). It is important to note, however, that testicular volume is not a reliable indicator of pubertal status in boys treated with gonadotoxic therapies such as testicular radiotherapy or alkylating agents. Such individuals may retain Leydig cell function (and hence testosterone secretion) despite having small testes due to treatment-induced Sertoli cell and germ cell depletion (Sklar *et al.*, 1990; Siimes and Rautonen, 1990; Ishiguro *et al.*, 2007). The diagnosis can then be supported by other clinical signs of puberty such as pubic hair development, penile length, and scrotal thinning, and by measuring morning plasma testosterone levels (recognizing the limitation that commercial assays may under- or overestimate levels in pediatric ranges). As discussed in the section on GHD, growth patterns should be interpreted according to pubertal stage and not only chronological age; skeletal maturation based on bone age can help one to assess a patient's growth potential with the understanding that the full effect of exposure to sex steroids may appear in a delayed fashion on the X-ray (**Fig. 2**) (Chemaitilly *et al.*, 2016b). Gonadotropin-releasing hormone agonist depot preparations are the mainstay of CPP treatment in CCS; their use follows the same guidelines as in the general pediatric population (Carel *et al.*, 2009).

LH/FSH Deficiency

Prevalence and risk factors

The reported prevalence of LH/FSHD is 6.5% in CCS (Brignardello *et al.*, 2016) and 11% in individuals treated with HP radiotherapy (Chemaitilly *et al.*, 2015). HP injury due to tumor effect, surgical resection, or radiation doses ≥ 30 Gy represent the main risk factors (Constine *et al.*, 1993; Chemaitilly *et al.*, 2015). Patients treated with lower doses of radiotherapy may experience LH/FSHD if observed over a long period of time (Chemaitilly *et al.*, 2015; Brignardello *et al.*, 2016).

Diagnosis and management

Patients may present with delayed or stalled pubertal development, amenorrhea, or signs/symptoms of estrogen deficiency such as hot flashes (females), or signs/symptoms of low testosterone secretion such as decrease in erections (males), depending on the age at onset of LH/FSHD. The diagnosis and management follow guidelines available in the general non-CCS population of adolescents and adults (Fleseriu *et al.*, 2016; Palmert and Dunkel, 2012; Boehm *et al.*, 2015). The treatment of LH/FSHD consists of sex-hormone replacement therapy. Medical providers should be aware of potential interactions between estrogens in particular and other hormonal (GH, thyroid replacement) and non-hormonal (anti-epileptics) treatments, and be ready to titrate medications accordingly (Fleseriu *et al.*, 2016). Adult patients should be encouraged to consult with reproductive endocrinologists regarding fertility options (Metzger *et al.*, 2013; Kenney *et al.*, 2012).

TSH Deficiency

Prevalence and risk factors

The prevalence of TSHD has been reported at 7.5%–9.2% in CCS treated with HP radiotherapy (Chemaitilly *et al.*, 2015). HP injury due to tumor effect, surgical resection, or radiation doses ≥ 30 Gy represent the main risk factors (Chemaitilly *et al.*, 2015; Clement *et al.*, 2016). Patients treated with lower doses of radiotherapy may experience TSHD if observed over a long period of time (Chemaitilly *et al.*, 2015).

Diagnosis and management

Patients with TSHD may experience signs/symptoms of hypothyroidism such as slow growth (in children and adolescents), weight gain, fatigue, and cold intolerance, although these findings may be subtle or not present. The laboratory diagnosis is based on the observation of plasma free T4 (FT4) levels below the normal range coinciding with TSH levels that are either low, inappropriately

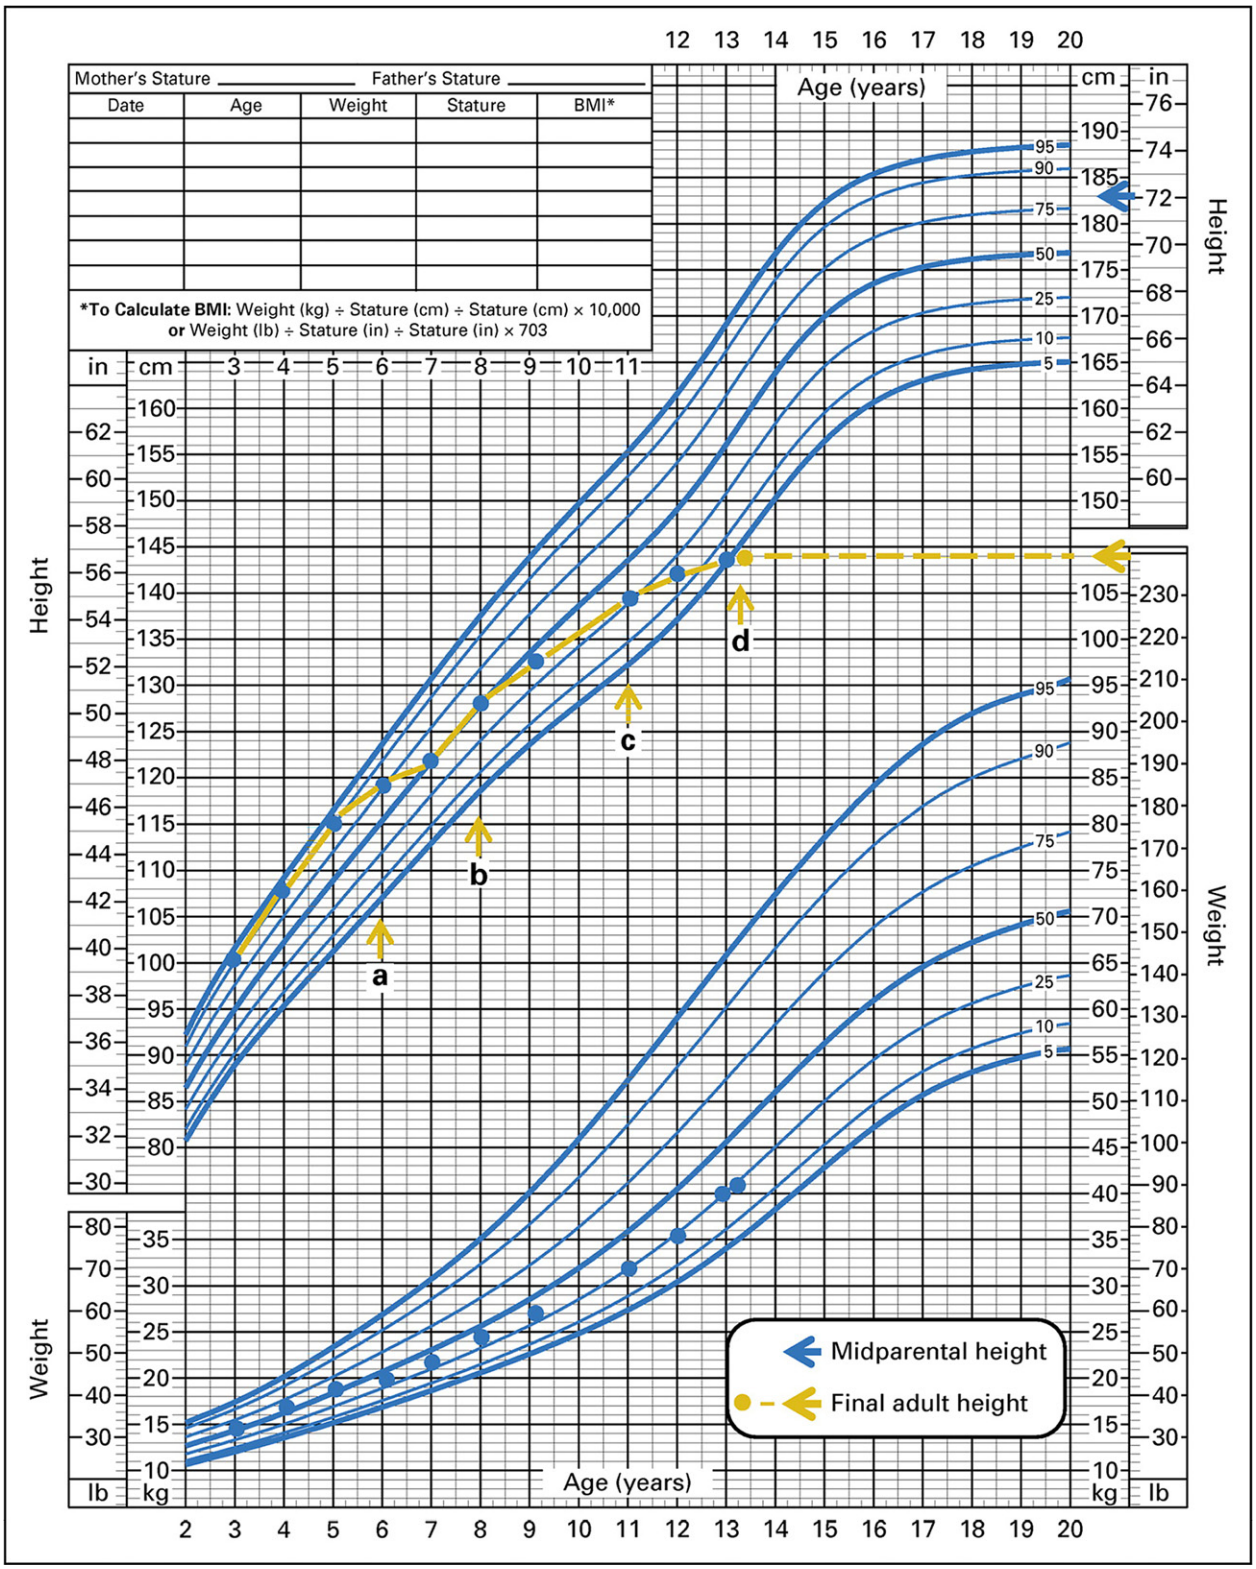

Fig. 2 Growth pattern observed with overlapping growth hormone deficiency and central precocious puberty. Growth chart of a male survivor of diagnosed at the age of 3 years with a brain tumor with metastatic disease involving the hypothalamic/pituitary region and treatment with chemotherapy alone. Time point a: initial growth deceleration, possible onset of GH deficiency (GHD). Time point b: apparent recovery of growth, possible onset of central precocious puberty. Time point c: growth deceleration due to bone age advancement, initiation of referral to endocrinologist. Small testes contrasting with full Tanner stage IV virilization noted on clinical examination, belated diagnosis of GHD, initiation of GH replacement. Time point d: Final adult height attained. Reproduced with permission from (Chemaitilly, W., Armstrong, G. T., Gajjar, A. and Hudson, M. M. (2016). Hypothalamic–pituitary axis dysfunction in survivors of childhood CNS tumors: Importance of systematic follow-up and early endocrine consultation. *Journal of Clinical Oncology*, **34**, 4315–4319, American Society of Clinical Oncology. Growth chart source: Centers for Disease Control: http://www.cdc.gov/growthcharts/data/set1clinical/cj41l021.pdf.

normal (Fleseriu *et al.*, 2016), or occasionally mildly elevated in the case of hypothalamic damage. Caution should be made in the interpretation of thyroid function tests as being due to TSHD itself, since similar patterns can be seen in non-thyroidal illness or with treatment with other medications such as high-dose glucocorticoids or anticonvulsants (Fleseriu *et al.*, 2016).

The treatment relies on replacement with levothyroxine and follows the same steps as in the general non-CCS population (Fleseriu *et al.*, 2016). It is important to remember that the adjustment of levothyroxine doses in patients treated for TSH deficiency should rely exclusively on FT4 levels, and there is no utility in the measurement of TSH levels after diagnosis. In patients at risk of multiple HP deficits, assessment of the ACTH–cortisol axis should be performed prior to initiating thyroid replacement, as patients with unrecognized or untreated adrenal insufficiency may develop adrenal crisis if they are treated for hypothyroidism (Fleseriu *et al.*, 2016).

ACTH Deficiency

Prevalence and risk factors

The prevalence of ACTHD was reported at 4%–5% in CCS treated with HP radiotherapy (Chemaitilly *et al.*, 2015; Clement *et al.*, 2016). The main risk factors include HP injury from tumor growth or surgery as well as radiotherapy at doses $\geq$30 Gy (Chemaitilly *et al.*, 2015; Constine *et al.*, 1993). ACTHD may also occur following the exposure to lower doses of HP radiotherapy after extended periods of follow-up (Follin and Erfurth, 2016; Chemaitilly *et al.*, 2015).

Diagnosis and management

Patients with ACTHD experience glucocorticoid (cortisol) insufficiency because their adrenal glands lack adequate stimulation from the hypothalamus/pituitary; they do not experience salt wasting because adrenal mineralocorticoid (aldosterone) secretion is primarily controlled by the renin–angiotensin–aldosterone system, not ACTH. Symptoms of ACTHD include fatigability and increased infection risk. Patients with ACTHD who are exposed to additional and significant medical stressors (e.g., severe illness, surgery) may experience a rapid deterioration in their clinical state due to adrenal crisis with severe complications such as hypoglycemia, seizures, and shock (Fleseriu *et al.*, 2016). As in the non-CCS population, patients at risk can be screened using serum morning cortisol levels and the diagnosis can be confirmed via dynamic testing; replacement therapy relies on oral hydrocortisone at maintenance doses during regular days and at higher oral or parenteral "stress" doses during times of illness (Patterson *et al.*, 2009; Fleseriu *et al.*, 2016). As with all patients with adrenal insufficiency, CCS with ACTHD should be encouraged to carry at all times some documentation of their risk of adrenal crisis (card, bracelet, etc.) and should receive, along with their families, dedicated teaching on how to recognize and quickly address emergent medical situations (Fleseriu *et al.*, 2016). Assessment of the ACTH–cortisol axis should precede treatment of hypothyroidism in CCS given the risk of adrenal crisis following initiation of thyroid replacement in patients with either undiagnosed or untreated adrenal insufficiency (Fleseriu *et al.*, 2016).

Hyperprolactinemia

The prevalence of hyperprolactinemia was reported as high as 30% in CCS exposed to high-dose (39.6–70.2Gy) HP radiotherapy (Constine *et al.*, 1993). The main symptoms of hyperprolactinemia are hypogonadism (due to LH/FSHD) and galactorrhea. Radiation-induced hyperprolactinemia is generally moderate and rarely symptomatic (Fleseriu *et al.*, 2016). Given that hyperprolactinemia primarily manifests through gonadal suppression, CCS experiencing it as a consequence of radiotherapy rarely require treatment for it because they frequently also have primary gonadal insufficiency due to co-treatment with gonadotoxic agents (Balachandar *et al.*, 2015).

Primary Thyroid Disease

CCS may experience a variety of thyroid disorders such as primary hypothyroidism, hyperthyroidism, autoimmune conditions, and secondary thyroid cancer (Mostoufi-Moab *et al.*, 2016).

Primary Hypothyroidism

Prevalence and risk factors

The prevalence of primary hypothyroidism in CCS has been reported at 13.8%–20.8% (Brignardello *et al.*, 2013; Hudson *et al.*, 2013), making it one of the most frequently observed late effects in this population. Thyroid irradiation confers the highest risk; the latter tends to increase with the dose of radiotherapy and the duration of follow-up (Sklar *et al.*, 2000; Mostoufi-Moab *et al.*, 2016). High-risk populations therefore include: survivors of Hodgkin lymphoma treated with radiotherapy (Sklar *et al.*, 2000), CNS tumor survivors treated with craniospinal radiotherapy (Laughton *et al.*, 2008), pediatric HSCT recipients conditioned with TBI, especially when delivered in a single fraction (Boulad *et al.*, 1995), and survivors of solid tumors of the head and neck such as retinoblastoma (Friedman *et al.*, 2013), nasopharyngeal carcinoma (Cheuk *et al.*, 2011), and rhabdomyosarcoma (Clement *et al.*,

2015; Shalitin *et al.*, 2014), with treatment-related radiation exposures. Survivors of neuroblastoma treated with (131) I-metaiodobenzylguanidine (^{131}I-MIBG) are also at risk of primary hypothyroidism despite prophylaxis with potassium iodide (van Santen *et al.*, 2005). Novel TKI agents such as imatinib, sunitinib, and sorafenib may also cause primary hypothyroidism (Lodish, 2013; Torino *et al.*, 2013).

Diagnosis and management

Patients with primary hypothyroidism may present with slow growth (in children and adolescents), weight gain, fatigue, and cold intolerance. Given the high prevalence of primary hypothyroidism in certain groups of CCS, patients at risk should be screened with measurements of plasma FT4 and TSH at least yearly (more frequently during childhood) without waiting for clinical manifestations. Patients treated with TKI should also be screened regularly (Lodish, 2013). The treatment of primary hypothyroidism relies on substitution with levothyroxine with the aim to normalize plasma TSH and FT4 levels. Given the trophic effect of TSH on the thyroid and possible associations between chronically elevated TSH levels and thyroid neoplasia (de Vathaire *et al.*, 2015), it is common practice to treat patients with a history of neck irradiation and whose labs suggest compensated primary hypothyroidism (elevated TSH and normal FT4 plasma levels) with levothyroxine. Treatment of compensated forms is discouraged in patients on TKIs (Lodish, 2013). It is important to remember that CCS with primary hypothyroidism due to craniospinal radiotherapy may subsequently develop TSHD and ACTHD as late effects of HP irradiation. In these patients, declining TSH values over time should not be interpreted as necessarily reflective of over-dosage with levothyroxine, and FT4 levels should primarily be used to guide substitution doses. The ACTH–cortisol axis of these individuals should also be assessed prior to treatment with levothyroxine, as patients with ACTHD may experience clinical deterioration if their adrenal insufficiency is not treated prior to the initiation of thyroid replacement (Fleseriu *et al.*, 2016).

Hyperthyroidism

Hyperthyroidism is very uncommon in CCS and has been primarily reported as a consequence of transferred autoimmunity in pediatric HSCT recipients, exposure to craniospinal radiotherapy in CNS tumor survivors, or treatment with high doses of radiotherapy (35–40 Gy) for pediatric Hodgkin lymphoma (Sklar *et al.*, 2000, 2001; Mostoufi-Moab *et al.*, 2016). Hyperthyroidism may be transient and a subset of patients may subsequently become hypothyroid (Sklar *et al.*, 2001).

Autoimmune Conditions

Pediatric HSCT recipients may develop autoimmune thyroid disease due to the transfer of abnormal lymphocyte clones from the donor; a subset could require treatment for primary hypothyroidism, or more rarely hyperthyroidism (Sklar *et al.*, 2001). Immunomodulators used in maintenance chemotherapy including anti-CTLA4 monoclonal antibodies (ipilimumab or bevacizumab) and pegylated interferon may cause autoimmune thyroiditis and hypothyroidism (Torino *et al.*, 2013; Corsello *et al.*, 2013). Patients treated with these agents should be screened by measuring plasma FT4, TSH, and thyroid autoantibodies at the start of therapy and should be offered regular monitoring of FT4 and TSH levels during treatment (Corsello *et al.*, 2013).

Secondary Thyroid Cancer

Prevalence and risk factors

Thyroid cancer is one of the most frequently reported secondary malignancies in CCS with a history of neck irradiation (Mostoufi-Moab *et al.*, 2016). The prevalence of thyroid cancer was 18 times higher in pediatric Hodgkin lymphoma survivors treated with radiotherapy fields involving the thyroid than what would be expected based on general population statistics (Sklar *et al.*, 2000). The latency period between the primary cancer diagnosis and the diagnosis of secondary thyroid cancer varied between 5 and 26 years in this population (Sklar *et al.*, 2000). Secondary thyroid cancer has also been reported following craniospinal radiotherapy for CNS tumors (Ning *et al.*, 2015) and conditioning with TBI for HSCT (Cohen *et al.*, 2007; Acharya *et al.*, 2003; Inamoto *et al.*, 2015), as well as in other instances involving treatment-related direct or scatter irradiation of the thyroid (Acharya *et al.*, 2003; van Santen *et al.*, 2012; Clement *et al.*, 2015). The risk of secondary thyroid cancer in relation to radiotherapy doses follows an inverted U-shaped curve, increasing with the dose until 20–30 Gy and then decreasing at higher doses likely because of the extent of the damage to the thyroid (Bhatti *et al.*, 2010). Cancer diagnosis before 10 years of age (Sklar *et al.*, 2000) and alkylating chemotherapy agents may further increase the risk of secondary thyroid malignancy (Veiga *et al.*, 2012).

Diagnosis and management

Consensus regarding the screening strategy for thyroid cancer in CCS is lacking (Francis *et al.*, 2015). While some have suggested that yearly screening should primarily rely on the careful clinical examination of the neck in order to assess for palpable nodules or abnormal cervical lymph nodes (Acharya *et al.*, 2003), others have called for systematic screening with thyroid ultrasound to detect the disease at an earlier stage in patients with the highest risk factors (Rivkees *et al.*, 2011). The diagnosis and management of secondary thyroid malignancy follow the same processes as for primary thyroid cancer (Francis *et al.*, 2015; Cooper *et al.*, 2009).

Primary Testicular Disorders

The endocrine (testosterone secretion/virilization) and reproductive (sperm production/fertility) functions of the testes are carried out within two compartments that differ in their relative degrees of vulnerability to gonadotoxic cancer therapies. This difference is due to the lower vulnerability of the rather quiescent testosterone producing Leydig cells when compared to that of rapidly multiplying germ cells. Therefore, and while both functions may be affected by testicular exposure to radiotherapy and/or treatment with gonadotoxic chemotherapy drugs such as alkylating agents or heavy metals (cisplatin, carboplatin), the prevalence of Leydig cell failure manifesting via low testosterone secretion is substantially lower than that of oligo- or azoospermia due to germ cell injury in males exposed to such treatments (Kenney *et al.*, 2012). Medical providers should be aware that male CCS exposed to gonadotoxic treatments are frequently able to maintain normal testosterone secretion even if their clinical examination (small testes) or laboratory investigations are suggestive of impaired fertility (Chemaitilly *et al.*, 2016b).

Leydig Cell Failure

Prevalence and risk factors

The prevalence of Leydig cell failure was reported at 11.5%–13.3% in adult CCS exposed to alkylating agents or testicular irradiation (Hudson *et al.*, 2013; Brignardello *et al.*, 2013). Leydig cell failure following chemotherapy alone tends to be compensated with most patients able to maintain normal testosterone levels albeit with rising LH values, and rarely requires sex hormone replacement therapy (Romerius *et al.*, 2009; Greenfield *et al.*, 2007; Howell *et al.*, 1999). On the other hand, the majority of patients treated with testicular radiotherapy with doses >20 Gy have been reported to require testosterone replacement (Grundy *et al.*, 1997).

Diagnosis and management

Depending on the achieved pubertal stage at the time of onset of Leydig cell failure, patients may present with delayed or arrested pubertal development or symptoms of low testosterone secretion such as fatigue, depression, decreased libido, or bone or metabolic abnormalities. The primary testicular origin of the disorder is evidenced by elevated morning plasma LH values contrasting with testosterone levels that are below the normal range for an individual's age (Bhasin *et al.*, 2010; Giannetta *et al.*, 2012). Management follows the same steps as in the general non-CCS population (Bhasin *et al.*, 2010; Palmert and Dunkel, 2012).

Germ Cell Failure

Prevalence and risk factors

The prevalence of infertility due to germ cell failure following treatment with alkylating agents or radiotherapy varies between 40% and 70% depending on the method used for assessment (semen analysis (Hudson *et al.*, 2013) versus measurements of plasma FSH and inhibin B (Brignardello *et al.*, 2013)). Treatment with alkylating agents at cumulative cyclophosphamide equivalent doses ≥ 4000 mg/m^2 (Green *et al.*, 2014), or testicular radiotherapy at any dose, even as low as 0.15 Gy (Meistrich, 2013), represent the main risk factors. Treatment regimens associated with a high risk of germ cell failure may be required for the treatment of some cases of ALL (Romerius *et al.*, 2011; Green *et al.*, 2014; Meistrich, 2013); pediatric Hodgkin lymphoma (Papadakis *et al.*, 1999; Heikens *et al.*, 1996), CNS malignancies (Schmiegelow *et al.*, 2001; Ahmed *et al.*, 1983), and non-brain solid tumors (Kenney *et al.*, 2001, 2014; Moreno *et al.*, 2013; Friedman *et al.*, 2013; Trahair *et al.*, 2007; Shalitin *et al.*, 2014), as well as for conditioning for HSCT (Grigg *et al.*, 2000; Anserini *et al.*, 2002; Rovo *et al.*, 2006; Sanders *et al.*, 1996). Targeted chemotherapy agents may also affect male fertility (Mariani *et al.*, 2011; Seshadri *et al.*, 2004; Breccia *et al.*, 2014).

Diagnosis and management

The diagnosis of germ cell failure requires a semen analysis to check for oligo-/azoospermia as indirect hormonal markers such as plasma levels of FSH and inhibin B are not always reliable (Lopez Andreu *et al.*, 2000). Sperm banking prior to the exposure to gonadotoxic treatments should be offered to male patients whenever feasible (Kenney *et al.*, 2012).

Premature Ovarian Insufficiency

In contrast to what is observed in males, the endocrine (hormone-producing granulosa cells) and reproductive (oocyte) compartments in females are strongly interdependent. Hence, premature ovarian insufficiency (POI), which is the most commonly accepted term to designate gonadal failure due to a primary ovarian cause, refers to both estrogen deficiency and fertility (Anderson *et al.*, 2015; van Dorp *et al.*, 2016).

Prevalence and Risk Factors

The prevalence of POI was reported at 11% in a large cohort of CCS with extended follow-up time (Hudson *et al.*, 2013; Chemaitilly *et al.*, 2017). The main risk factors of POI include alkylating agents and ovarian irradiation (Chemaitilly *et al.*, 2006, 2017; Sklar *et al.*, 2006; Mostoufi-Moab *et al.*, 2016), including because of scatter from spinal radiotherapy for CNS cancers (Balachandar *et al.*, 2015). High-risk groups also include HSCT recipients because of alkylating agent with or without TBI for conditioning (Afify *et al.*, 2000; Sklar *et al.*, 2001; Frisk *et al.*, 2004), pediatric Hodgkin lymphoma treated with pelvic irradiation (van Dorp *et al.*, 2012; Papadakis *et al.*, 1999), and survivors of solid tumors treated with high-dose alkylating agents and/or radiotherapy involving the abdomen or pelvis (Wright *et al.*, 2009; Oue *et al.*, 2015). Host factors include older age at treatment (Chemaitilly *et al.*, 2006; Anderson *et al.*, 2015). Female CCS treated with radiotherapy also have a higher than expected prevalence of miscarriage and premature delivery; this is likely due to radiation-induced damage to the uterus and/or its vascularization (Sanders *et al.*, 1996; Holm *et al.*, 1999; Bath *et al.*, 1999). Data on the impact of targeted chemotherapy agents are limited (Lodish, 2013; Breccia *et al.*, 2014).

Diagnosis and Management

Patients may present with delayed or interrupted pubertal development, amenorrhea (primary or secondary) before the age of 40 years, or other signs/symptoms of estrogen deficiency such as hot flashes depending on the timing of onset of POI in relation to achieved pubertal stage. (Metzger *et al.*, 2013; Sklar *et al.*, 2006). It is important to note that patients frequently experience arrested puberty or amenorrhea during active therapy for cancer. Therefore, evaluations for possible POI are generally deferred until 2 years after the completion of therapy (Jacobson *et al.*, 2016), although treatment of potentially transient POI may need to be considered. Laboratory findings consistent with POI include elevated FSH with low plasma estradiol (van Dorp *et al.*, 2016). Other markers of ovarian function (or "follicular reserve") include plasma anti-Mullerian hormone levels and antral follicle count via ultrasound; the role of these modalities in counseling CCS has yet to be determined (van Dorp *et al.*, 2016), especially in adolescents. Sex-hormone replacement therapy may be offered to CCS in order to induce puberty; this therapy may also have a role in improving general health outcomes (cardiovascular, bone health, psychological, and psychosexual) in adults with POI without necessarily increasing the risk of secondary breast cancer when compared to female CCS without POI (Chemaitilly *et al.*, 2017; Moskowitz *et al.*, 2017; van Dorp *et al.*, 2016). Treatment follows the same steps as in the general non-CCS population (van Dorp *et al.*, 2016; Palmert and Dunkel, 2012). Fertility preservation via mature oocyte cryopreservation should be offered to pubertal patients at high risk of POI whenever feasible (Practice Committees of American Society for Reproductive Medicine and Society for Assisted Reproductive Technology, 2013; Anderson *et al.*, 2015).

Bone Mineral Density Deficit

Children with newly diagnosed leukemia may present from the outset with impaired bone health (Mostoufi-Moab *et al.*, 2012a; Wasilewski-Masker *et al.*, 2008). Severe BMD deficit (defined by a sex- and age-adjusted z-score < -2) has been reported in up to 70% of patients at the time of ALL diagnosis, with a subset experiencing fractures even before being exposed to high-dose glucocorticoids (Mostoufi-Moab and Halton, 2014). While signs of skeletal recovery have been reported within 2 years of completion of therapy, a subset of patients may have persistently low BMD, and this may be contributing to overall worse health outcomes in this population (Mostoufi-Moab *et al.*, 2012a; Wasilewski-Masker *et al.*, 2008; Gurney *et al.*, 2014).

Prevalence and Risk Factors

The prevalence of BMD deficit in CCS has been reported at 13%–18% (Brignardello *et al.*, 2013). High-risk populations include survivors of childhood leukemia, especially those with relapsed disease and those treated with HSCT, because of the effects of the primary disease on the bone structure and additional insults from prolonged treatment with systemic glucocorticoids, conditioning with TBI, and medical and nutritional complications related to transplant (Mostoufi-Moab *et al.*, 2012b; Petryk *et al.*, 2006; Kaste *et al.*, 2004). Other risk factors include cranial irradiation (Gilsanz *et al.*, 1990), which is likely to be due to its resultant pituitary hormone deficiencies, GHD (Mostoufi-Moab *et al.*, 2012b), and/or sex hormone deficiency (Cohen *et al.*, 2012; Gurney *et al.*, 2003; Chemaitilly *et al.*, 2017). Targeted chemotherapy agents such as TKI may cause secondary hyperparathyroidism and changes in bone structure; the full effect of prolonged treatment with these agents has yet to be elucidated (Lodish, 2013).

Diagnosis and Management

The diagnosis of severe BMD deficit relies on measurements using dual X-ray absorptiometry (DXA) in patients at risk and adjusting the measure to sex and age (z-score and not T-score, as commonly done for adults) (Hudson *et al.*, 2013). Confounders of DXA measures include small stature and abnormally timed puberty (Wasilewski-Masker *et al.*, 2008). The management of severe BMD deficit includes the proper substitution of associated hormonal deficiencies (including vitamin D) and optimizing diet to

include at least the recommended daily intake for calcium, in addition to the promotion of a healthy lifestyle (regular exercise and smoking cessation) (Sala and Barr, 2007).

Obesity and Diabetes Mellitus

Prevalence and Risk Factors

CCS reported being diagnosed with obesity (relative risk, 1.8; 95% CI, 1.7–2.0) and diabetes mellitus (relative risk, 1.9; 95% CI, 1.6–2.4) at significantly higher rates than siblings controls in a recent report; this indicates a significant risk owed to survivorship even when potential genetic and social confounders are taken into account (Mostoufi-Moab *et al.*, 2016). Hypothalamic injury due to tumor growth or surgery may cause a particularly challenging form of obesity with rapid weight gain (Lustig *et al.*, 2003b; Muller, 2014). Survivors of childhood ALL, including those treated with contemporary regimens without cranial irradiation, seem to continue to struggle with persistent obesity many years after completing treatment (Garmey *et al.*, 2008); this is possibly because of the prolonged exposure to systemic glucocorticoids (Zhang *et al.*, 2014). Abnormal body composition with increased waist-to-height ratio and abnormal glucose metabolism regardless of BMI have been reported in survivors of pediatric HSCT, especially those treated with TBI (Armenian *et al.*, 2017; Hoffmeister *et al.*, 2004; Taskinen *et al.*, 2000; Chow *et al.*, 2013; Neville *et al.*, 2006). The metabolic derangements observed in this population may be due to abnormal body fat distribution and/or islet cell injury due to irradiation (Wei *et al.*, 2015a,b). Similarly, a higher risk of glucose intolerance/diabetes mellitus has been reported following abdominal radiotherapy to treat various solid tumors (Cohen *et al.*, 2014; Meacham *et al.*, 2009; Shalitin *et al.*, 2014; de Vathaire *et al.*, 2012).

Diagnosis and Management

Patients should be monitored for cardiovascular risk factors by measuring their height, weight, BMI, and blood pressure at least yearly. Screening for diabetes mellitus using fasting blood glucose is suggested in patients exposed to TBI or abdominal radiotherapy regardless of their BMI (Baker *et al.*, 2012). Emphasis on lifestyle improvement needs to be maintained in CCS as in the general non-CCS population. The long-term efficacy and safety of medications to treat hypothalamic obesity such as diazoxide (Brauner *et al.*, 2016; Hamilton *et al.*, 2011), octrerotide (Lustig *et al.*, 2003a), glucagon-like peptide 1 receptor agonists (Lomenick *et al.*, 2016), or amphetamine derivatives (Mason *et al.*, 2002) have not been well established (Cohen, 2016).

Conclusion

Endocrine late effects are among the most frequently reported chronic health conditions in CCS. They may occur many years after the exposure to cancer therapies. The importance of systematic screening, early diagnosis, and long-term follow-up of CCS who are at risk of developing endocrine complications as late effects of cancer and its treatments cannot be overemphasized.

Disturbances of Sodium and Water. Diabetes Insipidus in Children

Rasa Verkauskiene and Ruta Navardauskaite, Lithuanian University of Health Sciences, Kaunas, Lithuania

Abbreviations

ADH	Antidiuretic hormone
ANH	Atrial natriuretic hormone
ANP	Atrial natriuretic peptide
AVP	Arginine vasopressin
***AVP-NPII* gene**	Arginine vasopressin-neurophysin II gene
AQP2	Aquaporin 2
BNP	Brain natriuretic peptide
CDI	Central diabetes insipidus
CNS	Central nervous system
CSW	Cerebral salt wasting
DDAVP	Desmopressin (1-desamino-8-D-arginine-vasopressin)
DI	Diabetes insipidus
ECF	Extracellular fluid
ICF	Intracellular fluid
i/v	Intravenously
LCH	Langerhans cell histiocytosis
MAO inhibitors	Monoamine oxidase inhibitors
MRI	Magnetic resonance imaging
NDI	Nephrogenic diabetes insipidus
SIADH	Syndrome of inappropriate antidiuretic hormone secretion
TBW	Total body water
V2R	Vasopressin V2 receptor
WDT	Water deprivation test

Glossary

Hyposthenuria The secretion of urine of low specific gravity due to inability of the kidney to concentrate the urine normally.

Infundibulum Pituitary stalk.

Polydipsia Is excessive thirst or excess drinking.

Poliuria Is excessive or an abnormally large production of urine.

Disturbances of Sodium and Water

Disturbance of sodium and water is among the most common disorders in clinical practice because of high prevalence of diseases associated with dehydration. Basic water and sodium balance understanding is necessary for correct diagnosis and safe management, especially in pediatric patients. In a minority of patients, specialized testing will be required.

Total body water (TBW) content is divided in two major fluid compartments: two thirds of TBW is intracellular fluid (ICF) and one-third is extracellular fluid (ECF), subdivided into the interstitial fluid (75%), and plasma (25%). The TBW comprises approximately 70% of body weight in infants, 65% in children, and 60% in adults.

Infants and children require relatively larger volumes of water than adults to maintain their fluid balance and are more sensitive to volume consumption. Significant fluid losses may occur rapidly, leading to depletion of the intravascular volume (Kuhnle-Kral and Kausman, 2011).

Pathophysiology

Plasma osmolality and volume is regulated by the synthesis and secretion of arginine vasopressin (AVP), the kidney's response to AVP and by the thirst mechanism. AVP is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus, transported via the supraopticohypophyseal tract through the infundibulum and accumulated in the posterior pituitary. It binds to vasopressin V2 receptors (V2R) in the distal nephron and induces translocation of aquaporin water channels in the plasma membrane to retain water. The osmoreceptors and baroreceptors are two main types of receptors which are involved in the control of the body water balance. Osmoreceptors located in hypothalamus are very sensitive to changes of ECF osmolality. Normal plasma osmolality ranges from 280 to 300 mOsm/kg. An increase of 1% of plasma osmolality may cause an increase in AVP levels. Baroreceptors are mechanoreceptors that sense blood pressure in the vessels wall. Response from baroreceptors influence sympathetic outflow, vessel tonus, and cardiac output. Sodium is always related to water and 90%–95% of plasma osmolality depends on sodium. The most important regulatory system of sodium balance is renin–angiotensin–aldosterone system. Aldosterone regulates sodium homeostasis by stimulating sodium reabsorbtion in the distal nephron and the distal colon. While the most important organ system for sodium regulation is the kidney, it is lost largely via gastrointestinal tract. Acute diarrhea is associated with salt and water loss and results in hyponatremic or hypernatremic dehydration. The main features of dehydration according to severity is presented in **Table 1** (Di Iorgi *et al.*, 2012; Bourque, 2008; de Bree and Burbach, 1998; Batista *et al.*, 2010).

Table 1 Physical examination findings in pediatric dehydration

Symptom	*Degree of dehydration*		
	Mild (<3% body weight lost)	*Moderate (3%–9% body weight lost)*	*Severe (>9% body weight lost)*
Mental status	Normal, alert	Restless or fatigued, irritable	Apathetic, lethargic, unconscious
Heart rate	Normal	Normal to increased	Tachycardia or bradycardia
Quality of pulse	Normal	Normal to decreased	Weak, thread, impalpable
Breathing	Normal	Normal to increased	Tachypnea and hyperpnea
Eyes	Normal	Slightly sunken	Deeply sunken
Fontanelles	Normal	Slightly sunken	Deeply sunken
Tears	Normal	Normal to decreased	Absent
Mucous membranes	Moist	Dry	Parched
Skin turgor	Instant recoil	Recoil <2 s	Recoil >2 s
Capillary refill	<2 s	Prolonged	Minimal
Extremities	Warm	Cool	Mottled, cyanotic

Table 2 Causes on hyponatremia in children

Hypovolemic hyponatremia	*Euvolemic hyponatremia*	*Hypervolemic hyponatremia*
Extrarenal water losses • Gastrointestinal (vomiting, diarrhea) • Skin (sweating or burns) • Third-space extravasation of intravascular fluid (e.g., pancreatitis, peritonitis, sepsis, heart failure, nephrotic syndrome, protein-losing enteropathy, bowel obstruction) *Renal water losses* • Thiazide or loop diuretics • Osmotic diuresis • Postobstructive diuresis • Polyuric phase of acute tubular necrosis • Autosomal recessive polycistic kidney disease • Tubulointestitial nephritis • Obstructive uropathy • Cerebral salt wasting (CSW) • Proximal renal tubular acidosis • Lack of aldosterone effect (high serum potassium): ○ Absence of aldosterone (e.g., 21-hydroxylase deficiency) ○ Pseudohypoaldosteronism type I ○ Urinary tract infection	• Syndrome of inappropriate antidiuretic hormone secretion (SIADH) • Gliucocorticoid deficiency • Hypothyroidism • Nephrogenic syndrome of inappropriate antidiuresis (NSIAD) • Iatrogenic desmopressin (DDAVP) overtreatment (as complication of therapy) • Water intoxication: ○ Iatrogenic (excess hypotonic intravenous fluids) ○ Tap water enema ○ Child abuse ○ Psychogenic polydipsia ○ Diluted formula	• Congestive heart failure • Cirrhosis • Nephrogenic syndrome • Renal failure • Capillary leak due to sepsis • Hypoalbuminemia due to gastrointestinal disease (protein-losing enteropathy)

Hyponatremia

Hyponatremia is the most common (15%–30%) electrolyte abnormality in hospitalized children and it is an independent mortality risk factor in intensive care. Hyponatremia is defined as serum sodium less than 135 mmol/L. Serum sodium 120-–129 mmol/L is attributed to mild hyponatremia and less than 120 mmol/L is considered as severe hyponatremia. The causes of hyponatremia are classified according to body fluid volume status: hypovolemic, hypervolemic, and euvolemic hyponatremia. The main causes are presented in **Table 2** (Yeates *et al.*, 2004).

Pseudohyponatremia can occur due to hyperglycemia (e.g., in diabetic ketoacidosis), and elevated anion gap. Pseudohyponatremia can also be diagnosed due to elevated total and low-density lipoprotein cholesterol levels (hyperlipidemia).

Hyponatremia is also classified depending on timing of development to acute (<24 h) and chronic (>24 h). Acute hyponatremia is very dangerous because of lack of time for activation of compensatory mechanisms, leading to cerebral edema. The clinical features of hyponatremia occur when plasma sodium decreases to less than 125 mmol/L. The symptoms are nonspecific: headache, nausea, vomiting, progressing to letargy, desorientation, confusion, psychosis, respiratory arrest. Plasma sodium decrease of 10% induces increase in brain volume by 10% leading to cerebral edema and more than 10% increase in brain volume leads to brain herniation (Kuhnle-Kral and Kausman, 2011; Abka *et al.*, 2011; Grant *et al.*, 2015; Liamis *et al.*, 2010; Zieg, 2017).

Symptoms of chronic hyponatremia are not expressed or are much milder in the presence of even significant hyponatremia due to development of adaptation mechanisms. Chronic hyponatremia has significant impact on bone quality (increased risk for osteoporosis and fractures) (Ranadive and Rosenthal, 2009).

Treatment of hyponatremia

- Hypovolemic hyponatremia: administration of one or more boluses of 0.9% NaCl solution 20 mL/kg over 1 h each to correct hypovolemic shock, followed by intravenous fluid repletion with 0.45%–0.9% NaCl according to serum sodium level.
- Euvolemic hyponatremia: water restriction by 50%–75% in SIADH or in case of water intoxicaton. Sodium replacement with intravenous 0.9% NaCl is sometimes required.
- Hypervolemic hyponatremia: restrict fluid and salt. Loop diuretics may be used, for example, Furosemide 0.5–1 mg/kg.

For treatment of symptomatic patients with severe hyponatremia (serum sodium less than 120 mmol/L and hyponatremia duration is $<$24–48 h), sodium correction no more than 10–12 mmol/L/24 h is recommended to prevent brain herniation and neurological damage from cerebral ischemia. Recommended treatment of acute hyponatremia varies by symptoms severity:

- Severe symptoms: 3 mmol/kg of sodium as hypertonic saline (3% NaCl) should be infused intravenously over 30 min to increase the serum sodium by 5 mmol/L.
- Mild to moderate symptoms, in patients at low risk for herniation: correction of sodium should occur over 24–48 h using 0.45%–0.9% NaCl intravenously saline (Vaidya *et al.*, 2010).

Syndrome of inappropriate ADH secretion (SIADH)

SIADH is defined by euvolemic hyponatremia and hypoosmolality resulting from inappropriate continued secretion or action of the AVP, resulting in impaired water excretion. In children, the vast majority of SIADH cases are acute and transient, and are generally caused by central nervous system (CNS) injuries (brain infecions, tumor, head trauma) or severe pulmonary diseases (infections, asthma, cystic fibrosis). Ectopic AVP secretion in lung cancer (less often gastrointestinal and urogenital cancers, lymphoma, sarcomas) is the most common cause of SIADH in adults. Also, drugs which stimulate AVP release or potentiate effects of AVP action, may cause SIADH (e.g., acetylcholine, cyclophosphamide, vincristine, and vinblastine) (Grant *et al.*, 2015).

Criteria of SIADH

- Hyponatremia and decreased effective osmolality of the extracellular fluid (Posm $<$275 mOsm/kg);
- Urine osmolality near or above plasma osmolality;
- Clinically observed euvolemia.
- Elevated urinary sodium excretion while on normal salt and water intake;
- Absence of other causes of hyponatremia—adrenal insufficiency, hypothyroidism, cardiac failure, pituitary insufficiency, renal disease with salt wasting, hepatic disease, drugs that impair renal water excretion;
- Correction of hyponatremia not effective by volume expansion, and is achieved by fluid restriction;
- Plasma AVP level inappropriately elevated relative to plasma osmolality (Bartter and Schwartz, 1967).

Treatment of SIADH

Fluid restriction by 50%–75% (with a goal of 500 mL/d below the 24-h urine volume) is generally first-line therapy. In children, most SIADH cases are acute and transient and respond well to conservative management. In adults, some cases may be prolonged and warrant pharmacologic treatment with AVP antagosnists (vaptans).

Management and treatment of SIADH depends on SIADH duration and severity of hyponatremia:

- Treat the underlying cause when possible.
- Moderate and asymptomatic hyponatremia (Na $>$120 mmol/L):
  - Fluid restriction to 600–800 mL/m^2/day.
  - Hyponatremia correction—to increased Na $\leq$0.5 mmol/L/h.
- Severe hyponatremia ($<$120 mmol/L) with neurogical symptoms:
  - Fluid restriction to 600–800 mL/m^2/day.
  - Intravenous hypertonic saline 3% NaCl—1–2 mL/kg/h, to avoid rapid hyponatremia correction. Plasma sodium should increase by 1–2 mmol/L/h in the presence of severe symptoms (severe confusion, convulsions, or coma) continue until symptoms resolve or for the first 3–4 h. However, total correction in the first 24 h must not exceed 10–12 mmol/L and there are various recommendations for the correction limit/day for chronic SIADH, varying from 0.5 to 1 mmol/L/h (6–8 mmol/L/day). The intravenous administration of hypertonic saline (3%) should be discontinued when neurological symptoms disappear.
  - The use of loop diuretics (furosemide) with hypertonic saline 3% in case of severe water intoxication.

Table 3 Differential diagnosis SIADH versus CSW (Edate and Albanese, 2015)

	SIADH	*CSW*
Plasma volume	Normal/high	Low
Evidence of volume depletion	No	Yes
Plasma osmolality	Low	Low
Plasma sodium	Low	Low
Urine sodium	High	High
Net sodium loss	Normal	Very high
Urine output	Usually low	Very high
Serum uric acid	Low	Normal/low
Plasma renin	Suppressed	Suppressed
Plasma aldosterone	Normal/high	Suppressed
Plasma AVP	High	Suppressed
Plasma ANP	High	High
Plasma BNP	Normal	High
Central venous pressure	Normal/high	Low

- Moderate and symptomatic hyponatremia is treated by raising the serum sodium level by 0.5–1 mmol/L/h for a total of 8 mmol/L during the first day.
- Drugs:
  - Demeclocycline can be used in chronic situations when fluid restrictions are difficult to maintain; demeclocycline is the most potent inhibitor of AVP action. Prolonged use of demeclocycline should be avoided due to extensive side effects profile, including skin photosensitivity, and nephrotoxicity.
  - Urea orally at a dose of 30 g/day increases urinary solute and water excretion.
  - Vaptans (in adults)
    - Conivaptan—an antagonist of both V_{1a} and V_2 AVP receptors.
    - Tolvaptan—an antagonist of the V_2 AVP receptor (Grant *et al.*, 2015; Kuhnle-Kral and Kausman, 2011).

Cerebral salt wasting (CSW)

CSW is a rare endocrine condition characterized by hyponatremia and dehydration in response to CNS disease. CSW may occur after neurosurgery, head injury and particularly in patients with subarachnoid hemorrhage. CSW is characterized by hyponatremia and ECF depletion due to inappropriate sodium wasting in the urine. CSW may occur after the first days or week from the cerebral injury event, and it takes usually 2–4 weeks, but may continue for months. The central nervous system damage can directly cause CSW by oversecretion of atrial natriuretic hormone (ANH), resulting in natriuresis and polyuria, leading to hyponatremia and reduced effective volume mass. Alternatively, CSW can be a secondary response to SIADH by stimulation of ANH secretion via AVP or plasma volume expansion. The abnormal sympathetic outflow to the kidney with a pressure natriuresis as well as abnormal secretion of AVP or brain natriuretic peptide (BNP) have been proposed as potential causes (Edate and Albanese, 2015; Yee *et al.*, 2010; Bettinelli *et al.*, 2012).

The diagnostic criteria of CSW syndrome (Yee et al., 2010; Wu et al., 2016)

- Serum sodium <135 mmol/L;
- Urinary sodium >40 mmol/L;
- Negative sodium balance;
- A low serum uric acid concentration due to urate wasting in the urine;
- Plasma omolality <280 mOsm/kg;
- An inappropriately elevated urine osmolality (above 100 mOsm/kg and usually above 300 mOsm/kg);
- Central venous pressure <6 cm H_2O and pulmonary capillary wedge pressure <8 cm H_2O.
- Whole-body dehydration.

In some cases, biochemical findings may resemble SIADH. Differential features of SIADH and CSW are presented in **Table 3**.

*Treatment options of cerebral salt wasting syndrome (CSW) (*Edate and Albanese, 2015)

In contrast to SIADH, normal to high fluids administration is required together with sodium supplementation with gradual tapering.

- Intravenous isotonic or hypertonic saline to raise serum sodium no faster than 0.7 mmol/L/h, for a maximum total daily change 10–12 mmol/L.
- Fludrocortisone may be considered in prologed cases of CSW.

Table 4 Causes of hypernatremia in children

Water deficit (euvolemic hypernatremia)	*Water and sodium deficit (hypovolemic hypernatremia)*	*Excess sodium (hypervolemic hypernatremia)*

• Central diabetes insipidus (CDI)
• Nephrogenic diabetes insipidus (NDI)
• Wolfram syndrome
• Increased insensible losses:
  ○ Premature infants
  ○ Radiant warmers
  ○ Phototherapy
• Poor intake:
  ○ Ineffective breastfeeding
  ○ Child neglect or abuse
  ○ Adipsia (lack of thirst)
	• Gastrointestinal losses:
	  ○ Diarrhea
	  ○ Emesis/nasogastric suction
	  ○ Osmotic cathartics (lactulose)
	• Cutaneous losses:
	  ○ Burns
	  ○ Excessive sweating
	• Renal losses:
	  ○ Osmotic diuretics (mannitol)
	  ○ Diabetes mellitus
	  ○ Chronic kidney disease (dysplasia and obstructive uropathy)
	  ○ Polyuric phase of acute tubular necrosis
	  ○ Postobstructive diuresis
		• Improperly mixed formula
		• Excess sodium bicarbonate administration
		• Ingestion of seawater or sodium chloride
		• Intentional salt poisoning
		• Intravenous hypertonic saline
		• Hyperaldosteronism
		• Cushing syndrome
		• Hemodialysis

- Oral sodium chloride can be administered once the patients are able to take oral medications.
- Monitoring of body weight, fluid balance, and serum sodium concentration is essential during the whole treatment period (Cerda-Esteve *et al.*, 2008; Dholke *et al.*, 2016).

Hypernatremia

Hypernatremia is defined as serum sodium higher than 145 mmol/L and is a result of a deficit of total body water (TBW) relative to total body sodium levels due to either loss of free water, or infrequently, the administration of hypertonic sodium solutions. Mortality due to hypernatremia is approximately 30%–48%. The causes of hypernatremia in children are presented in **Table 4**.

Most patients present with nonspecific signs, such as fever, headaches, nausea, dehydration, changes in muscle tone, lethargy and weakness. In cases of severe hypernatremia, impaired conscious state and seizures may occur. Due to hypernatremia, as a result of osmotic changes, the cells lose water and shrink, blood vessels rupture can occur leading to subarachnoid hemorrhage and eventual death.

Children with chronic hypernatremia present with weight loss, linear growth retardation, anorexia, and irritability; infants often have episodes of hyperthermia, and excessive crying (**Table 4**) (Kuhnle-Kral and Kausman, 2011).

Treatment of hypernatremia

The main rule for hypernatremia treatment is to maintain maximum decrease of serum sodium level by 0.5 mmol/L/h and the correction of sodium to the upper limit of normal should be achieved over 48–72 h to avoid acute cerebral oedema.

The principles of hypernatremia management:

- Monitoring of weight, fluid balance (intake and output) and serum sodium; serum sodium levels should be monitored every 1–4 h.
- Monitoring of serum potassium.
- Shock should be corrected with one or several boluses of 0.9% NaCl 20 mL/kg over 1 h each until perfusion is adequate.
- Body water deficit may be calculated according total body water (TBW), which is 60% of body weight in children and 70% in infant.
- Body water deficit may be calculated with this formula:
  - Water deficit (in L) = [(current Na level in mEq/L − 145 mEq/L)/145 in mEq/L] × 0.6 × weight (in kg).
  - Water deficit (in L) = [1 − (145 mEq/L ÷ current Na level in mEq/L)] × 0.6 × weight (in kg).
- The volume of replacement fluid needed to correct the water deficit is determined by using the concentration of sodium in the replacement fluid. The replacement volume can be determined as follows:
  - Replacement volume (in L) = TBW deficit × 1 ÷ [1 − (Na concentration in replacement fluid in mEq/L ÷ 154 mEq/L)].
- Intravenous fluid administration:
  - If the patient is hypotensive, normal saline (lactated Ringer solution, or 5% albumin solution) should be used regardless of a high serum sodium concentration.
  - In hypernatremic dehydration, 0.45% or 0.2% NaCl should be used as a replacement fluid to prevent excessive delivery of free water and a too-rapid decrease in the serum sodium concentration.
  - In cases of hypernatremia caused by sodium overload, sodium-free intravenous fluid (5% dextrose) may be used, and a loop diuretic may be added (Kuhnle-Kral and Kausman, 2011).

Table 5 Etiological classification of diabetes insipidus (Edate and Albanese, 2015; Di Iorgi *et al.*, 2012; Robertson, 2016)

Central DI

Congenital

- Genetic
  - *AVP-NPII* gene defect
  - Familial autosomal dominant CDI
  - Familial autosomal recessive CDI
  - *WFS1* gene defect—DIDMOAD syndrome
  - Wolfram syndrome
  - X-linked lissencephaly with ambiguous genitalia
- Congenital anatomic defect
  - Septo-optic-dysplasia
  - Holoprosencephaly
  - Agenesis of corpus callosum
  - Kabuki syndrome
  - Familial pituitary hypoplasia
  - Infundibulum defect
- Others
  - Vasopressinase excess
  - Syndrome of defective osmoregulation

Aquired

- Primary tumors or metastasis
  - Germinoma
  - Pinealoma
  - Craniopharyngioma
  - Glioma
  - Pituitary stalk thickening
- Infections/infiltrative lesions
  - Meningitis/encephalitis (transient CDI)
  - Congenital cytomegalovirus infection
  - Toxoplasmosis
  - Tuberculosis
  - Cryptococcus
  - Sarcoidosis
  - Langerhans cell histiocytosis
  - Leukemia
  - Hemochromatosis
  - Amyloidosis
- Drugs
  - Adrenergic drugs
  - Carbamazepine
  - Phenytoin
  - Valproic acid
- Trauma/surgery
- Autoimmune disorders
  - Hypophysitis
- Hypoxic-ischemic encephalopathy
- Electrolyte disturbances
  - Hypokalemia
  - Hypercalcemia

Idiopathic

Nephrogenic DI

Congenital

- X linked NDI—Xq28 encoding AVPR2
- Autosomal recessive NDI—Ch12q13 encoding AQP2
- Autosomal dominant NDI
- Bardet-Biedl syndrome

Acquired

  - Primary renal diseases
  - Polycystic kidney disease
  - Ureteral obstruction
  - Uremia

Primary polydypsia
Psychogenic

Diabetes Insipidus

Diabetes insipidus (DI) is a condition when large volumes of dilute urine are excreted due to defect of syntesis or deficiency of AVP secretion—central DI (CDI), or due to renal tubular resistence to AVP—nephrogenic DI (NDI), and sometimes can occur due to secondary suppression of AVP production after excessive fluid intake (primary polydipsia). DI is a disease characterized by polyuria and polydipsia with hyposthenuria, causing dehydration and hypernatremia if the patient is deprived of water. Polyuria is characterized by a urine volume in excess of 1.5–2 L/m^2/24 h, approximately $>$150 mL/kg/24 h at birth, $>$100–110/mL/kg/24 h in infants, 75 mL/kg/24 h in young children, $>$40–50 mL/kg/24 h in older children and adults, or urine output of more than 4 mL/kg/h in children and more than 6 mL/kg/h in neonates. Polydipsia is characterized then water intake $>$2 L/m^2/d (Edate and Albanese, 2015; Di Iorgi *et al.*, 2012).

Anatomy

The AVP, or antidiuretic hormone (ADH) is a peptide produced by the hypothalamus in paraventricular and supraoptical nuclei and is transferred by posterior neuronal axons to the posterior part of the pituitary gland (neurohypophysis) and is stored in neurosecretory granules. These axons store quantities of AVP sufficient to sustain basal release for 30–50 days or to allow maximum antidiuresis for 5–10 days. While the blood supply for the anterior pituitary is via the hypothalamic–pituitary portal system from the suprahypophyseal arteries, the vascularization of the posterior pituitary is direct from the inferior hypophyseal arteries (Edate and Albanese, 2015; Di Iorgi *et al.*, 2012).

Physiology

AVP secretion from neurophysiophysis to the blood stream is stimulated by increased plasma osmolality and 5%–10% decreased blood volume. In addition, stimulation of hypothalamus ventromedial nuclei induces the thirst sense. Other nonosmal factors that promote the release of AVP are nausea, vomiting, stress, physical activity, acute hypoxia and hypercapnia, hypoglycaemia, and some medicines and chemicals (vincristine, carbamazepine, cyclophosphamide, antidepressants, monoamine oxidase inhibitors (MAO) inhibitors, nicotine, etc.). AVP secretion is suppressed by alcohol and caffeine.

AVP acts on aquaporin channels located in the kidney collecting duct and promotes water retention and increases urine osmolality (de Bree and Burbach, 1998).

Epidemiology

The incidence of DI is 3–4 cases in 100,000, with a slightly higher males predominance (60%). Less than 10% of all DI cases are heredited. In children, NDI is more common than CDI and is most often acquired. X-linked NDI represents 90% of cases of congenital NDI and occurs with a frequency of 4–8 per 1 million male live births; autosomal NDI accounts for approximately 10% of the remaining cases. No gender difference has been reported for the other forms. The frequency of autosomal dominant CDI is currently unknown (Fenske and Allolio, 2012).

Etiology

The classification of diabetes insipidus in children according to etiology is presented in **Table 5** (Edate and Albanese, 2015; Di Iorgi *et al.*, 2012; Mishra and Chandrashekhar, 2011).

Central diabetes insipidus

CDI is caused by the destruction or degeneration of neurons originating in the supraoptic and paraventricular nuclei. The known causes of these lesions including local inflammatory or autoimmune diseases (hypophysitis), vascular diseases, infiltrative conditions such as Langerhans cell histiocytosis (LCH), sarcoidosis, tuberculosis, germinoma/craniopharyngioma, trauma resulting from surgery or an accident, metastases and midline cerebral and cranial malformations (Capatina *et al.*, 2015; Secco *et al.*, 2011). In rare cases (accounting for 1%–5% of all cases), CDI may be inherited as an autosomal dominant or autosomal recessive disease caused by mutations of the arginine vasopressin-neurophysin II (*AVP-NPII*) gene, and presents with gradual onset during infancy (autosomal recessive CDI) or early childhood between 1 and 6 years (autosomal dominant CDI). Mutations of the *AVP* gene impair the synthesis or secretion of AVP. To date, 73 mutations in *AVP-NPII* gene resulting in an autosomal dominant familial CDI and 3 autosomal recessive mutations are identified. The *AVP-NPII* gene is located on chromosome 20p13 (Abu Libdeh *et al.*, 2010; Babey *et al.*, 2011; Land *et al.*, 1982; Lin *et al.*, 2009; Matarazzo *et al.*, 2004).

More than 170 different mutation are indentified in *WFS1* gene causing autosomal recessive CDI, resulting in Wolfram syndrome. It is mostly caused by homozygous or compound heterozygous mutations in the *WFS1* gene located on chromosome 4p, encoding wolframin. Wolframin functions as an endoplasmic reticulum channel and regulates intracellular ionized calcium (Ca^{2+}) levels. Walfram syndrome is defined by the presence of diabetes mellitus and optic atrophy, approximately 70% of patients also present with central diabetes insipidus due to AVP deficiency. It has recently been suggested that a dosage effect of specific *WFS1* mutations with different tissue sensitivities to *WFS1* deficiency may be responsible for partial phenotypes. Clinically, diabetes insipidus in the context of Wolfram syndrome is characterized by late onset in the second or third decade of life (Barrett *et al.*, 1995; Elli *et al.*, 2012).

X-linked CDI has been reported in one family; however, genetic mutations were not indentified. CDI manifested at young age (<1 year), with decreased basal and stimulated AVP, and remission on standard doses of DDAVP. Reduction or absence of the posterior pituitary bright spot in these male patients could indicate posterior pituitary degeneration similar to autosomal dominant familial CDI (Abu Libdeh *et al.*, 2010; Babey *et al.*, 2011; Di Iorgi *et al.*, 2014; Lin *et al.*, 2009; Matarazzo *et al.*, 2004).

Nephrogenic diabetes insipidus

In children, NDI is more common than CDI and it is most often acquired, secondary to damage to distal nephron leading to tubular defect and it is due to kidney diseases (obstruction, pyelonephritis, dysplasia, nephrocalcinosis), severe electrolite disturbances, drugs (lithium, tetracyclines), and infiltrative diseases (sarcoidosis).

Congentital forms of NDI are due to mutations in arginine vasopressin receptor 2 (*AVPR2)* gene (90%) and aquaporin 2 (*AQP2*) gene (10%) causing the insensitivity of the distal nephron to AVP leading to impaired water reabsorption.

NDI due to mutation in *AVPR2* gene is X-linked recessive disorder; males are severely afected, while female carriers often presents with moderately impared urine concentration capacity. More than 200 different *AVPR2* gene mutations have been described in more than 300 families. Onset of symptoms of X-linked NDI is usually in early infancy. Hypernatremia does not occur with free access to fluids but can become a problem during states of dehydration.

AQP2 gene mutations are responsible for 10% of congenital NDI inherited in both autosomal recessive or dominant maner. *AQP2* gene is located on chromosome 12q13 and encodes the water channel AQP2 allowing AVP stimulated water reabsorption from the renal distal tubule. To date, 52 mutations in *AQP2* gene are indentified resulting in autosomal recessive NDI forms and 11 mutations of dominant recessive disease. The NDI symptoms present from early infancy in both forms of NDI (Moeller *et al.*, 2016; Schernthaner-Reiter *et al.*, 2017).

Diagnosis (Di Iorgi *et al.*, 2014, Kuhnle-Kral & Kausman, 2011)

Clinical features

Regardless of the cause, DI features are polyuria and polydipsia.

If the patient is deprived of water, following symptoms will occur:

- Dehydration;
- Weight loss;
- Fever;
- Constipation;
- Failure to thrive and developmental delay.

Features in infants:

- Vigorous suck;
- Vomiting;
- Recurrent episodes of fever without obvious cause;
- Excessive crying;
- Irritability.

Features in younger children:

- Often manifest with primary enuresis;
- Difficulies of toilet training.

Older children:

- High urine output;
- Nocturia leading to disturbed sleep;
- Anorexia due to preference of water over food.

Other clinical features/complains depending on etiology of DI:

- Neurological features (headache, visual disturbance);
- Other pituitary hormone deficiencies;
- Variable severity of mental retardation in children with NDI (attributed to intracranial calcifications).

Primary polydypsia is usually gradual in onset: absence of nocturia, need to drink water at night time.

Diagnostic tests (Di Iorgi et al., 2012; Kuhnle-Kral and Kausman, 2011; Mishra and Chandrashekhar, 2011; Robertson, 2016; Wu et al., 2016)

Basal diagniostic test:

- Confirm polyuria 24 h diuresis;

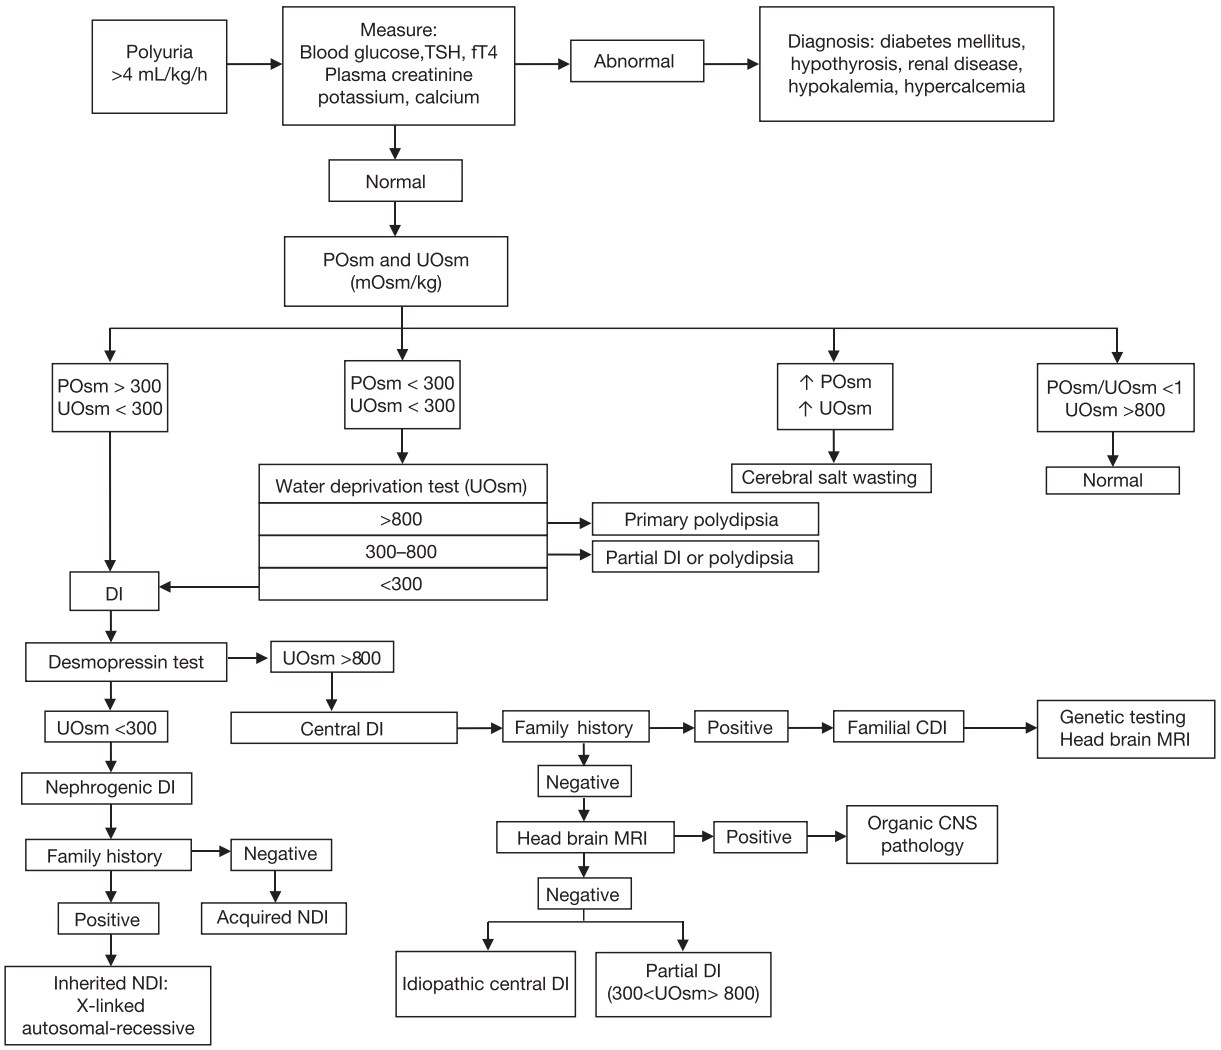

Fig. 1 Differential diagnosis of polyuria.

Table 6 Interpretation of DDAVP and water deprivation test

Diagnosis	*After water deprivation test Urine osmolality, mOsm/kg*	*After desmopressin test Urine osmolality, mOsm/kg*
Central DI	<300	>800
Nephrogenic DI	<300	<300
Primary polydipsia	>800	>800
Partial DI or polydipsia	300–800	<800

- Exclusion of other disorders (glycemia, serum calcium, blood, and urine pH);
- Paired morning blood and urine samples for osmolality: if the blood osmolality exceeds 295 mOsm/kg, while urine osmolality <300 mOsm/kg, DI diagnosis is confirmed (**Fig. 1**).

Water deprivation test (WDT)

Generally, if the patient has free access to water, DI is not diagnosed with basal tests. WDT with DDAVP administration is most commonly used to establish diabetes insipidus and to differentiate between nephrogenic and neurohypophyseal forms. It is important to exclude cortisol deficiency prior to WDT, since glucorticoid deficiency impairs the ability to appropriately excrete water load causing water retention.

In patients wihout severe polyria, WDT is started at 6 pm and stopped at 8 am. In infants and in patients with severe polyuria (exceeding 4 L/24 h), because of the risk of severe dehydration, the test should start in the morning. Patients are not allowed to drink or eat, and blood pressure and weight are monitored every 1–2 h. After 6–8 h fast and water deprivation, weight, urine volume, serum and urine osmolality and serum sodium levels are measured. The WDT is stopped at any time, if:

- Urine osmolality >750 or more than 600 mOsm/kg and stable for two consecutive times;
- Plasma osmolality >300 mOsm/kg and urine osmolality <300 mOsm/kg;
- If 5% weight loss and/or vital signs disclose hypovolaemia.
- Serum sodium exceeds 145 mmol/L.

DDAVP test

With the aim to differentate between CDI and NDI, immediatly after WDT 5–10 μg of DDAVP is administrated intranasally, followed by paired serum and urine osmolality tests after 1 h. More than 50% increase in urine osmolality and decrease in serum sodium and osmolarity are characteristic of CDI. Urine osmolality does not change or slightly increased in NDI (**Table 6**).

Neuroimaging

Brain magnetic resonance imaging (MRI) is performed to determine the underlying cause of CDI and may confirm the diagnosis of CDI in the absence of the hyperintensive signal of posterior pituitary—"bright spot," which may also be ectopic. The presence of a thickened pituitary stalk points towards possibility of LCH, germinoma and hypophysitis (either inflammatory or autoimmune). In cases of idiopatic CDI with pituitary stalk thikning, longitudinal follow-up is recommended repeating MRI ever 4–6 months for 2 years, then every year for 3 years. If the initial MRI is normal, some authors suggest to repeat MRI every 6–12 months, but it is unclear how long it is necessary to repeat imaging to exclude underlying diagnoses.

Treatment of DI

Treatment of CDI (Edate and Albanese, 2015; Robertson, 2016)

Confirmed CDI is treated with synthetic vasopressin analog DDAVP:

- Orally, intranasally, intravenously (i/v);
- Urine output decrease in 1–2 h after administration;
- Duration of action 6–18 h;
- Large variations in dose requirement:
  - Orally 0.1–1.2 mg in three divided doses,
  - Intranasal 2–40 μg (once or twice a day),
  - Vasopressin 0.1–1 μg i/v in emergency situations,
- Start with low dose, increase as necessary. Dose titration is best achieved under close supervision in hospital, especially for young children and infants;
- Infants may be treated with adequate fluid supply. Alternatively, low doses of diluted DDAVP may be administered.

*Treatment of NDI (*Mishra and Chandrashekhar, 2011)

- Low salt diet;
- Thiazide diuretics ± nonsteroid antiinfamatory drugs (indomethacin). Avoid overcorrection;
- New drugs under investigation: targeting enhancement of AQP2 function (Saifan *et al.*, 2013):
  - Phosphodiesterase inhibitors,
  - Statins (Bonfrate *et al.*, 2015),
  - Prostaglandins,
  - Metformin,
  - Thyrosine kinase inhibitors.

*Treatment of partial AVP deficiency (*Mishra and Chandrashekhar, 2011)

- Patients can maintain normal or near normal water balance when permitted to drink water in response to thirst;
- DDAVP;
- Drugs that potentiate action of otherwise insufficient amounts of endogenous ADH:
  - Chlorpropramide,
  - Thiazide diuretics.

Obesity, Childhood, and Adolescence

Wieland Kiess, University of Leipzig, Leipzig, Germany

Introduction and Scope of the Problem

The prevalence of overweight and obesity is high in adults and already in children and adolescents across most developed and developing countries with a 20%–35% prevalence. Although the prevalence of obesity at a young age seems to stabilize in some countries, the number of adolescents and especially of adults with obesity is still increasing dramatically worldwide. This is a major concern, considering the well described association of overweight and obesity with long-term health problems, such as cardiovascular disease leading for example to myocardial infarction and stroke, type 2 diabetes and cancer. In the majority of individuals, weight gain is the result of exposure to an "obesogenic" environment, superimposed on a background of genetic susceptibility brought about through evolutionary and cultural adaptation. A large number of genes have been identified by genome wide association studies (GWAS) and candidate gene approaches that are associated with the regulation of appetite, food intake, and body weight. Therapeutic and preventive strategies have to follow complex and multifactorial themes and are often not efficient nor efficacious (Kiess *et al.* 2001) (**Table 1**) (**Fig. 1**).

Definitions and Differential Diagnosis

The definition and diagnosis of obesity in children and adolescents is surprisingly difficult. The level of fatness at which morbidity and also mortality increases is determined on an actuarial basis. In children and adolescents the degree of body fat mass depends upon ethnic and genetic background, gender, developmental stage, and age. Waist and neck circumference, skin-fold thickness and body mass index are the most useful noninvasive clinical measures to determine the degree of body fatness and define obesity. Body mass index has been used as a surrogate marker of body fat and is the most frequently used tool to diagnose overweight and obesity also at a young age. However, BMI has surprisingly low sensitivity and specificity when compared to other body mass indices such as skinfold measurements, waist circumference and such. Comparative data and reference values have to be used and percentiles or standard-deviation scores have to be calculated in order to give a good representation of a subject's fat and lean body mass in relation to peers considering ethnicity, gender, pubertal stage, and age. The relative unreliability of BMI for diagnosing childhood obesity is partly due to the fact that for example in early puberty in boys, body mass increments are due to muscle and bone mass increase while in girls there is also adipose tissue increments in stages of early puberty.

BMI is used to define obesity clinically. Accordingly, a child with a BMI above the 97th percentile in regard to age and gender is considered to be obese. A child with a BMI greater than the 90th but below the 97th percentile would be considered overweight. In adults, a BMI greater than 28 kg/m^2 is associated with an increased risk of morbidity such as stroke, ischemic heart disease, sleep–apnea syndrome, orthopedic diseases or type II diabetes mellitus. Adults with a BMI greater than 30 kg/m^2 are uniformly classified as being obese (grade 2 overweight) while those with a BMI between 25 and 29.9 kg/m^2 are considered to be grade 1 overweight. A BMI over 40 kg/m^2 is classified as grade 3 overweight (WHO classification). A central distribution of

Table 1 Factors which contribute to the development of obesity and may constitute risk factors for a child to develop increased body weight and fat mass

Genetic factors:
Possibly polymorphisms and/or mutations in any of the following: Adrenergic receptors, leptin, Ob-R, SOCS-3, TNF, POMC, MCH, MC4R, NPY, NPY receptors, CRH, TRH, urocortin, orexin A and B, galanin, neurotensin, serotonin and many others, polygenic causes
Environmental/exogenous factors:
Increase of sedate activities (screen time etc.)
Decrease in physical activity
Shift in diet towards more fast/prepackaged foods with high fat/calorie
Content
Sugar-sweetened beverages
Endocrine disrupting chemicals
Loneliness and social isolation
Psychosocial/family problems
Low parental income
Low parental education

Childhood overweight: a contextual model and recommendations for future research. Obesity reviews: an official journal of the International Association for the Study of Obesity 2 3 (2001): 159-71.

Table 2 Disorders which can present with obesity in childhood—differential diagnosis of obesity disorders

Endocrine disorders such as:
Cushing's syndrome/disease
Hypothyroidism
Growth hormone deficiency
Hyperinsulinemia
(Pseudo) hypoparathyroidism (Albright's hereditary dystrophy)
Central nervous system disorders/brain damage in relation to:
Hypothalamic tumor
Neurosurgery
Trauma
Postinflammation (meningoencephalitis)
Postchemotherapy
Corticosteroid therapy
Antiepileptic therapy
CNS irradiation

body fat is also associated with a higher risk of morbidity and mortality in adulthood. In addition and most importantly, an increased risk of death from cardiovascular disease and myocardial infarction and stroke in particular has been found in adults whose BMI had been greater than the 75th percentile as adolescents. The International Obesity Task Force has proposed that the adult body mass index cut-off points (25 and 30 kg/m^2) should be linked to body mass index percentiles for children to provide for child cut-off points. Accordingly, age and gender specific BMI values for 2–18 years corresponding to BMI values of 25 and 30 kg/m^2 at 18 years of age have been published by Cole *et al.* (2000).

Differential diagnosis of obesity can be quite difficult. "Exogenous obesity" which may also be referred to as "simple" or "primary" obesity is still, by far, the most common diagnosis in the obese child. However, in addition to many monogenic traits of morbid obesity there are numerous, largely rather rare, disorders that can also present with obesity early in life. These usually include both genetic syndromes and also a variety of underlying disorders such as hypothalamic tumors, other brain lesions and endocrine disorders (**Table 2**). The diagnosis of primary or simple or "exogenous" obesity is usually easy to make and depends upon family and personal history and a careful physical exam. Only rarely more extensive laboratory tests and finally molecular genetic analysis will be necessary in routine clinical work up.

A simple diagnostic algorithm which aids in making a diagnosis in children and adolescents with obesity is highlighted in Fig. 1. Usually, no laboratory investigations are recommended unless substantial comorbidity such as hypercholesterolemia or liver disease is suspected. However, a primary determination of serum concentrations of thyroid stimulating hormone (TSH), T3 and T4 and lipid measurements are carried out in most centers in Europe and the United States.

Etiology of Obesity

The etiopathology of obesity has to be related to an intricate interplay between many genes, epigenetics, adipose tissue factors including inflammatory molecules, adipocytokines and immune cells, signaling molecules, food stuffs, metabolites, microbiota, and environmental chemicals. In addition, social inheritance, obesogenic environment, urbanization, socio-demographic factors including income, poverty and education play an important role in the development of obesity both in the individual and in societies. Nutrition and malnutrition, lack of physical activity and sedentary behavior, media use, and cultural habits and beliefs add to the obesogenic risks. Lastly, human evolution has led to an increased prevalence of obesity in the recent history of mankind (Kiess *et al.*, 2001; Lobstein *et al.*, 2015).

Monogenic

Overall, monogenic forms of obesity are rare but taken together are present in a substantial number of people affected by early onset and extreme obesity. It is important to diagnose children with the monogenic obesity forms since there are treatments available for many of them and counseling the family as well as finding appropriate decisions for care and schooling must be based upon clear diagnoses. The majority of genes identified in monogenic cases of obesity such as the genes encoding for the melanocortin 4 receptor (MC4R), proopiomelanocorticotropin (POMC) or the leptin receptor appear to be involved in the central regulation of energy intake. Variants of genes involved with energy utilization such as the ones encoding β-adrenergic receptors 2 and 3, hormone-sensitive lipase, and mitochondrial uncoupling proteins 1, 2, and 3 have also been associated with contributing to common obesity. Of the single gene defects which lead to obesity, MC4R defects are relatively common accounting for approximately 4% of cases of early onset childhood obesity. Large chromosomal deletions and also copy number variation have been linked to early onset obesity. Large deletions of chromosome 16p11.2 are for example found in about 0.7% of patients with morbid obesity (Fig. 2).

Syndromal Obesity

A number of syndromal disorders are associated with severe and mostly early onset obesity. Mostly, these syndromes include mild to moderate retardation and additional organ manifestations. Many are caused by alterations of neuroendocrine signaling circuits that regulate hunger and satiety either by disturbing ciliar function in CNS neurons like in Bardet–Biedel syndrome or interfering with hypothalamic function like in Prader–Willi syndrome. Table 3 gives an overview on the most frequently occurring forms of syndromal obesity.

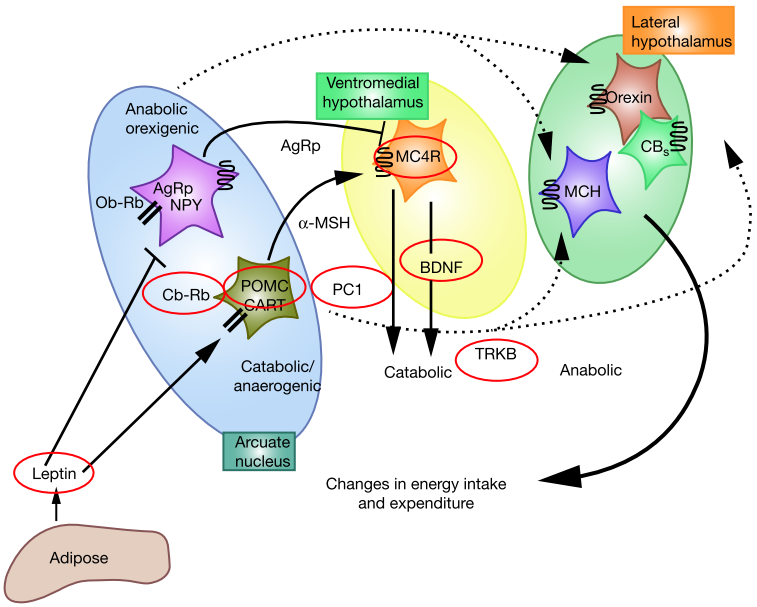

Fig. 2 Human mutations in molecules involved in weight regulation.

Table 3 Genetic syndromes that may be associated with childhood obesity

Albright hereditary osteodytrophy (pseudohypoparathyroidism type 1A)
Prader–Labhard–Willi syndrome
MOMO (macrocephaly, ocular, mental retardation, obesity) syndrome
Alstrom syndrome
Bardet–Biedl syndrome
Carpenter syndrome
Börjeson–Forssman–Lehmann syndrome
WAGR (Wilms tumor, aniridia, genitourinary anomaly, mental retardation) syndrome
Cohen syndrome
ROHHAD syndrome (rapid onset obesity, hypothalamic dysfunction, hypoventilation, and autonomic dysfunction)
Primary (simple/"exogenous") obesity
(multifactorial and multigenetic susceptibility)

Polygenetic

Multiple factors are related to the high incidence of childhood obesity. Both genetic/endogenous and environmental/exogenous factors contribute to the development of a high degree of body fatness early in life (**Tables 1** and **2**). In fact, twin studies suggest that at least 50% of the tendency toward obesity is inherited. There is also increasing evidence that responsiveness to dietary intervention is genetically determined. In fact, recent reviews on the genetics of body-weight regulation emphasize the contribution of the interaction between genes and environment to the development of obesity. Approximately 40%–70% of interindividual differences in body weight and composition is thought to be due to genetic variation. According to the thrifty gene hypothesis, evolutionary selection pressure has selected genes which allow individuals to survive periods of food deprivation. Within our modern obesogenic environment, however, these same genetic susceptibility traits now appear to be detrimental by promoting obesity and its associated metabolic and cardiovascular as well as related diseases (Körner *et al.*, 2008).

Less than 5% of cases of childhood obesity can be attributed to a specific cause be it an underlying endocrine disease, an obesity-related syndrome, a monogenic form of obesity or a specific damage to the hypothalamus. Exogenous factors such as overconsumption of fat-rich diets, the excessive use of modern media and in particular television viewing (**Table 5**) and lack of physical activity (sedentary life style) all heavily contribute to the development of obesity in childhood and adolescence as well as in adulthood. Nutrition and diet early in infancy is thought to influence growth rate and body fatness beyond infancy. Some authors have suggested that intrauterine growth retardation predisposes for the development of obesity and syndrome X later in life. This phenomenon has been termed "fetal programming." However, the mechanisms leading to fat patterning as a result to differences in fetal or early postnatal nutrition are still not completely understood. Intergenerational metabolic programming has also been discovered: for example, paternal diet will determine weight development in the off spring (Veldhuis *et al.*, 2005; von Kries *et al.*, 1999).

Neurons in the arcuate nucleus of the hypothalamus coordinate behavioral and autonomic functions which control energy homeostasis. Many genes that have been related to contribute to the etiology of either monogenic or polygenic obesity such as the genes encoding for the melanocortin 4 receptor (MC4R), proopiomelanocorticotropin (POMC), CART (cocaine- and amphetamine-related transcript), neuropeptide Y (NPY), agouti-related protein (ArRP) or the leptin receptor (ObR) or the single-minded 1 (SIM1), brain-derived neurotrophic factor (BDNF), TrkB or FTO gene and are expressed in the hypothalamus. They are involved in the central regulation of energy intake, satiety, hunger, and behavioral traits related to the control of food intake (**Fig. 2**).

Hypothalamic dysfunction has emerged as an important mechanism involved in the development of obesity and its comorbidities. In fact, hypothalamic obesity has been identified as a condition where obesity develops after damage to the hypothalamus for example after trauma or surgery or due to tumorous masses such as craniopharyngiomas. In addition, hypothalamic obesity is frequently a feature of serious diseases and disorders and in itself is very difficult to treat (Bereket *et al.*, 2012).

Selection of palatable meals, food intake, and satiety elucidate pleasure and positive emotional, hedonistic, signals. The endogenous opioid system in the brain is linked to positive and motivating emotional signals. Also, it has been found that the opioid system is involved in affective and stress responses. It is therefore positioned as a mediator between food intake, hedonic responses and their emotional regulation. It has been hypothesized that obesity, overeating and food-seeking behavior has indeed features of addiction and dependency. Findings suggest that the central opioid system not only relates to affective states and stress but also to chronic obesity and weight loss. Food intake is considered a readout of the hedonic, pleasurable pathway. When functional, the hedonic pathway will then help to reduce food intake in situations where energy stores are full. Dysfunction of this pathway may then increase food intake and lead to obesity (**Fig. 3**).

Adipose tissue develops as subcutaneous adipose tissue, visceral fat, and intra organ fat. Fetal adipose tissue development is regulated by a complex interaction of a number of transcription factors, many nutrients and signaling molecules, termed adipocytokines. Maternal, endocrine, and paracrine factors also influence specific changes in angiogenesis, adipogenesis, and metabolism. During embryogenesis and in fetal life, leptin and adiponectin, two important adipocytokines, are present at high concentrations in the circulation and in tissues. In obese subjects, adiponectin serum concentrations are low while leptin serum concentrations are elevated. Developmental stages and metabolic processes influenced by specific hormones and paracrine factors have been identified through examination of the offspring of obese and diabetic pregnancies, hormonal manipulation during late

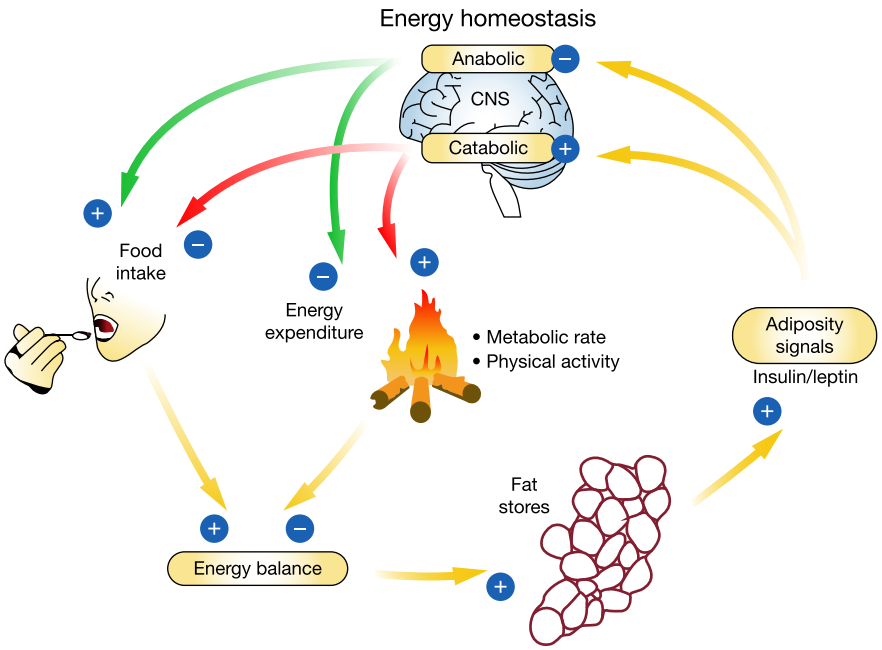

Fig. 3 Energy homeostasis. Schwartz MW, Woods SC, Porte D Jr, Seeley RJ, Baskin DG. Central nervous system control of food intake. Nature. 2000, 404:661-71.

pregnancy in animal models, and the use of cell cultures. Collectively, the results of these studies delineate the basis for imprinting or conditioning of fetal preadipocytes at the paracrine/autocrine level, and of fetal adipose tissue development and metabolism.

Many signaling molecules and metabolites are released from brown adipose tissue (BAT) and some of them are even induced during brown adipocyte differentiation and/or thermogenic activation. Some of these factors might have an autocrine or paracrine role. BAT also secretes nonpeptide signaling molecules such as prostaglandins which may play a role in thyroid hormone function, differentiation of preadipocytes into beige adipocytes and synthesis of nitric oxide. Lack of BAT in obese individuals might then reduce energy expenditure and enhance energy storage in white adipose tissue.

Intestinal microbiota from obese rodents and humans differ from those from lean individuals. Acquisition of the microbiota in the gut begins at birth, and a stable microbial community develops from a succession of key organisms. Disruption of the microbiota during maturation by low-dose antibiotic exposure can alter host metabolism and adiposity (Gensollen *et al.*, 2016). For example, low-dose penicillin (LDP), delivered from birth, induces metabolic alterations and affects ileal expression of genes involved in immunity. LDP that is limited to early life transiently perturbs the microbiota, which is sufficient to induce sustained effects on body composition, indicating that microbiota interactions in infancy may be critical determinants of long-term host metabolic effects. In conclusion, there is early-life microbe-host metabolic interaction and this is consistently linked with metabolic alterations later in life (Falony *et al.*, 2016; Pedersen *et al.*, 2016).

In order to better understand the pathogenesis of comorbidities and also in order to find out what surrogate markers could be useful to differentiate between metabolically and cardiovascularly healthy from unhealthy obesity many a surrogate marker be it adipocytokines, lipoproteins, lipids or growth factors and a variety of hormones have been studied and subsequently were identified to be related to obesity or cause progression of the disease or its comorbidities. For example osteocalcin serum levels are inversely related to markers of body adiposity and leptin levels. Thus, a relation between obesity and bone health has been suggested. Also, the adipocyte appears to be a major site of extraovarian synthesis of estrogens. A recent longitudinal study noted that girls with greater BMI had lower serum estradiol levels at the onset of thelarche (onset of breast development) than those with BMI in the normal range. Previous studies have noted suppressed values of gonadotropins in obese girls. Together these findings suggest peripheral conversion of androgens into estrogens, through increased adiposity and greater aromatase activity.

Recently, it has been suggested that epigenetic modifications may be involved in both obesity and T2DM development. Epigenetics plays a pivotal role in the regulation of gene expression by the reversible modifications of chromatin structure without any changes in DNA sequence. Epigenetic modifications include DNA methylation, posttranslational histone modifications and miRNA interference. Many of the epigenetic changes associated with obesity affected genes are known to raise diabetes risk.

It has become obvious that the socio-cultural inheritance of body fat mass, weight, and weight control is also very largely contributing to the obesity epidemic that is obvious today. A quantitative analysis of the nature and extent of the person-to-person spread of obesity as a possible factor contributing to the obesity epidemic was for example carried out within a densely interconnected social network of 12,067 people repeatedly re-assessed from one as part of the Framingham Heart Study (1971–2003). Longitudinal screening revealed that weight gain in one person was associated with weight gain in his or her friends, siblings,

spouse, and neighbors. A person's chances of becoming obese increased by 57% if he or she had a friend who became obese in a given interval and by 40% among pairs of adult siblings, if one sibling became obese (Grow *et al.*, 2010).

In industrialized countries such as France, the United Kingdom, the United States, Germany, Australia, and Sweden the prevalence of obesity in children strongly relates to socio-demographic parameters: children of low income families and of families with low parental education are much more frequently overweight and obese than children from affluent and well educated parents. In low-income countries as well as in Brasil, India, China and the countries of the Arab peninsula, the reverse is seen: children from the high income part of the population are more frequently overweight and obese than children from the poor. In fact, in many countries in Africa and in South America starvation and poverty are related while high income and malnutrition and obesity are present at the same time and maybe even so in the same individual. Urbanization might also be a causative factor for the increase in obesity prevalence in Chinese children in the Shanghai area (Farpour-Lambert *et al.*, 2015; Zhang *et al.*, 2012).

Dietary Factors

Dietary factors that may facilitate the development of overweight and obesity early in age include total caloric intake, fat intake, protein intake, and fiber intake. In recent reviews, there was no consistent association of total caloric intake with overweight and obesity. Dietary protein was associated with earlier onset of weight accretion and of the pubertal growth spurt, age of peak height velocity, and menarche/voice break, and may be related to enhanced IGF secretion. Dietary fiber has also been recognized for its impact on cardiovascular disease, insulin resistance and diabetes, and several cancers. In respect to the endocrine system dietary fiber was noted to delay age of menarche and breast development, although other studies which documented lower overall intake of fiber did not note later menarche.

The automation of the process of extracting sugars in the 1900s reduced cost and increased availability of sugars leading to a dramatic rise in consumption, which reached a peak in the 1970s. There are different definitions for sugars not naturally available in foods, and free sugars is the term used by WHO. The epidemiological evidence of the associations between sugars and obesity and type 2 diabetes mellitus is fairly strong and consistent, particularly for sugar sweetened drinks in adults. However, the sugar beverage industries as well as sugar industries have been quite successful in leading the public to believe that sugar sweetened beverages are not much related to the obesity epidemic seen in parallel with the increasing consumption of sugar. However, it is believed that high fructose intake might accelerate weight gain and also directly cause nonalcoholic liver disease and hepatic fibrosis.

Physical activity plays an important role in the prevention of becoming overweight and obese in childhood and adolescence, and reducing the risk of obesity in adulthood. Puberty and the following adolescent period are acknowledged as particularly vulnerable times for the development of obesity due to, in many individuals, a concomitant reduction in physical activity. In many Western settings, a large proportion of children and adolescents do not meet recommended physical activity guidelines and, typically, those who are more physically active have lower levels of body fat than those who are less active. Low income families are more likely to not support sports activity and sports club membership of their off spring than are middle or high income parents.

Sedentary behavior is associated with health indicators; however, there are only few studies that have examined these associations, especially in conjunction with psychological factors, in children. Excess sedentary behavior relates into higher levels of behavioral/emotional problems and anxiety. However, a clear relation to weight gain and/or obesity and sedentary behavior has been difficult to prove.

Endocrine disrupting chemicals, EDCs, are frequently seen as obesogens: they represent several classes of chemicals which may impact on early weight gain, metabolic consequences later in life and timing of puberty through regulating peroxisome proliferator–activated receptor gamma (PPARγ) or through modulation of aromatase. These chemicals have been proposed to promote adipogenesis (adipocyte number and/or size) through modulating signaling pathways, or through stimulation of mesenchymal stem cells to preadipocytes, and maturation of preadipocytes into adipocytes (Garcia-Arevalo *et al.*, 2014).

Today's children and adolescents are immersed in both traditional and new forms of digital media. Research on traditional media, such as television, has identified health concerns and negative outcomes that correlate with the duration and content of viewing. For example, television viewing, daily duration of viewing, and particularly viewing during evenings after evening meals, are all associated with higher weights and the development of obesity even in young children. Over the past decade, the use of digital media, including interactive and social media, has grown, and research evidence suggests that these newer media offer both benefits and risks to the health of children and teenagers. Risks of such media include negative health effects on sleep, attention, and learning; a higher incidence of obesity and depression; exposure to inaccurate, inappropriate, or unsafe content and contacts; and compromised privacy and confidentiality (Lipek *et al.*, 2015; Swinburn *et al.*, 1999).

Epidemiology

Current and projected obesity rates (BMI $\geq 30\ \mathrm{kg\ m^{-2}}$) in the adult population of the United States are 20% for the year 2000, 30% for the year 2015 and over 40% for the year 2025. The Bogalusa heart study found that 22% of the children surveyed in 1990 had a body mass index greater than the 85th percentile established in a similar survey conducted in 1980. There was little change in the cohorts of children with a BMI less than the 50th percentile. In contrast, there was a large increase in BMI in the cohorts with a BMI greater than the 50th percentile. In summary, over time, obese children have a tendency toward even more excessive weight.

It has become clear that childhood obesity has reached epidemic proportions in all industrialized countries. The current age-adjusted prevalence may be as high as 20%–35% (Zhang *et al.*, 2012).

Interestingly, in industrialized countries such as in Sweden, France, Germany, and Australia, the prevalence of obesity in young children is plateauing or even declines, however, obesity prevalence in adolescents still increases throughout the world. There is indeed a global trend of stabilizing prevalence rates of childhood obesity at a high level in highly developed countries and add important information for individual age groups why the obesity epidemic in adults seems to even accelerate. Approximately 60%–85% of obese children of school age will stay obese in adulthood. The prevalence of overweight and obesity in children has increased continuously in developing and poor countries. Obesity is found in parallel with malnutrition and undernutrition in the same population in different social strata but in some countries even within the same social class (Sundblom *et al.*, 2008, Blüher *et al.*, 2011).

Comorbidities and Consequences

Sequelae of primary childhood obesity include hypertension, dyslipidemia, and psychosocial problems. A more complete list of comorbidity disorders is shown in **Table 3**. These disorders which arise from overweight and subsequent biochemical changes actually predispose to additional comorbidity such as cardiovascular disease in early adulthood. These comorbidities represent a major health burden in industrialized societies (Colditz, 1999). In addition, childhood obesity seems to increase the risk of subsequent morbidity whether or not obesity persists in adulthood. It is, therefore, mandatory to carefully examine all obese children in respect to the presence of comorbidity even at a young age. Such examinations should include blood pressure monitoring and checking of lipid status (**Table 4**). The opinion of orthopedic surgeons and child psychiatrists should be sought

Table 4 Comorbidity of obesity in childhood and adolescence

Psychosocial—psychiatric
Poor self-image
Social isolation
Autoaggression

Legg-Calve-Perthes disease
Back pain
Dermatological
Paronychia
Akanthosis nigricans
Striae rubrae

much more frequently than is being done so currently. Most importantly, type 2 diabetes, which until recently had been considered a disorder of the older population, is being increasingly recognized in children and adolescents especially in children of African–American and Hispanic ethnicity. In fact, during the last decade type 2 diabetes has been diagnosed with increasing frequency in adolescents and even young children. The clinical picture in these children and the fact that most affected patients come from families with type 2 diabetes mellitus have led physicians to conclude that affected children will respond to the same treatments used in adults and that clinical courses will be similar to those described in adults (Körner *et al.*, 2012).

The prevalence of the metabolic syndrome in obese children is reported to be 30%, irrespective of the definition applied. Insulin resistance may eventually lead to type 2 diabetes and therefore represents one of the most clinically relevant comorbidities of obesity. Hyperinsulinemia is found in approximately 30% of obese children and adolescents indicating insulin resistance and glucose intolerance. There is a strong relation between cardiorespiratory fitness and markers of insulin resistance. It is interesting to note that maintenance and/or improvement of cardiorespiratory fitness prevents the development of insulin resistance. Type 2 diabetes develops in obese children with Asian, Hispanic, and Afro American ethnic background, while in white subjects, type 2 diabetes in the obese usually only develops after age 10 years.

The formation of atherosclerosis starts at an early age. For this atherosclerosis forming process serum lipids are seen as crucial risk factors. The prevalence of dyslipidemia in children and adolescents from 0 to 16 years in Germany is 6%–22%. In a study from Brazil, which, however, included young adults aged 23–25 years only, a significant ($P < .05$) influence of the social status on total cholesterol, LDL and HDL cholesterol described. Higher HDL concentrations and lower triglyceride levels are usually recorded in children and adolescents with higher social status. Accordingly, children with lower social status would be exposed to a higher cardiovascular risk (Reich *et al.*, 2003; Körner *et al.*, 2007).

There is also a higher prevalence of orthopedic conditions such as joint and back pain in overweight and obese children than in lean subjects. Increased joint and back pain is commonly reported by overweight children, with decreases in physical activity. Overweight children typically display a slower, more tentative walking pattern with increased forces to the hip, knee, and ankle during "normal" gait. On the other hand, the association between obesity and various musculoskeletal disorders such as slipped capital femoral epiphysis and Blount disease is well reported. Recent evidence suggests an increased association between obesity and musculoskeletal pain and increased fracture risk due to decreased bone mineral content and impaired bone structure.

Nonalcoholic fatty liver disease, NAFLD, due to obesity is the most common form of liver disease in children age 2–19. Its prevalence has more than doubled over the past 20 years. The prevalence of NAFLD in children and adolescents reaches from 3% to 11% and is strongly influenced by age, sex, race, and ethnicity. In obese children, the prevalence ranges from 38% to 80%. The prevalence of NAFLD is highest in American Hispanics (45%), medium in Caucasians (33%), and lowest in African–American (24%). In Europe, Australia, and the Middle East the prevalence ranges from 20% to 30%, which is comparable to that reported from Japan, China, Latin America, and India (Calle *et al.*, 1999).

In 2004 the International Diabetes Federation (IDF) published a definition of the metabolic syndrome in adults which defined hypertension, dyslipidemia, glucose intolerance and abdominal obesity as constituents of the syndrome. This cluster of risk factors is related to the development of cardiovascular diseases and type 2 diabetes. Metabolic syndrome does not only occur in adults but has also been described in children and adolescents. The term metabolic syndrome is applied if a child has abdominal obesity, high blood pressure, abnormal blood lipids, and disturbed glucose/insulin metabolism (Weiss and Caprio, 2005).

An increased prevalence of urogenital infections including bacterial infections of the kidney and nonspecific cystitis as well as fungal infections of the preputium or vulva (vulvovaginitis; balanitis) has been suggested in obese subjects when compared to the prevalence in lean children. In addition, outcomes of renal disease are thought to be less favorable in obese and overweight children than in normal weight young subjects. Polycystic ovarian syndrome is characterized by ovarian cysts, very frequently obesity, and hyperandrogenism. Pseudoprecocious puberty is thought to be misdiagnosed in obese girls.

Many cross-sectional analyses, as well as longitudinal studies, have examined the association between markers of adipocity and pubertal development. In addition, the putative impact of an increased fat mass upon reproduction and fertility both in human obese males and in male animal models of obesity has been studied: a trend toward earlier pubertal development and maturation in obese individuals of both sexes has been shown, and the previously held notion that obese boys might progress to puberty at a slower pace than their nonobese peers can no longer be substantiated. Secondly, impaired fertility markers and reduced reproductive functions have been observed both in obese humans and in animal models of obesity. Low sperm counts and reduced sperm function have been reported in obese men (Wagner *et al.*, 2012).

It is hypothesized that the emergence of a "pandemic" of childhood obesity may have been a major driving force for earlier maturation in both genders. There is still much debate regarding the true impact of childhood obesity on testicular development in boys (Toppari and Juul, 2010) (**Table 5**).

Genetic variants may also directly account for a link between obesity and pubertal timing. Variations in LIN28B, a human ortholog of the gene-regulating processing of micro-RNAs was recently reported to be associated with timing of puberty in humans. Genetic variation in LIN28B was associated with earlier voice breaking and more advanced pubic hair development in boys. Many additional studies also indicate that the timing of pubertal onset is under strong genetic control (Aksglaede *et al.*, 2009) (**Table 5**).

It has become clear that there are a number of common psychological consequences associated with childhood obesity. A systematic search shows that overweight and obesity at a young age is negatively associated with psychological comorbidities, such as depression, poorer perceived lower scores on health-related quality of life, emotional and behavioral disorders, and self-esteem during childhood. However, evidence related to the association between attention-deficit/hyperactivity disorder (ADHD) and

Table 5 Hypothetical mechanisms of how obesity might affect onset and tempo of pubertal development and sexual functions

Common genes linking energy metabolism and puberty
Nutritional factors (protein, sugars)
Energy supply (calories)
Adipocytokines (signalling)
Insulin/insulin-like growth factor effects (i.e., on ovary)
Nicotinamide phosphoribosyltransferase (NAMPT), and other enzymes providing increased amounts of energy to gonads

obesity remains unconvincing because of contradictory findings from different studies. Overweight children are more likely to experience multiple associated psychosocial problems than their healthy-weight peers, which may be adversely influenced by obesity stigma, teasing, and bullying. Obesity stigma, teasing, and bullying are pervasive and can have serious consequences for emotional and physical health and performance especially in children and adolescents.

All individuals are subject to multiple risk factors for mortality. There are many interactions between certain major socio-demographic and behavioral risk factors associated with all-cause mortality. In principle, there are two forms of interaction between risk factors, additive and multiplicative relations. Usually, expectations about interactions among socio-demographic variables, and their relation to behavioral variables, have been stated in terms of additivity and/or of multiplicatively. Therefore, the nature of interactions among the five major risk factors associated with all-cause mortality: smoking, obesity, race, sex, and educational attainment have to be seen as a complex multifaceted interaction. Obesity has been found to be additive with each of the remaining four variables. These traits, established at birth or during childhood, literally result in deadly combinations. Adolescent BMI, including values within the currently accepted "normal" range, strongly predicts diabetes mortality up to the seventh decade. In light of the worldwide increase in childhood obesity, the association between body-mass index (BMI) in late adolescence and death from cardiovascular causes in adulthood has been investigated: Data on BMI, as measured from 1967 through 2010 in 2.3 million Israeli adolescents (mean age, 17.3 $\pm$ 0.4 years), were grouped according to age- and sex-specific percentiles from the United States Centers for Disease Control and Prevention. Primary outcomes were the number of deaths attributed to coronary heart disease, stroke, and sudden death from an unknown cause, or a combination of all three categories (total cardiovascular causes) by mid-2011. Hazard ratios in the obese group ($\geq$95th percentile for BMI), as compared with the reference group in the 5th to 24th percentiles, were 4.9 (95% confidence interval [CI], 3.9–6.1) for death from coronary heart disease, 2.6 (95% CI, 1.7–4.1) for death from stroke, 2.1 (95% CI, 1.5–2.9) for sudden death, and 3.5 (95% CI, 2.9–4.1) for death from total cardiovascular causes, after adjustment for sex, age, birth year, socio-demographic characteristics, and height. Thus, overweight and obesity are strongly associated with increased cardiovascular mortality in adulthood.

The financial burden of childhood obesity for industrialized societies can only be estimated. The annual economic costs due to medical expenses and lost income as a result of complications of adult obesity is approximately $70 billion in the United States. At least another $30 billion are thought to be spent on diet foods, products and programs to lose weight. If one is to calculate the prospective costs of obesity forms that have started at an early age, the prospective financial costs are even higher. On the other hand, it is almost too ironic to state that sales and profits of the obesity treatment industry have already reached an enormous sum. Therefore, obesity in childhood and adolescence has already become a major factor in health-care planning systems and within the health-care industry as such (Colditz, 1999; Cohen-Cole and Fletcher, 2008).

Treatments and Medical Management

Any metaanalysis on the efficacy of treatment of obesity and even more so on the prevention of overweight and obesity at a young age has failed to show large effects of treatment and/or prevention strategies. Barriers to participate and obstacles to access treatment and prevention programs are but one reason for the failure of therapeutic and preventive strategies in the long term. Very often families with an obese child will have little educational and socioeconomic resources and even will sometimes completely fail to understand the importance and or relevance of treating childhood obesity. In addition, very often the affected child will have obese family members whose obesogenic environment and lifestyle will ultimately influence the child's environment and lifestyle. Since in many cases the comorbidities of obesity are not felt at a young age, there is little individual and personal incentive to change habits and or unhealthy lifestyles. Lastly, if one is to live with obese peers, the motivation to lose weight or change one's unhealthy behavior will be very limited indeed (Alff *et al.*, 2012).

Therapeutic strategies have so far included psychological and family therapy interventions, lifestyle/behavior modification and nutrition education (**Table 5**). The role of regular exercise and exercise programs is emphasized. Intermittent exercise (high intensity followed by low intensity sports) may result in greater reduction in weight and body fat mass. Such approaches also increase compliance/adherence rates of the youths. Multidisciplinary outpatient treatments are considered to be the most effective treatment strategy (Ebbeling *et al.*, 2002).

Repeated dieting with intermediate weight loss and weight gain and even with cycling of body weight does not lead to solid weight loss and sustained weight maintenance but might even be harmful both in respect to higher weight in the end and increasing the likelihood of comorbidities even further. Reducing high fructose and high sucrose intake does indeed maintain a healthy body weight. Reducing the consumption of sugar-sweetened soft drinks is thought to add to any obesity treatment concept. Snacking has been found to be associated with the development of obesity both in the individual and in societies in general. Therefore, to organize food intake at infant and school age in a way that breakfast, lunch and dinner are eaten together in the family or community setting and be there only a small snack be it fruit or vegetable in the morning and one in the afternoon helps to structure the day.

No single behavioral or environmental intervention for the obese child can possibly be effective on its own. There have been numerous attempts to identify the optimal psychological intervention and namely behavioral modification techniques to treat obesity even at a young age. Taken into account that no behavioral therapy can intervene with the environmental, societal, socio-demographic, genetic, and biologic causes of childhood obesity it is not surprising that all such attempts have been proven quite unsuccessful. In addition, barriers that prevent families and obese children to participate in behavioral and also multidisciplinary treatment programs are still not fully identified nor understood.

In Cochrane reviews by which putative positive factors from which one might extract effective means to treat childhood obesity have been identified, it has become apparent that approaches targeting both the family and the community setting are the most promising strategies for treating and preventing childhood obesity. It seems that the individual needs peer or family support to change a potentially obesogenic lifestyle and adhere to a healthy way of living. Mixed and multi professional and interdisciplinary approaches to treat childhood obesity are cumbersome to carry out, costly and only marginally successful: in the long term success is usually small with changes in BMI SDS of not more than—0.2 SDS being seen in most studies (Walther *et al.* 2009).

Bariatric surgery has become an effective option as a last line treatment for severe obesity in adults. In the United States bariatric interventions are now the most commonly undertaken surgical procedures. In adolescents and young adults much less data is available as to safety and effectiveness of bariatric surgery and whether or not such procedures do add to treatment options for this age group. Weight and BMI reduction are uniformly lower for gastric banding as compared to gastric bypass or sleeve gastrectomy. Large scale long-term observations are still missing and this prohibits a final conclusion about lasting effectiveness and safety at the present time. Laparoscopic adjustable gastric banding is being increasingly considered to be the treatment of choice in very obese adults. Early complications of such interventions and significant late complications such as pouch dilatation and stomach slippage have been reported. Whether or not such invasive treatment options will ultimately be considered in children is still open to debate (Lennerz *et al.*, 2014).

Long-term treatment of childhood obesity probably also including extended pharmacotherapy may be necessary for the majority of very obese adolescents. **Table 6** lists some drugs used in obesity management in adults. At the present time, two of these, orlistat and sibutramine, are increasingly being used in obese adults. Orlistat binds to gastrointestinal lipases and causes a partial inhibition of fat reabsorption from the gut. In contrast, sibutramine causes a centrally mediated increase in satiety and energy expenditure. It is of great concern that some of these drugs are being found to be prescribed to youngsters by primary care physicians upon parental request (own observations) outside any scientific follow-up studies and without careful and systematic follow-up (Heymsfield *et al.*, 1999).

Children with type 2 diabetes who are acutely ill are treated with insulin. Some of these children will have to b transitioned to oral antidiabetic agents. Safety and efficacy of these have not been established for children and adolescents. The only drug currently approved for therapy of children with diabetes is insulin. Even less is known about therapy in children with comorbid conditions which frequently accompany type 2 diabetes mellitus. There are no guidelines for what therapy to use or when to

Table 6 Drugs that could potentially be used in obesity management in children and adolescents

Drugs approved for the use in adult obesity in some countries at some time:
Sibutramine
Phentermine
Mazindol
Diethylpropion
Orlistat
Drugs under development:
Leptin and leptin analogues
Brain and gut peptide agonists or antagonists
MC4-receptor peptide agonists
NPY-Y1 or—Y5 antagonists
Galanin receptor antagonists
Orexin receptor antagonists
Alpha1-receptor agonists
Beta2-receptor agonists

(*Note*: most of these are not recommended/licensed for use in children!).

employ it for such important states as hyperlipidemia and hypertension. Very recently, a multicenter trial of metformin use in children with type 2 diabetes mellitus has been completed in the United States.

Prevention

There are at least three reasons to focus not only on individual characteristics when planning or implementing interventions against obesity.

(1) Complex problems need complex solutions. The reasons for obesity are multidimensional. Consequently, preventing or treating obesity needs multidimensional strategies focusing on different levels of influence (individual, familial, institutional, and environmental).
(2) Environmental changes are possible, effective, and sustainable. Individual or family characteristics such as socio-economic position, family habits, and health behavior are difficult to change on a long term by person-based educational programs. Changes at the environmental level (e.g., changes in food supply in schools, more physical activity in school—during lessons or breaks) are relatively easy to apply but have the potential to change individual behaviors as well as attitudes sustainably.
(3) Environmental or community approaches may reach those who are really in need. "Traditional" interventions that focus on individual behaviors have failed to reach those population groups that are at the highest risk (individuals with low socio-economic status). Interventions that promote environmental changes have the potential to influence those who are "hard to reach" (Lipek *et al.*, 2015).

As prevention has to start very early in life and perhaps even before postnatal life, a population and community approach for prevention seems to be the most promising and reasonable. Primary prevention has proven to be difficult or impossible in most societies at this point in time. Again, a multidisciplinary team approach is asked for to develop and secure preventive strategies. Good nutrition and modest exercise for pregnant women as well as monitoring of intrauterine growth of the child are mandatory. After birth, rapid weight gain should be avoided and principles of good nutrition and physical activities should be taught at all ages. Breast-feeding should be strongly recommended. Children's food choice can be influenced by early intervention and guidance. Parents should be encouraged to make healthy foods easily available to the child and serve these foods in positive mealtime situations in order to help their child to develop healthy food habits. Joint actions by physicians, health authorities and politicians both in the community and also using modern media and mass media are being asked for to implement nation-wide prevention programs. Such programs have to take into account cultural and racial preferences and attitudes in respect to food preparation and eating habits. Most importantly, food industries have to take up their responsibilities and should be made to stop marketing unhealthy foods and advertising to children and adolescents (Ludwig *et al.*, 2011)!

Obesogenic environments are "the sum of influences that the surroundings, opportunities, or conditions of life have on promoting obesity in individuals or populations." They comprise a resident's aggregate socioeconomic status (SES) as well as aspects of their social and physical environments. Evidence suggests that children living in low SES areas are more often overweight or obese. Regarding the physical environment, three domains that may influence obesity have been identified: (1) facilities for physical activity (i.e., parks, playgrounds, sports clubs that promote active play, and sports); (2) land use and transportation (i.e., mixed land use, walkability, access to public transport or walking/cycling paths that facilitate active commuting to school/work); and (3) foodscape (availability of healthy or unhealthy food). In this sense it was reported that fewer resources for recreation (e.g., parks, playgrounds), sports or active commuting (street connectivity, land-use-mix) and a high density of fast food outlets are related to overweight and obesity in children and adolescents. Summing up, the development of overweight and obesity during childhood is a result of complex mechanisms at different levels of influence (individual, social, environmental) (**Fig. 1**). There are various theoretical environmental factors that can be targeted for prevention strategies (Lipek *et al.*, 2015).

The potential role of intestinal microbiota in the etiology of many human diseases has attracted a lot of attention. The intestinal microbiota has been suggested to be an important factor for the development of obesity and obesity-related metabolic dysfunction. The distal human intestine represents an anaerobic bioreactor programmed with an enormous population of bacteria, dominated by relatively few strains that are very diverse at the strain/subspecies level. It is now partially understood how certain members of the microbiota function as to maintain the stability and functional adaptability of the microbial organ. This might suggest that microbiome-targeting approaches may help to prevent and even treat obesity in early life.

Access to playgrounds, restrictions on food marketing for children, low prizing of healthy food stuffs and changes in food supplies in cafeterias, walkability of living quarters and the planning of cities altogether all have to be considered if one is to seriously prevent childhood obesity on a large scale. Green areas should be interspersed in living quarters and free access to pedestrian zones should be ensured. There is a large quantity of research that indicates how cities should be developed to support healthy lifestyles especially in the young. However, since in most countries there is no legislation that secures such developments most city dwellings are developed following financial incentives of investors rather than scientific reasoning (Huang *et al.*, 2015).

In some countries advertisements targeting children and youngsters is already forbidden and may be punished by law. However, there is still food advertising targeting children in many areas of the world. In many instances large sums are invested by food industries to invent the most clever and attractive way to seduce children. Sugar sweetened beverages are but one example how children are falsely educated to consume too many calories and too many carbohydrates. In addition, food industries are

good at diluting the evidence that indeed sugar-rich beverages and foods are not healthy and contribute to the obesity epidemic by placing advertisements in physician's journals and many other media. Bans of advertising for tobacco have shown the way to go for the food industry: after tobacco advertising was banned on a large scale and cigarettes were taxed heavily both the number of smokers and the prevalence of lung cancer have declined dramatically. Taxes on unhealthy foods be it fat- or sugar-rich have been implemented in Denmark and the United Kingdom (Livingstone *et al.*, 2006).

Conclusions

The amount and nature of adipose tissue of a child at which morbidity acutely and/or later in life increases is determined on an actuarial basis. Direct measurements of body fat, for example hydrodensitometry, bioimpedance, or DEXA, is only useful in a research context. In contrast, body mass index (BMI) is easy to calculate and is widely accepted to define obesity in children and adolescents clinically and for practical purposes. An increased risk of death from cardiovascular disease in adults has been found in subjects whose BMI had been greater than the 75th percentile as adolescents. Childhood obesity seems to also substantially increase the risk of subsequent morbidity whether or not obesity persists into adulthood. The genetic basis of childhood obesity has been elucidated to a large extent through the discovery of leptin, and the increasing knowledge on the role of neuropeptides such as POMC, neuropeptide Y (NPY) and the melanocyte concentrating hormone receptors (for example, MC4R) and the discovery of FTO as an obesity risk allele. However, environmental/exogenous factors largely contribute to the development of a high degree of body fatness early in life. Twin studies suggest that approximately 50% of the tendency toward obesity is inherited while 50% are related to socioeconomic and life style factors. There are numerous disorders including a number of endocrine disorders (Cushing syndrome, hypothyroidism, etc.) and genetic syndromes (Prader–Labhard–Willi syndrome, Cohen and Alström syndrome, Bardet–Biedl syndrome, etc.) that are associated with an increased body fat mass. Usually, a simple clinical diagnostic algorithm allows for the differentiation between primary or secondary obesity. Among the most common sequelae of primary childhood obesity are hypertension, dyslipidemia, impaired insulin sensitivity, back pain and psychosocial problems such as behavior problems, exclusion from social participation and attention deficit hyperactivity and depression. Therapeutic strategies include psychological and family therapy, lifestyle/behavior modification and nutrition education. The role of regular exercise and exercise programs has to be emphasized. Surgical procedures and drugs used in adult obesity are still not generally recommended in children and adolescents with obesity. As obesity is the most common chronic disorder in industrialized societies, its impact on individual lives as well as on health economics has to be recognized more widely. Finally, one should aim to increase public awareness of the ever increasing health burden and economic dimension of the childhood obesity epidemic that is present around the globe. It is clear that we have to strengthen our efforts in respect to investigate prevention and interventions that will work both on an individual and a societal level. The questions that are to be asked are the questions that need to be answered in order to improve quality of life of patients, reduce suffering from the disease, and increase the survival of patients and importantly to increase our chances to successfully prevent obesity at an early age.

It is now well known that obesity is the most common chronic disorder in industrialized societies. In some countries, the prevalence of obesity in childhood and adolescence has become higher than that of the allergic disorders including both asthma and eczema. As has been said, childhood obesity is associated with substantial comorbidity and late sequelae. While diagnostic strategies are clear and straight forward, treatment remains difficult and frustrating both for the patient, family and the multi-disciplinary team caring for children with obesity. In conclusion, much more attention should be given to prevention and the development of preventive strategies at all ages. Prevention should, in any case, start very early in life possibly during pregnancy and fetal life. New drugs are being developed that promise to be useful for treatment and secondary prevention. However, no data are available for the use of such agents in childhood and adolescence. This notion also applies to the treatment of type 2 diabetes mellitus and comorbid conditions that frequently accompany type 2 diabetes and/or obesity in children and adolescents. Finally, public awareness of the ever increasing health burden and economic dimension of the childhood obesity epidemic has to be asked for and also has to be insisted on repeatedly and constantly. Political measures have to be taken to ensure and enable healthy lifestyles at an early age and to combat the financial interest of industries that may harm children's health.

Appetite and Weight

Clare H Llewellyn, University College London, London, United Kingdom
Alison Fildes, University of Leeds, Leeds, United Kingdom

Introduction

In 2016, worldwide there were over 340 million children and adolescents aged 5–19 with overweight or obesity (Ezzati *et al.*, 2017; WHO, 2017). In the same year, the number of infants and young children (aged 0–5 years) with overweight or obesity reached 41 million globally (WHO, 2017). If current trends continue, the figure is expected to reach 70 million by 2025. Overweight and obesity in childhood tend to persist into adulthood (Simmonds *et al.*, 2016), putting those children at greater risk of developing related chronic diseases later in life (Abdullah *et al.*, 2011; Lobstein *et al.*, 2004; Must *et al.*, 1992; Park *et al.*, 2012). Understanding the mechanisms behind the etiology of obesity in early life is therefore essential.

The rapid increases in population weight observed over recent decades have been widely attributed to changes in lifestyle. The modern environment is often referred to as "obesogenic," because it encourages excessive weight gain through offering readily available low-cost energy-dense and palatable foods, discouraging physical activity, and promoting sedentary behavior. For many people the modern food and activity environment leads to positive energy imbalance (more energy is consumed than is expended) and, consequently, weight gain and obesity. However, this is not the outcome for everyone; some people are more susceptible to the "obesogenic" effects of the environment than others. In fact, body weight varies enormously in the population, and stark differences can often be seen even between siblings growing up in the same household. The source of variation in susceptibility to obesity in a seemingly pervasive "obesogenic" environment has been of great interest to researchers. Studying individual differences in body weight can shed light not only on the causes of obesity, but also on the key factors that bestow resilience to it.

We know from nearly a century of twin and family studies that variation in human body weight has a strong genetic basis, with 50%–90% of population variation being attributable to genetic differences between people (Elks *et al.*, 2012; Maes *et al.*, 1997). In fact, body mass index (BMI) is as heritable now – following the obesity epidemic – as it was prior to its onset (Rokholm *et al.*, 2011). What is more, since the advent of genome-wide association studies at the turn of the 21st century, more than a hundred common genetic variants (in the form of single nucleotide polymorphisms, SNPs) have been identified that are robustly associated with variation in BMI (Locke *et al.*, 2015). Our genetic endowment explains *why* some of us develop obesity, and others do not, while all seemingly living in the same "obesogenic" environment. But the question remained, *how* do genes "determine" our weight?

The Behavioral Susceptibility Theory of obesity (BST) hypothesizes that genes influence weight through appetitive mechanisms. In short, it hypothesizes that inherited differences in appetite cause people to respond differently to the opportunities to eat offered by the modern food environment (Llewellyn and Wardle, 2015). At the heart of this theory is the idea that there are large and measurable individual differences in appetite that confer greater or lower risk of obesity, and that appetite is genetically determined. BST can help to explain how weight can be *both* genetic and environmental at the same time; it proposes that obesity arises from a combination of genetic susceptibility to overeating, and exposure to an "obesogenic" environment that both encourages and permits positive energy imbalance. Evidence for the validity of Behavioural Susceptibility Theory has come from studies demonstrating: (i) large individual differences in appetite from early in life; (ii) appetite prospectively predicting early weight gain; and (iii) strong genetic influence on appetite from early life. This chapter describes the evidence base for Behavioural Susceptibility Theory, and its implications.

Appetite and Weight in Adults

The role of appetite in obesity has been studied for well over half a century, but early research focused largely on adults because, until recently, obesity was rare in children. During the 1960s an innovative scientist called Stanley Schachter ran a series of imaginative laboratory-based experiments in which he compared the eating behavior of obese and healthy weight adults (Schachter, 1968, 1971). He observed that participants with obesity were much more responsive to the external cues of palatable food (such as the sight, smell or taste) than healthy-weight participants, insofar as they would eat considerably more of the foods that were good tasting and attractive, than lean controls. He also observed that participants with obesity were less responsive to their internal sensations of satiety, failing to demonstrate the same level of compensation as their healthy-weight peers when presented with a meal that had been preceded by an energy-dense snack (called a "preload"). This indicated adults with obesity were either less sensitive to their internal feelings of fullness, or were overriding them and continuing to eat when the food on offer was highly palatable. On the basis of his observations Schachter developed "externality theory." He proposed that there are two key aspects of appetite regulation that vary greatly between individuals, and play a key role in susceptibility to obesity: food responsiveness – wanting to eat (or eat more) in response to the sight, smell and taste of palatable food; and satiety

 doi:10.1016/B978-0-12-801238-3.65829-4

sensitivity – the amount of food needed to provide a satisfying level of fullness. Arguably, Schachter's "externality theory" of obesity is of even greater salience in the modern obesogenic environment. The abundance of low-cost, energy-dense and palatable foods places food responsive individuals at high risk of overeating and weight gain, especially if they are not protected by strong satiety sensitivity.

Schachter was certain that there was a biological basis to obesity. He hypothesized that these aberrations in appetite regulation were likely to be caused by problems in the central control of appetite, regulated primarily by the ventromedial hypothalamus. Externality theory therefore proposed that obesity was somewhat innate, hardwired, and rooted firmly in biology.

At around the same time that Schachter was developing "externality theory," Kaplan and Kaplan were developing the Psychosomatic Theory of obesity, which focused on the psychological or emotional drivers of eating. They proposed that some individuals overeat to reduce anxiety, and it is this "emotional eating" that is responsible for the hyperphagia (excessive appetite) that causes obesity (Kaplan and Kaplan, 1957). They suggested that individuals with obesity are not able to discriminate between the physiological arousal caused by negative emotional states (e.g. feeling anxious, stressed or depressed), and hunger; which results in eating in response to emotion in the absence of physiological hunger. The central idea was that emotional eating may be the result of classical conditioning in early life – if negative emotions are always paired with consumption of palatable food (for example, if parents feed their child in order to soothe them, so-called emotional feeding), a classically-conditioned hunger response will eventually develop in the context of negative emotion. Schachter had also proposed that obese adults eat more than healthy weight controls under conditions of stress, but his theory was different (Schachter *et al.*, 1968). He suggested that healthy weight individuals eat *less* when anxious, which is the normal biological response to stress. On the other hand, the appetites of adults with obesity were abnormal in not being obliterated by negative emotion. Either way, both theories hypothesized that differences in food intake between obese and normal weight adults would be more marked in states of heightened emotional arousal, and highlighted emotion as a regulator of eating.

Early research set the stage by highlighting a great deal of variation in three key features of appetite – food responsiveness, satiety sensitivity and emotional eating. As interest in these appetitive traits began to grow, self-report psychometric measures were developed, which allowed researchers to measure different eating styles in very large numbers of participants, using a standardized tool. The first questionnaires to be developed were the "Three Factor Eating Questionnaire" (TFEQ) (Stunkard and Messick, 1985), and the "Dutch Eating Behaviour Questionnaire" (DEBQ) (Vanstrien *et al.*, 1986); the Adult Eating Behaviour Questionnaire (AEBQ) was developed very recently (Hunot *et al.*, 2016). Aside from the cost benefit of questionnaire measures over traditional laboratory-based testing, they also enable habitual eating behavior to be characterized across many contexts, as well as over time. While the objectivity and detail offered by direct observation is compromised, psychometric measures arguably capture enduring appetitive "traits" rather than the more transitory "states" of hunger or satiety manifested during an experimental situation. Decades of subsequent research with much larger samples of adults supported the early laboratory-based findings that individuals who are more food responsive and who have a tendency to overeat in response to emotion tend to carry more body fat (French *et al.*, 2012). Satiety responsiveness has been under-researched among adults in comparison, because the older questionnaires did not measure it. However, the newly developed AEBQ has shown that adults with weaker satiety have a higher BMI (Hunot *et al.*, 2016; Mallan *et al.*, 2017).

As the appetite model of obesity gained traction, researchers became increasingly interested in establishing the cause-effect relationship between appetite and weight. However, the vast majority of adult studies were cross-sectional, partly because obesity often develops before adulthood and is usually well established by middle- and older age; making it difficult to design studies that capture the transition from healthy weight to obesity during adult life. Cross-sectional studies cannot determine if differences in appetite are the cause of obesity, or if obesity itself causes abnormalities in appetite. Further complications arise when studying adult participants with longstanding obesity, which can cause abnormalities in the biology controlling appetite regulation (such as resistance to the effects of the satiety hormone leptin). Added to this is the fact that overweight adults are often dieting, and so may have altered their eating behavior in order to control their weight. A more insightful approach to understanding the relationship between appetite and weight is to measure them in children. The added benefit of studying younger children, in particular, is that they are too young to have had longstanding obesity with all of its complications, and they are less likely to be dieting.

Appetite and Weight in Children

Historically, the greatest concern in relation to pediatric weight was not obesity, but weight faltering (insufficient weight gain over a period of months) and underweight. As such, the few early studies of child appetite focused on characterizing the eating behaviors of those who were "failing to thrive" (Drewett *et al.*, 2003; Garcia *et al.*, 1990; Parkinson *et al.*, 2004; Wright *et al.*, 2000). The key behavioral features were poor appetite (lack of hunger), a slow eating speed, and pickiness (being highly selective about the foods one is willing to eat). However, the emergence of the childhood obesity crisis in the 21st century turned the spotlight on the role of appetite in the development of pediatric *overweight*. In 2001, Professor Jane Wardle developed the first comprehensive psychometric measure of children's appetitive traits, with the aim of characterizing the eating behaviors of children from across the weight spectrum – from underweight to obese. The Child Eating Behaviour Questionnaire (CEBQ) (Wardle *et al.*, 2001) enabled a broad range of appetitive traits to be measured reliably in large samples of children, providing the opportunity to discover if appetite was implicated in the development of both under- and overweight as they start to emerge. As children are unable to report

on their own eating behavior, the CEBQ is completed by parents. Parent-report is necessarily subjective and vulnerable to bias, but the CEBQ has been successfully validated against objective measures of children's eating behavior (Carnell and Wardle, 2007).

Wardle was interested in finding out if children with obesity demonstrated the same distinctive eating styles that Schachter observed among obese adults, and fewer of the behaviors that characterized children with weight faltering. Seven food-related appetitive traits can be broadly grouped into those hypothesized to play a causal role in overweight - "food approach" behaviors - and those thought to protect against overweight - "food avoidant" behaviors. The "food approach" behaviors include two scales measuring responsivity to food cues; "food responsiveness" is the tendency to want to eat in response to palatable foods (e.g. "even if my child is full up, s/he finds room for his/her favourite food"), and "enjoyment of food" is the pleasure a child gains from eating (e.g. "my child enjoys eating"). A third "food approach" scale measures the tendency to overeat in response to negative emotions "emotional overeating" (e.g. "my child eats more when worried"). Higher scores on these scales indicate a more avid appetite.

The "food avoidant" behaviors include two measures of responsivity to internal satiety cues; "satiety responsiveness" measures a child's response to feelings of fullness (e.g. "my child gets full before his/her meal is finished"), and "slowness in eating" captures eating speed under the premise that slower eating allows time for biological satiety mechanisms to take effect (e.g. "my child takes more than 30 min to finish a meal"). A third scale measures "emotional undereating," which is the tendency to undereat (as opposed to overeat) in response to negative emotions (e.g. "my child eats less when upset"). Higher scores on these scales are considered indicative of better appetite control, and very high scores indicate a poorer appetite. The "food fussiness" scale measures a child's tendency to be highly selective about the foods he or she is willing to eat, capturing both refusal of unfamiliar foods (termed "neophobia," e.g. "my child refuses new foods at first") and rejection of foods based on properties such as texture and taste, regardless of their familiarity (e.g. "my child is difficult to please with meals"). Because fussiness is a common characteristic among children who fail to thrive and may offer some protection against overweight (de Barse *et al.*, 2015; Drewett *et al.*, 2003; Dubois *et al.*, 2007), it tends to be grouped with the other "food avoidant" behaviors.

The first large-scale population-based study of appetite and adiposity using the CEBQ was conducted in 10,364 children aged eight to 11 years old from Twins Early Development Study (TEDS) (Carnell and Wardle, 2008). This study showed that children with a higher BMI or waist circumference scored higher on the "food approach traits" and lower on the "food avoidance" traits. Children with a lower BMI or smaller waist circumference showed the reverse pattern. Importantly, these appetitive traits were related to differences in bodyweight across the *whole adiposity spectrum* – not only did these appetitive traits distinguish obese, healthy weight and underweight children, but they explained smaller differences in weight among children within the healthy range. Crucially, the obese and underweight children weren't behaving in odd or unusual ways; they simply had much larger and poorer appetites than the children who were of a healthy weight. The CEBQ has been translated into multiple languages and has been widely used to study the appetites of many thousands of children across several continents (including Europe, North America, South America, Australia and Asia) (Demir and Bektas, 2017; Domoff *et al.*, 2015; Jansen *et al.*, 2012; Mallan *et al.*, 2013; Nasreddine *et al.*, 2017; Sanchez *et al.*, 2016; Spence *et al.*, 2011; Steinsbekk and Wichstrom, 2015; Tay *et al.*, 2016). A large body of cross-sectional research has now accumulated, supporting the hypothesis that children with a more avid appetite carry more body fat, and are more likely to be overweight or obese, while those with poorer appetites carry less body fat and are more likely to be underweight.

Research has also shown that appetitive traits are relatively stable from early to late childhood, although appetite regulation generally worsens with age for all children. In 428 children from the TEDS cohort, the CEBQ tracked strongly from 4 to 11 years of age, indicating continuity across time at the level of the individual (Ashcroft *et al.*, 2008). This suggests that appetitive traits are already firmly established by 4 years of age, raising questions about their origin – nature or nurture? At the same time, scores for the "food approach" traits increased with age, and those for the "food avoidance" traits decreased, such that children on the whole became more appetitive – more food responsive, enjoyed food more, emotionally overate more, ate faster, became less satiety sensitive and were less likely to emotionally undereat. This pattern of change suggests that children are at increasing risk of overeating and weight gain as they get older. This may reflect increasing autonomy to express their individual appetite. For example, a child will not be able to show a tendency to overeat highly palatable foods until they gain the independence necessary to do so. This trait may therefore be less salient among young children whose access to these foods is controlled largely by their parents.

Like the early studies in adults, research with the CEBQ highlighted that children vary considerably in their appetite, and that individual differences in appetite help to explain why some children are overweight, and others are underweight. However, the cause–effect relationship was still unclear; appetite can cause differences in early weight gain, but a child's appetite might also reflect their varying energy needs that are programmed by their growth. Prospective designs are needed to show that variation in appetite precedes the development of obesity over time, rather than the other way around. In addition, very little was known about the appetites of infants. Given that rapid infant weight gain is one of the most important risk factors for child and adult obesity (Matthews *et al.*, 2017; Ong *et al.*, 2000), understanding the role of appetite in early postnatal growth was of great interest to researchers. Prospective data *from birth* was therefore needed to shed light on the relationship between appetite and weight as it first starts to emerge in early postnatal life.

Appetite and Weight in Infancy

In 2007, Wardle and colleagues established Gemini (van Jaarsveld *et al.*, 2010), a large population-based prospective birth cohort of 2402 British families with twins. Gemini is the largest study ever undertaken into the origins of infant appetite and the role that appetite plays in early weight gain. The weights and heights of up to 4800 twin children have been collected every 3 months since the study began, making it one of the richest growth datasets in the world. The appetites of the twins were measured during the first few weeks of life, and again when they were 16 months and 5 years of age. Detailed records of their food intake were also collected over 3 days when they were 21 months old, in order to characterize their "everyday" eating patterns; this represents the largest contemporary dietary dataset for toddlers in the United Kingdom.

In order to study appetite in the period before solid food is introduced, the CEBQ was adapted so parents could report on their infant's milk feeding behavior. The Baby Eating Behaviour Questionnaire (BEBQ) (Llewellyn *et al.*, 2011) captures four different aspects of infant appetite during the period of exclusive milk feeding, which correspond to dimensions of children's appetite: "food responsiveness"; "enjoyment of food"; "satiety responsiveness"; and "slowness in eating."

Gemini was the first study to examine the bidirectional, prospective relationships between appetite and weight, and explored the associations from 3 to 15 months in a subsample of 2213 infants. The key finding was that the association between BEBQ-measured appetite at 3 months and subsequent weight gain (from 3 to 15 months) was stronger than the reverse association between weight at 3 months and subsequent change in appetite (from 3 to 15 months) (van Jaarsveld *et al.*, 2011). This strongly supported the hypothesis that variation in appetite drives early weight, not the other way around. However, the possibility of residual confounding in samples of unrelated individuals means that other unmeasured factors could in fact be responsible for the observed association.

Comparing the weight gain in twins discordant for early appetite provides a more stringent test of causality than studying appetite and weight gain in unrelated children, because all environmental factors shared completely by twin pairs (e.g. maternal weight, maternal diet, ethnicity, and socioeconomic status) are controlled for. A second study used this approach in Gemini to strengthen the hypothesis that differences in early appetite cause differences in early growth. The growth trajectories from birth to 15 months of age were compared for same-sex twin pairs ($n = 172$) who were considerably discordant for appetite (by at least 1 SD) at 3 months of age (van Jaarsveld *et al.*, 2014). The twins with more avid appetites (characterized by higher food responsiveness and lower satiety responsiveness) grew significantly faster than their co-twins with poorer appetites. By the time they were 15 months old there was a 1 kg difference in weight between twin pairs, which equated to a substantial 10% difference in body weight. A subsequent Singaporean study of 210 singleton infants replicated these findings, demonstrating that infants with a more avid appetite, characterized using the BEBQ, grew more rapidly over the first 2 years of life (Quah *et al.*, 2015).

Together these studies offer convincing evidence that variation in infant appetite plays a causal role in early weight gain, providing strong support for Behavioural Susceptibility Theory. However, the question of *how* appetitive traits lead to overeating, and therefore excessive weight gain remained. This is important for intervention development. It is clear that children with a more avid appetite consume more energy, and those with a poorer appetite consume less, but the "everyday" behavioral expressions of food approach and food avoidance traits were largely unknown. The dietary data collected when the Gemini twins were 21 months old was used to characterize the eating patterns of toddlers who varied in measures of food responsiveness and satiety sensitivity at 16 months (Syrad *et al.*, 2016b). These two appetitive traits were characterized by distinct patterns of overeating. Children who were more food responsive ate *more frequently* throughout the day (i.e. they had more eating occasions). The most food responsive toddlers consumed three extra meals per week, compared to the least food responsive; adding up to 540 extra calories per week, or 2340 extra calories per month (nearly two and a half extra days of food intake). In contrast, children with blunted satiety sensitivity did not eat more frequently but instead ate *larger portions* of food every time they ate. Compared to the most satiety sensitive children, those with the lowest scores consumed 37 cal more at each meal; this equated to 185 extra calories per day, 1295 extra calories per week, or 5627 cal per month (the equivalent of five and a half extra days of food intake). In the current "obesogenic" environment it makes sense that children who are highly responsive to the sight or smell of foods will eat more often in response to the food cues they inevitably encounter throughout the day. At the same time, it is perhaps unsurprising that children with weakened sensitivity to feelings of fullness will eat larger portions of food given the opportunity; because they take longer to feel sated, or require a larger amount of food. A follow up study demonstrated that average meal size was a more important driver of early weight gain (between the ages of two and five) than eating frequency (Syrad *et al.*, 2016a); highlighting the need for vigilance with children's portion sizes.

Observing large individual differences in appetite so early in life indicated that appetite might have a genetic basis, in line with Behavioural Susceptibility Theory. However, this view was at odds with the widespread belief among researchers and health professionals that all infants are born with a natural ability to adequately self-regulate their milk intake if allowed to do so. The nature and nurture of infant appetite was something that Gemini was well-placed to establish, because a twin cohort is a genetically sensitive design.

Genetic Influence on Appetite

Twins can be used to quantify the relative importance of genetic and environmental influence on variation in any measured trait. The basis of the twin method is to compare resemblance between identical twins (monozygotic, MZs) who are 100% genetically

identical, with that between nonidentical twins (dizygotic, DZs) who share approximately 50% of their segregating genes. Because both types of twins share their environments to a very similar extent (e.g. they grow up in the same household and are of the same socioeconomic status, etc.), any difference in resemblance can only be attributable to genetic differences. Greater similarity in appetite between MZ pairs compared to DZs pairs therefore indicates a genetic contribution to appetite, and the larger the difference in resemblance the greater the genetic influence. The statistic derived from twin studies is called "heritability" which estimates the proportion of variation in a trait (i.e. appetite) that is explained by genetic differences in the population studied. Heritability can range from 0% (genes play no role in variation in a trait) to 100% (variation in a trait is entirely explained by genes). Twin studies also separate out the contributions of different sources of environmental influence. The "shared environment" includes aspects of the environment that twin pairs share completely, which contribute to their within-pair similarity (e.g. socioeconomic status); the "unique environment" captures factors that are unique to each individual twin (i.e. unshared with their co-twin, such as an illness affecting only one twin in a family) as well as random measurement error, which contribute to differences within pairs. The twin design can also be extended to examine the extent of common genetic and environmental etiology underlying multiple traits.

Gemini was the first study to establish the genetic and environmental influence on infant appetite, in the first 3 months of life, during the period of exclusive milk feeding. Heritability was substantial for all BEBQ-measured appetitive traits: "enjoyment of food" (53%); "food responsiveness" (59%); "satiety responsiveness" (72%); and "slowness in eating" (84%) (Llewellyn *et al.*, 2010). A follow-up study in Gemini quantified the extent to which appetite and weight share a common genetic architecture at 3 months of age (Llewellyn *et al.*, 2012). Approximately one third of the genetic influences underlying appetite and weight were the same, suggesting that genes are influencing weight partly through the biological mechanisms that regulate appetite, in line with Schachter's early proposition half a century ago.

These findings demonstrate that in the earliest period of life, variation in appetite is strongly genetically determined, not learned. By virtue of their genes, some children are born with more avid appetites and lower self-regulatory ability placing them at increased risk of excess weight gain. While these findings provide convincing support for Behavioural Susceptibility Theory, they contrasted with the prevailing view that infants are born with the ability to regulate their milk intake perfectly, if fed responsively to hunger and satiety. In fact, these findings suggest that infants are not born on a level playing field; some are naturally much better at regulating their food intake than others, by virtue of their genetic endowment.

Wardle and colleagues had also explored the heritability of "enjoyment of food" and "satiety responsiveness," captured using the CEBQ, in a very large sample of 10-year-old twin children ($n = 5435$ pairs) from TEDS (Carnell *et al.*, 2008). In line with the estimates for infants, heritability was substantial for both "enjoyment of food" (75%) and "satiety responsiveness" (63%) indicating that genes play an important role in shaping these aspects of appetite in later childhood as well. When the Gemini children were older, the etiology of other appetitive traits measured by the CEBQ were also established. Variation in food fussiness (in relation to familiar foods) as well as neophobia (rejection of novel foods) were found to have substantial genetic underpinnings at 15 months (46% and 58% respectively) (Smith *et al.*, 2017). However, in stark contrast to all other appetitive traits, emotional over- and undereating were almost entirely shaped by the shared environment. Genes contributed very little (7%) to variation in the tendency to either emotionally over- or undereat in response to stress at 5 years of age (Herle *et al.*, 2017). Instead, aspects of the environment shared by twins (e.g. parental feeding strategies) explained variation in emotional eating in childhood. These findings suggest that the four traits enshrined in both the BEBQ and CEBQ all have a strong genetic basis, along with food fussiness; but emotional eating has a distinct etiology and is entirely learned during early life.

Molecular genetic research has shed more light on the relationship between appetite and weight. In particular, many of the BMI-associated common genetic variants (SNPs) appear to influence adiposity via appetitive mechanisms. The fat mass and obesity associated gene (FTO) was the first SNP to be discovered (Frayling *et al.*, 2007), and explains the largest amount of variation in BMI of all the variants identified to date. On average, adults (of average height) who carry two copies of the high-risk FTO variant (AA) weigh approximately 3 kg more than those who carry two copies of the low-risk variant (TT). Shortly after the discovery of FTO, Wardle and colleagues used data from the TEDS cohort to show that 10-year-old children ($n = 3337$) who carried at least one copy of the lower risk variant (TT or AT) scored significantly higher on the CEBQ satiety responsiveness scale than those carrying two copies of the high-risk variant (AA) (Wardle *et al.*, 2008). Furthermore, this effect remained after adjustment for BMI, suggesting that FTO influences body weight via appetite. A second study in a subsample of the same cohort ($n = 131$) replicated this finding using a behavioral measure of satiety sensitivity conducted when the twins were 5 years old (Wardle *et al.*, 2009). These findings were confirmed in a third unrelated study of 97 Scottish four to 10 year olds, where children carrying the high risk A allele ingested more energy-dense foods at a test-meal following a preload of food, than did the children not carrying the A allele (Cecil *et al.*, 2008).

FTO is not the only common genetic variant shown to confer a predisposition to obesity through the regulation of energy intake. A more recent study from the TEDS cohort ($n = 2258$) demonstrated that a composite genetic risk score comprising 28 BMI-associated variants (other than FTO), was also associated with CEBQ-measured satiety responsiveness at 10 years of age (Llewellyn *et al.*, 2014). Satiety sensitivity significantly mediated part of the association between genetic risk and adiposity, confirming that many of the obesity-related genetic variants identified so far influence adiposity partly via mechanisms that regulate appetite.

Together, the findings from twin and molecular genetic studies strongly support Behavioural Susceptibility Theory. However, this field of research is not without its critics. The main concern is that genetic research of any kind undermines the personal responsibility necessary to manage our own or our children's health, and can lead to fatalism. This criticism is fueled by a common

misconception that behaviors under strong genetic influence cannot be changed or modified. Genes are not "the whole story" when it comes to complex behavior, especially appetite. A strong genetic influence means some individuals are born with a *predisposition* to have a more avid appetite, but the extent to which genes are expressed is almost certainly dependent on environmental exposure. A commonly used example is the genetic predisposition to lung cancer. Even people born at higher genetic risk of lung cancer are unlikely to develop the disease unless they smoke. The same is true of appetite. A child predisposed to overeat by virtue of his or her genes will only gain weight in an environment that enables them to do so. To this extent, the environment may act as a volume control for genetically-determined behavior. George Bray put it well when he said: "Genes load the gun, but the environment pulls the trigger." (Bray, 1996).

Moreover, although most appetitive traits have a substantial genetic basis in infancy and childhood, they are not *entirely* genetically determined. In fact, considerable environmental influence was identified for many of the traits (Herle *et al.*, 2017; Llewellyn *et al.*, 2010; Smith *et al.*, 2017). In particular, the tendency to emotionally over- or undereat in response to stress is entirely shaped by early environmental experiences (Herle *et al.*, 2017). For this particular trait, aspects of the environment shared by twins (e.g. parental feeding strategies) are responsible for the development of emotional eating in the preschool years. These findings highlighted the sizeable contribution of the family environment to certain aspects of appetite development in early life.

Environmental Influence on Appetite

Perhaps unsurprisingly, of all potential external shapers of children's appetites, parental feeding practices have received the most attention. Feeding practices of particular interest are parents' use of pressure to encourage their child to eat, excessive restriction of the types or amount of food their child consumes, and the use of emotional feeding (feeding to soothe). Historically, the assumption has been that parental feeding practices causally influence child appetite and weight gain, raising the risk of overweight or underweight by undermining the child's ability to self-regulate their food intake (Birch and Fisher, 1998; Birch *et al.*, 2003; Costanzo and Woody, 1985; Johnson and Birch, 1994). Restricting a child's access to certain foods is thought to lead to the "forbidden fruit effect," whereby the child develops an even greater desire for the restricted food and eats more of it when it subsequently becomes available. Pressuring a child to eat could either cause them to override their internal satiety cues and overeat, or conversely lead to mealtime anxiety and even food aversion. While using food to food to soothe an unhappy child is thought to nurture emotional overeating.

Cross-sectional studies have supported some of these hypotheses. In particular, several studies have demonstrated a positive relationship between parental restriction and child weight (Johnson and Birch, 1994; Shloim *et al.*, 2015). Greater parental pressure to eat has sometimes been associated with lower child body weight, although findings have been equivocal (Shloim *et al.*, 2015). In addition, studies exploring the relationship between parental feeding and child appetite have found restriction to be associated with stronger food approach appetitive traits (e.g. food responsiveness), while pressure to eat has been linked with food avoidant traits (satiety responsiveness, slowness in eating, and food fussiness) (Webber *et al.*, 2010).

While it has been suggested that parental pressure or restriction might play a causal role in the development of children's eating behaviors, much of the evidence is also consistent with a child-responsive model of parent feeding. Parents vary their levels of pressure and restriction in line with characteristics of their child from very early in life, even during the period of exclusive milk feeding (Fildes *et al.*, 2015; Gross *et al.*, 2011). Gemini mothers ($n = 1920$) were found to use more pressure when their infant was 3 months old if they had a lower birth weight or smaller appetite, and were more likely to restrict when their infant had a larger appetite (Fildes *et al.*, 2015). This indicates that infant characteristics influence mothers' feeding practices from the offset. Twin studies have also been used to untangle the complicated relationship between parent feeding and children's appetite. A study of 1012 pairs of twin toddlers from Gemini, of whom 247 were discordant in food fussiness, found that mothers pressured their fussier toddler more than their less fussy co-twin (Harris *et al.*, 2016); indicating that parents adapt their feeding practices in response to the different characteristics of each child. The discordant twin design is powerful because it controls for other potentially confounding environmental factors shared by siblings in a family, but longitudinal studies provide a better indication of the likely direction of the relationship between parent and child behavior.

Recent longitudinal analyses of other large European birth cohorts have demonstrated bidirectional relationships between children's appetitive characteristics and parental feeding practices. A study of emotional feeding and emotional eating in 801 Norwegian 4 year-olds, followed up at ages 6, 8, and 10 revealed a reciprocal relationship; higher levels of parent emotional feeding predicted greater child emotional eating over time, and vice versa (Steinsbekk *et al.*, 2017). Longitudinal analyses also assessed the directionality of the relationship between fussy eating and parental pressure to eat in 4845 mother-child dyads from the Generation R cohort in the Netherlands, when the children were 3–6 years old (Jansen *et al.*, 2017). The findings suggested parental pressure was a reactive feeding strategy developed in response to children's fussy eating, but the relationship was also bidirectional indicating parental pressure exacerbated child fussy eating. A second longitudinal study in the same cohort explored the relationship between parental restriction and child BMI (Derks *et al.*, 2017). Child BMI at age four was found to predict parents' use of restrictive feeding practices at age 10, but parental restriction at 4 was not associated with increases in child BMI over time, suggesting parental restriction is primarily adopted in response to – rather than a cause of – child overweight.

Randomized controlled trials offer a more stringent test of the causal effect of parental feeding practices on children's appetite, than prospective studies. There is evidence that providing parents with anticipatory guidance on positive feeding practices may result in improved appetite regulation in younger children. The NOURISH randomized controlled trial successfully reduced

parents' use of nonresponsive feeding practices (including pressure and restriction), resulting in children being less food responsive, and more satiety sensitive 3 years after the intervention (Magarey *et al.*, 2016). However, the intervention failed to impact on children's levels of food fussiness, suggesting not all appetitive traits are equally amenable to an early life parent feeding intervention.

Taken together, these findings suggest a reciprocal relationship between child appetite and parental feeding. Children's heritable appetitive traits seem to "elicit" certain feeding strategies from parents. Children are not simply passive recipients of their parents" chosen feeding practices. At the same time, children do not direct or shape all aspects of parent feeding, and research suggests that parents' feeding strategies can influence the development of their child's appetite. However, the extent to which parent feeding practices or child characteristics can be considered the key driver of this relationship likely depends on the domains being measured and the age of the children in question.

Implications and Conclusion

Over the last half a century researchers have made great headway in showing the importance of appetite for risk of both over- and underweight, especially among children. Appetite has a strong genetic basis and appears to be a key mechanism mediating genetic risk of obesity. This has important and far-reaching implications for both policy and clinical practice. When it comes to appetite control not everyone is born equal. In the context of the modern food environment some individuals will be "battling their biology" from early in life, and will find it harder than others to maintain a healthy weight. The current food environment exploits these vulnerabilities because it encourages overeating. Behavioural Susceptibility Theory would suggest that changes to the food environment that support those who are genetically susceptible to overeating would make a meaningful impact on obesity rates. For example, reducing palatable food cues (such as food advertising) and portion sizes may be effective in supporting individuals with high food responsiveness and low satiety sensitivity. Regulatory actions from policymakers and increased efforts from industry are necessary to enforce wider environmental changes, but such measures are often not well supported by the public. The research on feeding practices also suggests a few key points for parents. The natural parental response to a child with a poor appetite seems to be coercion and pressure, and for a child with an avid appetite, excessive restriction. However, these may not be the most fruitful strategies in the long run, and may nurture an already poor or voracious appetite. Responsive feeding of the type promoted in the NOURISH trial appears to support the development of good appetite regulation, and would provide parents with better alternative feeding practices. What is clear is that the development of appetite is complex, and evolves through a combination of genetic expression and environmental experience.

Management of Obesity in Children and Adolescents: Lifestyle and Exercise Options

James D Nobles and Paul J Gately, Leeds Beckett University, Leeds, United Kingdom

Childhood overweight and obesity is a pressing issue across the world, with almost one in four children (males: 23.8%, females: 22.6%), aged 5–17 years old, being classified with overweight and obesity (Ng *et al.*, 2014). This represents a 47% increase since 1980 among this age group. Within the United Kingdom, the context in which this article is positioned, obesity affects one in five children, aged 10–11 years (NHS Digital, 2016). This estimate rises to one in three when figures include overweight (NHS Digital, 2016). The prevalence of overweight and obesity increases proportional to deprivation (NHS Digital, 2016), tracks strongly into adulthood (Simmonds *et al.*, 2016), leads to premature mortality (The Global BMI Mortality Collaboration, 2016), and has numerous health-, economic-, and social- ramifications. Recent data suggest that the global economic burden of obesity (2.8% gross domestic product [GDP]) comes third to smoking [2.9% GCP) and armed violence, war, and terrorism (2.8% GDP) (McKinsey Global Institute, 2015), costing the UK economy £27 billion per year (Foresight, 2007). In light of the evidence aforementioned and given that 80% of children with obesity are predicted to have obesity as an adult (Simmonds *et al.*, 2016), the need for both prevention and treatment of childhood obesity is paramount.

The Context of Weight Management in the United Kingdom

Although this article is placed in the context of England and the United Kingdom, it is anticipated that all topics discussed will be pertinent to those outside of this context. Indeed, it may be that other contexts share many similar characteristics with the UK context. The context must be considered when discussing the approach to treating obesity in the United Kingdom.

We begin this article from the viewpoint of the national health systems in the United Kingdom. Overseeing the health system and the budget of the health sector is the Department of Health and Social Care; a ministerial department within the British government. However, due to the varied demographics in the United Kingdom, a centralized system is not considered to be the best approach to account for differences across local geographic areas. As part of a significant health care reform in 2012, the national government devolved the responsibility for Public Health to Local Government Authorities (LAs: $n = 152$ across England) and Clinical Commissioning Groups (CCGs: $n = 209$ across England) (HM Government, 2012). These two bodies—alongside NHS England (who oversee the commissioning of specialist national health care services)—are responsible for the prevention and treatment of obesity in England.

Within England, the Obesity Care Pathway (**Fig. 1**)—a four Tiered approach to preventing and managing obesity—has been developed (Blackshaw *et al.*, 2014; Department of Health, 2013); each Tier being commissioned by one of the three bodies. The first Tier of the pathway focuses on the prevention of overweight and obesity, primarily through marketing campaigns, awareness raising, and knowledge building (e.g., "Change4Life" and "This Girl Can"). Tiers 2–4 are dedicated to obesity treatment. The

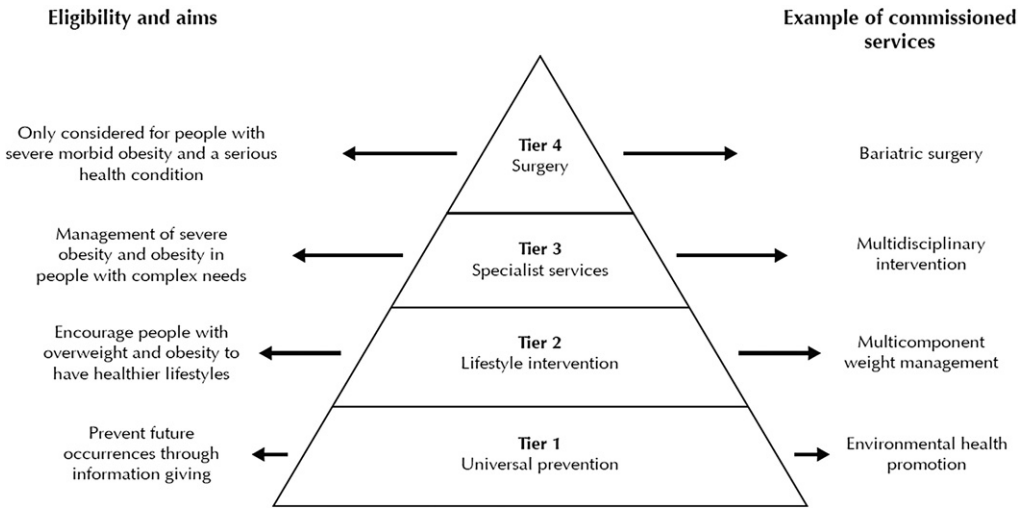

Fig. 1 The obesity care pathway. Adapted from the Department of Health (2013). Developing a specification for lifestyle weight management services: Best practice guidance for tier 2 services. London, UK: Department of Health.

pathway stipulates that more specialist treatment is provided in line with the greater degree and complexity of obesity, insofar that Tier 2 provides generic weight management (WM) advice for children with overweight, Tier 3 provides specialist intervention from a multidisciplinary team for children with obesity, and Tier 4 offers intensive treatment, residential camps, pharmacotherapy, and bariatric surgery for children with severe obesity (Nobles *et al.*, 2016b; Blackshaw *et al.*, 2014). This pathway is most notably referred to for the management of adult obesity, but it is frequently being implemented for childhood populations (Public Health England, 2015).

The aim of nonbariatric/nonpharmacological WM programs is to stabilize and reduce the weight of the child through education in lifestyle modification, dietary improvement, physical activity increases, and sedentary behavior decreases (NICE, 2013). These services often provide weekly, group-based intervention for families over a period of 10–12 weeks. Programs tend to be delivered by paraprofessionals (i.e., trained nonexperts), and conducted in a nonclinical format (NICE, 2013). Tier 3 services should utilize a multidisciplinary team (i.e., possibly a doctor, dietician, psychologist and an exercise professional) and may be clinically-based (Wright and Wales, 2016). Tier 4 nonbariatric services are residential in nature, providing an immersive experience for young people; with programs including camp-based models (i.e., more holistic approach) and hospital-based models (i.e., more clinical approach). Effectiveness of these WM programs is ubiquitously measured through mean change in standardized body mass index (BMI SDS), pre- to postprogram.

As may be evident here, the United Kingdom adheres to a medicalized model of care when aiming to treat obesity. The more severe an individual's obesity becomes, the greater the promotion of medicalized intervention. Epitomizing this are Tier 4 bariatric services; those which aim to alter the physiological functioning of the human body in order to bring about an energy deficit. The extent to which the Obesity Care Pathway accurately reflects the realities and needs of the children living with obesity shall be discussed at a later point in this article; where we speak to both the current UK service provision and also that which we believe is required in the future.

Given the burgeoning prevalence of obesity in England, the national government has made two public commitments to rally action against obesity (National Audit Office, 2006; HM Government, 2008). Yet despite such governmental prioritization of obesity, local level action is scant. In 2015, Public Health England (PHE: an executive agency of the Department of Health and Social Care) reported that 56% and 61% of LAs had a Tier 2 service for children and adults respectively (Public Health England, 2015). At Tier 3, PHE declared that insufficient information was available to generate conclusions—very few CCGs indicated having these services. This is despite estimates that there are 140,000 children with severe obesity and 2.5 million children with obesity (Ells *et al.*, 2015). The picture of service provision is further clarified when examining LA expenditure on WM programs. In the government's annual LA revenue expenditure reports (HM Government, 2016b)—when compared against the 2015/16 Public Health grant (£2.80b)—the total spend on prevention and treatment of obesity was £101.7 m (3.6%), with £40.4 m of that spent on children. This expenditure is in stark contrast to that on substance misuse (£767.3 m, 27.5%), sexual health (£631.1 m, 22.6%), and smoking cessation (£111.2 m, 4.5%) (**Figs. 2** and **3**).

Identifying Appropriate Treatment Options

When thinking about the management of obesity, it is imperative that the initial assessment considers the holistic health of the individual, as opposed to solely the consideration of their weight status. In adult cohorts, tools such as the Edmonton Obesity Staging System (Sharma and Kushner, 2009) can be used to understand the support- and need- requirements for those with obesity. This tool—which has been widely utilized—assesses physical symptomology (i.e., associated comorbidities), psychological symptomology (e.g., depression, anxiety, maladaptive eating practices, suicidal ideation), and functional limitations (e.g.,

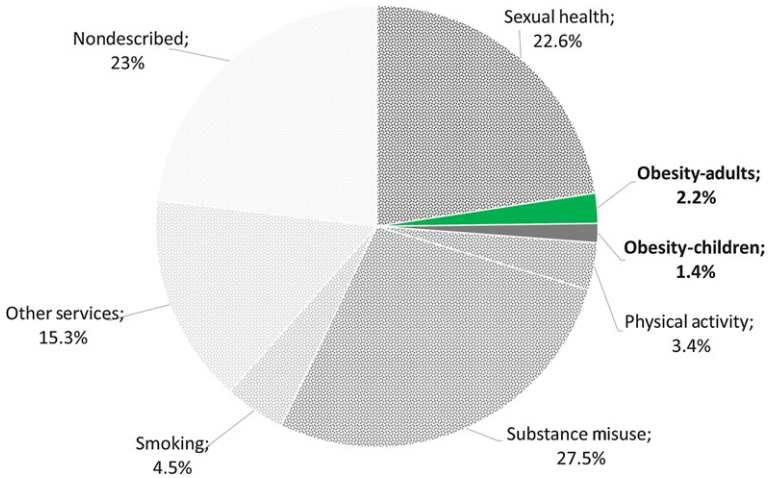

Fig. 2 Public health spend in England. Calculated as a proportion of the £2.8b Public Health Grant in 2015/16.

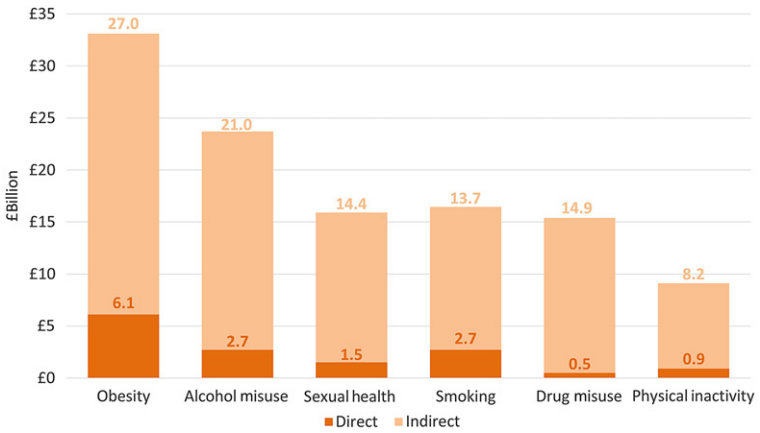

Fig. 3 Estimated cost of several public health issues in England.

ability to work, complete daily tasks, quality of life) of the individual. These tools can then help signpost adults to the most appropriate services, acknowledging that a "one-size-fits-all" approach is inadequate. Comprehensive tool such as the Edmonton Obesity Staging System are not yet available for young people, hence reporting of research and practice-based outcomes vary considerably.

In the United Kingdom, the National Institute for Health and Care Excellence (NICE) provide evidence-based guidance to help shape the delivery of the health and social care services. NICE have created a number of guidance documents to assist health professionals in designing effective WM programs (NICE, 2013; NICE, 2014; NICE, 2016). These documents state—for both young people and adults with obesity—that the complex needs of individuals should be assessed. However, how one defines "complex needs" is unclear. NICE suggest that assessments should consider presenting symptoms, eating behaviors, comorbidities, lifestyle factors, psychosocial factors, medical problems, the social environment, and readiness to change as a starting point for understanding complex needs (NICE, 2014). In children, these assessments are recommended for those with obesity as opposed to those with overweight—albeit that there is no empirical evidence to suggest why this is so. Dependent on the needs of the individual, the health professional can then look to refer the individual to a Tier 2, 3, or 4 WM program. Further work is needed to help health professionals ascertain a comprehensive picture of the individual—child or adult—in an efficient manner.

Treatment should—dependent on the outcome of these assessments—then be tailored to the individual needs of the individual. This could be achieved through the use of a Stepped Care Approach (Sharman and Nobles, 2016), where the intensity and specificity of treatment options is increased relative to the need of the individual. For example, at SHINE—a not-for-profit WM provider—an initial assessment of 1.5 h is undertaken with young people and their parents. The assessment considers some of the factors listed above, including anthropometric and physiological functioning (e.g., height, weight, blood pressure, peak flow, and medical history), and psychosocial symptomology (e.g., self-esteem, anxiety, depression, maladaptive eating practices, weight-related bullying, and self-harming). After determining the preferences of the individual, SHINE then offer individuals access to one of seven treatment options (Sharman and Nobles, 2016). Although this is one example of good practice, SHINE provides a Tier 3 service within the voluntary sector, and so their approach is not governed by those who traditionally commission WM programs.

Types of Weight Management

Whilst the Obesity Care Pathway lays out a four-tiered approach to WM, it is also important to note that there are various types of children's WM program. The review of Altman and Wilfley (2014) eloquently classifies a range of different WM programs. As aforementioned, the majority of programs aim to modify dietary intake, physical activity and sedentary behaviors through the use of behavior change strategies/techniques (Altman and Wilfley, 2014), however some have started to acknowledge the wider biopsychosocial factors associated with obesity. There are a myriad of ways in which these aims can be accomplished, and the effectiveness of the different types of program varies too.

The first element to note when differentiating between programs is the type of *family involvement*. Altman and Wilfley (2014) identify two types of program here, family-based behavioral treatment (FBT) and behavioral weight loss (BWL). The distinguishing factor is the extent to which goals are set for both parents and children. In FBT, specific goals are set for both parents and children, whereas in BWL goals are only set for one of these parties—often the child. FBT emphasizes that parents act as an agent for change, role modeling and advocating the behaviors they wish their children to make (Epstein *et al.*, 2014). There is however a third type of program to note associated with family involvement, parent-only programs (POP). The review of Altman and Wilfley (2014) included 14 POPs, some of which focused on the involvement of fathers only (Morgan *et al.*, 2014). The rationale for the POP being that parents can, independently, act as the change agent and modify the home environment—additionally making the

treatment easier to implement (Boutelle *et al.*, 2011; Ball *et al.*, 2017). Thus, the age of the child is a pertinent factor to consider regarding family involvement.

Treatment modality can also help to differentiate between programs. Modality, the method of administering treatment, can differ substantially. In the previous section, community-based (i.e., delivered by paraprofessionals in a local community venue) and clinically-based (i.e., delivered by multidisciplinary teams in a primary care setting/specialist facilities) WM programs were mentioned, as were group-based (i.e., delivered to more than one family at the same time) and individual-based (i.e., delivered to one family at a time) programs. In recent years though, additional modalities have started to form. Firstly, commercial WM programs have emerged as an option for children and young people—especially adolescents (Bonham *et al.*, 2017; Dordevic *et al.*, 2015; Stubbs *et al.*, 2012). Commercial programs are delivered by private sector organizations, providing their own WM guidance, and are popular among adult cohorts (Gudzune *et al.*, 2015). They provide a scalable alternative to clinical programs, whereby participants can pay to access said group-based services. Resources—such as meal replacements and prepackaged food—are often advocated by these providers. They rely fundamentally on the alteration of energy intake, thus not considered to be a holistic, multicomponent service (Gudzune *et al.*, 2015).

Residential WM camps (i.e., Tier 4 WM) are also another type of treatment modality. Camp models can be found in the United Kingdom (Holt *et al.*, 2005) and in the United States (Gately *et al.*, 2000), with hospital models also being common (Braet *et al.*, 2004; Endo *et al.*, 1992; Rolland-Cachera *et al.*, 2004; Wabitsch *et al.*, 1996; Widhalm *et al.*, 1983). Camp models tend to be holistic in nature, creating energy imbalance through dietary restriction and physical activity, however doing so within a social, fun-, and experiential environment. These programs are led by education professions with support from clinicians (Psychologists, Dieticians and exercise experts). Hospital-based models typically use a variety of dietary methods (including very low calorie diets and liquid diets), and tend to be led by clinical teams (Physicians, Psychologists, Nurses, and Dieticians).

The penultimate noteworthy WM modality is through interactive *m*-health or *e*-health programs (e.g., mobile applications, internet-based programs, tele-interventions). This modality also offers a wider dissemination in conjunction with flexibility around the timings in consuming information (Altman and Wilfley, 2014), alongside the easy setting, and real-time tracking, of goals/performance (Norliza *et al.*, 2014). Lastly is a self-help modality—whereby primary care physicians refer their patients to helpful WM resources (e.g., handouts, online materials, information) (Sharman and Nobles, 2016).

Focus is the final program characteristic to differentiate between types (Oude Luttikhuis *et al.*, 2009). Oude Luttikhuis *et al.* (2009) characterized WM programs into three broad groups, those with a focus on (1) diet only, (2) physical activity and sedentary behavior only, and lastly, (3) behavioral programs. Whilst there is a general consensus that multicomponent programs (i.e., focused on all three of the above) are preferred, a plethora of research and evidence exists for each of these program types. As spoken to earlier in this article, WM programs should seriously consider the wider biopsychosocial factor associated with obesity. Although very few children's WM programs exist like this, some services such as SHINE and MoreLife place a concerted effort on addressing these wider factors in their session content (Nobles *et al.*, 2016a; Nobles *et al.*, 2016b). Both provide a psychosocial intervention with dedicated program content focusing on the importance of social relationships, personal hygiene, stress management, dealing with bullying, and improving self-esteem (Hester *et al.*, 2010; Nobles *et al.*, 2016b). This program content is provided in equal measures to advice on diet and physical activity.

The involvement of family members, treatment modality and treatment focus are distinctive, observable elements of a WM program. But given that the aim of a WM program is to bring about changes in behavior, the active ingredients of a WM program lie within the behavior change techniques (Michie *et al.*, 2015). Behavior change techniques (BCT) are defined as "the smallest components compatible with retaining the postulated active ingredients (i.e., the proposed mechanisms of change)" (Michie *et al.*, 2015)—of which Michie *et al.* (2013) have identified a list of 93 in their most recent taxonomy, categorized into 16 groupings. These active ingredients—all of which are clearly labeled, distinct, irreducible and precise (Cane *et al.*, 2015)—include among others, goal setting and planning, social support, feedback and monitoring, covert learning, threats and rewards, and natural consequences (Michie *et al.*, 2013). The ability to identify these active components is dependent upon the clarity and depth of program reporting, for example in program protocols or via standardized reporting templates (e.g., TIDieR: Hoffmann *et al.*, 2014).

As can be deduced from the previous text, WM programs—particularly when studying their macro (e.g., modality) and micro (e.g., BCT) details—are heterogenous. This is without appraisal of the specific program content (i.e., information on diet), the treatment dose (i.e., intensity, duration and follow up), the wider context, the level of support, the characteristics of program delivery staff, and the use of adjunctive inputs (e.g., pharmacological intervention)—among others. There has been a substantial volume of research into the use of WM programs (and to a lesser degree, the study of BCTs) for the treatment of childhood overweight and obesity, but the effectiveness of these programs is yet to be discussed.

Effective Weight Management

The effectiveness of a WM program is often assessed against one primary outcome in both academic and Public Health arenas, a change in weight status (NICE, 2013; NICE, 2015; NICE, 2014; Altman and Wilfley, 2014; Department of Health, 2013; Roberts *et al.*, 2009; Oude Luttikhuis *et al.*, 2009; Upton *et al.*, 2014; Janicke *et al.*, 2014). Whilst the range of outcomes related to a change in weight status is vast (e.g., absolute weight, change in BMI percentage, percent overweight etc.…), the mean change in BMI SDS, from baseline to postintervention, is frequently utilized to measure the effectiveness (i.e., under real-world conditions) or efficacy

(i.e., under optimum controlled conditions) of children's WM programs (Upton *et al.*, 2013; NICE, 2013; Roberts *et al.*, 2009). The measure, BMI SDS, accounts for the child's age and sex, and subsequently enables the score to be compared against a reference population (usually national or international growth charts–see Cole *et al.*, 1995). Once the mean change in BMI SDS has been calculated for the WM program, the program effectiveness can be established by comparing the outcome against a benchmark.

Cochrane reviews create this benchmark; these reviews collate high quality research studies and pool their effects into an overall estimate. The most recent Cochrane review examines the efficacy of various pediatric WM program types (Oude Luttikhuis *et al.*, 2009). Behavioral interventions (i.e., those most closely aligned with multicomponent interventions) were included in the review, with the results separated into two childhood age groups (i.e., those <12 years or those ≥ 12 years). At 6 months, the pooled average reduction in BMI SDS for those attending a behavioral intervention targeting younger children was 0.06 units (95% CI: -0.12 to -0.01), whilst for those interventions targeting older children, the pooled average reduction was 0.14 units (95% CI: -0.17 to -0.12). And linked to the previous section, certain types of programs and those employing various BCTs—are more efficacious than others. Firstly, the Cochrane review established that combined behavioral interventions (i.e., *treatment focus*) were more efficacious than those with a single focus (e.g., diet only) and/or a self-help intervention—conclusions confirmed by van Hoek *et al.* (2014). The review of Altman and Wilfley (2014) goes further to suggest that FBT (9/10 studies efficacious) and POP (14/14 studies efficacious), as opposed to control interventions and BWL (4/10 studies efficacious), bring about greater weight-related change. Both FBT and POP have a multicomponent treatment focus and family involvement—with BWL only focused upon goal setting for children or parents independently.

Additional reviews of Janicke *et al.* (2014), van Hoek *et al.* (2014), and Whitlock *et al.* (2010) suggest that behavioral WM programs of moderate-to-high intensity (i.e., >26 h contact), in-person sessions, and one-to-one sessions (opposed to group-based) were more effective in evoking positive changes in weight status among children. Extending from the above, Hayes *et al.* (2015)—via a systematic review of evidence—concluded that mixed sessions (i.e., a combination of individual- and group-based sessions) demonstrated greatest efficacy. The age of the child, the degree of childhood obesity, and parental weight loss success are often moderating factors of program efficacy (Altman and Wilfley, 2014).

As for the active components of a WM program (i.e., the BCT), Martin *et al.* (2013) drew on the CALO-RE taxonomy (Michie *et al.*, 2011a) to investigate the BCTs included within 9 RCTs viewed as effective (≥ 0.13 unit reduction in BMI SDS; $n = 6$ trials) and noneffective (<0.13 unit reduction; $n = 3$ trials) in the management of childhood obesity. Although the study adopted an older version of the CALO-RE taxonomy (41 items rather than 93), six BCTS were found useful: (1) provide information on consequences of behavior to the individual, (2) environmental restructuring, (3) prompt identification as role model/position advocate, (4) stress management/emotional control training, (5) general communication skills training and (6) prompt practice. Additional reviews—whilst less robust—also suggest that goal setting, interactive sessions, social support, rewards/incentives, self-monitoring, and stimulus control are effective (Altman and Wilfley, 2014; Sahota *et al.*, 2010; Sutcliffe *et al.*, 2017). Sahota *et al.* (2010) stated that many BCTs come as a "package" rather than acting in isolation, yet notwithstanding this, Dombrowski *et al.* (2012) emphasized that programs with more BCTs may not necessarily generate better outcomes, and instead should carefully be selected. The interaction of combined BCTs are yet to be examined.

Whilst the examination of high-quality systematic reviews and meta-analyses are fundamental to understand the efficacy of WM programs, they tend to focus on studies of RCT design, predominantly delivered in a clinical setting. These RCTs do not reflect real-world commissioned WM programs that are delivered under service-level conditions (Service-level conditions: programs or interventions which are not conducted for the primary purpose of research. RCTs are highly controlled, and the conditions which they are carried out do not reflect real-world practices) and constrained budgets, and therefore these estimates may be less achievable. The reviews of Altman and Wilfley (2014), Upton *et al.* (2014), and Whitlock *et al.* (2010) include non-RCT study designs within their remit; with the review of Upton *et al.* (2014) being of particular pertinence. Upton *et al.* reviewed the change in BMI SDS for all community-based, family WM programs in the United Kingdom with published results ($n = 10$). The review illustrates that the effectiveness of WM greatly differs between programs; the change in BMI SDS (pre- to postmeasurement) ranged from -0.01 units (Rudolf *et al.*, 2006) to -0.18 units (Robertson *et al.*, 2008). Albeit that the SHINE program was not included in the review of Upton *et al.* (2014), a service evaluation of the psychosocial intervention demonstrated mean BMI SDS reductions of 0.19 units at 3 months, and 0.29, 0.35, and 0.41 units at 6, 9, and 12 months respectively (Nobles *et al.*, 2016b). Again, although not included in the review of Upton *et al.* (2014), in the context of Tier 4 residential WM camps, there is evidence for short and long-term effectiveness (Gately *et al.*, 2000). These differences in outcomes between WM programs are largely attributable to the various design, dose, delivery, and contextual characteristics of the WM programs—as detailed above.

NICE guidance not only provide information on how services can be designed, they also highlight what type of results are to be expected/should be promoted in WM programs. As aforementioned, there is a desire for WM programs to generate a mean reduction in BMI SDS. However, NICE recommends that childhood WM programs should encourage weight maintenance in the short term, rather than weight loss. (Given that BMI SDS is the primary measure of effectiveness, weight (i.e., kg) does not need to change in order to evoke a reduction in BMI SDS, providing that the individual is still growing. A WM goal that promotes a reduction in weight may be counter-productive—program effectiveness is measured based upon change in BMI SDS, whilst an individual is likely to measure their success based upon a change in weight). That said, this goal may not be appropriate for those who have either stopped growing or have severe obesity (BMI SDS ≥ 99.6th centile); a gradual reduction in body weight of 1 kg/month is recommended (Scottish Intercollegiate Guideline Network, 2010; Wright and Wales, 2016; NICE, 2006). With this in mind, any program which reports a mean maintenance in BMI SDS could be viewed as effective (for those with overweight or

obesity). This is without considering the wider outcomes that families, children, and parents may value when attending a program (e.g., self-esteem, friendships, confidence, quality of life)—this will be discussed later in this article.

Weight Maintenance

Although the chronic and relapsing nature of obesity in children and adults is well documented, the evidence base has been dominated by programs seeking short-term outcomes over 3–6 months. Seldom do we see, particularly in the childhood arena, programs that offer long-term support for weight maintenance. This is despite evidence from families that longer term support is wanted, as—after 12 weeks of intervention—many do not yet feel confident in their future WM endeavors (Nguyen *et al.*, 2015; Reece *et al.*, 2015). The presence of a maintenance/follow up intervention is reliant on the design of the WM program. Some WM programs include a maintenance intervention (Brennan *et al.*, 2012; Nobles *et al.*, 2016b; Spence *et al.*, 2017), whilst others do not (Jensen *et al.*, 2012; Sacher *et al.*, 2010). Maintenance interventions hope to shift the attribution of outcomes from WM services to families, with self-management of obesity being the promoted strategy (Nobles *et al.*, 2018).

The paucity of evidence for maintenance programs is exemplified in the recent systematic review and meta-analysis of van der Heijden *et al.* (2018). The review concluded that across the 11 included studies, continued treatment does have a stabilizing effect on BMI SDS. Furthermore, the review highlighted that whilst there was no evidence to recommend a certain program dose over another, face to face interventions were preferable over virtual intervention. Perhaps due to this lack of evidence, there is minimal guidance to support the development of effective maintenance programs.

Due to the study design of the SHINE article (Nobles *et al.*, 2016b)—a service level evaluation—it was not included in the review of van der Heijden *et al.* (2018). However, SHINE has a carefully designed one-year maintenance program aiming to equip families with skills for long-term WM (including mental health, social relationships, and enjoyment of physical activity). It is important to ensure that families do not become dependent on service provision (Reece *et al.*, 2015), and so SHINE seeks to ensure that families internalize outcomes as a product of their own efforts. A phased approach to weight maintenance—where the intensity of support reduces over time—may be useful, particularly as van der Heijden *et al.* (2018) found no difference in outcomes between maintenance programs of differing dose. As with other issues raised in this article, further research is warranted to facilitate our understanding of weight maintenance programs.

Implementing Weight Management: What Do Key Stakeholders Look for?

As we move from research and policy into practice, we must consider key stakeholder opinions in order to understand how the management of obesity is best delivered. Three stakeholder groups are of importance here: service users (i.e., individuals and families), service providers (e.g., MoreLife and SHINE), and service purchasers (i.e., commissioners). Not only would accounting for the opinions of key stakeholders influence the design of the WM program, but it also provides further insight into the complex realities of working in the sphere of WM.

Service Users

Qualitative studies have identified numerous non-weight-related outcomes which are valued by prospective WM participants equal to weight loss, including: reduced self-harm and depression; improved school results; social acceptance; making new friendships; learning to cook; reducing incidence of bullying; and, being more independent (Dixey *et al.*, 2006; Law *et al.*, 2014; Perez *et al.*, 2016; Jensen *et al.*, 2014; Reece *et al.*, 2015). These outcomes are seldom appraised in policy or by service purchasers, and as such, are rarely assessed formally. However, if policy makers and service purchasers begin to understand these valued outcomes and if WM programs are shaped to the needs of attending families, then higher attendance should be expected which brings about greater weight-related outcomes (Nobles *et al.*, 2017). Low participant engagement is an omnipresent challenge in WM—with approximately 50% of individuals completing the program to which they enroll (Nobles *et al.*, 2018)—and so strategies to mitigate against this should be emplaced.

These points also link back to the earlier conversation around complexity; as professionals working in the space of WM, we must seek to understand the factors which drive individual-level obesity and also understand the family motives for attending WM. We cannot assume that all children want to engage in WM programs to lose/manage their weight. In many cases, the decision to attend a WM program will have been made exclusively by the parent(s). Shared decision making, person-centered care, motivational interviewing and action orientated counseling are useful approaches to understand family preferences and to create a common agenda and shared goals (Cohen, 2016; Lucas *et al.*, 2014; McPherson *et al.*, 2017). For example, if the child, the parent, and the health professional set out their expectations in a preprogram assessment (e.g., what they think the program will include, what outcomes are important, how often they can attend), then a mutual agreement can be in place between all parties.

The final point to mention here is surrounding weight-related expectations in children's WM programs. Many children, parents, practitioners, and policy makers would expect a WM program to help a child and their family to *lose weight*. Linked to previous discussion, weight loss per se is not required to reduce BMI SDS (i.e., the primary objective of commissioned WM

programs) for children who have not reached complete maturation, and hence, weight loss should not be the promoted strategy. Weight maintenance may suffice to reduce BMI SDS and work towards a healthier body composition. Only if the child has stopped growing and/or has severe obesity should gradual weight loss (e.g., 1-2 kg/month) be considered. Expectations are powerful mediators of program engagement and must, therefore, be adequately managed; if a program does not elicit the expected outcomes, many families and children will find it difficult to continue attending. Thus, shared decision making is again a useful tool for health professionals to ensure that appropriate and realistic expectations are held by the participating child and parent.

Service Providers

As aforementioned, it is important for service providers to determine the biopsychosocial needs of young people when identifying the most appropriate treatment options. All services should shape the design of their programs around the unique needs of their clientele to optimize treatment outcomes for individuals and also for service commissioners. These services should therefore include an in-depth initial assessment to understand individual needs, albeit that a comprehensive and efficient tool is not yet available for young people. An appropriate theoretical framework(s)—such as the self-determination theory (Deci and Ryan, 1985) or COM-B (Michie *et al.*, 2011b)—will also be useful to underpin the WM service delivery model. Such models are rarely used adequately.

In addition, there are a plethora of implementation and logistic considerations to account for, including: settings (community-based, clinical, digital/virtual etc.…); program dose (program duration and session frequency); group-based versus one-to-one; ancillary tools (e.g., wearable monitors and mobile applications); staff to client ratio; recruitment and development of WM staff; development of program content; intervention components (e.g., BCTs); communication and marketing; service monitoring, evaluation and evolution; level of individual need (Tier 2–4); and, support for different group makeups (e.g., ethnic diversity, socio-economic status, physical/learning disabilities etc.…). As with other elements included within this article, whilst some guidance is available nationally (NICE, 2013; NICE, 2014; NICE, 2016) and internationally (World Health Organisation, 2016), it does not account for or provide recommendations on the considerations above. This continues to limit the standardized development and implementation of high quality services.

Furthering this call for comprehensive guidance is the need for regulatory bodies to monitor the quality of WM provision (excluding bariatric surgery and pharmacotherapy). Many organizations can—at least within England—establish themselves as WM providers; from individuals (with minimal training or qualifications) offering WM advice to specialist centers within clinical settings (with high levels of clinical expertise and governance). The absence of regulation leads to a dilution of service quality whilst increasing the pool of WM providers. In the context of the financial challenges faced by governments and healthcare systems in the United Kingdom and elsewhere, this issue becomes more salient. A study by Nobles *et al.* (2016a) highlighted a 37.5% decrease between 2009 and 2014 in the funding allocated per capita for those attending a WM program. In a market with little accountability and care quality standards, service provision can become more dictated by price rather than clinical or operational quality.

Service Purchasers

Whether they be local or national service purchasers, it is important to understand what purchasers look for when acquiring WM programs. More to the point, what constitutes an effective WM program through the eyes of those commissioning the services? Service purchases tend to focus on three factors: cost-effectiveness/cost; evidence-based results (i.e., change in main outcome measures); and the perceived political and public need for a program (Willmott *et al.*, 2015; Hughes, 2015; Law *et al.*, 2014; Masters *et al.*, 2017). Given the diminishing Public Health budgets due to austerity, a WM program must be cost-effective by ensuring that it delivers a return on investment (Masters *et al.*, 2017). Initial commissioning depends largely on having a substantial body of evidence to verify the program's claims of being *effective* (Willmott *et al.*, 2015; Law *et al.*, 2014). The view of service purchasers adds additional complexity; a program must be cost-effective and aligned to the political agenda—alongside having positive results.

As previously outlined, England has different government bodies responsible for different parts of the Obesity Care Pathway; Tiers 1–2 are traditionally commissioned by LAs, with Tier 3 being a CCG responsibility, and Tier 4 commissioned by CCGs and/or NHS England (Blackshaw *et al.*, 2014). Not only are these government bodies pursuing different outcomes, the standards or care (clinical governance), the use of the evidence base, and the political context varies considerably. For example, commissioning decisions made by LAs will be influenced by the political party leading local government (and the respective elected members) whereas the CCGs operate within a NHS governed system, albeit with its own measures of politics and strong emphasis on evidence-based practice. Given that CCGs are NHS governed, they are more likely to adhere to a medicalized model of care—as is emphasized through the Obesity Care Pathway; higher degrees of obesity requiring more specialized and multidisciplinary care.

Yet despite the amount of media and political attention that childhood obesity receives, alongside the well documented direct and indirect impacts on our society, local level action remains scant. A recent review illustrated that 56% of LA provide a Tier 2 WM service, and that insufficient evidence was available to determine the volume of Tier 3 services (Public Health England, 2015). There could be a variety of reasons for this:

- There is a lack of long term evidence for WM outcomes;
- There is a lack of clarity on which government sectors and bodies are best placed to tackle obesity;
- Obesity is not a "*burning platform*" issue—i.e., obesity is not perceived to have immediate impacts therefore politicians, civil servants and policy makers are not required to act in the short-term;
- Action on issues like obesity is considered by many as "*nanny state*" intervention;
- There is a lack of clarity on what benefits will be gained for which government sectors (i.e., who benefits as opposed to who finances).

This section presents the case for service improvement. If many of these considerations were taken forth into practice, the quality and accountability for WM provision should be enhanced. This will require a complete recognition of the needs of service users, service providers, and service commissioners. Adequate prioritization and resourcing is then needed by national and local governments to ensure that these enhanced services can be provided.

Where Next?

In light of the discussion within this article, it is important to consider what the future for childhood WM could look like. This final section presents two advocated next steps: (1) the conjoining of prevention and treatment efforts, and (2) doing so as part of a whole systems approach.

From Prevention vs. Treatment to Prevention and Treatment

A constant challenge in the Public Health arena is the assumed dichotomy of obesity prevention versus obesity treatment. Many stakeholders working in the field of obesity are often encouraged to pitch their tent in one of these two camps. From our standpoint and others, such dichotomies are unhelpful when aiming for healthier individuals and populations (Roberto *et al.*, 2015). As Roberto *et al.* (2015) alludes to, there are many important insights to be seen at the intersect of these dichotomies. We cannot expect treatment programs to be efficacious in the long-term if peoples' environments are not salutogenic. Nor can we expect a preventative approach to adequately support the needs of individuals already with overweight and obesity. If we can enable individuals to develop new attitudes, behaviors and habits which in turn bring about long-term WM *and* simultaneously create a salutogenic environment, then population change in weight is more likely. This salutogenic environment would both support those of a healthy weight and those who have accessed WM services. By appreciating that obesity is a chronic and relapsing condition, and one that is influenced by myriad socioecological factors, we must view both prevention and treatment within the context of a complex adaptive system. Singular interventions—be those prevention or treatment orientated—will not influence the prevalence of obesity alone.

Whole Systems Approaches

Progressions in the field of WM will be hampered if the environments to which people return remain unchanged. WM programs constitute only one part of what is referred to as a whole systems approach; a framework that enables stakeholders to come together and understand the complex adaptive system driving obesity (at the individual, community, social, and political levels), and then collectively identify places to alter the functioning of the system to bring about a healthier environment. WM programs aim to alter numerous elements of the causal system, but is insufficient on its own to tackle obesity. As we have highlighted throughout this article, obesity is a notoriously complex issue at all levels. Taking a whole systems approach to obesity will require the input of many stakeholders from across many sectors. Obesity is not just an issue for Public Health teams to solve; for example, Urban Planning teams can create health promoting environments, Transport teams can ensure that well connected infrastructure is in place to support active journeys, and Housing teams can provide high quality homes which are also well linked to local amenities and resources. Central to a whole systems approach is that these efforts are coordinated to achieve maximum effect. Our current systems are set up in a manner that promotes obesity—"Obesity is a normal response to an abnormal environment" (The Lancet, 2011)—and this needs to be altered.

Whole systems approaches are in the infancy in Public Health and within the Healthcare System more broadly. There is an opportunity through whole systems approaches to overcome the dichotomous perspective of prevention versus treatment. Rather, a whole systems approach recognizes and responses to the varied needs of individuals within the system. Therefore, preventative and treatment efforts are aligned so they are complementary and symbiotic—ensuring the right people get the right support at the right time. The collective impact of an aligned agenda will likely have the greatest impact on population-wide obesity prevalence (Gortmaker *et al.*, 2011; Peeters and Backholer, 2017; Swinburn *et al.*, 2011).

To exemplify one avenue for how this could be achieved in the United Kingdom, we can draw on the soon-to-be-introduced Soft Drinks Industry Levy (SDIL: HM Government, 2016a). As part of a national obesity strategy (HM Government, 2016a), the national government is going to implement the SDIL which will tax producers dependent on the volume of sugar per 100 mL in their offerings. The revenue (estimated at £500 m/year) generated via the SDIL will be used to support action on childhood obesity through schools. Schools currently receive approximately £10,000/year in the form of a School Sports Premium, a figure which

will be doubled based on the revenue of the SDIL (i.e., to £20,000). However, the guidance from the Department for Education (2017) on how to use the money is focused on the provision of school sport and physical activity. It does not state that it could be used to help tackle obesity.

In comparison to the £40m per annum that is invested in childhood obesity services, the anticipated £500 m per annum poses as a significant opportunity to help drive system change. If the School Sports Premium is doubled without the provision of adequate guidance for schools, then there is a real risk that this investment could make the current situation worse. If the premium is invested in sports equipment, facilities, and opportunities to take part in sport as per the guidance, then we may see children who are already active continuing to be active, and those who dislike sport and physical activity continuing to be so as well. This would widen inequalities rather than reduce them, and have a negligible impact on childhood obesity. A whole systems approach would understand where this money could be best placed in a school setting, and how additional actions could then support change within schools. For example, specialists could work with schools to utilize this money to create a salubrious whole school environment. Money could be invested to help teachers increase their knowledge, capability and capacity to help children with overweight and obesity—a role which is traditionally filled by Public Health teams in LAs. Work could also be done with school meal providers to improve the quality of their offer. Schools are under great pressures to achieve outcomes associated with literacy and numeracy, but what if health was also an outcome that was of equal importance? This too would be part of a whole systems approach.

One can see the logic in shifting some responsibility to other national and local government agencies (e.g., Department for Education), and supporting schools to increase sport and physical activity as part of the Childhood Obesity Plan. However, this thinking is narrow, naïve and linear and does not appreciate the complex adaptive system of obesity. Taking a whole systems approach has a great potential to focus attention on how to most effectively disrupt the system in a sustainable way towards the desired outcome.

Summary

Childhood obesity is one of the greatest challenges of this century. It can severely limit the lives of those who live with overweight and obesity, but also has the potential to impair the health services of the future. Due to the complex nature of obesity and the lack of success in reducing its prevalence, there has been little sustained action to date in the United Kingdom. Although the short-term evidence of WM programs for children with obesity is clear, that multidisciplinary services are effective and cost effective, this article has illustrated how the political and environmental contexts are limiting factors of their efficacy. Whilst many different programs are available, we must acknowledge that WM will only ever be truly effective if implemented as part of a wider system wide approach. For those wishing to implement WM in the future, it is paramount that one understands the context in which their program is implemented. It is also important that one seeks the perspectives of all stakeholders who would be involved in their implementation—from service users through to service purchases—to design a WM program that is fit for purpose. As hopefully evidenced throughout, WM is far more than the creation of a sustained energy imbalance.

Congenital Hypothyroidism: Screening, Early Management, and Outcome

Tim Cheetham, Newcastle University, Newcastle-upon-Tyne, United Kingdom

Introduction

Congenital hypothyroidism (CHT) is one of the more frequent endocrine disorders managed by pediatricians and pediatric endocrinologists and is the commonest preventable cause of neurodisability. The early identification of babies with CHT and their management with thyroid hormone replacement will have a major impact on neurodevelopmental outcome (Grosse and Van Vliet, 2011). An understanding of the perinatal physiology of thyroid stimulating hormone (TSH) and thyroid hormone secretion is important when assessing and managing the neonate with suspected thyroid dysfunction. Understanding how TSH and thyroid hormone concentrations change in early life is also important when establishing or refining a neonatal screening program for CHT.

Perinatal Physiology of TSH and Thyroid Hormone Secretion

In the first trimester thyroid hormone in the fetus will be derived primarily from the mother. Maternal free thyroxine (Free T4) crosses the placenta and is then converted to tri-iodothyronine (T3). The fetal hypothalamo-pituitary-thyroid axis is starting to function by mid-gestation. Endogenous fetal thyroid hormone production rises steadily although a substantial amount of circulating thyroid hormone—30% to 50%—is still derived from mother in the final trimester (Vulsma *et al.*, 1989). The importance of maternal thyroid hormone transfer in the latter stages of pregnancy is illustrated by the life threatening illness seen in hypothyroid infants born to hypothyroid mothers (De Zegher *et al.*, 1995). Thyroid hormone (T4) has a half-life of around 7–10 days and so maternal thyroid hormone will continue to have a neuroprotective effect in the neonate with CHT in the first days of life.

Thyroid hormone metabolism in utero

In cord and foetal serum, T4, T3, and thyroid binding globulin (TBG) levels increase during gestation until term. TSH, FT4, and rT3 levels increase and peak in the late second/early third trimester and then fall until term (Williams *et al.*, 2004). A system of enzymes regulates the amount of active T3 delivered to fetal tissues during pregnancy. Most circulating T_3 is derived from peripheral monodeiodination of the outer ring of T_4, which therefore acts as a reservoir for the more active T_3. An alternative monodeiodination affects the inner ring of T_4 and produces reverse T_3 (rT_3) which is inactive. There is therefore a mechanism for regulating production of the most active and least active thyroid hormones. There are three deiodinases—type I (D1), which has outer and inner deiodination activity (generating T3 and rT3), type II deiodinase (D2), which catalyzes outer-ring deiodination (generating T3), and type III deiodinase (D3), which catalyzes inner-ring deiodination (generating rT3) (Maia *et al.*, 2011; Williams and Bassett, 2011).

Fetal thyroid hormone metabolism is characterized by a predominance of D3 activity outside the CNS. Tissues such as the liver and kidney convert maternal and endogenous fetal T_4 preferentially to rT_3 which may help to reduce tissue thermogenesis. Thyroxine (rather than T_3) is required by the developing brain, and the appropriate deiodinases (particularly D2) are expressed in a temporal and spatial manner in different brain regions. Sulphotransferase enzymes have an additional role in normal thyroid hormone metabolism. T_4 sulphation blocks outer-ring deiodination to T_3 whilst promoting inner-ring conversion to inactive rT_3. The activity of sulphotransferase enzymes in tissues like the liver will therefore also contribute to the availability of thyroid hormone.

Thyroid function in the neonatal period

Birth is associated with a surge in TSH concentrations that peaks after around 30 min. TSH levels then fall steadily in the next 72 h. The TSH surge stimulates thyroid hormone production by the thyroid gland. TSH and thyroid hormone concentrations during the first days of life are therefore elevated when compared to those observed beyond the neonatal period. Enhanced peripheral conversion of T_4 to T3, a reflection of D2 activity, also occurs after birth.

Thyroid function in preterm infants

The pattern of thyroid hormone concentrations in cord blood provides some insight into the level of thyroid hormones during pregnancy (Williams *et al.*, 2004). In preterm infants the levels of T3 remain higher than cord values of babies of equivalent gestational age for several weeks (Williams *et al.*, 2004). Preterm infants (down to 30 weeks) show similar but lesser changes in TSH and thyroid hormone concentrations although the most preterm babies (23–27 weeks) have relatively low T4 values. By 1–2 months of age, thyroid hormone levels are comparable to those in term infants. In the case of infants under 30 weeks' gestation, the postnatal TSH surge is markedly attenuated and T_4 levels frequently fall to a nadir around 1–2 weeks of age

 doi:10.1016/B978-0-12-801238-3.65359-X

(Murphy *et al.*, 2004). This pattern is more pronounced with increasing prematurity. Thyroxine levels remain below those of full-term infants through the first few weeks of life and climb gradually to normal postnatal levels.

Congenital Hypothyroidism

CHT is characterized by abnormalities of the hypothalamo-pituitary thyroid axis with abnormally low perinatal thyroid hormone production. This may reflect a primary abnormality of thyroid gland function (primary CHT) which is therefore associated with elevated TSH concentrations or it may reflect reduced pituitary TSH generation reflecting hypothalamic or pituitary disease with associated reduced thyroid gland stimulation (secondary CHT or central CHT—CCHT). TSH and thyroxine concentrations in primary CHT can be viewed as a continuum with increasing TSH levels more likely to be associated with a low T4.

Primary CHT

Incidence and epidemiology

The incidence of primary CHT in many countries that have neonatal screening programs is 1 in 2000–4000 births. Females are affected twice as commonly as males in babies at the severe end of the disease spectrum. Severe primary CHT is characterized by markedly elevated TSH concentrations in the context of very low thyroid hormone levels. Abnormal thyroid function at the milder end of the spectrum tends to have a more equal sex incidence, suggesting a different underlying pathogenesis in many of these babies (described in more detail below). CHT may be more common in Asian, Native American and Hispanic populations and less common in White and Black populations. The incidence is relatively low in Sub-Saharan Africa. CHT appears to be more common in the context of multiple pregnancies (Olivieri *et al.*, 2007). Some studies have reported a rise in the incidence of primary CHT in recent decades in Europe and North America (Olivieri *et al.*, 2015). TSH concentrations form a continuum and a change in neonatal screening practice over the years with a reduction in the TSH cut-off value used to separate pathology from normality is one reason for this trend (Pollitt, 2016). There is, nevertheless, evidence to suggest that the incidence of primary CHT may be rising independently of a change in screening practice. This could be linked to factors such as a change in the ethnic mix of the screening population and increased survival of preterm babies (Olivieri *et al.*, 2007).

Etiology

Dysgenesis

Eighty-five percentage of cases of primary CHT at the more severe end of the phenotypic spectrum are caused by thyroid dysgenesis (defects in thyroid gland development) consisting of thyroid gland ectopia, hypoplasia, and athyreosis. An ectopic thyroid accounts for around two thirds of thyroid dysgenesis. The cause of thyroid dysgenesis is unclear in most instances. Clustering of cases of babies with raised TSH values in Northern England suggests that environmental factors may be involved in the etiology of CHT due to gland dysgenesis (Pearce *et al.*, 2011) although another study concluded that a stable incidence with no monthly variability suggests that this is not the case (Deladoey *et al.*, 2011).

Dyshormonogenesis

Around 15% of CHT cases at the more severe end of the phenotypic spectrum are caused by dyshormonogenesis. In thyroid dyshormonogenesis there is an inborn error of thyroxine synthesis or thyroid hormone secretion. Thyroid dyshormonogenesis is usually inherited in an autosomal recessive pattern with an underlying defect in one of the known steps in the thyroid hormone biosynthesis pathway. Dominant inheritance has been described in some thyroid hormone synthetic defects.

CHT at the mild end of the phenotypic spectrum

It has become clear that the distribution of babies with dysgenesis and dyshormonogenesis at the milder end of the phenotypic spectrum is different to that originally described in babies with CHT (Olivieri *et al.*, 2013). The sex incidence is equal at this mild end of the spectrum and thyroid dysgenesis is less common. Babies in this group are more likely to be preterm, to have been exposed to medications and the thyroid dysfunction is more likely to be transient. A relatively high proportion of babies appear to have abnormalities of DUOX although there are many babies who do not have a specific underlying explanation for the mildly elevated TSH levels.

Iodine and CHT

Iodine is a key component of thyroid hormone synthesis and iodine deficiency is a major cause of CHT in some parts of the world. Nearly one third of the world's population live in areas of iodine deficiency with South-Asia and Sub-Saharan Africa particularly affected. Iodine deficiency is the most common cause of thyroid disorders worldwide and may also cause transient CHT in developed countries. When severe iodine deficiency occurs during pregnancy, it is associated with severe neurocognitive defects in the offspring and increased neonatal and infant mortality. There has been a recent focus on the iodine status of many countries in Europe and up to 60% of girls and pregnant women in the United Kingdom have insufficient dietary intake of iodine (Vanderpump *et al.*, 2011). Recent data suggest that iodine status in utero is related to subsequent neurodevelopment (Bath *et al.*,

2013) although iodine status does not appear to impact greatly on neonatal thyroid TSH concentrations in some parts of the United Kingdom (Evans *et al.*, 2014). Iodine exposure (as a topical disinfectant or as a radiology agent) is a recognized cause of a transient increase in neonatal TSH levels and can result in babies screening "positive" on neonatal screening programs with subsequent normalization of thyroid function.

CHT and prematurity

Some studies have indicated that the incidence of CHT is higher in preterm infants although many reported abnormalities of thyroid function in these babies are transient and/or at the milder end of the biochemical spectrum and the underlying pathology where thyroid dysfunction is permanent is not usually dysgenesis (Olivieri *et al.*, 2013; Mengreli *et al.*, 2010; Mitchell *et al.*, 2011). The reported increased incidence in some studies can partly be explained on the basis of a relative immaturity of the thyroid axis as well as an increased prevalence of illness and drug exposure. Preterm babies are more likely to be exposed to topical iodine or iodine containing radiographic agents which can interfere with thyroid hormone generation (the Wolff–Chiakoff effect) as alluded to above. There is little evidence to suggest that thyroid dysgenesis is increased in the preterm population and it is of note that severe CHT is classically associated with babies being born postterm.

Clinical assessment of primary CHT

A detailed history should be obtained with a view to establishing whether family members (parents, siblings) have thyroid disorders and whether the baby or mother has been exposed to medications that can impact on thyroid function. The baby should be examined and it is important to remember that congenital malformations may be more common in this group of babies (Azar-Kolakez *et al.*, 2013). The clinical features of CHT are outlined in **Table 1**.

Babies with severe primary CHT may have feeding difficulties, sleepiness, constipation, and prolonged jaundice. Babies with very low thyroid hormone concentrations may have a characteristic facies with a flat nasal bridge, a large posterior fontanelle, macroglossia, a distended abdomen with umbilical hernia, bradycardia and hypotonia with delayed reflexes. The skin may be cool and mottled in appearance. Many infants with primary CHT have few clinical manifestations of thyroid hormone deficiency in the initial phase (Grant *et al.*, 1992) and in the absence of neonatal screening will present with slow growth or abnormal development at a later stage. Sixteen percentage of babies with severe biochemical hypothyroidism have no obvious symptoms of hypothyroidism prior to detection by neonatal screening (Grant *et al.*, 1992). This may reflect the protective effect of thyroid hormone transfer from mother and its' impact on phenotype. There is an inverse relationship between age at treatment initiation and intelligence quotient (IQ) in later life and so babies with CHT should be managed as swiftly as possible.

Investigation

Although the most valuable index of thyroid status is the measurement of TSH and thyroid hormone concentrations it is useful to establish the etiology by one or more investigations such as isotope scanning (technetium-99m pertechnetate or iodine (^{123}I)), ultrasonography (Lucas-Herald *et al.*, 2014) and/or measurement of thyroglobulin as well as genetic analysis. **Fig. 1**A shows an MRI scan conducted in a baby with stridor and an ectopic thyroid gland and **Fig. 1**B shows an isotope scan of an ectopic thyroid gland. The potential advantages of thyroid imaging and further investigation are as follows:

Table 1 Key clinical features of congenital hypothyroidism

Clinical features of congenital hypothyroidism
• Asymptomatic
• Increased birth weight
• Lethargy
• Hoarse cry
• Feeding problems
• Cool peripheries
• Constipation
• Macroglossia
• Coarse features
• Umbilical hernia
• Large fontanelles
• Hypotonia
• Hypothermia
• Bradycardia
• Dry skin
• Prolonged jaundice
• Goiter

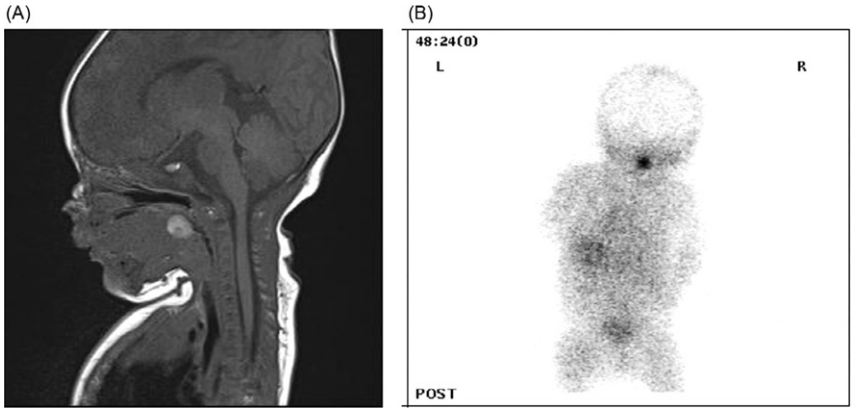

Fig. 1 (A) MRI demonstrating an ectopic thyroid gland in a baby investigated for stridor. (B) Technetium radioisotope scan demonstrating thyroid ectopia.

1. If the baby has thyroid agenesis then the family can be informed that thyroid hormone treatment will be needed for life. The baby with an in situ gland may still prove to have transient hypothyroidism because, for example, antibody transfer from mother may be interfering with thyroid gland stimulation.
2. If the thyroid gland is in situ then the baby may have dyshormonogenesis with a 1 in 4 recurrence risk. Families frequently ask about recurrence risk and so investigation will help to address this question satisfactorily.
3. Thyroid agenesis is more likely to be associated with other developmental problems and highlights the need for a detailed assessment, looking for other congenital anomalies. Hearing screening is particularly important in these babies.
4. This information may help to refine treatment by indicating that the baby may need a larger (in the case of agenesis) or smaller (in the case of thyroid ectopy) dose of levothyroxine.

Some clinicians still feel that imaging is not crucial because it does not influence whether the baby is treated with thyroxine. Investigations will also entail hospital visits and may involve exposure to ionizing radiation. These issues should be discussed with families so they can make an informed choice about whether they feel further investigation is warranted.

An isotope scan can most easily be interpreted when TSH levels are elevated but can still be performed several days post therapy because of the time taken for TSH to normalize. An X-ray of the knee is a guide to the extent of the in utero thyroid hormone deficiency—if the tibial/femoral epiphysis is absent then this suggests more severe in utero thyroid hormone deficiency. Increasingly genetic analysis can be undertaken in children with an in situ gland suggestive of a dyshormonogenesis, looking for abnormalities of (for example) the thyroglobulin or TSHR genes. Hearing assessment is important in babies with CHT because of the strong association with sensorineural deafness—even in the absence of Pendred syndrome (Léger *et al.*, 2014; Bruno *et al.*, 2015).

Treatment

Initial management and monitoring

Babies who screen-positive on a neonatal screening program for CHT should have formal serum thyroid function tests checked as soon as possible and ideally within 24 h. The result of thyroid function tests will frequently be available soon afterwards but if not then it is advisable to treat the baby with thyroxine if the baby has clinical features in keeping with CHT or if the blood-spot TSH is greater than 40 mU/L. If the blood spot TSH is in the range 20–40 mU/L then there is an argument for waiting until thyroid function is available the following day (Léger *et al.*, 2014; Pokrovska *et al.*, 2016).

The goal of thyroxine therapy is to ensure that children have growth and neurodevelopment that is as near to their genetic potential as possible. Levothyroxine (l-thyroxine) is the treatment of choice and has a bioavailability of 50%–80%. Soy milk and medication such as iron can significantly impair thyroxine absorption. Although triiodithyronine (T3) is the biologically active form of the hormone, most T3 in the brain is formed from local deiodination of T4 and so T3 replacement is not usually required. The exception would be the baby with CHT who cannot be fed because of gut pathology in which case T3 is the only thyroid hormone available in intravenous form. The recommended initial l-thyroxine dose is 10–15 μg/kg/day (Léger *et al.*, 2014) for babies at the more severe end of the spectrum. In term infants this amounts to an average of 37.5–50 μg/day. Children with significant endogenous thyroid hormone production—as evidenced by a more subtle TSH increase and an in situ or ectopic gland—may need smaller doses of T4 around 5–10 μg/kg/day. It is important to review the baby again within the first 2 weeks to make sure that the biochemistry is improving. Babies started on larger doses of levothyroxine may need a dose reduction in the subsequent weeks.

Plasma FT3 and FT4 concentrations reach the normal range a few days after thyroxine treatment is started but it can take several weeks for TSH concentrations to normalize. A relationship between the time taken for TSH to normalize and neurodevelopmental

outcome has been described and it is important to closely monitor infants and adjust the l-thyroxine dose frequently until the desired level is achieved.

Normal TSH levels in some babies with dysgenesis on thyroxine replacement may be associated with relatively high circulating FT4 concentrations. This is because the thyroid gland produces both T4 and T3 and generating adequate tissue T3 may require higher than normal circulating FT4 concentrations in the absence of endogenous thyroid gland T3 release. It has been suggested that larger doses of T4 may also be required to normalize TSH concentrations in some children with CHT when compared to other forms of hypothyroidism because of pituitary-thyroid hormone resistance that reflects a period of relative hypothyroxinaemia in utero.

The developing brain has a critical dependence on thyroid hormone in the first 2–3 years of life and so frequent monitoring is important. Outpatient review and thyroid function testing may be needed every 4 weeks during the phase of particularly rapid growth in the first year of life (Balhara *et al.*, 2011).

There is a strong argument for these babies being under the care of a pediatrician with a specialist interest and experience of treating babies with CHT and hence who is more likely to be aware of the pitfalls and nuances of management.

Which thyroid hormone formulation?

The preferred means of administration is with levothyroxine tablets that have been crushed and administered via a small spoon in a few milliliters of water, bottle or breast milk (Léger *et al.*, 2014). Pharmaceutically produced solutions can be used but are expensive and of different strengths which can result in confusion and inappropriate dosing. New preparations of 12.5 μg of thyroxine have recently become available. They are particularly useful in children but are more expensive than the earlier, standard tablet doses.

What biochemical threshold warrants intervention?

One of the more controversial areas in pediatric endocrinology is the question of the TSH threshold at which levothyroxine should be commenced (Lain *et al.*, 2017). The significance of borderline TSH elevation is unclear although a recent association between mild TSH elevation (as opposed to the profound increase in TSH seen in thyroid dysgenesis) and suboptimal neurodevelopment has been described in a large study from Australia (Lain *et al.*, 2016). In contrast an earlier study from Belgium had shown no association between TSH groups (<5, 5–9, >10 mU/L) and cognitive outcome (Trumpff *et al.*, 2015). An association between TSH >10 mU/L but less than 15mU/L and a lower verbal IQ was not present following adjustment for potential confounders such as household income and maternal education (Trumpff *et al.*, 2015). This uncertainty helps to explain why there are regional and national differences in screening cut-off values and differences in the way babies are managed. When venous TSH levels are 10–20 mU/L in the presence of age appropriate FT4 levels it is reasonable to repeat the blood test in one to 2 weeks and to consider an ultrasound or isotope scan in the interim. However a serum TSH greater than 10mU is more than three SD above the mean in most populations and may be considered a criterion for intervention on these grounds alone.

Transient hypothyroidism

Between 19% and 28% of babies diagnosed with CHT have transient CHT (Mitchell *et al.*, 2011; Korzeniewski *et al.*, 2013). Transient CHT is more likely at the milder end of the biochemical spectrum. Transient CHT can be caused by maternal or neonatal factors and can persist for a variable amount of time postnatally. Maternal factors include iodine deficiency or excess, transplacental passage of antithyroid antibodies and fetal exposure to antithyroid medication. Neonatal factors include iodine deficiency or excess, and hepatic haemangiomas (which increase type 3 iodothyronine deiodinase activity, converting T4, and T3 to inactive metabolites). Although thyroid dyshormonogenesis is typically seen as a cause of permanent CHT it is known that mutations in *DUOX2* and *DUOX2A* can cause transient CHT (Hoste *et al.*, 2010). In this instance thyroid hormone production is compromised with an increase in TSH in early life but not necessarily at a later stage—presumably because the demand for thyroid hormone is reduced beyond infancy.

Down's syndrome

Babies with Down's syndrome have an altered relationship between TSH and thyroid hormone concentrations when compared to the population as a whole. Down's syndrome babies overall have higher TSH levels but also higher thyroid hormone concentrations. The relatively high TSH levels are therefore a normal observation in healthy Down's babies and the threshold for intervention should therefore be higher than the population as a whole. In one study the 95th centile for TSH concentrations was around 9mU/L in Down's babies versus 5.5mU/L in the population as a whole (Meyerovitch *et al.*, 2012). The reason for the altered TSH/thyroid hormone axis is unclear and it is of note that none of the genes known to be involved in HPT regulation are encoded on chromosome 21. Babies with Down's syndrome can still have CHT due to thyroid dysgenesis.

Secondary CHT

Etiology

Most cases of central hypothyroidism (CCHT) where TSH is not secreted appropriately by the pituitary gland are associated with other pituitary hormone deficiencies in the context of combined pituitary hormone deficiency (CPHD). Babies with CCHT may

therefore have additional phenotypic clues such as hypoglycaemia due to adrenocorticotropic hormone (ACTH) and growth hormone (GH) deficiency as well as microphallus due to gonadotrophin deficiency. Babies with CCHT may also have conjugated hyperbilirubinaemia because of cortisol and thyroid hormone deficiency. Transient CCHT may be due to TSH suppression because of excessive thyroid hormone transfer from a mother with Graves' disease.

Incidence

The incidence of isolated TSHD elucidated from neonatal screening programs for CHT depends upon the strategy used and whether cases at the milder end of the phenotypic spectrum are detected. The incidence based on a program that measured TSH and T4/FT4 in Japan was 1 in 160,000 (Asakura *et al.*, 2002) but a strategy that included the measurement of thyroid binding globulin (TBG) revealed an incidence of 1 in 16,000 in Western Europe (Kempers *et al.*, 2006; Lanting *et al.*, 2005). The overall incidence of CCHT (babies with and without other pituitary hormone deficiencies) in Western Europe, based on more intensive screening programs that measure thyroid hormone levels as well as TSH and thyroid-binding globulin (TBG), is around 1 in 20,000. Around 75%–80% of these babies will have CPHD.

Clinical Features

Babies do not necessarily present in the early neonatal period (Kempers *et al.*, 2006; Lanting *et al.*, 2005) and thyroid function should be checked in any baby with symptoms suggestive of CPHD such as hypoglycaemia, prolonged jaundice (particularly conjugated hyperbilirubinaemia) or microphallus. Features of isolated TSHD may be relatively subtle but there may also be a classical neonatal hypothyroid phenotype. Late treatment can be associated with neurodevelopmental problems, particularly in those babies at the more severe end of the phenotypic spectrum.

Investigation

The diagnosis of TSHD requires the identification of low T4 levels together with low or "inappropriately" normal TSH concentrations. Screening programs and laboratories that only measure TSH concentrations will not identify cases of central hypothyroidism. TSH concentrations in CPHD can also be paradoxically mildly elevated which may reflect impaired biological activity with retained immunoreactivity although hypothalamic somatostatin deficiency could be a contributing factor. The TRH test as a means of investigating infants with suspected central hypothyroidism has both advocates and detractors (Van Tijn *et al.*, 2008; Mehta *et al.*, 2003).

Treatment of secondary CHT

The objective of therapy in CCHT is to achieve FT4 concentrations in the top part of the age-appropriate reference range (Persani, 2012). TSH cannot be used as a guide to therapy and will typically become unrecordable in instances where it has previously been mildly elevated or normal (see above). Other pituitary hormones should be evaluated in patients with central hypothyroidism, especially assessment of the hypothalamic-pituitary-adrenal axis to exclude hypocortisolism. Babies with abnormal ACTH/cortisol secretion should be treated prior to initiating thyroid hormone replacement.

Newborn Screening for CHT

The objective of screening for CHT is to eradicate mental retardation arising as a consequence of CHT, Screening for CHT has been shown to be highly cost effective (Rose *et al.*, 2006; Geelhoed *et al.*, 2005). In many countries, newborn infants are screened via a blood spot sample taken on "filter-paper" at 3–5 days of age. Screening programs for CHT have relied on two major methods: a primary TSH method ($\pm$ backup T4 below a certain threshold) and a primary T4 method ($\pm$ backup TSH above a certain threshold). Most programs in Europe, the United States, Japan and Canada use the primary TSH method, but there a number of programs that routinely measure both TSH and T4 (Kempers *et al.*, 2006). There are advantages and disadvantages to each method used (**Table 2**). Improved assay sensitivity (fewer false negatives) will typically be associated with compromised specificity (more

Table 2 Major advantages of screening strategies relying on either TSH or T4 as primary testing method

Testing method	*Advantages*	*Disadvantages*
Primary TSH ($\pm T_4$ backup)	• Will detect primary hypothyroidism with elevated TSH • High sensitivity and specificity • Age-adjusted TSH cut-offs allow earlier testing for discharge <48 h	• Will not detect central hypothyroidism • Will not detect cases where TSH elevation is delayed although this may be less of an issue with a relatively low TSH cut-off
Primary T_4 ($\pm$TSH backup)	• Will detect primary hypothyroidism if T4 low • Will detect central hypothyroidism	• May not detect mild CHT with increase in TSH • Normal T4 with delayed rise of TSH • Can be associated with a higher number of false-positives resulting in a high recall rate

false positives) and the concern with lower TSH screening "cut-offs" is that more families are subjected to the anxiety of being notified as screen "positive" that is then disproved by normal serum thyroid function tests.

A combined approach where both TSH and Free thyroid hormone (FT4) is determined is very attractive in principle because it can detect both primary and secondary hypothyroidism, but measuring FT4 in blood spot samples is not straight-forward which is why some programs measure T4 with TBG to gauge the amount of "free" thyroid hormone (Kempers *et al.*, 2006).

Screening programs will not detect all cases of CHT and health professionals need to be alert to the signs of hypothyroidism and have a low threshold for formally testing thyroid function irrespective of earlier screening.

Selecting an appropriate screening threshold

All screening programs will miss affected babies and improving sensitivity by (for example) reducing a TSH threshold will reduce specificity with more false positives. As TSH assays have become more refined then so screening primary TSH programs have tended to use a lower threshold at which diagnostic investigation is indicated. Many programs have a borderline TSH category which necessitates a repeat blood spot sample being taken if the preliminary value is above the "norm" but below a threshold at which primary CHT is highly likely. Many of these babies will then have a normal "repeat" blood spot TSH with further investigation therefore unnecessary. The threshold for a positive result varies across the United Kingdom and Europe even though similar assay techniques are used. Although the likelihood of detecting cases of permanent CHT is reduced as TSH falls there are still programs that report around 20% of cases of dysgenesis in babies with permanent CHT whose baseline blood spot TSH was less than 15 mU/L (Olivieri *et al.*, 2013). In the United Kingdom some regions selected a blood spot TSH cut-off below 10 mU/L because they too identified thyroid pathology that would have been "missed" by a higher value (Langham *et al.*, 2013). Consideration of the risks and benefits is important because whilst a lower threshold will detect additional cases of CHT, these cases will tend to be at the milder end of the phenotypic spectrum in terms of the extent to which thyroid hormone production is compromised (Krude and Blankenstein, 2011; Cheetham, 2011). Lower thresholds will lead to a marked increase in the number of repeat tests with implications for families as well as laboratory workload (Pollitt, 2016). The process of recalling a baby who ultimately turns out not to have CHT on further investigations is not without cost (Hewlett and Waisbren, 2006).

Whilst there has been a great deal of focus on what constitutes an appropriate cut-off there are other factors that will impact on (for example) the TSH concentration such as the timing of the sample - a sample taken at just over 4 days ($\sim$ 97 h) will be greater than a sample taken at just less than 5 days (119 h) and an assay performed on a sample taken from the center of a large blood spot will tend to generate a higher TSH value than a sample taken from the periphery of a smaller blood spot. There are other causes of a raised TSH besides CHT (**Table 3**).

Screening preterm infants

A concern is that TSH concentrations in preterm infants may not rise in the presence of impaired thyroid hormone generation as they do in term babies although some studies have shown that this is not an issue in practice (Vincent *et al.*, 2002). This observation is usually attributed to relative immaturity of the hypothalamo-pituitary thyroid axis and has implications for neonatal screening. A concern is that CHT screening programs linked to TSH measurement may miss cases because the TSH has yet to rise (Murphy *et al.*, 2004). CHT in preterm babies may also be masked by suppression of TSH caused by drug administration, fetal blood mixing in multiple births and by the impact of serious neonatal illness on thyroid function. Because of this many countries now undertake repeat screening on babies born before a certain gestation or under a certain weight. In the United Kingdom all babies born less than 32 weeks gestation undergo a repeat test 4 weeks later or at the time of discharge. Whilst this strategy may help to detect babies with longer term thyroid dysfunction it remains unclear to what extent an initial screen with a

Table 3 Principle causes of a raised TSH in infancy

Principle causes of a raised TSH in infancy

• Maternal antibody exposure
• Hypopituitarism
• Drugs
• Downs' syndrome
• Adrenal insufficiency
• Thyroid hormone resistance
• MTC deficiency
• Pseudohypoparathyroidism

relatively low threshold and later screening at 5 days rather than within 48 h will also detect these babies (Korada *et al.*, 2008). It is also unclear to what extent the babies who screen positive on second screen have transient as opposed to permanent thyroid dysfunction.

Re-evaluation of the thyroid axis in babies with primary CHT

Babies who have not required an increase in levothyroxine dose, have not had imaging confirming CHT or have had earlier normal imaging, warrant a trial off therapy at around 3 years of age. This is then beyond the critical phase of brain growth. In one study only a third of children diagnosed with CHT and who had a gland in situ required long term thyroxine therapy (Rabbiosi *et al.*, 2013). It is possible to simply stop the levothyroxine for 2–3 weeks and then check thyroid function tests. If thyroid function is normal, our practice is to repeat the testing again after a further 6 weeks and then consider discharge if the biochemistry remains normal.

Early neurodevelopmental outcome in CHT

Thyroid hormone deficiency has a deleterious impact on central nervous system development. CHT is the most common preventable cause of intellectual disability in children and the link with abnormal cognitive development is the key reason for the introduction of neonatal screening programmes for CHT. The mean intelligence quotient (IQ) score of patients with CHT presenting clinically is around 80 with an IQ score less than 50 in around 5% of such children (Grosse and Van Vliet, 2011). As a general rule it appears that the later the diagnosis and treatment in a baby with clinical manifestations of CHT, the lower the IQ score. Average IQ scores around 90 are seen in babies with CHT treated prior to 3 months, 70 in those treated between 3 and 6 months of age with a mean IQ of 35 reported when the diagnosis of CHT is delayed beyond 6 months of age (Grosse and Van Vliet, 2011; Klein *et al.*, 1972). On the other hand, patients with a substantial increase in TSH concentrations but without overt clinical signs of CHT have an IQ that is close to average with none having an IQ <70 (Alm *et al.*, 1984). Primary CHT represents a spectrum of severity ranging from babies with no endogenous thyroid function to babies with elevated TSH concentrations in the context of thyroid hormone concentrations within the age-related reference range. There is evidence to suggest that there is a point on this spectrum below which there is an unequivocal, detrimental impact of thyroid hormone insufficiency on neurodevelopmental outcome (Tillotson *et al.*, 1994).

Factors determining outcome in CHT

Screening programmes for CHT have been a great success but despite early diagnosis and treatment numerous authors have noted subtle deficits in terms of speech and language, visuospatial function, attention span as well as minor motor problems in many children with CHT when compared to the healthy population (Rovet and Ehrlich, 2000). Investigators have looked at the potential explanations for this and have noted that there are three main variables that seem to impact on neurodevelopmental outcome in CHT—two of which are modifiable.

1. Severity of the thyroid hormone deficiency
   A positive association between motor outcome in CHT (Oerbeck *et al.*, 2003) as well as IQ (Kempers *et al.*, 2006) with serum thyroid hormone concentration at diagnosis has been reported. Children at the mild end of the biochemical spectrum with higher thyroid hormone concentrations may not be at risk of intellectual impairment (Tillotson *et al.*, 1994; Alm *et al.*, 1984). Babies with more severe CHT will have had substantially lower thyroid hormone concentrations in utero and transplacental transfer of thyroid hormone from mother alone is insufficient to normalize brain development in these circumstances.
2. Interval between birth and thyroid hormone intervention
   Data from the prescreening era clearly show that the later the child is treated, the more profound is the likely impact of thyroid hormone deficiency on neurodevelopment, as outlined above. The extent to which the timing of intervention is important within the first 3 weeks of life is less clear (Boileau *et al.*, 2004) and of note is the fact that in the first days of life there will still be circulating thyroid hormone from mother providing some neuronal protection.
3. Thyroid hormone treatment dose
   A number of studies have now shown that higher doses of thyroxine are associated with a reduction in the discrepancy between the IQ observed in children with CHT versus children who do not have CHT (Dubuis *et al.*, 1996; Bongers-Schokking *et al.*, 2000). This observation has recently been noted once again in the context of a cohort of children from Germany and an associated meta-analysis (Aleksander *et al.*, 2018). Normalizing TSH in babies with severe CHT is frequently associated with relatively high thyroid hormone concentrations. The reported impact of relatively high doses of thyroxine on neurodevelopment is not always positive with this approach also linked to neurobehavioral issues such as anxiety, social withdrawal, and poorer concentration (Rovet and Ehrlich, 1995; Bongers-Schokking *et al.*, 2013). The potential deleterious effects of relatively high-dose T4 therapy have not been noted in all studies (Oerbeck *et al.*, 2005). Whether all the consequences of a substantial reduction in circulating thyroid hormone concentrations in utero can truly be abrogated by prompt and generous thyroxine replacement in the neonatal period remains to be established.

Health outcomes in adult life

While the focus of many neonatal programmes and associated studies has been neurodevelopmental outcome in childhood it has become clear that the diagnosis of CHT may carry with it a risk of subtle health issues in later life (Rovet and Ehrlich, 2000; van der

Sluijs Veer *et al.*, 2008; Léger *et al.*, 2011). Adults with CHT are more likely to be overweight with hearing and visual problems when compared to the population as a whole (Léger *et al.*, 2011). Adults are more likely to have chronic health problems with a lower health-related quality of life and are less likely to be in full-time employment. CHT severity and treatment adequacy as measured by TSH concentrations above or below 20 mU/L were key determinants of long term outcome in one study (Léger *et al.*, 2011). The extent to which close biochemical monitoring in early life with more generous starting doses of T4 in excess of 10 mcg/kg per day will address these issues is unclear as alluded to above. Many authors have described abnormalities of growth in childhood in CHT but final height appears to be similar to that observed in the normal population (Salerno *et al.*, 2001).

Role of monitoring in refining neonatal outcome

There is evidence to indicate that close monitoring of CHT with maintenance of age-appropriate TSH concentrations can also help to improve neurodevelopmental outcome in CHT. Regular clinical and biochemical review with the normalization of TSH concentrations throughout early childhood is key (Balhara *et al.*, 2011; Salerno *et al.*, 2001). In the baby with little endogenous thyroid function this may require regular, monthly review throughout the first year of life (Balhara *et al.*, 2011).

The impact of maternal thyroid status on fetal outcome has been under close scrutiny in recent years. It is becoming clear that the optimization of thyroxine therapy in mothers with CHT around the time of conception and during pregnancy is important based on differences in early developmental milestones in their offspring (Léger *et al.*, 2018).

Genetic Causes of Congenital Hypothyroidism

Nadia Schoenmakers, University of Cambridge Metabolic Research Laboratories, Cambridge, United Kingdom

Primary Congenital Hypothyroidism

Classification and Etiology

Primary congenital hypothyroidism (CH) has traditionally been classified as thyroid dysgenesis (TD) or dyshormonogenesis. TD refers to a spectrum of aberrant thyroid gland development, including thyroid ectopy (an abnormally situated thyroid gland, accounting for the majority of TD), athyreosis (complete absence of the thyroid), affecting 20%–30% of TD cases or a normally located but hypoplastic thyroid (approximately 5% of cases). Dyshormonogenesis refers to failure of thyroid hormone production by a structurally intact thyroid gland which lacks a complete, functional molecular pathway for thyroid hormone biosynthesis. Historically, 75%–85% of CH cases have been attributed to TD with the remaining 20% occurring due to dyshormonogenesis. However, more recent studies undertaken in populations using lower screening TSH diagnostic cut-points have reported a doubling in the incidence of CH largely due to increased diagnosis of cases with a normally located gland in situ (GIS) (Corbetta *et al.*, 2009; Szinnai, 2014).

Genetic causes of TD involve genes mediating thyroid growth and development. Although multiple genes have been implicated, TD is generally considered to be a sporadic disease with $<5\%$ cases attributable to an identifiable genetic mutation. The transcription factors involved are usually not thyroid-specific, therefore mutations in the genes encoding them may result in additional congenital abnormalities, reflecting their extrathyroidal expression pattern. Dyshormonogenesis, in contrast, is usually familial, with the majority of affected individuals harboring mutations in genes encoding known components of the thyroid hormone biosynthesis machinery (Grasberger and Refetoff, 2011; Cherella and Wassner, 2017).

Thyroid Gland Development

The identification of monogenic causes of thyroid dysgenesis in patients with CH has informed our understanding of human thyroid development. Moreover, although not identical, human and murine thyroid morphogenesis have a comparable molecular basis, and major morphogenetic steps are conserved in the two species. Therefore studies in these organisms have been crucial both in defining novel CH candidate genes relevant to the human setting, and in elucidating their function.

Genes Involved in the Molecular Control of Thyroid Development

Intrinsic Factors

Transcription factors: NKX2-1, PAX8, HHEX, FOXE1

Early thyroid development is defined by the combined expression of an indispensible quartet of transcription factors; *PAX8* (paired box 8), *NKX2-1* (NK2 homeobox 1, previously known as TTF1), *HHEX* (hemopoetically expressed homeobox) and *FOXE1* (forkhead box E1, previously known as TTF2). Each of these transcription factors also has a developmental role in extra-thyroidal tissues, but their combined expression to mediate organogenesis is observed only in epithelial thyroid follicular cells. Studies of mouse thyroid development have shown that NKX2-1, PAX8 and HHEX are initially expressed independently, but subsequently participate in a network of reciprocal regulatory interaction. FOXE1 is expressed later, requiring PAX8 for the onset of expression. These transcription factors have pleiotrophic roles in the thyroid, mediating the formation of the thyroid bud and facilitating survival of thyroid progenitor cells, as well as driving functional differentiation, and regulating the expression of genes involved in thyroid hormone biosynthesis. Additionally, NKX2-1, PAX8 and FOXE1 play a role in the maintenance of the mature thyroid gland, and FOXE1 has a particular involvement in thyroid migration. Mutations in *NKX2-1*, *PAX8* and *FOXE1* are all associated with thyroid dysgenesis in humans (Trueba *et al.*, 2005; Fernandez *et al.*, 2015; Nilsson and Fagman, 2017; Kimura *et al.*, 1996; Mansouri *et al.*, 1998; de Felice *et al.*, 1998; Martinez Barbera *et al.*, 2000).

TSHR

Early thyroid development is TSH independent, including thyroglobulin synthesis (TG) at the onset of folliculogenesis. However, once morphogenesis is complete, TSH has a role in thyroid growth from the third trimester and drives expression of the components of the thyroid hormone biosynthetic machinery, with murine studies confirming its importance for expression of the sodium-iodide symporter (NIS) and TPO, during terminal differentiation. In developing human thyroid, membrane detection of TSHR precedes accumulation of NIS in the basolateral membrane, consistent with a role for TSH in enabling onset of thyroid hormone synthesis by the fetal thyroid gland (Szinnai *et al.*, 2007; Nilsson and Fagman, 2017).

Extrinsic Factors

The close proximity of the developing thyroid to cardiac mesenchyme and vasculature, and observations that cardiovascular malformations have an increased frequency in patients with thyroid dysgenesis, have lead to the suggestion that extrinsic, noncell autonomous factors may play a role in thyroid development (Devos *et al.*, 1999). Zebrafish and murine models have been used to identify pathways involved. These include mesoderm-derived Tbx1-Fgf8 signaling which may influence thyroid growth and positioning (Fagman *et al.*, 2007). Additionally, recent zebrafish studies suggest that mesenchymal netrin 1, a laminin superfamily member with a role in mediating guidance cues may play an important role both in thyroid morphogenesis and vasculogenesis (Opitz *et al.*, 2015). Although poorly understood, specification of the thyroid domain at the onset of thyroid morphogenesis, must be dependent on extrinsic signals. Recent advances in stem cell technology have enabled the directed differentiation of mouse and human ESCs and human induced pluripotent stem cells (iPSCs) into functional thyrocytes. These experiments have demonstrated that FGF2 and BMP4 are necessary and sufficient for this process, provided that cells are preprogrammed to definitive endoderm (Kurmann *et al.*, 2015) suggesting that FGF2 and BMP4 are likely to play a key role in thyroid specification although their source remains unclear.

Thyroid Dysgenesis

Genes Implicated in Thyroid Dysgenesis (Summarized in Fig. 1 and Table 1)

TSHR

The most commonly mutated gene in TD is the *TSHR* (Cangul *et al.*, 2012; Szinnai, 2014), however, mutations in this gene are associated with a variable spectrum of resistance to TSH, the severity of which depends both on the deleteriousness of the mutation, and the number of mutated *TSHR* alleles. In partial TSH resistance, patients exhibit a euthyroid compensated state with elevated TSH concentrations, normal thyroid hormone concentrations and a normal-sized, eutopic thyroid gland. If TSH resistance is complete, severe CH is associated with marked thyroid hypoplasia, which may be mistaken for athyreosis. However, since early fetal thyroid growth and TG synthesis are TSH independent, serum thyroglobulin (TG) is always detectable in such cases, who exhibit "apparent athyreosis" (Persani *et al.*, 2010).

TSH binds a G-protein coupled receptor, TSH-receptor (TSHR) in the thyroid, for which cyclic AMP (cAMP) is the major second messenger at physiological concentrations although coupling may also occur to Gq. Signaling via TSHR stimulates both follicular cell growth and thyroid hormone synthesis and release (Persani *et al.*, 2010).

More than 60 inactivating *TSHR* mutations have been described, the population frequency of which is dependent on the screening criteria used and may also be influenced by the presence of founder mutations in particular ethnic groups, for example, TSHR p.R450H in individuals from East Asia (Chang *et al.*, 2012; Szinnai, 2014). In populations with TD, a mean prevalence of heterozygous and homozygous *TSHR* mutations was estimated to be 4.3%, but mutations are more common in pediatric cases with nonautoimmune hyperthyrotropinemia due to partial TSH resistance (prevalence 11%–29%) (Nicoletti *et al.*, 2009; Cassio *et al.*, 2013; Szinnai, 2014).

Management of CH due to complete TSH resistance requires levothyroxine replacement but thyroid hormone supplementation in individuals with partial TSH resistance remains controversial (Cassio *et al.*, 2013). These individuals may have compensated hyperthyrotropinemia with resetting of the hypothalamic–pituitary–thyroid axis such that supraphysiological FT4 concentrations are required to achieve a TSH level in the normal range. Since peripheral sensitivity to thyroid hormone is preserved, normalization of TSH may therefore provoke thyrotoxic symptoms, leading to the suggestion that treatment may not be required. In addition to anecdotal reports describing normal growth, development and pituitary appearances in untreated cases despite chronically raised TSH (Clifton-Bligh *et al.*, 1997), two recent studies have assessed the long-term clinical and biochemical outcomes in patients with subclinical hypothyroidism due to *TSHR* mutations. In patients with heterozygous mutations, subclinical hypothyroidism was found to be a stable compensated state which may not usually require thyroid hormone replacement. However, levothyroxine treatment may be required in some patients with either heterozygous mutations and additional risk factors for thyroid dysfunction, or biallelic mutations, in whom incompletely compensated subclinical hypothyroidism may progress (Tenenbaum-Rakover *et al.*, 2015; Vigone *et al.*, 2017). Larger studies, involving a broader spectrum of TSH resistance are still required to guide management definitively.

Key Transcription Factor Mutations in TD

Mutations in three of the four key transcription factor mutations involved in thyroid morphogenesis (*NKX2-1*, *PAX8* and *FOXE1)*, are rare but well-recognized causes of TD with characteristic associated syndromes reflecting their extrathyroidal expression patterns. However, penetrance of both the thyroid phenotype and additional congenital abnormalities associated with these mutations may be highly variable, even within the same family (Szinnai, 2014; Carre *et al.*, 2009). Additionally, biallelic *GLIS3* mutations are now robustly associated with CH in the context of a multisystem phenotype (Dimitri, 2017).

NKX2-1

NKX2-1 belongs to the homeodomain-containing transcription factor family, and is one of the key transcription factors mediating thyroid development. Additionally, it is expressed in the distal pulmonary epithelium where it plays a role in surfactant production, the ventral forebrain, and hypothalamic neurons. Heterozygous *NKX2-1* mutations are the commonest transcription

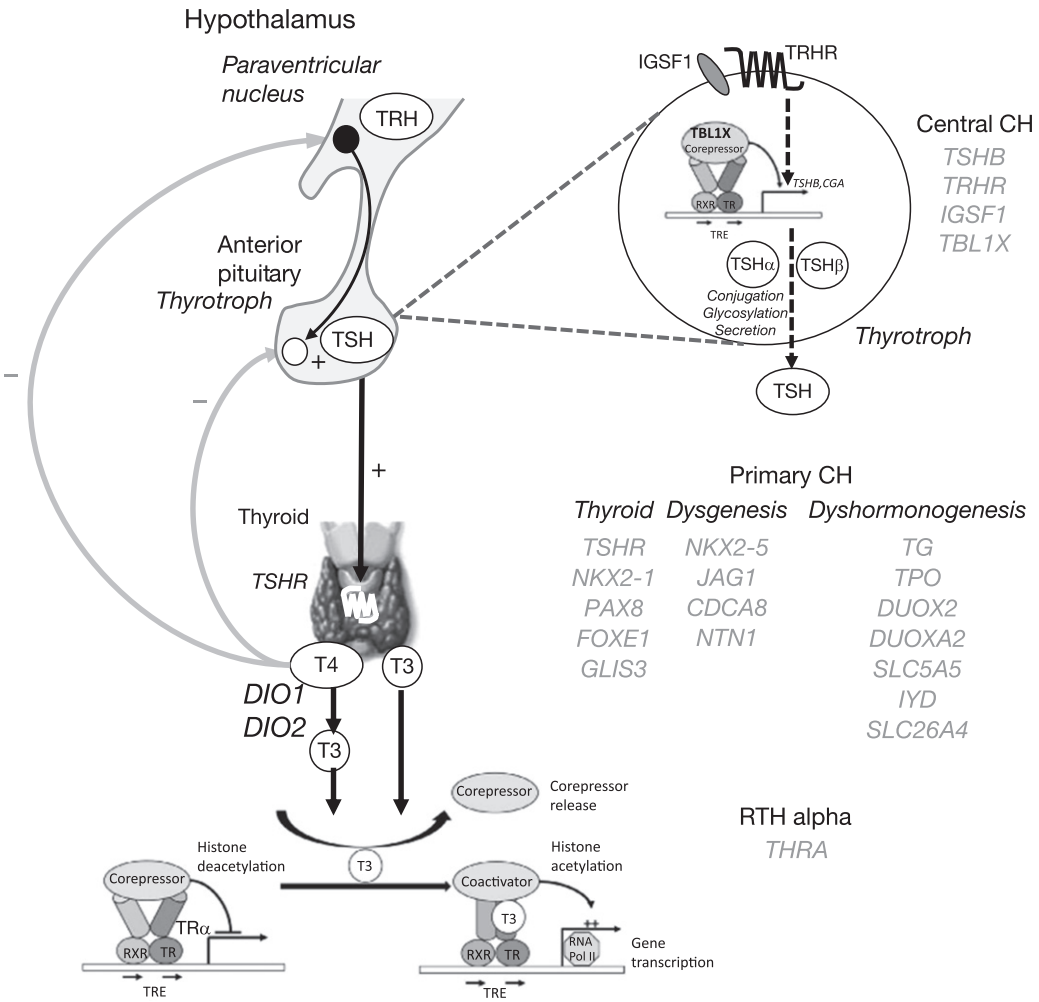

Fig. 1 Schematic summarizing the key genes (gray) implicated in isolated congenital central hypothyroidism (CCH), primary hypothyroidism and RTH alpha. The hypothalamic–pituitary–thyroid axis is illustrated; processes stimulated by TRHR signaling (TSH alpha and beta subunit transcription and conjugation, glycosylation and secretion of mature TSH) are shown by black dotted lines. T4 secreted by the thyroid gland is converted to T3 (the active hormone) by deiodinase enzymes (DIO1, DIO2) before binding its nuclear receptors, enabling corepressor release and coactivator recruitment with subsequent transcriptional activation of positively regulated genes. Proteins encoded by genes implicated in CCH and RTH alpha are shown in *bold type* at their site of action.

factor mutation underlying CH and may cause a spectrum of brain, lung and thyroid disease although penetrance is highly variable, even within the same family, and a complete triad of phenotypes is found in only ~50% of patients (Carre *et al.*, 2009).

The commonest clinical manifestations of *NKX2-1* mutations are neurological (affecting >90% of cases), usually comprising a benign hereditary chorea, although more subtle features such as delayed motor milestones may also occur. Overt or subclinical hypothyroidism occurs in >75% cases and is usually mild, however thyroid morphology ranges from normal (in 55%) to hypoplasia, hemiagenesis or athyreosis. Only 54%–78% of cases exhibit a pulmonary phenotype (most commonly infant respiratory distress syndrome, IRDS), however, this carries an associated mortality of up to 16% (Carre *et al.*, 2009; Thorwarth *et al.*, 2014).

NKX2-1 mutations frequently occur de novo, which, if confirmed, may reassure parents of an affected child that their risk of future affected offspring is similar to that of the background population (Carre *et al.*, 2009; Maquet *et al.*, 2009). There are a significant number of reported deletions involving *NKX2-1*, therefore multiple ligation-dependent probe amplification (MLPA) is required for definitive exclusion of NKX2-1 deficiency (Teissier *et al.*, 2012). Additionally, deletions proximal to *NKX2-1* have also been implicated in the brain-ling-thyroid syndrome (Kharbanda *et al.*, 2017).

PAX8

PAX8 belongs to the paired homeodomain transcription factor family and more than 20 heterozygous, loss of function *PAX8* mutations have been reported, with autosomal dominant inheritance. Most mutations are missense or nonsense substitutions affecting the DNA binding domain of PAX8 but small deletions and promoter region mutations have also been described (de Sanctis *et al.*, 2004; Hermanns *et al.*, 2014b; Perone *et al.*, 2016). The thyroid biochemical phenotype of affected patients is highly

Table 1 A summary of the genetic defects implicated in congenital hypothyroidism and typical clinical features

Gene	*M/B*	*Additional clinical features*	*Typical biochemical features*	*Radiological features*
NKX2-1	M	Neurological (BHC, ~90% cases), respiratory (IRDS, recurrent infections, >50% cases)	Euthyroid–severe CH	GIS–athyreosis
PAX8	M	Urogenital tract malformations (rare)	Euthyroid–severe CH	Typically hypoplasia, range GIS–athyreosis
FOXE1	B	Cleft palate, spiky hair (universal), choanal atresia	Severe CH	Athyreosis
GLIS3	B	Neonatal diabetes, dysmorphic facies, renal cystic dysplasia, hepatic fibrosis, congenital glaucoma, learning difficulties and skeletal abnormalities	Severe CH, TSH resistance	GIS–athyreosis
NKX2-5	M	Congenital heart disease	Euthyroid–severe CH	GIS–ectopy–athyreosis
CDCA8	M/B		Congenital heart disease[a]	Euthyroid–severe CH
Athyreosis-		–ectopy–hemiagenesis–nodules	*JAG1*	M
Alagille syn-		drome/congenital heart disease/isolated CH	Euthyroid/mildly elevated TSH–severe CH	GIS–hypoplasia–ectopy
NTN1[b]	M	Congenital heart disease	Severe CH	Ectopy
TSHR	M/B		May be TSH resistant to L-T4 treatment	Mildly elevated TSH–severe CH
GIS-		–severe hypoplasia	*TG*	B
May cause fetal goiter	E-	uthyroid–severe CH Inappropriately low TG when TSH is elevated	GIS–goiter Normal organification of iodide	
TPO	B[c]	May cause fetal goiter	Severe CH	GIS–goiter TIOD, rarely PIOD
DUOX2	M/B		Transient or permanent, blood spot TSH may be borderline	Mild/transient–severe CH
GIS-		–goiter PIOD		
DUOXA2	M/B		Transient or permanent	Mild/transient CH
GIS-		–goiter PIOD		
Pendrin	M	Sensorineural hearing loss with EVA	Euthyroid/mild hypothyroidism	GIS–goiter PIOD
NIS	M	May present later in childhood resulting in neurodevelopmental delay	Euthyroid–severe CH	GIS–goiter Severely impaired thyroid 123I/Tc uptake
IYD	M/B		Raised urinary MIT and DIT May present later in childhood resulting in neurodevelopmental delay	Euthyroid–severe CH/later onset hypothyroidism
Goiter Normal organification of iodide				

[a] $n = 1$ case.

[b] $n = 1$ case, additional variants: 47, XYY karyotype; and atypical 22q11 deletion.

[c] Occasional monoallelic cases reported.

GIS, normally located thyroid gland in situ; *BHC*, benign hereditary chorea; *EVA*, enlarged vestibular aqueduct; *IRDS*, infant respiratory distress syndrome; *PIOD*, partial iodide organification defect; *TIOD*, total iodide organification defect; *M*, monoallelic; *B*, biallelic.

variable, ranging from euthyroidism to severe hypothyroidism and although the characteristic thyroid morphology comprises thyroid hypoplasia, both thyroid agenesis and normal-sized thyroid glands have been reported. PAX8 is also expressed in the nephrogenic mesenchyme and adult kidney and in rare cases *PAX8* mutations may be associated with urogenital tract abnormalities (Montanelli and Tonacchera, 2010; Ramos *et al.*, 2014; Vincenzi *et al.*, 2014; Carvalho *et al.*, 2013).

FOXE1

FOXE1 belongs to the forkhead/winged-helix transcription factor family and although rarely reported, loss of function biallelic mutations usually cause a consistent syndrome of athyreosis or severe thyroid hypoplasia, cleft palate and spiky hair (Bamforth–Lazarus syndrome), in addition to choanal atresia and bifid epiglottis in some cases. These extrathyroidal congenital abnormalities reflect the expression of FOXE1 in epiglottis, palate, esophagus, definitive choanae and hair follicles (Castanet and Polak, 2010; Clifton-Bligh *et al.*, 1998). All reported loss-of-function mutations are located in the forkhead DNA binding domain and exhibit recessive inheritance, although a gain of function mutation in the same region has been associated with a similar clinical phenotype (Carre *et al.*, 2014). Recently, isolated, nonsyndromic thyroid hypoplasia has been reported in a patient with biallelic *FOXE1* mutations. Although the variants were not subjected to functional characterization, observations suggest a broader phenotypic spectrum may occur with *FOXE1* mutations than previously suspected (de Filippis *et al.*, 2017). *FOXE1* also contains a long polyalanine tract, the length of which may be associated with risk of TD with a longer tract length being protective (Carre *et al.*, 2007).

GLIS3

GLIS3 belongs to the GLI-similar zinc finger protein family and has a critical role both in repression and activation of transcription from early in embryogenesis (Dimitri, 2017). Recessively inherited mutations in *GLIS3* are associated with a multisystem phenotype usually comprising CH (with the exception of one reported patient) and permanent neonatal diabetes, in association with other developmental abnormalities including dysmorphic facies, renal cystic dysplasia, hepatic fibrosis, congenital glaucoma, learning difficulties and skeletal abnormalities (Senée *et al.*, 2006; Dimitri, 2017). Genetic background, or size and position of the *GLIS3* mutation may affect the associated phenotype, especially given that two major *GLIS3* transcripts exhibit differential, tissue-specific expression (Senée *et al.*, 2006). Thyroid morphology may range from hypoplasia or gland athyreosis to apparently normal, however, in a single patient for whom histological analysis of the thyroid has been undertaken, a paucity of colloid as well as extensive fibrosis was demonstrated, despite initially normal thyroid ultrasonography (Dimitri *et al.*, 2015).

Significant TSH resistance has been a prominent biochemical characteristic in some cases with *GLIS3* mutations (Dimitri, 2017), perhaps explained by recent data demonstrating that GLIS3 acts downstream of TSH and the TSHR, being indispensable for TSH/TSHR-mediated proliferation of thyroid follicular cells and biosynthesis of thyroid hormone (Kang *et al.*, 2017).

Additional Genes Associated With TD

NKX2-5

NKX2-5 is a homeodomain-containing transcription factor of the NKX2 family. Although robustly implicated in congenital heart disease, its role in thyroid dysgenesis remains ambiguous. NKX2-5 is an attractive candidate gene for TD since murine *Nkx2-5* null embryos exhibit thyroid bud hypoplasia and following an initial report of four patients with thyroid ectopy or athyreosis harboring heterozygous *NKX2-5* mutations, several further TD cases with NKX2-5 mutations have been described, including one with a heterozygous *NKX2-5* mutation in association with a *PAX8* promoter mutation (Dentice *et al.*, 2006; van Engelen *et al.*, 2012; Hermanns *et al.*, 2011; Opitz *et al.*, 2015). However, penetrance is highly variable; carrier parents frequently have no morphological or biochemical evidence of CH and apparently pathogenic mutations (p.R25C) may occur frequently in healthy populations, or (p.A119S) in patients with congenital heart disease but normal thyroid morphology (Dentice *et al.*, 2006; van Engelen *et al.*, 2012). These observations suggest that although NKX2-5 may contribute to TD risk, other factors/genes are likely to play a significant role modulating penetrance and expressivity.

JAG1

JAG1 encodes a ligand of the Notch receptor required for normal thyroid development in zebrafish. Human heterozygous *JAG1* mutations are associated with a multisystem disorder (Alagille syndrome) in which congenital heart disease (CHD) may associated with variable hepatic, eye and skeletal defects together with dysmorphic facies. Recently, evaluation of thyroid function in a cohort of 21 cases with Alagille syndrome revealed six cases with mild, nonautoimmune hypothyroidism. Additionally, evaluation of *JAG1* in 100 CH cases without associated Alagille syndrome identified four cases harboring heterozygous *JAG1* variants with partial loss of function, two with associated CHD. Detection of further rare *JAG1* variants in a cohort of >300 CH cases further substantiated the notion that JAG1 may contribute to the pathogenesis of CH. Thyroid morphology in affected humans ranges from eutopic thyroid to gland dysgenesis including hypoplasia or ectopy (de Filippis *et al.*, 2016, 2017).

Borealin

Borealin (CDCA8) is a major component of the Chromosomal Passenger Complex (CPC) which has well-described functions in chromosome segregation and cytokinesis. Mono- and biallelic *CDCA8* mutations were recently reported in association with TD in three unrelated families, in which the carrier parents were all euthyroid but exhibited variable thyroid structural abnormalities. A

homozygous mutation (p.S148F) in two children was associated with CH and thyroid ectopy, or euthyroidism with thyroid hemiagenesis; the heterozygous parents exhibited an asymmetric thyroid or thyroid nodules. In a second family, a heterozygous mutation (p.R114Q) in the proband was associated with CH and thyroid ectopy; the heterozygous mother had an asymmetric thyroid with papillary thyroid cancer. Finally, another heterozygous mutation (p.L177W) was associated with CH and athyreosis in the proband and thyroid nodules in the carrier mother. Expression of mutant Borealin in a thyroid cell line resulted in altered cellular migration and adhesion by decreasing the expression of genes implicated in focal adhesion (Carré *et al.*, 2017).

Netrin 1 (NTN1)

Netrin 1 is a laminin superfamily member with a role in mediating guidance cues during embryogenesis. A heterozygous deletion involving part of *NTN1* has been reported in one patient, with VSD and thyroid ectopy, in addition to a 47, XYY karyotype and an atypical 22q11 deletion. Subsequent zebrafish studies demonstrated defective aortic arch artery formation in ntn1a-deficient embryos in addition to abnormal thyroid morphogenesis, likely due to lack of proper guidance exerted by the dysplastic vasculature of ntn1a-deficient embryos. The extent to which NTN1 mutations contribute to shared thyroid and cardiac congenital defects in the population remains unclear (Opitz *et al.*, 2015).

Syndromes Which May Be Associated With CH

Risk of CH may be increased in the context of several genetically defined syndromes for which the major associated abnormalities are extrathyroidal. Candidate genes involved include *SALL1* (Townes–Brocks syndrome), *TBX1* (di George syndrome), *URB1* (Johanson–Blizzard syndrome), *DYRK1A* (Trisomy 21), *ELN* (Williams–Beuren syndrome), *KMT2D/MLL2*, *KDM6A* (Kabuki syndrome) and *KAT6B* (Ohdo syndrome, Genitopatelar syndrome (Cherella and Wassner, 2017).

Thyroid Hormone Biosynthesis (Summarized in Fig. 2)

Thyroid hormone biosynthesis occurs at the apical surface of polarized thyroid follicular cells and requires an intact synthesis pathway comprising transporter molecules, enzymes and thyroglobulin as well as adequate dietary iodide (**Fig. 2**). Dyshormonogenesis occurs due to loss of function mutations in any of the known genes encoding the components of the thyroid hormone biosynthetic machinery. The initial step in thyroid hormone production is the active uptake of circulating iodide across the basolateral membrane by the sodium-iodide symporter, NIS (SLC5A5), which co-transports one iodide ion against its

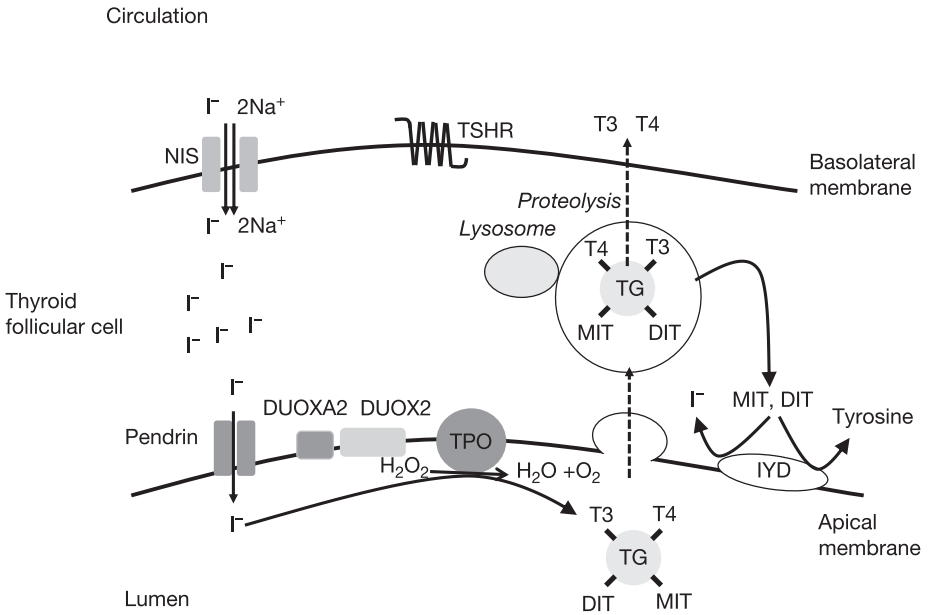

Fig. 2 Schematic summarizing the key steps in thyroid hormone biosynthesis. Iodide is concentrated in the thyroid follicular cell following active uptake by the sodium-iodide symporter (NIS, SLC5A5). Pendrin (SLC26A4) and other less well characterized transporters facilitate iodide efflux across the apical membrane, whereupon iodide is oxidized in a hydrogen-peroxide dependent process, catalyzed by the thyroid peroxidase enzyme (TPO). H_2O_2 is primarily generated by the NADPH-oxidase DUOX2 and its accessory protein DUOXA2. TPO also catalyzes the organification of iodide, that is, its incorporation into mono and di-iodotyrosyl residues (MIT, DIT) on the surface of thyroglobulin (TG) and their coupling to form thyroid hormones T3 and T4. Iodotyrosine dehalogenase (IYD) recycles unused iodide moieties and TSH signaling via the TSH receptor stimulates both thyroid hormone biosynthesis and gland growth.

electrochemical gradient together with two sodium ions along a sodium gradient generated by the Na + /K + -ATPase. Iodide efflux at the apical membrane is likely to be at least partially mediated by Pendrin, encoded by *SLC26A4*, a multifunctional anion transporter which exchanges chloride for either iodide or bicarbonate. Iodide is oxidized at the follicular lumen and then organified into tyrosyl residues of thyroglobulin (TG), the matrix glyoprotein upon which thyroid hormone is synthesized. Mono- and diiodotyrosines (MIT, DIT) undergo coupling to generate iodothyronines (predominantly T4, with smaller amounts of T3). Oxidation and organification of iodide and the subsequent coupling reaction are catalyzed by the thyroid-specific enzyme thyroid peroxidase (TPO). Hydrogen peroxide (H_2O_2), the essential electron acceptor for the iodination and coupling reactions, is produced mainly by NADPH oxidase dual oxidase 2 (DUOX2, previously known as THOX2) and its accessory protein dual oxidase maturation factor 2 (DUOXA2). Triodothyronine (T3) and thyroxine (T4) are stored in the colloid until TG is taken up by thyroid follicular cells through macro- and micropinocytosis and digested in lysosomes. Secretion of thyroid hormones then occurs into the bloodstream at the basolateral membrane. Uncoupled mono- and diiodotyrosines (MIT, DIT) are subject to NADPH-dependent reductive deiodination by intracellular iodotyrosine dehalogenase (IYD, previously known as DEHAL1) which enables them to be recycled (Grasberger and Refetoff, 2011) (**Fig. 2**).

Dyshormonogenesis (Genetic Causes Summarized in Fig. 1 and Table 1)

Dyshormonogenesis refers to inadequate thyroid hormone synthesis due to a specific defect in one of the components of the thyroid hormone biosynthetic machinery. In all forms of dyshormonogenesis, compensatory gland hyperplasia may result in goiter. Other clinical, radiological and biochemical features are dependent on the site of the defect in the thyroid hormone synthesis pathway. If the dysfunctional protein results in impaired organification of iodide, a perchlorate discharge test will be positive. This investigation involves the quantitation of an administered dose of radioiodine (^{123}I) in the thyroid before and after the patient is given perchlorate, which inhibits further thyroidal uptake of iodide. Under normal circumstances, if organification is intact, >90% of ^{123}I remains in the thyroid follicle bound to TG but, if organification is impaired, <90% of the thyroidal ^{123}I can be organified and >10% leaks back into the circulation. Severe enzymatic defects cause loss of >90% of the applied ^{123}I dose (total iodide organification defect, TIOD) but enzymatic defects with residual function cause partial iodine organification (PIOD) defined as 10%–90% of ^{123}I washout after perchlorate (Grasberger and Refetoff, 2011).

SLC5A5 (NIS)

Autosomal recessively inherited mutations in the sodium-iodide symporter (*NIS*) are a rare cause of dyshormonogenesis, disrupting uptake of iodide across the basolateral thyrocyte membrane. Individuals with NIS mutations may develop severe congenital hypothyroidism, or, especially in areas where dietary iodine content is high, euthyroid goiter. CH due to NIS mutations may not manifest neonatally and affected children with normal TSH screening results may develop severe hypothyroidism unexpectedly in childhood with concomitant neurodevelopmental delay (Grasberger and Refetoff, 2011; Szinnai *et al.*, 2006).

Characteristic radiological features associated with NIS mutations are a blunted or absent radioiodine uptake by the thyroid despite ultrasonographic evidence of a normally located, usually enlarged gland (0%–5% vs. the normal range of 10%–40%) (Szinnai *et al.*, 2006). Since NIS is also expressed in gastric parietal cells and salivary glands, these tissues also fail to concentrate iodine if the transporter is defective. This feature can be exploited diagnostically, since the ratio of salivary: plasma iodine following injection of radioiodine will be decreased (Montanelli *et al.*, 2009).

SLC26A4 (Pendrin)

Pendrin mediates chloride bicarbonate transport in the inner ear where is it essential for maintaining acid-base homeostasis of the endolymphatic fluid. Biallelic mutations in Pendrin are a well-recognized cause of congenital sensorineural hearing impairment with enlarged vestibular aqueduct (80%–100%) and a subset of cases also harbor a Mondini cochlear malformation (incomplete partition of the cochlea) (Phelps *et al.*, 1998; Luxon *et al.*, 2003; Cremers *et al.*, 1998).

Pendrin also has a putative role in thyrocyte apical iodine transport and Pendred syndrome refers to the association of congenital bilateral sensorineural hearing loss and vestibular dysfunction with diffuse or multinodular goiter resulting from a PIOD. Most affected patients who are iodide replete remain euthyroid and if hypothyroidism does occur this is usually after the second decade, such that Pendrin mutations represent an unusual cause of CH (Wémeau and Kopp, 2017; Reardon *et al.*, 1999).

TG

Autosomal recessively inherited *TG* mutations are rare in the general population, but one of the more common causes of dyshormonogenesis; >100 different mutations have been described with an estimated frequency of 1:100,000 births (Ieiri *et al.*, 1991, Targovnik *et al.*, 2017). *TG* mutations frequently result in goiter, which may manifest in the neonatal period; rarely, cases are complicated by fetal goiter (Vasudevan *et al.*, 2017). The spectrum of biochemical thyroid dysfunction ranges from euthyroidism

to severe hypothyroidism and diagnostic hallmarks of *TG* mutations include low thyroglobulin despite elevated TSH and goiter or failure of TG to rise after stimulation with exogenous TSH. Thyroidal iodide uptake is enhanced and organification of iodide is preserved on perchlorate discharge test (Targovnik *et al.*, 2011, 2017).

TPO

Autosomal recessively inherited *TPO* mutations disrupt the final enzymatic steps in thyroid hormone biosynthesis and are a common cause of dyshormonogenesis, representing the main underlying mechanism for TIOD (Abramowicz *et al.*, 1992; Bakker *et al.*, 2000; Cangul *et al.*, 2013). More than 100 mutations have been described, and missense variants generally cluster around the heme binding catalytic domain. Affected individuals with biallelic mutations usually exhibit severe CH, often with goiter and fetal goiter may rarely occur. Investigations usually demonstrate preserved iodide uptake and TG biosynthesis with TIOD (Targovnik *et al.*, 2017; Ris-Stalpers and Bikker, 2010). Rarely, monoallelic mutations are associated with CH and PIOD, or, in isolated cases, with TIOD, perhaps due to monoallelic expression of TPO in thyroid (Nascimento *et al.*, 2003; Fugazzola *et al.*, 2003).

DUOX2

Both monoallelic and biallelic *DUOX2* mutations may result in CH, usually with PIOD. Since the first association of *DUOX2* mutations with CH, DUOX2 has been increasingly implicated in the pathogenesis of dyshormonogenesis, especially in East Asian populations (Jin *et al.*, 2014; Moreno *et al.*, 2002). Although biallelic mutations were first associated with permanent CH, and monoallelic mutations with transient CH (Moreno *et al.*, 2002), subsequent studies have demonstrated permanent CH in association with monoallelic mutations (de Marco *et al.*, 2011) and transient CH in the context of biallelic, truncating mutations (Hoste *et al.*, 2010). This variable penetrance of DUOX2 deficiency is incompletely understood; iodine deficiency is thought to exacerbate the phenotype and variants in other H_2O_2-synthesizing enzymes capable of compensating for DUOX2 deficiency, for example, DUOX1, may also modulate CH severity (Grasberger and Refetoff, 2011; Aycan *et al.*, 2017). Cases harboring *DUOX2* mutations may be missed on neonatal screening since screening TSH measurements may be only marginally elevated; confirmatory venous TSH and TG measurements are usually more markedly raised and iodide uptake is preserved (Muzza *et al.*, 2014).

DUOXA2

DUOXA2 mutations are a rare cause of dyshormonogenesis, with <10 variants currently reported. The first reported case exhibited mild permanent CH in association with biallelic mutations and PIOD. Both monoallelic and biallelic defects have now been described, in association with both mild permanent and transient CH although clinical data for affected cases is sparse. The small number of reported cases suggests that *DUOXA2* defects are rare causes of CH which may also be more common in East Asian populations, especially the recurrent mutation, p.Y138* (Zamproni *et al.*, 2008; Liu *et al.*, 2015; Park *et al.*, 2016).

IYD (Previously Known as DEHAL1)

Goitrous individuals in whom iodide recycling is impaired were first described many years ago, but a molecular diagnosis was only achieved more recently (Hubble, 1953; Moreno *et al.*, 2008). Both monoallelic and biallelic *IYD* mutations can cause goitrous hypothyroidism and affected individuals exhibit rapid thyroidal uptake of iodide with a normal perchlorate discharge test (Moreno *et al.*, 2008; Burniat *et al.*, 2012; Afink *et al.*, 2008). Urinary concentrations of MIT and DIT are characteristically increased. Hypothyroidism may manifest in childhood following a normal neonatal CH screening test result resulting in neurodevelopmental delay if diagnosis is delayed (Moreno *et al.*, 2008).

Evidence for an Undiagnosed Genetic Component in TD

Until recently, studies in TD have used Sanger sequencing to screen small numbers of known TD-associated genes individually, often in small TD populations. On the basis of such studies, which have revealed causative mutations in $<5\%$ cases, it has been argued that TD is a sporadic disease. This notion is further supported by $>90\%$ discordance between monozygotic twins with CH (Perry *et al.*, 2002) and observations that there is a strong female preponderance of CH, especially due to thyroid ectopy (Devos *et al.*, 1999). Since these features are not consistent with simple Mendelian inheritance, it has been hypothesized that TD may occur due to somatic mutations restricted to the thyroid or epigenetic events.

However, there is also evidence to suggest a more significant etiological role for germline mutations in TD than currently diagnosed. A French National Survey of CH cases demonstrated that 2% of TD cases have an affected relative; this value is 15-fold greater than predicted by chance alone. Moreover, thyroid developmental abnormalities occur more commonly in euthyroid first degree relatives of CH cases than in controls (Castanet *et al.*, 2000, 2001, 2005; Leger *et al.*, 2002). Several studies have also shown an increased incidence of extrathyroidal developmental malformations in patients with CH, and CH occurs more frequently in

consanguineous or less genetically diverse populations (Kreisner *et al.*, 2005; Ordookhani *et al.*, 2004; Stoppa-Vaucher *et al.*, 2011).

Alternative Genetic Etiologies in TD and Dyshormonogenetic CH

Possible mechanisms which may reconcile these observations include a two-hit mechanism, where a germline predisposing mutation occurs in association with an additional genetic or epigenetic alteration within the thyroid tissue or surrounding structures (Deladoey *et al.*, 2007). However, no firm evidence for this has been established. Analysis of ectopic thyroid has not demonstrated significantly different somatic methylation gene expression profile differences or thyroid specific copy number variants (CNV's) compared with normal thyroid although ectopic thyroid did exhibit a different gene expression pattern (Abu-Khudir *et al.*, 2010). Additionally, sequencing of lymphocyte DNA from monozygotic twins discordant for TD did not reveal somatic mutations (Magne *et al.*, 2015) although somatic mosaicism for a PAX8 mutation has been reported (Narumi *et al.*, 2011). Autosomal monoallelic expression has been reported for some genes in both ectopic and eutopic thyroid, suggesting this may be implicated (Magne *et al.*, 2016); however, monoallelic expression of a mutant allele has only been reported for TPO in association with dyshormonogenetic CH and TIOD (Neves *et al.*, 2010; Fugazzola *et al.*, 2003). Recurrent copy number variants have also not been identified (Thorwarth *et al.*, 2010).

Apparently sporadic cases could also have an oligogenic basis, as has been established for Kallmann syndrome (Van Vliet and Deladoey, 2015). Support for this proposition initially came from observations that mice with heterozygous *TTF1* or *PAX8* mutations are euthyroid, but strain-specific TD occurs in mice with combined partial deficiencies of TTF1 and PAX8 (Amendola *et al.*, 2005). Until recently, only anecdotal reports had been published of patients harboring digenic mutations in association with CH, however, recent larger, human studies have also confirmed a role for oligogenic inheritance in both CH with eutopic gland-in-situ and thyroid dysgenesis (Nicholas *et al.*, 2016; Löf *et al.*, 2016). This includes a study of >150 Italian patients with CH of all types, in which 23% harbored a likely pathogenic variant in more than one gene (de Filippis *et al.*, 2017). In addition to oligogenicity for known-CH-associated genes, digenic *DUOX2* and *DUOX1* homozygous mutations were recently reported in association with unusually severe CH (Aycan *et al.*, 2017). DUOX2 is thought to be the main H_2O_2-generating enzyme in the thyroid on the basis of its higher expression levels. However, it has been suggested that enhanced expression of DUOX1 may help compensate for DUOX2 deficiency in CH due to DUOX2 mutations, suggesting that variants in DUOX1 may contribute to phenotypic severity in DUOX2 mutation cases.

The advent of next generation sequencing has also enabled the screening of genes classically associated with TD or dyshormonogenesis in mixed CH populations. The outcome of these studies has been a realization that there may be overlap of genetic etiologies in the two morphological subgroups. de Filippis et al. demonstrated mutations in genes characteristically associated with TD (e.g., biallelic *FOXE1* mutations), in association with isolated CH and a normal thyroid gland, although functional characterization of the mutations was not undertaken (de Filippis *et al.*, 2017). Conversely, Pendrin mutations have been reported in patients with TD, where a potential mechanism was thought to be a secondary atrophy of the thyroid, perhaps due to increased oxidative stress (Kühnen *et al.*, 2014).

Isolated Central Congenital Hypothyroidism

The Hypothalamic–Pituitary–Thyroid Axis: Positive Regulation of Thyroid Hormone Synthesis

Thyroid hormone biosynthesis is positively regulated by the actions of hypothalamic thyrotropin-releasing hormone (TRH) and pituitary thyroid stimulating hormone (TSH). TRH is synthesized in the paraventricular nucleus (PVN) of the hypothalamus and following maturation, undergoes axonal transport to the median eminence, reaching the thyrotrophs of the anterior pituitary gland via the hypothalamic portal vein. TRH then binds the TRH receptor (TRHR), a G-protein coupled receptor, which activates a Gq/11 dependent pathway involving mobilization of intracellular calcium and activation of protein kinase C. TRH upregulates transcription of the TSH alpha (αGSU) and beta subunit genes (*CGA* and *TSHB*) but also exerts important posttranslational effecting including mediating conjugation of TSH alpha and beta subunits and stimulating both secretion of heterodimeric TSH and its glycosylation to confer normal bioactivity (Fekete and Lechan, 2014, Persani, 1998, **Fig. 1**).

Central congenital hypothyroidism (CCH) is a rare disorder which occurs when hypothalamic or pituitary pathology results in defective stimulation of a normal thyroid gland by thyroid stimulating hormone (TSH). Since TSH is not elevated in CCH, TSH-based, primary CH screening programs will not detect CCH in the neonatal period, and patients are at risk of neurodevelopmental delay if detection and treatment of severe CCH is delayed. Additionally, for CCH occurring as part of a syndrome of combined pituitary hormone deficits, delayed diagnosis of other hormone deficiencies (adrenocorticotrophic hormone, ACTH; growth hormone, GH) may pose significant risks, such as life threatening hypoglycemia (Schoenmakers *et al.*, 2015).

In a minority of cases (estimated incidence 1:65000), TSH deficiency is isolated and may occur as a result of defects in genes driving or regulating the TSH biosynthetic pathway. Four main genes have been implicated, in which mutations result predominantly in quantitative and/or qualitative defects in TSH secretion; thyrotropin-releasing hormone receptor (*TRHR*), thyroid stimulating hormone beta subunit (*TSHB*), immunoglobulin superfamily member 1 gene (*IGSF1*) and the transducin beta like 1X-linked gene, *TBL1X* (Schoenmakers *et al.*, 2015; Heinen *et al.*, 2016).

Table 2 Endocrine, neuroradiological and extrapituitary manifestations of mutations in genes implicated in CCH in humans

Gene	*Inheritance*	*Hormone deficits*	*TRH test responses*	*MRI*	*Additional features*
TSHB	AR	TSH	Absent TSH response, preserved PRL peak	E, N	–
TRHR	AR	TSH	Absent/preserved TSH & PRL peak	N	–
TBL1X	XL[a]	TSH	Normal TSH response	N	Sensorineural hearing loss
Isolated TSH deficiency or combined pituitary hormone deficiency					
IGSF1	XL[a]	TSH ± PRL, GH (transient)	Low normal/normal TSH response	N	Macroorchidism (males) Ovarian cysts (females)

[a]Females may also be affected.

E, enlarged; *N*, normal; *TSH*, thyroid-stimulating hormone; *PRL*, prolactin; *GH*, growth hormone; *AR*, autosomal recessive; *XL*, X-linked.

Isolated Central Congenital Hypothyroidism (Genetic Causes Are Summarized in Fig. 1 and Table 2)

TSHB *mutations*

Biallelic loss of function, *TSHB* mutations are invariably associated with severe CCH. Cases residing in countries operating TSH-based neonatal CH screening programs are usually diagnosed when they present clinically, and frequently exhibit neurodevelopmental impairment, the extent of which correlates with the degree of treatment delay. In cases who are diagnosed and treated from birth due to ascertainment following a prior genetic diagnosis in their family, developmental outcome is often improved (Karges *et al.*, 2004; Brumm *et al.*, 2002, Nicholas *et al.*, 2017).

Mature TSH comprises a heterodimer of the common alpha subunit (αGSU) shared with other glycoprotein hormone (LH, FSH, CG) family members and a TSH-specific beta-subunit (TSHB). Naturally occurring mutations either truncate the protein, or perturb key structural features required for maintaining the integrity of the heterodimer. A "seat belt" formed from the TSH beta subunit, wraps around the long loop of the alpha subunit and forms an intramolecular disulfide "buckle" to stabilize the heterodimer and additional alpha–beta subunit interactions occur around a conserved CAGYC sequence motif (Szkudlinski *et al.*, 2002; Jiang *et al.*, 2014). All described missense mutations disrupt key disulfide bridges required for heterodimeric integrity, truncate the protein or disrupt the CAGYC region. The most common mutation is a single nucleotide deletion (c373delT) leading to a cysteine 125 to valine change (p.C125V) and subsequent frameshift and premature stop codon at position 134 (p.C125Vfs*10) (Medeiros-Neto *et al.*, 1996). Although reported worldwide in several, nonconsanguineous families, a founder effect has been described in German and Irish kindreds (Domene *et al.*, 2004; Brumm *et al.*, 2002; Nicholas *et al.*, 2017). In addition, two splice-site mutations (c162G>A, c.162 + 5G>A) (Baquedano *et al.*, 2010; Pohlenz *et al.*, 2002) and two *TSHB* deletions (Hermanns *et al.*, 2014a; Nicholas *et al.*, 2017) have been described. (The nomenclature of these mutations follows the most recent HGNC guidelines to include the 20 amino acid signal peptide of TSHB, such that the annotation may differ from that cited in the original published articles).

Biochemical hallmarks of CCH due to *TSHB* mutations include elevated pituitary glycoprotein alpha subunit, and impaired TSH response to TRH administration, despite a preserved serum Prolactin rise (Bonomi *et al.*, 2001). Mutations (p.G49R, p.Q32*), which disrupt heterodimer formation between TSHalpha and beta polypeptides generally result in undetectable serum TSH concentrations, whereas in cases with mutations resulting in synthesis of nonbioactive heterodimeric TSH (e.g., p.Q69*, IVS2 + 5G>A, c.373delT), immunoreactive TSH will be detected in an immunoassay-dependent manner if epitopes recognized by the anti-TSH monoclonal antibody are preserved (Bonomi *et al.*, 2001).

TRHR *mutations*

Only four unrelated kindreds have been reported, in which affected cases harbor biallelic *TRHR* mutations. In three probands, TRHR activity was completely abrogated; the first case was compound heterozygous for a nonsense mutation (p.R17*), and an in-frame deletion of three amino acids (S115, I116, and T117) with one substitution (p.A118T). In the second reported kindred, affected individuals were homozygous for the p.R17* mutation and the third proband harbored a highly deleterious homozygous p.P81R missense variant (Bonomi *et al.*, 2009; Collu *et al.*, 1997; Koulouri *et al.*, 2016). Homozygous individuals in these families exhibited T4 concentrations 40%–88% lower limit of the normal range and heterozygous carriers had normal FT4 levels. In a fourth kindred, harboring a p.I131T mutation, signal transduction was impaired but not completely absent, with two homozygotes exhibiting either moderate CCH or isolated hyperthyrotropinemia. Heterozygotes in this kindred exhibited isolated hyperthyrotropinemia, for which the mechanism is unclear (García *et al.*, 2017).

The main reported clinical manifestations in kindreds harboring severe biallelic mutations comprised growth retardation and delayed bone age. Some affected patients were first diagnosed with central hypothyroidism in late childhood or even adulthood, but did not exhibit any significant neurological deficit suggesting that thyroid hormone production was sufficiently preserved in infancy to prevent overt mental retardation. However, even relatively asymptomatic cases exhibited improved quality of life following initiation of levothyroxine therapy (Bonomi *et al.*, 2009).

Since TRHR is expressed in lactotrophs as well as thyrotrophs, intravenous TRH usually stimulates a prolactin response as well as a TSH response, and both responses were absent in patients with severe bilallelic *TRHR* mutations but preserved with the milder p.I131T mutation. One female with a homozygous, nonsense *TRHR* mutation (p.R17*), was only diagnosed with central hypothyroidism following family screening at the age of 33, having previously achieved two normal pregnancies with subsequent

lactation. These observations suggest that TRH action is not obligatory for pregnancy and lactation in humans (Bonomi *et al.*, 2009). Although serum TSH was inappropriately normal for the low serum FT4 levels in affected cases, circulating T4 levels did rise appropriately following levothyroxine withdrawal, indicating that synthesis of bioactive TSH could occur in the absence of TRH signaling (Collu *et al.*, 1997; Bonomi *et al.*, 2009; Koulouri *et al.*, 2016; García *et al.*, 2017).

IGSF1 *mutations*

Mutations in the immunoglobulin superfamily member 1 (*IGSF1*) gene are now thought to be the most common genetic abnormality underlying CCH (Joustra *et al.*, 2013; Sun *et al.*, 2012). *IGSF1* encodes an X chromosomal membrane glycoprotein which is highly expressed at mRNA level, in Rathke's pouch (the developing pituitary primordium) and in adult pituitary gland (Sun *et al.*, 2012). Expression studies of the human protein have been impeded by the fact that there are no reliable antihuman IGSF1 antibodies; however, in murine and rat pituitary, IGSF1 protein is detected in cells of the Pit1 lineage (thyrotropes, somatotropes and lactotropes, but not gonadotropes) (Sun *et al.*, 2012; Joustra *et al.*, 2015). The IGSF1 carboxyterminal portion trafficks to the plasma membrane where it is expressed as a large extracellular domain with a short intracellular cytoplasmic tail (Robakis *et al.*, 2008), however, in both humans and rodents, its precise physiological function remains undefined (Sun *et al.*, 2012).

More than 30 pathogenic mutations involving the *IGSF1* gene have now been described (Sun *et al.*, 2012; Nakamura *et al.*, 2013; Tajima *et al.*, 2013; Joustra *et al.*, 2016), almost all of which result in decreased plasma membrane expression of IGSF1 and are either located in the extracellular portion of the carboxyterminal domain or result in *IGSF1* deletion. Clinical evaluation of patients with *IGSF1* mutations have confirmed that males invariably exhibit CCH, which is usually mild to moderate. Additionally, male pubertal development is usually disharmonious, with delayed pubertal growth spurt and testosterone rise but normal onset of testicular growth and subsequent macroorchidism in adulthood, for which the underlying mechanism has not been elucidated. Basal prolactin levels are subnormal in >60% cases and infrequently, GH production may be transiently impaired in childhood, necessitating GH replacement. In adulthood, IGF-1 levels are paradoxically in the upper half of the reference range, or mildly elevated and acromegaloid features may develop. Although X-linked, ~20% of heterozygous females harboring *IGSF1* mutations exhibit central hypothyroidism, and the remainder generally exhibit thyroid hormone levels in the lower tertile of the normal range. Up to 20% demonstrate hypoprolactinemia and 4 of 18 females investigated have required surgery for benign ovarian cysts (Sun *et al.*, 2012; Joustra *et al.*, 2013, 2016).

Murine studies in two different IGSF1 deficient mouse lines have demonstrated impaired TRH signaling associated with IGSF1 deficiency and decreased pituitary expression of TRHR despite normal TRH synthesis (Sun *et al.*, 2012, Turgeon *et al.*, 2017). The mild–moderate CCH observed in most humans with hemizygous IGSF1 mutations would also be consistent with impaired TRH signaling in humans with IGSF1 deficiency, although this has not yet been confirmed at a molecular level (Yamada and Mori, 2008). TSH response to TRH is usually subnormal in neonates, but within the lower half of the reference range in child- and adulthood (Joustra *et al.*, 2016).

TBL1X *(transducin β-like protein 1)*

Most recently, missense mutations in *TBL1X* have been reported in patients with isolated CeCH. TBL1X is an essential component of the main nuclear receptor corepressor complex (NCoR/SMRT) involved in T3-regulated gene expression, and mutations are thought to result in impaired basal activation of genes such as *TRH* and *TSHB*, which are negatively regulated by thyroid hormone. *TBL1X* is located on the X chromosome and eight males harboring hemizygous mutations, as well as 11 females harboring heterozygous mutations were identified in six unrelated kindreds. Although FT4 levels in affected adults were significantly lower than in controls, only six males and three females exhibited CCH with FT4 concentrations below the lower limit of the reference range. Where present, CCH was isolated, and mild–moderate, with normal TRH test responses. Additionally, individuals frequently exhibited associated sensorineural hearing loss (Heinen *et al.*, 2016).

Congenital Hypothyroidism Due to Impaired Thyroid Hormone Action

Thyroid Hormone Receptor Isoforms

The genomic effects of thyroid hormone are mediated by the nuclear thyroid hormone receptors (TRs) encoded by the *THRA* and *B* genes on chromosomes 17 and 3 respectively. Four different thyroid hormone receptor protein isoforms (TRα1, α2, β1, and β2) are expressed in humans, which are generated by alternative splicing and use of a different tissue-specific promoter (TRβ). All except the C-terminal TRα variant (TRα2) bind T3, and the physiological role for TRα2 remains unclear. TRs bind preferentially to specific DNA response elements (TREs) as a heterodimer with the retinoid X receptor (RXR). TREs are usually located in the promoter regions of target genes, and when TRs bind these elements, transcription is modulated in a ligand-dependent manner (Ortiga-Carvalho *et al.*, 2014).

Where genes are positively regulated by thyroid hormones, unliganded TRs mediate basal repression of the gene by binding the TRE together with a large repressor complex including corepressors (e.g., NCoR, SMRT), transducin-like protein (TBL1X) and histone deacetylase. This complex modulates local chromatin structure to repress basal transcription. T3 binding drives a conformational change of the receptor ligand binding domain, enabling coactivator recruitment (e.g., SRC-1, -2, -3) and histone

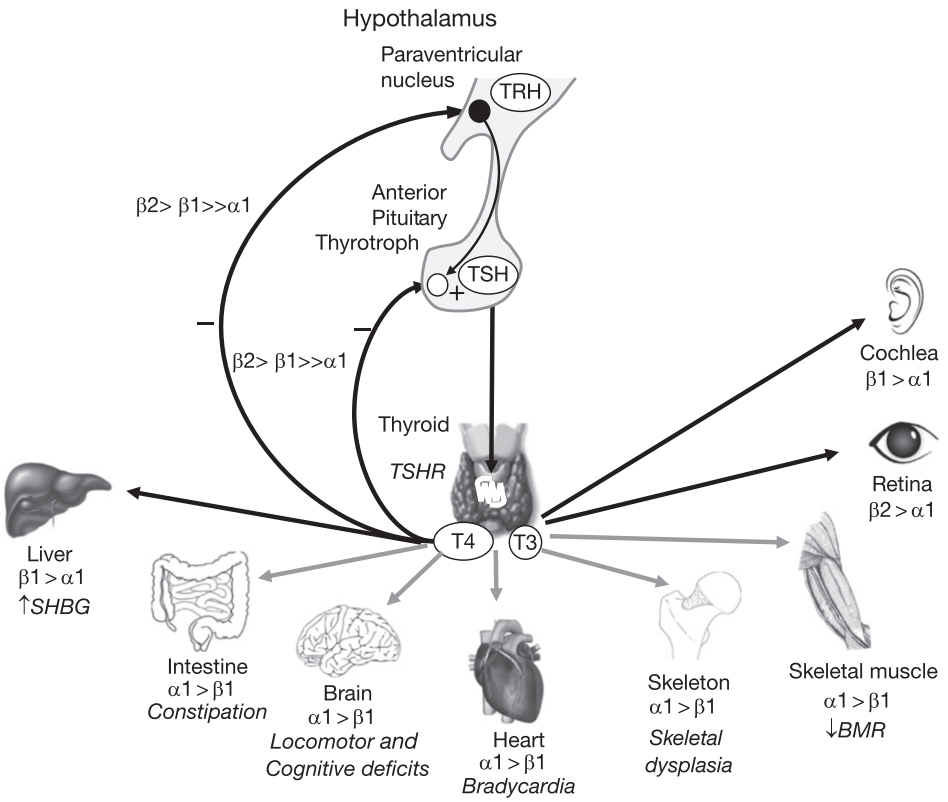

Fig. 3 Schematic summarizing the major tissue-specific thyroid hormone receptor isoform expression patterns and corresponding phenotypes noted in RTHα. In this syndrome, tissues expressing mainly TRα are resistant to thyroid hormone action (impaired, shown in gray), while TR*β*-expressing tissues are sensitive (not obviously impaired, shown in black).

acetylation, enabling the chromatin to achieve a more open conformation, facilitating transcriptional activation (**Fig. 1**). Some genes, including TRH and TSH*β* are negatively regulated by thyroid hormone for which the mechanism remains poorly understood (Ortiga-Carvalho *et al.*, 2014). Postulated mechanisms include recruitment of corepressors instead of coactivators or *trans*-repression, where liganded TRs interact with and inhibit the activity of other transcription factors, for example, GATA2 during TR-mediated repression of *TSHB* (Santos *et al.*, 2011).

Isoform Expression (Summarized in Fig. 3)

Individual tissues exhibit specific patterns of TR isoform expression such that tissue-specific thyroid hormone effects are mediated predominantly by one TR isoform. Expression of thyroid hormone receptor *β*2 is largely confined to the pituitary and hypothalamus, where it is the principal mediator of the negative feedback loop regulating circulating thyroid hormone levels. It also plays a role in cochlea and retina. TR*β*1 predominates in kidney and liver, where it plays a role in cholesterol metabolism, including stimulation of enzymes regulating lipolysis, lipogenesis and oxidative processes (Ortiga-Carvalho *et al.*, 2014).

TRα1 and the nonhormone binding splice variant TRα2 are expressed more widely. TRα1 is the dominant TR isoform in endochondral and intramembranous bone, mediating the anabolic effects of thyroid hormone on the developing skeleton, where it is crucial for normal bone growth, mineralization and turnover and for the maintenance of bone strength (Bassett and Williams, 2016). As the most abundant myocardial TR isoform TRα1 also plays an important role in the regulation of heart rate and contractility, with stimulatory effects on both these processes (Klein and Danzi, 2007; Kahaly and Dillmann, 2005). Additionally, normal gut motility is dependent on TRα1, which is expressed both in gut epithelium and in smooth muscle cells (Plateroti *et al.*, 1999; Shafer *et al.*, 1984), and in skeletal muscle, thyroid hormone acting via TRα1 may have profound effects on muscle mass, metabolism and contractility (Finsterer *et al.*, 1999). 70%–80% cerebral TR isoform expression comprises TRα1, which is predominantly expressed in cerebrum and cerebellum. Multiple neurodevelopmental processes in the fetus and neonate are thyroid hormone dependent, including neurogenesis, cell migration and differentiation, synaptogenesis and myelination, in which TRα1 plays a crucial role (Rovet, 2014). Experiments investigating isoform-specific neurodevelopmental roles of thyroid hormone receptors have demonstrated redundancy in some areas, for example, cerebellar Purkinje differentiation, which is mediated by TRα1 and TR*β*1, whereas other functions are isoform-specific, for example, cerebellar granule cell migration, which is TRα1-dependent (Morte *et al.*, 2002).

Resistance to Thyroid Hormone Alpha (RTH Alpha)

Heterozygous, dominant negative, loss of function mutations in the *THRA* gene cause resistance to thyroid hormone alpha (RTH alpha), the clinical features of which are explained by tissue-specific hypothyroidism in tissues predominantly expressing the defective TRα isoform (**Fig. 3**). The widespread tissue expression pattern of TRα mandates that severely affected children exhibit many of the features classically attributed to untreated primary hypothyroidism but paradoxically, thyroid function tests are near-normal, reflecting the central role of TR*β* in maintaining the axis set-point (Bochukova *et al.*, 2012).

In initial reports of RTH alpha, patients exhibited characteristic broad facies with macrocephaly, perhaps due to delayed fontanelle closure, and hypothyroid features including a flattened nose, prominent tongue and thick lips. An excessive number of skin tags were also noted in many cases (Bochukova *et al.*, 2012; Tylki-Szymanska *et al.*, 2015; Moran *et al.*, 2013). In keeping with the crucial role of TRα for normal skeletal maturation, affected individuals exhibited significant growth retardation which was characteristically lower segmental and accompanied by radiological evidence of childhood skeletal dysplasia including calvarial wormian bones (disordered, intramembranous ossification), femoral epiphyseal dysgenesis (disordered, endochondral ossification) and delayed dentition. Constipation (often severe) was a frequent association and a spectrum of neurocognitive deficits was reported, including delayed developmental milestones (motor, speech), impaired motor coordination and slow initiation of movement, manifesting as dyspraxia or broad-based gait and slow speech. Variably reduced IQ necessitated special schooling at the more severe end of the spectrum (Tylki-Szymanska *et al.*, 2015; Moran *et al.*, 2013; van Mullem *et al.*, 2013). Cardiac manifestations included bradycardia, and basal metabolic rate was also reduced (Bochukova *et al.*, 2012, **Fig. 3**).

Characteristic biochemical abnormalities in RTH alpha include low/low-normal T4 and high/high-normal T3 concentrations, a subnormal T4/T3 ratio and variably reduced reverse T3. Two mechanisms have been hypothesized to explain this altered thyroid hormone metabolism; analogous to mice with a dominant negative TRa1 mutation TRα1-PV, affected humans may exhibit increased hepatic DIO1 levels which may augment T4 to T3 conversion; alternatively, reduced tissue levels of DIO3, the expression of which is TRα1 regulated, may result in decreased inner-ring deiodination of T4 to rT3 and T3 to T2. Additional biochemical abnormalities include mildly elevated muscle creatine kinase, indicative of skeletal muscle hypothyroidism and mild, normocytic anemia (Moran and Chatterjee, 2015).

The initial *THRA* mutations involved the TRα1 (hormone-binding) isoform alone, and over the last 5 years, descriptions both of cases harboring mutations affecting TRα1 and TRα2 as well as mutations exhibiting differing degrees of functional impairment in vitro, have expanded our understanding of this syndrome. Patients with mutations affecting both TRα isoforms seem to exhibit overlapping phenotypes with TRα1-specific mutations without additional features attributable to TRα2 loss of function (Moran *et al.*, 2014; van Gucht *et al.*, 2016). Although one 27-year old female with a mutation affecting both isoforms exhibits unusual skeletal features (micrognathia, clavicular agenesis, hypoplasia, metacarpal fusion and syndactyly) as well as hyperparathyroidism and chronic diarrhea, these have not been reported in other RTH alpha cases and it remains unclear whether these are solely attributable to the TRα1 p.N359Y mutation (Espiard *et al.*, 2015). Correlation of receptor dysfunction with clinical manifestations has delineated a spectrum of phenotypes which may depend to some extent on the location and deleteriousness of the *THRA* mutation. Crucially, such analysis has shown that milder forms of RTH alpha may present with only subtle clinical features of hypothyroidism and free hormone measurements within the normal range, although FT4/FT3 ratio is usually perturbed (Demir *et al.*, 2016). Although <30 RTH alpha cases have been reported to date, this syndrome may be more common, especially in milder forms, but as yet incompletely ascertained due to its modest biochemical abnormalities and its association with non-endocrine phenotypes (Demir *et al.*, 2016).

In addition to supportive treatment for the extra-thyroidal abnormalities, levothyroxine (L-T4) therapy has been beneficial in some affected children, improving growth, alleviating constipation and improving motor development and wellbeing (Moran and Chatterjee, 2015; van Gucht *et al.*, 2016). In particular, individuals with milder mutations may benefit from L-T4 treatment, especially if it is commenced at an early age. TSH concentrations suppress readily on treatment with elevation of FT3 to supra-physiologic levels, which does raise the possibility that chronic excess TH exposure in thyroxine-treated RTH alpha patients might lead to unwanted toxicities in normal TR*β*-containing tissues such as liver or bone, however, no such adverse effects have yet been reported (Moran *et al.*, 2013; Bochukova *et al.*, 2012).

Congenital Hypothyroidism: A Historical Perspective on Cognitive Outcome

Heiko Krude, Charite–Medicine University, Berlin, Germany and Institute of Experimental Pediatric Endocrinology, Berlin, Germany

Introduction

The severe clinical manifestation of congenital hypothyroidism (CH) as documented in former historic untreated cases, appearing as the so called "cretinism," demonstrates how comprehensively human development is dependent on thyroid hormones (Osler, 1897). Motor developmental milestones are missed, the children do not start to walk until at least 5 years of life, contractures develop in the lower extremity and cognitive development is profoundly delayed with lack of speech development as well as depression. In addition, they are dwarf, obese and do not enter puberty. Today single cases are reported from immigration families who were born in countries without newborn-screening and who were missed by clinical diagnosis and developed a phenotype that is very close to that "historic cretinism" described in the 19th century (Osler, 1897).

In addition to CH, two monogenetic syndromes that affect the transport of thyroid hormones into the brain—MCT8 deficiency- and the function within the brain-thyroid hormone alpha receptor (TRalpha) defect- further shed light on the critical role of thyroid hormones especially for human brain maturation (Dumitrescu *et al.*, 2000). In both diseases cognitive development is impaired despite normal or even increased levels of thyroid hormones within the circulation.

Based on animal models studies demonstrated defects of brain maturation that did not interfere with the early steps of organogenesis and leave the overall brain architecture intact. Correspondingly the overall brain anatomy in congenital human thyroid defects as shown by MRI is also normal (Hamdoun *et al.*, 2016). Pharmacologically induced hypothyroidism in rodents did show more subtle disturbances of neuronal differentiation, connectivity and myelinisation. Interestingly these changes are increasingly found in the further development and maturation of several interneurons and oligodendrocytes, thus pointing on a particular role of thyroid hormones especially for postnatal brain development (Bernal, 2000).

In terms of brain development of CH patients these rodent data would argue for a role of thyroid hormones also for later steps of brain development. In addition the earlier development might be protected by maternal thyroid hormones that cross the placenta and contribute significant levels of thyroid hormones in the developing embryo. If this supply is impaired—like in cases of severe maternal hypothyroidism or especially in areas of severe iodine deficiency—the affected newborns suffer from severe cognitive impairment despite a later normal child thyroid function after birth (DeLange, 1994).

However, the question whether the prenatal lack of fetal thyroid hormones in CH lead to developmental defects that cannot be counterbalanced by later postnatal treatment remained for a long time unsolved. For decades it seemed more likely that indeed the prenatal hypothyroid state in severe cases results in noncompensable developmental defects, so that the cognitive outcome in those patients will not be normal at all.

Outcome in Patients Treated Before Newborn Screening

Treatment of CH was already introduced in the 19th century when thyroid extract was given to children with the clinical signs of "cretinism" (Osler, 1897). The changes achieved by this first substitution-treatment—long before thyroid hormones were discovered in the 1915 and became available as L-thyroxine after 1945- were tremendous with a complete metamorphosis of these hitherto extremely affected children. They did grow, improved in mood, entered motor milestones and eventually also reached puberty. Nevertheless, they did not reach normal cognitive development (Osler, 1897).

Data about the IQ outcome in these patients who were treated based on clinical diagnosis are sparse. Moreover, CH is a spectrum of different pathologies—thyroid dyshormonogenesis and thyroid dysgenesis as well as central versus primary hypothyroidism and syndromes with hypothyroidism as one feature among several- with a wide spectrum of manifestation and severity, which together makes it difficult to get comparable outcome data in general. However, already in the first decades of the 20th century studies were published describing the cognitive outcome of CH cases in relation to their different treatment modalities. In 1957 Smith and coworkers published about 128 patients with a "severe" form of CH and they found that patients who were treated after 6 months of life are severely retarded with an IQ on average of 50 (Smith *et al.*, 1957). Another later study from 1972 by Klein and coworker confirmed this low IQ in later treated children but in addition reported a much better IQ in those few patients who were diagnosed clinically already within the first 3 month of life when symptoms are very subtle.

Interestingly, when all patients with CH were included in these outcome studies the mean IQ was much better, suggesting a wide IQ range depending on CH severity. In a review of these studies by Grosse and Van Vliet (2011) the mean IQ of this prescreening treated children with CH was 82–87 but with a wide range from 40 to 112.

To overcome the profound mental retardation in the severe cases of CH Klein *et al.* suggested in 1972 (Klein *et al.*, 1972) to implement a new-born screening program which would allow to diagnose newborns by their endocrine alterations-elevated TSH or decreased T4- before their clinical symptoms occur later during development. Since they have discovered a much better IQ in

 doi:10.1016/B978-0-12-801238-3.66199-8

those children diagnosed within the first 3 months of life they assumed that an early detection of CH based will enable a more favorable cognitive outcome especially in the most severe cases.

Outcome in CH Patients Diagnosed in First Generation Screening Programs

The first CH patient diagnosed by newborn-screening was reported already in 1974 by Klein *et al.* from Pittsburgh, USA (Klein *et al.*, 1974). The patient was treated on day 22 of life with a combination of T3–T4; no evidence for the treatment with thyroid hormones in newborns was available at that time and treatment was started not in terms of clinical studies but rather as kind of "try and error."

The efficiency of this first implemented newborn-screening was already reported in 1981 from the "New England CH Collaborative" showing the complete eradication of mental retardation in those children treated since 1974. In 63 children treated at a mean of 25 days of life with a mean LT4 dose of 8 μg/kg a normal IQ was diagnosed (New England congenital hypothyroidism collaborative, 1981). However, the detailed cognitive outcome of children diagnosed in this first generation of newborn screening were reported later in the 1990th showing still some patients with an unfavorable IQ outcome. In a meta-analysis from 1996 of seven studies covering 675 CH patients diagnosed by newborn screening the authors found a significant difference of mean full IQ compared to controls of up to 10 and 10% of still retarded patients (Derksen-Lubsen and Verkerk, 1996). Other groups found IQ differences of 18 in a cohort from Canada (Glorieux *et al.*, 1992). These studies already reflected the need of appropriate control groups given the wide range of IQ in the normal population and especially the strong impact of the social status on IQ. In addition, it was recognized that CH can occur in more complex syndromic cases which *per se* show impaired development irrespective of hypothyroidism like Down syndrome and need to be excluded from CH outcome studies.

These considerations were included in the adult outcome studies of this first generation of CH patients, diagnosed in newborn screening programs during the 1970th. Now cohorts of CH patients were controlled with the respective siblings from the same family. While again the overall IQ of the cohorts were in the normal range a significant mean full IQ difference of 7,9 and 8,0 were found in studies from Canada and Norway, respectively (Rovet, 2005; Oerbeck *et al.*, 2003). Interestingly, in both studies it was shown that the more severe the disease at birth the lower the IQ.

One interpretation of these findings was, that the fetal hypothyroid state lead to a noncompensable defect of the brain before birth. Therefore, more efforts to improve the treatment would not overcome this prenatal damage. In contrast other groups questioned whether the treatment modalities of this first generation of CH patients treated in newborn screening programs, were not efficient to normalize TSH levels early enough. The starting dose of LT4 in these cohorts was 6–8 μg/kg and the treatment start was rather late with 24 days on average. Therefore, a higher starting dose above 10 μg/kg at the earliest starting time point as possible was recommended by these groups. However, such a treatment scenario results in fairly high fT4 levels when TSH is normalized, which raised conceptual concerns of several other authors.

Outcome in Patients With High Starting Dose of Lt4

One of the first outcome studies reported in children with such a higher starting dose (mean 11.6 μg/kg) and early start of treatment (mean 14 days) was from Montreal, Canada (JM1 *et al.*, 1996). Patients were evaluated at an age of 18 months by Griffiths developmental test and it was shown that there was no difference between severe and moderate cases any longer (patients were matched for their socio-economic status). These encouraging data prompted the authors to announce that the "developmental gap in CH is closed by early high dose treatment." However, the study was based on only 10 severely affected and 35 moderately affected children at an early age of 1.5 years and further studies were required to confirm this finding in more and older patients. Accordingly, several other groups reported about the IQ outcome in patients treated with higher doses, which all did show a better outcome with the higher dose, including the only prospective randomized study comparing 50 μg and 37.5 μg LT4, showing a significantly lower IQ in the latter although the number of patients was again very low (Selva *et al.*, 2005). For most of these studies the main comparison was between severely and moderately affected patients and no control sibling groups were available. Moreover, since earlier studies with lower starting doses did show IQ differences of only 5–10 the upcoming studies that aimed to demonstrate that such a difference is compensable by higher starting doses needed to be statistically powered enough by higher patient numbers. Furthermore, such studies definitely had to take into account the lower outcome of CH patient with particular syndromes like the Down syndrome, Bamforth syndrome (FOXE1 gene defect) or NKX2.1 gene deficiency, since in those patients brain function is disturbed by the primary genetic defect and cannot be compensated by optimal LT4 treatment.

Sibling Controlled Outcome Studies With High Lt4 Starting Dose

Such a study with an appropriate design was eventually published in 2013 from the New Zealand screening program, reporting about a sibling controlled CH cohort. The patients were diagnosed at a mean age of 9 days, treated with a LT4 dose between 10 and 15 μg/kg and TSH normalized within a median of 14 days of diagnosis. The power calculation predicted that the number of patients and siblings would be sufficient to detect a IQ difference of 5.2. There was no significant difference between the affected and nonaffected individuals tested (Albert *et al.*, 2013), suggesting for the first time, that an adequate treatment of CH can render a completely normal IQ.

However, two papers of a Dutch group induced further concern. They claimed that the higher starting dose of >10 μg/kg which cause higher than normal fT4 values during the first 2 years of life, will result in decreasing IQ in older children during adolescence (Bongers-Schokking and de Muinck Keizer-Schrama, 2005; Bongers-Schokking *et al.*, 2016). Although these data were calculated in very small subgroups and the study design did not include sibling controls, the concern of an unfavorable outcome due to "overtreatment" in the high-LT4 regimen was renewed; especially because the mean age of the CH patients in the New Zealand study was only 9.6 years.

The most recent study about the cognitive outcome in CH treated with a high dose was published by our group from Berlin (Aleksander *et al.*, 2018). We had the chance to investigate a cohort of 76 CH patients and their 40 siblings. The treatment modalities were very similar to the New Zealand cohort with a median age of diagnosis of 8 days, mean initial LT4 dose was 13,5 μg/kg and TSH normalized within median 15 days. In contrast to the younger age in the New Zealand group mean age of our patients was 18.1 years and of the sibling controls 19.8 years. We did not find significant differences of overall IQ (102.5 versus 102.5), neither for several other cognitive tests, attention, memory and fine motor skills. Moreover, there was no difference in quality of life scores. Also all anthropometric measurements like length, BMI, blood pressure were without significant difference. According to the Dutch study, we considered the impact of our treatment parameters during the first 2 years of life and tested for a correlations of the number of episodes of elevated fT4 and suppressed TSH with the final IQ, which was negative. Furthermore, we performed a meta-analysis of the previous outcome studies that compared the IQ outcome in moderate versus severe cases. We did find a significant difference of the IQ in the low starting dose (<8 μg/kg) and moderate starting dose (8–10 μg/kg) patient cohorts but not in the high starting dose group (>10 μg/kg). Together, our data argued against the Dutch prediction that high dose will disturb IQ in adolescents, since in our young adult cohorts we did not find a IQ difference despite we had multiple episodes of high fT4. In addition, the meta-analysis strongly argued for a normal outcome of severe cases only if they were treated with a high starting dose.

One interesting finding was again, that in our patient group the high LT4 starting dose resulted in almost all patients in supra-physiological fT4 values without any sign of hyperthyroidism while TSH and T3 were normal. Thus, the high LT4 dose which results in elevated fT4 values does not cause a state of "overtreatment" but instead -as depicted by the normal TSH—is necessary to normalize the physiological relevant active hormone values of T3. If lower doses are given as suggested by, for example, the Dutch group, the fT4 is normal but TSH remains in most patients elevated for a longer time, which reflects an under-treatment that results in lower IQ as shown in the two cited adult outcome studies from Canada and Norway (Rovet, 2005; Oerbeck *et al.*, 2003). Therefore, the appropriate target parameter for LT4 dosing to enable normal development is the serum TSH and not T4.

The particular constellation of supra-physiological fT4 while TSH and T3 are normal was also observed in LT4-treated adult patients after total thyroidectomy when aiming normal TSH values (Bagattini *et al.*, 2014). Also in our adult patients under study the same constellation of high fT4 and normal TSH and T3 was found again as in their infancy. One likely explanation for this higher serum T4/T3 ratio might be the lack of direct secretion of T3 from the missing thyroid that is compensated with higher fT4 as an additional resource for T3 production in the periphery.

Finally, after more than 100 years of clinical research in CH treatment, today evidence is available from two sufficiently powered outcome studies which justify a high starting dose of >10 μg/kg LT4 that will result in IQ values that is not any longer different to sibling controls. Moreover, the actual results imply that prenatal hypothyroidism seems not to cause noncompensable defects in brain development, since an early and high dose postnatal treatment enables a completely normal brain function later in life (**Fig 1**).

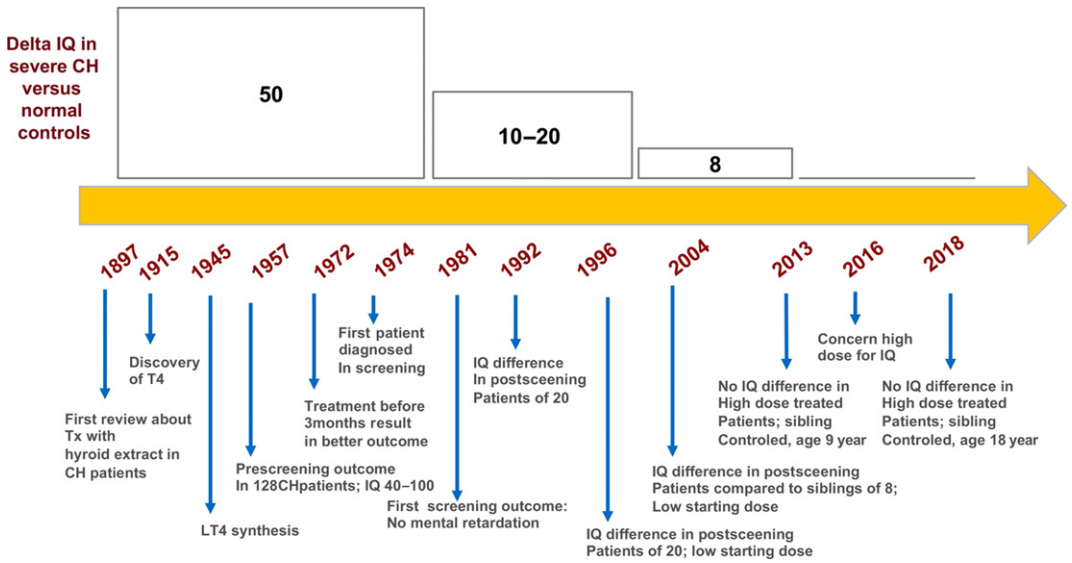

Fig. 1 Timeline of achievements in CH treatment.

Perspective

While acceptable evidence for the treatment of severe CH cases seems now be available, the most important further questions concerning cognitive outcome and newborn thyroid function relates to the milder end of the spectrum of thyroid dysfunction. Due to the introduction of lower TSH cut-off values in the CH screening programs a large number of children are diagnosed with only subtle biochemical alterations. The outcome of these children if remained untreated is unknown, but nevertheless most children are now under treatment due to the concern to not undertreat such individuals. Considering the aforementioned differences in IQ outcome even in severe cases with IQ ranging from 40 to 100, very accurate outcome studies with a large number of children are warranted to generate also appropriate evidence for the treatment and effect on IQ outcome in this large group of very mild CH cases.

Another focus of IQ outcome in newborn thyroid dysfunction relates to the two monogenic diseases of deficient thyroid hormone-transport and—action in children with the MCT8- and TRalpha defects. Here new therapeutic strategies need to be developed to also enable a better outcome; the success in treating severe CH patients during the last 100 years is promising that also these two particular groups of severely affected children will benefit from further clinical studies.

Hyperthyroidism, Childhood and Adolescence☆

Scott A Rivkees, University of Florida College of Medicine, Gainesville, FL, United States

Introduction

Hyperthyroidism can have profound effects on the growing child and adolescent, including somatic and behavioral effects. In the pediatric population, the hyperthyroid state can be present for extended periods before recognition, contributing to physical decline. A number of conditions can result in hyperthyroidism in childhood; however, Graves' disease (GD) is the most common cause. Fortunately, the different causes of hyperthyroidism can be distinguished and specific treatments rendered. Updated guidelines for the treatment of pediatric hyperthyroidism can be found from the American Thyroid Association (Ross *et al.*, 2016) and from the Japanese Pediatric Thyroid Committee (Committee on Pharmaceutical Affairs JSfPE *et al.*, 2017).

Clinical Evaluation of the Hyperthyroid State

Thyroid disease can present with overt symptoms, insidiously, or with isolated thyromegally. Thus, evaluation of the thyroid gland should be included in the routine examination of children. The thyroid gland can be visualized by having the patient look to the ceiling and swallow. As the thyroid moves, the margins of the gland are viewed to estimate size and symmetry. The thyroid should be palpated to assess size, consistency, and symmetry. This is best performed with the clinician standing behind the patient and palpating the neck with the fingertips. The texture of the thyroid can be assessed to determine if it is smooth or irregular and if nodules present, which may feel firm or soft. If any asymmetry or abnormal thyroid fullness is noted, ultrasonographic evaluation is recommended, as pathological thyroid nodules may feel like normal tissue.

To assess gland size, one may estimate the size of each thyroid lobe relative to that of a teaspoon (5 g) or a tablespoon (15 g). Generally, until the end of puberty, gland size (in grams) approximates the patient's age in years times 0.5–0.7 (Ueda, 1990). Thus, each thyroid lobe of a 10-year old is approximately one-half of a teaspoon for a total gland size of 5–7 g (Ueda, 1990). In adults, each lobe of the thyroid may reach one teaspoon in size for an approximate total gland size of about 10 g (Ueda, 1990).

When hyperthyroidism is suspected, the practitioner should look for somatic signs. One of the cardinal in universal features of hyperthyroidism is tachycardia (Talbot *et al.*, 1952; Wilkins, 1965). In the absence of such, it is unlikely that hyperthyroidism is present. Other clinical features can include a prominent stare and proptosis, although eye findings occur less commonly in children than in adults (Ross *et al.*, 2016; Rivkees, 2016). Although it is the common perception that children presenting with hyperthyroidism present thin and with weight loss, this is often not the situation (van Veenendaal and Rivkees, 2011).

Biochemical Evaluation of Thyroid Function

Approximately 97% of the thyroid hormone released from the thyroid gland is thyroxine (T_4) (Kaplan, 1999). After its release, less than 1% of T4 remains free. The rest of the thyroid hormone circulates bound to the proteins thyroglobulin (thyroid binding globulin or TBG; 70%), prealbumin (transthyretin; 10%), and albumin (15%–20%) (Kaplan, 1999). Triiodothyronine (T_3) is also released from the thyroid and is generated peripherally. Although T4 constitutes the bulk of circulating thyroid hormone, T3 has far greater affinity for nuclear thyroid hormone receptors and exerts most of the potent cellular effects of thyroid hormone action (Ribeiro *et al.*, 1995; Lazar, 1991).

Thyroid function can be assessed by measurement of total T4 and total T3 levels, along with indices that reflect thyroid hormone-binding proteins (T3 or T4 resin uptake) (Kaplan, 1999). The levels of estimated free (unbound) T4 (FT4) are measured to assess thyroid hormone status without the confounding influences of carrier proteins.

Several conditions are seen in which thyroid hormone levels are abnormal, yet the individual is euthyroid. Because of their confusing nature, these conditions may result in the patient's being erroneously diagnosed or treated for hypothyroidism or hyperthyroidism.

When FT4 values are normal yet total T4 values are high, familial dysalbuminemic hyperthyroxinemia (FDH) needs to be considered (Farror *et al.*, 1987; Ruiz *et al.*, 1982). This autosomal dominant disorder is most commonly seen in Hispanic individuals and can be diagnosed by thyroid hormone-binding protein electrophoresis. In some situations, FDH can be confused for hyperthyroidism, it is important to note that a distinguishing feature is that thyroid stimulating hormone (TSH) levels are not suppressed in FDH.

☆*Change History*: January, 2018. Scott A Rivkees updated the text and references.

This chapter is an update of Scott A. Rivkees, Hyperthyroidism, Childhood and Adolescence, In Encyclopedia of Endocrine Diseases, edited by Luciano Martini, Elsevier, New York, 2004, Pages 615–620.

 doi:10.1016/B978-0-12-801238-3.95991-9

T4 is much more abundant in the circulation and T3 is the more metabolically active thyroid hormone. T3 is produced peripherally from T4 and is also secreted by the thyroid. A metabolically inactive form of T3′ reverse T 3' is also produced, and its level is elevated in conditions such as euthyroid sick syndrome (De Groot, 1999).

Ultrasensitive TSH assays have been developed, and assessment of TSH has greatly improved the evaluation of thyroid status (Ross, 2001). TSH levels help to distinguish many thyroid disorders that present with either low or high T4 levels in most cases. TSH values within the normal range for the assay are indicative of a euthyroid state if the hypothalamic pituitary axis is intact. When both FT4 and TSH levels are elevated, TSH-producing pituitary adenomas and thyroid hormone resistance need to be considered. In the hyperthyroid state, though, TSH levels are generally completely suppressed (Ross *et al.*, 2016; Rivkees, 2016).

Hyperthyroidism

Hyperthyroidism occurs less commonly in children than hypothyroidism, yet is far more symptomatic (Talbot *et al.*, 1952; Wilkins, 1965; Rivkees, 2010; Bahn *et al.*, 2011; Bahn Chair *et al.*, 2011). Graves' disease is the most common cause of childhood thyrotoxicosis and is characterized by diffuse goiter, hyperthyroidism, and occasionally ophthalmopathy. Other causes of hyperthyroidism in children include autonomously functioning thyroid nodules, neonatal thyrotoxicosis, and infections of the thyroid. Hyperthyroidism also results from thyroid hormone ingestion, McCune-Albright syndrome, struma ovarii, and TSH-producing pituitary adenomas. Epidemic hyperthyroidism has also been seen when thyroid tissue has been inadvertently included in meat products (Hedberg *et al.*, 1987). In contrast to these disorders, thyroid hormone resistance may appear similar to hyperthyroidism, yet is best left untreated.

Graves' Disease

Graves' disease (GD) is the most common cause of hyperthyroidism in children and effects 1 in 10,000 children (Ueda, 1990). An autoimmune disorder, GD is due to thyroid gland stimulation by thyroid receptor antibodies (TRAbs; or thyroid stimulating immunoglobulins, TSI) and involves genetic factors (Ueda, 1990). Hyperthyroidism can exert profound adverse effects on children, including excessive physical activity, tremor, tachycardia, flushing, palpitations, weight loss, accelerated linear growth, reduced bone mineralization, and poor school performance (Hopwood *et al.*, 1976). In comparison with adults (Kaplan, 1999; Ribeiro *et al.*, 1995), eye disease occurs in the minority of pediatric patients with GD, and when it presents, is usually mild (Lazar, 1991).

Over the past several years additional outcome data have become available (Kaplan, 1999; Farror *et al.*, 1987; Ruiz *et al.*, 1982; Nikolai and Seal, 1967; De Groot, 1999) to complement older studies looking at spontaneous remission rates of children with GD (Ross, 2001; Spencer *et al.*, 2007; Zarkovic *et al.*, 2011; Volzke *et al.*, 2010; Surks *et al.*, 2005). Collectively, these studies show that the majority of pediatric patients with GD will not undergo spontaneous remission even after many years of antithyroid drug (ATD) therapy. Thus, most pediatric patients will require either radioactive iodine (^{131}I) or surgery (Verburg *et al.*, 2011; Lazar *et al.*, 2009; Brabant *et al.*, 2006; Talbot *et al.*, 1952).

Antithyroid Drug Therapy

ATDs act by inhibiting oxidation and organic binding of thyroid iodide to impair thyroid hormone production and include methimazole (MMI) and propylthiouracil (PTU) (Wilkins, 1965). MMI is 10- to 20-fold more potent than PTU and has a longer half-life (Rivkees, 2010). These medications do not cure the hyperthyroid state, rather they palliate the condition until spontaneous remission occurs or definitive therapy is rendered. Each of these medications is associated with adverse events that must be considered when prescribed. As such, prior to the initiation of drug therapy, a back-up plan that takes into account the patient's age and treatment risks must be developed at therapy onset in the event that a toxic reaction occurs.

Because it takes 1 or 2 months until biochemical hyperthyroidism resolves on drug therapy (Bahn *et al.*, 2011), treatment with beta-blockers (propranolol, atenolol, or metoprolol), can be used to control GD symptoms. Focusing on symptom control with beta-blockers also alleviates the perceived need for initial high-dose ATD therapy.

In 2008, Rivkees brought to public attention a number of serious complications associated with PTU therapy in children (Bahn Chair *et al.*, 2011; Hedberg *et al.*, 1987; LeFranchi and Mandel, 1995). PTU-induced liver injury occurs rapidly and is often irreversible (Chapman, 1983; Cooper, 2005). Thus, serial monitoring of transaminase levels in a child on PTU, is not viewed as useful in reducing the hepatotoxicity risk (Rivkees *et al.*, 1998). The only way to reduce the risks of PTU-related hepatotoxicity is to avoid the use of the medication.

PTU, though, may be needed in special circumstances (Cooper, 1998). These conditions include situations when neither prompt ^{131}I or surgical treatment are options in a patient who has had a toxic reaction to MMI, and ATD medication is necessary. In this setting, PTU use should only be short-term (Conference Proceeding, 2009). If PTU is prescribed, patients and guardians must be informed of the risk of liver failure and to be alert for signs and symptoms of liver abnormalities, including pruritus, jaundice, anorexia, light colored stools, dark urine, and abdominal pain. If these symptoms develop, the patient should

immediately stop the medication, a physician contacted, and laboratory tests obtained to evaluate hepatic function and transaminase levels (Conference Proceeding, 2009).

MMI is now the drug-of-choice for GD. The typical MMI doses described in published reports is 0.2–0.5 mg/kg per day and range from 0.1 to 1.0 mg/kg per day (Rivkees and Mattison, 2009; Abalovich *et al.*, 2007; Bahn *et al.*, 2009; Rivkees, 2006; Nakamura *et al.*, 2007; Rivkees *et al.*, 2010). However, as noted below, lower rather than higher doses should be considered. Although MMI is often prescribed in divided doses over the day, once a day dosing is usually sufficient (Tajiri and Noguchi, 2005) and is associated with better compliance than multiple daily doses (Cooper *et al.*, 1983).

MMI is available in 5, 10, and 20 mg tablets. When used in children, the following doses that are fractions of tablets can be used: infants, 1.25 mg per day; 1–5 years, 2.5–5.0 mg/day; 5–10 years, 5–10 mg/day; and 10–18 years, 10–20 mg/day. Because the hyperthyroid state can be associated with low white cell counts and patients will be treated with a medication that can depress neutrophil levels, one should obtain a complete blood count at therapy onset (Cooper, 2005).

It is important to recognize that one does not need to use high doses at treatment onset. The response to ATDs influencing circulating thyroid hormone levels is not instantaneous, and several months are needed for thyroid hormone levels to normalize (Tajiri and Noguchi, 2005; Cooper *et al.*, 1983). Thyroid function tests should be obtained monthly after therapy onset. After T4 levels become normal, the MMI doses can be cut by half to maintain euthyroidism (Cooper, 2005).

MMI therapy is not without risks. Minor side effects may affect up to 20% of children, and major side effects may occur in 1% of children (Glaser and Styne, 2008; Shulman *et al.*, 1997). The most common minor adverse side effects related to MMI are hives, arthralgia, and neutropenia (Kaguelidou *et al.*, 2008; Glaser and Styne, 1997). Children may also develop major side effects, including agranulocytosis, Stevens–Johnson syndrome, and vasculitis (Kaguelidou *et al.*, 2008). MMI adverse events most commonly occur within 6 months of therapy onset (Lazar *et al.*, 2000; Shulman *et al.*, 1997). Yet, children may develop adverse events more than 12 months after treatment onset.

Agranulocytosis is a potential serious ATD adverse event and occurs in 0.3% of adults taking PTU or MMI (Kaguelidou *et al.*, 2008; Glaser and Styne, 1997). The agranulocytosis risk is dose-dependent and is rare (Hamburger, 1985; Leger *et al.*, 2012). If an individual receiving MMI feels ill, becomes febrile or develops pharyngitis, MMI should be stopped immediately, a practitioner contacted, and a complete blood cell count obtained.

ATD Therapy Duration

Based on available evidence (Rivkees *et al.*, 1998; Read Jr. *et al.*, 2004; Levy *et al.*, 1988; Nebesio *et al.*, 2002; Rivkees and Cornelius, 2003; Rivkees and Dinauer, 2007; Ross *et al.*, 2016; Rivkees, 2016), prolonged ATD therapy will not result in an increased chance of remission for most children, whereas in others it may. As such, with the initial evaluation of a child with GD, practitioners should attempt to stratify children into two groups: those children with a 30%–40% chance of remission with prolonged ATD therapy and those with a slim chance of spontaneous remission.

Prospective studies in adults show that if remission does not occur after 12–18 months of ATD therapy, there is a very low likelihood of remission occurring with prolonged therapy (Rivkees and Cornelius, 2003). In the pediatric population, published data generally show that when ATDs are used for 1–2 years, remission rates are 15%–30%, and possibly up to 40% in some children (Rivkees and Cornelius, 2003; Kadmon *et al.*, 2001; Nebesio *et al.*, 2002; Rivkees, 2006, 2007; Rivkees *et al.*, 1998; Boice Jr, 2006, 2005). (Remission is defined as being either euthyroid or hypothyroid for 1 year or more after cessation of therapy.)

Yet, looking closely at these data, one can distinguish patients with a greater likelihood of remission from those with a much lower chance following prolonged ATD therapy. The chance of remission after years of ATDs will be low if the thyroid gland is large (greater than two times normal size for age), the child is young (<12 years), not Caucasian, serum TRAb/TSI levels are elevated, or the patient presents with profound hyperthyroidism at presentation (free $T_4 > 4$ ng/dL) (Dolphin, 1968; Boice Jr, 2006, 2005).

In adults, assessment of TRAb or TSI levels is useful in determining disease course and remission likelihood (Dolphin, 1968; Sigurdson *et al.*, 2005). This issue has been less studied in children. Consistent with the notion that GD will remit in only a small proportion of children, TRAb levels normalize after 24 months in only 18% of pediatric patients on ATDs (Dolphin, 1968). TRAb levels thus persist longer in children than in adults (Ron *et al.*, 1995). There are no data to show normalization of TRAb levels when patients are on ATDs for a longer time.

For those children with unfavorable risk factors for spontaneous remission at treatment onset, it is reasonable to treat children for up to 2 years with MMI and see whether spontaneous remission has occurred. At that point, if there is no remission, it is appropriate to move on to definitive therapy if desired by the family. Alternatively, treatment for longer periods can be considered, as long as side effects to medication do not occur. This approach may be especially useful if the child is considered too young for surgery or radioactive iodine. For the child with favorable risk factors for remission, if spontaneous remission has not occurred after the 2 years of ATDs, continuation of antithyroid medication for prolonged periods is also acceptable.

Radioactive Iodine Therapy for Graves' Disease

The goal for ^{131}I therapy for GD is to induce hypothyroidism. Radioactive iodine should not be given to cause euthyroidism in children, as this results in partially irradiated residual thyroid tissue that will be associated with a higher risk of thyroid neoplasm

than the normal population (Rivkees and Mandel, 2011; Van Vliet *et al.*, 2008). It has been suggested that dosages delivering 30,000–40,000 cGy (rad) to the thyroid are necessary to ablate the thyroid gland (Polak *et al.*, 2006; Luton *et al.*, 2005). But, dosages delivering 10,000–20,000 cGy to the thyroid are more often used and result in partial or complete destruction of the thyroid (Van Vliet *et al.*, 2008; Polak *et al.*, 2006; Luton *et al.*, 2005). Typically, administered thyroid doses of 150 μCi/g (5.5 MBq/g) generate radiation doses of 12,000 cGy to the thyroid (Van Vliet *et al.*, 2008).

Some centers give a fixed administered dosage of 10 or 15 mCi ^{131}I to all children (Polak *et al.*, 2006), rather than individually calculated administered activation. There are no studies comparing outcomes of fixed doses versus calculated doses in children. In adults, the two different approaches lead to similar outcomes (Luton *et al.*, 2005; Van Vliet *et al.*, 2008); however, in children, a potential advantage of calculated versus fixed dosing is that it might be possible to use lower dosages of ^{131}I if the administered dose is calculated.

When children are to be treated with ^{131}I, ATDs should be stopped 3–5 days prior to treatment (Polak *et al.*, 2006). Patients are placed on beta-blockers until T4 and/or free T4 levels normalize posttherapy. Whereas some clinicians restart ATDs after treatment with ^{131}I, this is rarely required in children (Luton *et al.*, 2005; Polak *et al.*, 2006; Check *et al.*, 1982; Skuza *et al.*, 1996). Thyroid hormone levels begin to decrease about 7 days after radioiodine therapy in children, and continued ATD use can make it difficult to assess if posttreatment hypothyroidism is the result of ^{131}I or the ATD.

Side effects of ^{131}I therapy are unusual. Less than 10% of children will complain of mild tenderness over the thyroid in the first week after ^{131}I therapy (Skuza *et al.*, 1996; McKenzie and Zakarija, 1992). This problem can be treated with either acetaminophen or nonsteroidal, antiinflammatory agents for 24–48 h (Zimmerman, 1999).

There are rare reports of children with severe hyperthyroidism developing thyroid storm after ^{131}I (Zimmerman, 1999). In general, these children were severely hyperthyroid when ^{131}I was rendered. Thus, if T4 levels are >20 µg/dL (200 nmol/L) or freeT4 levels are >5 ng/dL (60 pmol/L), children should be treated with MMI until T4 and/or free T4 levels normalize before proceeding with ^{131}I therapy (Daneman and Howard, 1980; Check *et al.*, 1982). It is important to recognize that most children with GD have been hyperthyroid for months prior to diagnosis; there is no need to rush to ^{131}I therapy.

It usually takes 6–12 weeks after ^{131}I treatment for the patient to become biochemically euthyroid or hypothyroid. Until then, symptoms of hyperthyroidism can be controlled using beta-blockers (Bruinse *et al.*, 1988; Momotani *et al.*, 1986; Zimmerman, 1999). The use of SSKI or Lugol's solution 1 week after ^{131}I will also quickly attenuate biochemical hyperthyroidism without adversely affecting the outcome of radioiodine therapy (McKenzie and Zakarija, 1992).

Several studies have reported the details of ^{131}I therapy for childhood GD (Tamaki *et al.*, 1989; Sunshine *et al.*, 1965; Jeng *et al.*, 1994; Vitti *et al.*, 1999). Children as young as 1 year old have been treated with ^{131}I with excellent results (Vitti *et al.*, 1999; Szabo and Allen, 1989). But, treatment of such young children is not common, nor is now recommended. ^{131}I dosages in children and teenagers have ranged from 100 to 400 μCi/g of thyroid tissue (Geva and Theodor, 1988). Similar to that found in adults (Lugo-Vicente *et al.*, 1998; Tonacchera *et al.*, 1998; Esapa *et al.*, 1997), responses to ^{131}I therapy are related to gland size and dose. 25%–40% of children treated with 50–100 μCi of ^{131}I per gram of thyroid tissue are hyperthyroid several years after therapy (Vattimo *et al.*, 1998). In children treated with 150–200 μCi of ^{131}I per gram thyroid, hyperthyroidism remains in 5%–20%, and 60%–90% become hypothyroid (David *et al.*, 1995; Hamburger and Hamburger, 1985; Derwahl and Studer, 2000).

The development of progression of ophthalmopathy following ^{131}I in adults has been reported (Barrio-Barrio *et al.*, 2015; Bahn, 2015; Wiersinga and Prummel, 2002). However, unlike adults, children rarely develop severe ophthalmopathy and proptosis is mild (Bahn *et al.*, 2011; Rivkees *et al.*, 1998). Studies show that disease worsens in only a small percentage of children with GD, irrespective of therapy type (Safa, 1975; Safa *et al.*, 1975; Barnes and Blizzard, 1977).

In adults, it has been shown that progression of ophthalmopathy can be prevented by treatment with prednisone for 3 months following ^{131}I therapy (Wiersinga and Prummel, 2002; Bahn *et al.*, 2011). Adjunctive prednisone therapy is not routinely recommended for the majority of children, as most do not have significant eye disease. The prolonged administration of prednisone is also associated with growth failure, weight gain, and immune suppression. Nevertheless, prednisone may be useful for the child who has moderate or severe eye disease and will be treated with ^{131}I.

Risks of Radioactive Iodine in Children Treated for GD

There is no evidence showing adverse effects to offspring of children treated with ^{131}I. Birth defects are not higher in 500 offspring born to about 370 individuals treated with ^{131}I for hyperthyroidism during childhood or adolescence (Rivkees *et al.*, 1998). Additionally, the rates of birth defects are not higher in children treated with 80–700 mCi of ^{131}I for thyroid cancer, which are dosages that are much higher than those used for GD (Sarkar *et al.*, 1976).

The thyroid gland is unique in its developmental sensitivity to malignancy after low-level radiation exposure (Boice Jr, 2005, 2006; Ron *et al.*, 1995; Dolphin, 1968). There is an increased risk of thyroid cancer in individuals less than 20 years of age at the time of low-level thyroid irradiation (Boice Jr, 2005, 2006; Ron *et al.*, 1995). In contrast, individuals who are older than 20 years of age, do not exhibit an increased risk of thyroid cancer when exposed to low-level thyroid irradiation (Boice Jr, 2005, 2006; Ron *et al.*, 1995; Dolphin, 1968).

The risk of thyroid neoplasms in children is greatest with exposure to low-level external radiation (0.1–25 Gy; $\sim$0.09–30 μCi/g) (Dolphin, 1968; Ron *et al.*, 1995; Boice Jr, 2006, 2005; Sigurdson *et al.*, 2005) and not with the higher dosages used to treat GD. At

present, we are not aware of any cases of thyroid cancer that developed in pediatric patients treated with >150 μCi of ^{131}I per gram of thyroid tissue for childhood GD that can be attributed to ^{131}I therapy.

Important in considering radioactive iodine use in children, is the potential influences of ^{131}I therapy on other cancers, as ^{131}I therapy results in low-level, whole body radiation exposure. Several studies in adults have examined potential risks of ^{131}I therapy for GD on cancers. These studies have generally not revealed increased mortality or increased rates of cancer following ^{131}I for GD (Flynn *et al.*, 2006; Franklyn *et al.*, 1998, 2005; Goldman *et al.*, 1990; Holm *et al.*, 1991; Metso *et al.*, 2007; Ron *et al.*, 1998).

In comparison with studies in adults, few studies have focused on outcomes of ^{131}I therapy for childhood GD. The most extensive study of pediatric patients involved 36-year outcomes of 116 patients who were less than 20-years old when treated with ^{131}I therapy for GD (Read Jr. *et al.*, 2004). There was no evidence for increase cancer risk in this population. Yet, this sample size is small.

The total-body radiation dose after ^{131}I varies with age, and the same absolute dose of ^{131}I will result in more radiation exposure in a young child than in an adolescent or adult (Toohey *et al.*, 2000; Toohey and Stabin, 1996). Currently, we do not have dosimetry data on ^{131}I use in pediatric patients with GD to assess total-body exposure in pediatric patients. Based on phantom modeling, it is estimated that at 0, 1, 5, 10, 15 years, and adulthood, respective total-body radiation doses will be 11.1, 4.6, 2.4 1.45, 0.90, and 0.85 rem (0.01 Sv) per mCi of ^{131}I administered (Toohey *et al.*, 2000; Toohey and Stabin, 1996). Based on the Biological Effects of Ionizing Radiation Committee V (BEIR VII) analysis of low-level, acute exposure to radiation (National Research Council, 2006), theoretical lifetime attributable risk of cancer mortality and all cancer incidence can be projected. Based on these theoretical calculations, we feel that it is prudent to avoid radioactive iodine therapy in children under 5 years of age and to avoid >10 mCi in patients less than 10 years old.

Thyroidectomy and Risks

Surgery is an effective form of therapy for GD if it can be performed by an expert surgeon and in some settings it is preferable to radioactive iodine. When surgery is performed, near total or total-thyroidectomy is indicated, as subtotal thyroidectomy is associated with a higher relapse rate (Miccoli *et al.*, 1996). Hypothyroidism is nearly universal in children and adults who undergo total thyroidectomy (Ching *et al.*, 1977; Buckingham *et al.*, 1981; Miccoli *et al.*, 1996; Rudberg *et al.*, 1996). In comparison, after subtotal thyroidectomy, hyperthyroidism recurs in 10%–15% of patients (Ching *et al.*, 1977; Buckingham *et al.*, 1981; Miccoli *et al.*, 1996).

Surgery is preferred in children younger than 5 years when definitive therapy is needed AND can be performed by a skilled thyroid surgeon. In individuals who have large thyroid glands (>80 g), the response to ^{131}I is poor (Peters *et al.*, 1996, 1997). Thus, surgery is also recommended for these patients.

In preparation for surgery, the patient should be rendered euthyroid. Typically, this is done by continuing MMI until T4 levels normalize. A week before surgery, iodine drops are started (1–3 drops, t.i.d.), which inhibits thyroid hormone production and causes the gland to become firm and less vascular.

Postoperatively, younger pediatric patients are at a higher risk for transient hypoparathyroidism than adolescents or adults (Sosa *et al.*, 2008). To mitigate postoperative hypocalcemia, we treat children with 0.5 mcg of calcitriol, twice a day, for 3 days prior to surgery. Postoperatively, the calcitriol is weaned over 15 days (0.5 mcg bid × 5 days; 0.5 mcg q.d. × 5 days; 0.5 mcg q.o.d. × 5 days) (Breuer *et al.*, 2013a). Using this approach only 5% of patients require postoperative calcium infusions versus 40% of patients without preoperative treatment (Breuer *et al.*, 2013a).

Acute complications that follow thyroidectomy include hemorrhage, hypocalcaemia, and recurrent laryngeal nerve paresis (Sosa *et al.*, 2008, 1998; Lal *et al.*, 2005; Boger and Perrier, 2004; Witte *et al.*, 2000). In children, rates from 0 to 6 years were 22%, from 7 to 12 years, 11%; and from 13 to 17 years, 11% (Sosa *et al.*, 2008). These rates are higher than those observed in adults.

Complication rates are related to the expertise of surgeon (Sosa *et al.*, 2008). Considering these data, if local pediatric thyroid surgery expertise is unavailable, referral of a child with GD to a high-volume, thyroid surgery center with pediatric experience should be considered (Breuer *et al.*, 2013b; Peroni *et al.*, 2012). Very low complication rates for children undergoing the thyroidectomies for GD have been reported with this type of multidisciplinary model (Breuer *et al.*, 2013a,b).

Other Causes of Hyperthyroidism

Neonatal Thyrotoxicosis

Thyrotoxicosis in the neonate is a severe and life-threatening condition that call be associated with lasting neurologic problems (Aslam and Inayat, 2008; Zimmerman, 1999). If a mother has GD, the chance is 1 in 80 that TRAbs will be transferred to the fetus, which will result in intrauterine or neonatal hyperthyroidism (Skuza *et al.*, 1996). Rarely neonatal thyrotoxicosis will persist, like the GD disease seen in older children (Zimmerman, 1999). In other rare cases, persistent neonatal thyrotoxicosis is caused by activation of the TSH receptor (Chester *et al.*, 2008; Watkins *et al.*, 2008).

The fetal thyroid gland is responsive to maternal TRAbs, which, if present at elevated levels, may result in hyperthyroidism (Van Vliet *et al.*, 2008; Polak *et al.*, 2006; Luton *et al.*, 2005; Bahn *et al.*, 2011). Fetal hyperthyroidism manifests during the second half of

gestation, as transfer of TRAbs from the mother to the fetus increases with progression of pregnancy (Van Vliet *et al.*, 2008; Polak *et al.*, 2006; Luton *et al.*, 2005).

The risk of fetal hyperthyroidism and neonatal Graves' disease is proportional to the magnitude of elevation of TRAb levels (Van Vliet *et al.*, 2008; Polak *et al.*, 2006; Luton *et al.*, 2005). Fetal hyperthyroidism is generally associated with levels of TRAbs more than two- to fourfold greater than the upper limit of normal for assay (Van Vliet *et al.*, 2008; Polak *et al.*, 2006; Luton *et al.*, 2005). Because the fetus is at risk for hyperthyroidism when there is active or past maternal GD, fetal growth and heart rate should be regularly assessed from midpregnancy onward (Van Vliet *et al.*, 2008; Polak *et al.*, 2006; Luton *et al.*, 2005). Excessive fetal heart rate (>160 beats per minute after 20 weeks) and the presence of a fetal goiter suggest hyperthyroidism in the fetus. In addition, accelerated maturation of the femoral ossification center is seen with fetal hyperthyroidism (Polak *et al.*, 2006).

If a mother with GD is taking antithyroid medications during pregnancy, fetal thyroid hormone synthesis will be inhibited, which will prevent the development of intrauterine hyperthyroidism (Check *et al.*, 1982). However, the infant may be born with a goiter and hypothyroidism. At birth, circulating levels of T4 may be low and TSH levels elevated. In most cases, the effects of antithyroid drugs wane, and thyroid function normalizes within a week (Skuza *et al.*, 1996). If significant transplacental passage of TRAbs has occurred, however, thyrotoxicosis will develop (Skuza *et al.*, 1996; McKenzie and Zakarija, 1992).

If a mother with a history of GD is not taking antithyroid drugs during pregnancy, the fetus may develop intrauterine hyperthyroidism (Zimmerman, 1999). If the condition is not recognized, it may result in profound intrauterine thyrotoxicosis and growth retardation (Zimmerman, 1999). Such infants have prematurely fused cranial sutures, advanced skeletal age, long-term learning problems, and mental retardation (Zimmerman, 1999; Daneman and Howard, 1980). If fetal hyperthyroidism is recognized prenatally by the presence of fetal tachycardia (heart rate higher than 160 beats per minute after 22 weeks), treatment of the mother with antithyroid drugs will reduce intrauterine thyrotoxicosis (Check *et al.*, 1982; Bruinse *et al.*, 1988; Momotani *et al.*, 1986).

Treatment of thyrotoxic infants consists of administration of antithyroid medications (PTU 5–10 mg per kg per day or MMI 0.5–1.0 mg per kg per day) and beta-blockers (propranolol 1 mg per kg per day). Lugol's solution or saturated potassium iodide may be given (1–2 drops every 8 h) for 7–10 days to more rapidly control biochemical hyperthyroidism. After approximately 2 weeks of antithyroid drug therapy, thyroid hormone levels will decline. When thyroid hormone levels fall below normal, supplementary levothyroxine (37.5 μg per day for full-term infants) is added to prevent hypothyroidism. As TRAbs are cleared from the infant's circulation, spontaneous recovery begins within 3 months and is usually complete by 6 months (Zimmerman, 1999; McKenzie and Zakarija, 1992). Thus, the infant can be weaned from treatment after 3 months. Monitoring of the infant's TRAb levels is also a useful predictor of when antithyroid medication can be tapered (Tamaki *et al.*, 1989; Sunshine *et al.*, 1965).

Infectious Thyroiditis

Occasionally a child presents with hyperthyroidism, tenderness over the thyroid gland, and fever due to bacterial infection of the thyroid, a condition called acute thyroiditis (Jeng *et al.*, 1994). Acute thyroiditis can be associated with the presence of a fistula connecting the piriform sinus on the left side of the pharynx to the thyroid (Jeng *et al.*, 1994). Fevers can be high, and erythrocyte sedimentation rates and white counts elevated. Ultrasonography may reveal a local abscess. In contrast to GD, uptake of technetium 99-pertechnetate or radioiodine is reduced when thyroid scanning is performed.

The offending bacteria include *Haemophilus influenza* and group A streptococci (Jeng *et al.*, 1994). Thus, treatment with an antibiotic resistant to disruption by beta-Iactamase is recommended. In severe cases, hospitalization and intravenous antibiotic administration is indicated, because lymphatic drainage into the mediastinal region may occur. Surgical drainage is needed if a localized abscess develops and the response to antibiotics is poor (Jeng *et al.*, 1994).

Because the infectious process results in destruction of thyroid tissue, release of preformed thyroid hormone and hyperthyroidism may occur during infection. The hyperthyroid state is usually transient, and treatment with antithyroid drugs is not indicated (Jeng *et al.*, 1994). If the patient becomes symptomatic, beta-blockers may be used.

After the child has recovered, pharyngography is indicated to test for a patent piriform sinus tract. Occasionally, the tract may close as the result of the infection. If the tract persists, however, and acute thyroiditis recurs, resection is needed.

Subacute Thyroiditis

Viral infections of the thyroid may occur and result in subacute thyroiditis (Vitti *et al.*, 1999). In comparison with acute thyroiditis, subacute thyroiditis may be less severe (Vitti *et al.*, 1999; Szabo and Allen, 1989). Fever, thyroid tenderness, and hyperthyroidism may be present and may last for several weeks (Geva and Theodor, 1988). Because clinically distinguishing between bacterial and viral thyroid infections is difficult, antibiotic treatment is indicated when infectious thyroiditis is suspected.

Hyperfunctioning Nodules

Warm or hot nodules lead to excessive production of thyroid hormone and can be associated with clinical and biochemical hyperthyroidism (Lugo-Vicente *et al.*, 1998). Interestingly, activating mutations of the TSH receptor and G_s have been discovered in hyperfunctioning nodules (Tonacchera *et al.*, 1998; Esapa *et al.*, 1997). Although hyperfunctioning nodules may be ablated with

radioiodine, surgical excision of hyperfunctioning nodules IS recommended in children and adolescents, because radiation-exposed normal thyroid tissue will remain after the hyperfunctioning nodule is ablated. Although the risk of malignancy in hyperfunctioning nodules is low, thyroid cancers have been described in warm nodules (Vattimo *et al.*, 1998; David *et al.*, 1995).

Toxic Multinodular Goiters

Multinodular goiters are uncommon in children, but patients with this condition can develop thyrotoxicosis, which is usually related to the time the goiter has been present and goiter size. In this setting, hyperthyroidism develops as a single nodule in the thyroid, becomes overly active, and functions autonomously (Hamburger and Hamburger, 1985; Derwahl and Studer, 2000). Forty-six percent of patients may have T3 thyrotoxicosis, and nodules are 3 cm or more in diameter (Hamburger and Hamburger, 1985; Derwahl and Studer, 2000).

In adults, ^{131}I is routinely used in the treatment of isolated toxic adenomas and toxic multinodular goiters (Hamburger and Hamburger, 1985; Derwahl and Studer, 2000). The use of radioiodine to treat these conditions in children is uncommon, however, and few follow-up data are available. Although strong justification exists for the use of radioiodine in the treatment of childhood Graves' disease, especially when appropriate doses are used, we recommend that radioiodine be avoided in children with toxic adenomas or multinodular goiters.

When a toxic nodule is present, either as an isolated nodule or in the setting of a multinodular goiter, thyroid function is suppressed in the nontoxic regions. When radioiodine is given, uptake will be limited to the autonomously functioning tissue, and if large doses are administered, the remaining thyroid tissue will receive external irradiation. Because the risk of thyroid cancer following external radiation is very low after 20 years of age (Nygaard *et al.*, 1999a,b), the use of radioiodine for toxic nodule ablation in adults is not associated with increased thyroid cancer risks. In the child or adolescent treated with ^{131}1 for toxic nodules, however, low-level irradiation to the remaining thyroid tissue may be associated with an increased thyroid cancer risk.

Thyroid Tumors in Children

Ari J Wassner, Boston Children's Hospital, Boston, MA, United States

Glossary

Anaplastic thyroid carcinoma An aggressive form of follicular cell-derived thyroid carcinoma that rarely occurs in children.

Follicular cell-derived thyroid carcinoma A type of carcinoma derived from thyroid follicular cells, which normally concentrate iodine and produce thyroid hormone. Papillary carcinoma and follicular carcinoma are two types of follicular cell-derived thyroid carcinoma, each with distinctive pathologic features.

Medullary thyroid carcinoma A type of carcinoma derived from thyroid C cells, which normally produce the hormone calcitonin.

Radioiodine (^{131}I) A radioactive isotope of iodine that emits beta and gamma radiation capable of damaging or destroying tissue. Radioiodine is taken up by thyroid follicular cells, including follicular cell-derived thyroid cancers, allowing it to be used for imaging or treatment of these thyroid cancers.

Thyroglobulin A protein produced exclusively by thyroid follicular cells, including follicular cell-derived thyroid cancers.

Thyroid nodule A mass within the thyroid gland.

Introduction

Tumors of the thyroid are common in adults but relatively rare in children. In many ways pediatric thyroid tumors resemble those in adults, but aspects of their pathology, clinical features, diagnosis, and management also differ in important respects. This article focuses on the unique aspects of thyroid tumors that occur in children; where appropriate, the reader is referred to other relevant entries for more detailed discussion of features common to both pediatric and adult thyroid tumors.

Epidemiology

Thyroid nodules occur in about 0.8%–1.8% of children (Rallison *et al.*, 1975; Hayashida *et al.*, 2013; Suzuki *et al.*, 2016). The prevalence of nodules increases with age throughout childhood, being very low (<0.5%) in children under age 10 and reaching a maximum of about 1.8% in adolescence. Pediatric thyroid nodules are twice as common in females as in males during adolescence, but not earlier in childhood (Hayashida *et al.*, 2013).

Although the risk of malignancy in a pediatric thyroid nodule (22%–26%) is substantially higher than that in an adult thyroid nodule (5%–15%), the majority of pediatric thyroid nodules are benign (Gupta *et al.*, 2013; Francis *et al.*, 2015). Thyroid carcinomas are rare in children, accounting for only 1.5% of malignancies in children under 15 (Vergamini *et al.*, 2014). The annual incidence of thyroid cancer in the United States rises with age and is 2, 8, and 29 per million among children aged 5–9, 10–14, and 15–19 years, respectively. Females are affected three to five times as frequently as males (Howlader *et al.*, 2017). In addition, over the last several decades the incidence of thyroid cancers in children has increased at an annual rate of about 3.8%. Part of this increase may be explained by increased use of radiological imaging leading to (sometimes incidental) detection of small tumors, but this does not appear to be the sole explanation for the rising incidence (Vergamini *et al.*, 2014).

Pathology

The principal cell type in the normal thyroid gland is the follicular cell, which synthesizes and secretes thyroid hormone. Malignancies derived from the follicular cell are often termed follicular cell-derived thyroid carcinomas. The most common form of follicular cell-derived thyroid carcinoma is papillary thyroid carcinoma, which accounts for over 90% of cases in children, while follicular thyroid carcinoma accounts for under 10% of cases. Anaplastic thyroid cancers are exceedingly rare in children. Medullary thyroid cancer is derived from the parafollicular cells (or C cells) of the thyroid and accounts for about 2% of thyroid cancers in children. The histopathologic features of thyroid cancers in children are similar to those in adults.

Etiology

Genetic Factors

The genetic alternations underlying the development and progression of follicular cell-derived thyroid carcinoma in adults are increasingly well understood. Adult thyroid cancers are generally associated with somatic mutations of the oncogenes *BRAF* or *RAS* (including *HRAS*, *NRAS*, and *KRAS*), or with gene fusions including the tyrosine kinase genes *RET*, *NTRK1/3*, or *ALK* (Cancer Genome Atlas Research, 2014). All of these genetic alterations cause abnormal activation of the MAP kinase and PI3 kinase pathways, leading to cell growth and tumorigenesis.

The genetic landscape of pediatric follicular cell-derived thyroid cancers is distinct from that of adults and is less well understood (**Table 1**). Mutations in *BRAF* (including the most common mutation, V600E) are present in 40%–60% of adult thyroid cancers (Xing, 2007; Cancer Genome Atlas Research, 2014) but are found in only 3%–40% of pediatric thyroid cancers (Bauer, 2017; Alzahrani *et al.*, 2017). Mutations in the *RAS* genes are relatively uncommon in children, occurring in around 10% of pediatric thyroid cancers. In contrast, the prevalence of gene rearrangements involving *RET* (termed *RET-PTC*) is significantly higher in both sporadic and radiation-induced pediatric thyroid cancers (40%–60%) than in adults (Nikiforov *et al.*, 1997; Rabes *et al.*, 2000; Fenton *et al.*, 2000; Bauer, 2017). Gene fusions involving *NTRK1/3* and *ALK* have been identified in children, but their prevalence is not yet clear. *PAX8-PPARG* rearrangements (found in many follicular thyroid cancers in adults) seem to be relatively uncommon in children (Bauer, 2017). Overall, in many pediatric follicular cell-derived thyroid cancers no recognized driver mutation has been found, indicating that much remains to be learned about the genetics of pediatric thyroid tumors.

While somatic mutations account for a large proportion of follicular cell-derived thyroid cancers, the presence of certain germline genetic mutations also increases a child's risk of developing thyroid nodules or cancer. Mutations in the gene phosphatase and tensin homolog (*PTEN*) cause the *PTEN* hamartoma tumor syndromes (Cowden, Bannayan-Riley-Ruvalcaba, and Proteus syndromes), which are characterized by macrocephaly, mucocutaneous lesions, breast and endometrial tumors, and thyroid nodules and cancer that can arise in children as young as 6 years (Smith *et al.*, 2011). Mutations in the *APC* gene cause familial adenomatous polyposis and are associated with an increase risk of thyroid cancer, particularly a specific histologic subtype of papillary thyroid carcinoma called the cribriform-morular variant (Uchino *et al.*, 2016). Germline mutations in *DICER1* are associated with childhood thyroid neoplasia as well as pleuropulmonary blastoma, ovarian tumors, and macrocephaly (Rutter *et al.*, 2016; Khan *et al.*, 2017).

Radiation Exposure

Exposure to radiation significantly increases the risk of developing thyroid nodules and follicular cell-derived thyroid cancer. Observations following the widespread release of radioactive isotopes from the Chernobyl Nuclear Power Plant in 1986 demonstrated that exposure to radioactive isotopes include ^{131}I (primarily by ingestion) is associated with an excess relative risk of thyroid cancer of 5.25 per Gray (Gy), and that this risk increases linearly up to doses of 6–7 Gy (Tronko *et al.*, 2006). Exposure to external radiation also markedly increases the risk of thyroid cancer, including in survivors of Hodgkin lymphoma, leukemia, central nervous system tumors, bone tumors, neuroblastoma, and bone marrow transplantation (Bhatti *et al.*, 2010; Veiga *et al.*, 2012; Inamoto *et al.*, 2015). The relative risk of thyroid cancer rises linearly to a maximum of about 15-fold at a thyroidal radiation dose of 10–30 Gy; above this dose the risk declines slowly, but does not return to baseline. The cumulative risk of developing thyroid cancer after radiation exposure increases over time. Age at exposure to radiation is another important factor, with the risk of thyroid cancer increasing the younger the patient's age at irradiation (Bhatti *et al.*, 2010; Veiga *et al.*, 2012).

Diagnosis

Clinical Features

Thyroid nodules in children are often asymptomatic but may present as a visible or palpable anterior neck mass. With larger nodules patients may note a globus sensation or difficulty swallowing due to impingement on the esophagus, or voice changes

Table 1 Common genetic driver mutations of follicular cell-derived thyroid carcinoma, and their prevalence in children compared to adults

Gene	*Prevalence in children*	*Prevalence in adults*
BRAF	3%–40%	40%–70%
RAS	3%–11%	13%–16%(30%–45% in follicular carcinoma)
RET-PTC	40%–60%	7%–16%
NTRK1/3	Minimal data	2%–3%
ALK	Minimal data	1%

Data from Kimura, E. T., Nikiforova, M. N. and Zhu, Z. *et al.* (2003). High prevalence of BRAF mutations in thyroid cancer: Genetic evidence for constitutive activation of the RET/PTC-RAS-BRAF signaling pathway in papillary thyroid carcinoma. Cancer Research 63, 1454–1457; Xing, M. (2013). Molecular pathogenesis and mechanisms of thyroid cancer. Nature Reviews. Cancer 13, 184–199. Cancer Genome Atlas Research, N. (2014). Integrated genomic characterization of papillary thyroid carcinoma. Cell 159, 676–690; Bauer, A. J. (2017). Molecular genetics of thyroid cancer in children and adolescents. Endocrinology and Metabolism Clinics of North America 46, 389–403.

(such as hoarseness) due to impingement on the recurrent laryngeal nerve. Most thyroid tumors in children are discovered by the patient or a family member, or by a physician performing a physical examination, while a minority are discovered incidentally on imaging studies performed for other reasons (Gupta *et al.*, 2014). Nodules that are very firm or fixed to surrounding tissue are more concerning for malignancy, but many pediatric thyroid cancers do not have these features. Patients may also present with cervical lymphadenopathy due to local metastasis of thyroid cancer.

Evaluation

The goal of evaluation of thyroid nodules in children is to identify the minority of nodules (22%–26%) that harbor malignancy, so as to provide appropriate treatment for thyroid cancers while avoiding unnecessary surgery for benign lesions. The latter point is particularly relevant for children, in whom the risks of thyroid surgery are higher than in adults (Wang *et al.*, 2009).

Evaluation of a thyroid nodule begins with measurement of the serum TSH concentration. A low TSH may indicate an autonomous (hyperfunctioning or "toxic") thyroid nodule, and this diagnosis can be confirmed with thyroid scintigraphy (using ^{123}I). In adults, autonomous nodules have a very low rate of malignancy (Haugen *et al.*, 2016). While it has been suggested that autonomous nodules in children have a higher malignancy rate (Niedziela *et al.*, 2002), in fact their malignancy rate may be very low when an autonomous nodule is defined strictly as exhibiting focal uptake of ^{123}I in the nodule under conditions of low TSH (<0.3 mIU/L), with suppressed uptake in the surrounding normal thyroid tissue (Ly *et al.*, 2016).

In children with a normal or elevated serum TSH concentration, ultrasound is the optimal imaging modality for suspected thyroid nodules (Francis *et al.*, 2015) and is superior to palpation in both sensitivity and specificity. Up to 50% of children referred for suspected thyroid nodules actually have no sonographically detectable nodule (Gupta *et al.*, 2013), and data from adults indicate that palpation alone fails to detect up to 24% of thyroid nodules of significant size (Marqusee *et al.*, 2000). Imaging of the cervical lymph nodes should be included in every ultrasound study performed for evaluation of a pediatric thyroid nodule because of the relatively high incidence of local lymph node metastases in children with thyroid carcinoma. It is important to employ an ultrasonographer with experience in pediatric thyroid ultrasound due to the prevalence in children of incidental findings that might inappropriately provoke evaluation for malignancy, including intrathyroidal thymic rests (2%) and benign lymphadenopathy (Hayashida *et al.*, 2013).

Nodules that are suspicious for malignancy are evaluated by ultrasound-guided fine-needle aspiration (FNA). In general, the sonographic features of pediatric thyroid nodules that are associated with a higher risk of malignancy are similar to those in adults, including hypoechogenicity, calcifications, irregular margins, and the presence of abnormal lymphadenopathy (Francis *et al.*, 2015; Martinez-Rios *et al.*, 2018). It is important to be aware that papillary thyroid carcinoma in children may present as a diffusely infiltrating process present throughout a lobe or the entire thyroid, rather than as a discrete nodule, often with microcalcifications and/or abnormal lymphadenopathy. FNA cytology is effective for identifying malignancy and guiding subsequent management in pediatric thyroid nodules (Stevens *et al.*, 2009; Gupta *et al.*, 2013; Francis *et al.*, 2015; Amirazodi *et al.*, 2016).

An important challenge in the evaluation of thyroid nodules is the approach to thyroid nodules with cytology that is indeterminate (neither clearly benign nor clearly malignant). In adults, molecular diagnostic techniques that assess genetic markers of malignancy or benignity are increasingly being used in the evaluation of such nodules to refine estimates of malignancy risk and guide management (Haugen *et al.*, 2016). In principle, molecular genetic tests that detect mutations that are highly associated with malignancy might be applicable to children. However, differences in the genetics between pediatric and adult thyroid cancer diminishes the utility of these tests, and currently they are not approved or routinely used for evaluation of pediatric thyroid nodules.

Prognostic Factors

Children with follicular cell-derived thyroid carcinomas tend to have more extensive disease at presentation than do adults. At diagnosis, lymph node metastases are present in 60%–80% of children with follicular cell-derived thyroid cancer and pulmonary metastases are present in 7%–25%; distant metastases to other sites (e.g., bone or brain) are rare (Pires *et al.*, 2016; Sung *et al.*, 2017; Wassner *et al.*, 2017; Francis *et al.*, 2015). Despite their relatively advanced disease at diagnosis, the prognosis of children with thyroid cancer is excellent, even in those with distant metastases. Long-term cause-specific mortality is very low (less than 2% over 50 years). However, disease recurrence is common and can occur years or decades after initial treatment. In one series of children diagnosed with thyroid cancer, recurrence was diagnosed in 20% of patients within 5 years, and in 32% of patients within 40 years (Hay *et al.*, 2010).

A variety of staging systems can be used to assess the risk of adverse outcomes in pediatric thyroid carcinomas. The most widely used is the American Joint Committee on Cancer tumor node metastasis (TNM) system (Tuttle *et al.*, 2017). However, this system has limitations when applied to pediatric patients, including the irrelevance of the age criterion for defining lower-stage disease (greater than or less than 55 years) and the limited ability to predict mortality, which is very low in pediatric patients. Recently, the American Thyroid Association has proposed a risk categorization system for pediatric thyroid

Table 2 American Thyroid Association risk categorization for pediatric follicular cell-derived thyroid carcinoma, and associated risk of persistent or recurrent disease over 5–9 years

Risk category	*Definition*	*Risk of persistent or recurrent disease*
Low risk	● Disease limited to the thyroid gland (T1–T3) ● No lymph node metastasis (N0), or only microscopic metastases to a small number of lymph nodes in the central compartment (minimal N1a)[a]	6%–10%
Intermediate risk	● Extensive metastases to central compartment lymph nodes (extensive N1a)[a], or ● Limited metastases to lymph nodes in the lateral compartment(s) or superior mediastinum (minimal N1b)[b]	17%–24%
High risk	● Locally invasive disease extending beyond the thyroid capsule (T4), or ● Extensive metastases to lymph nodes in the lateral compartment(s) or superior mediastinum (extensive N1b)[b], or ● Distant metastatic disease (M1)	44%–74%

[a]Proposed criteria for minimal N1a disease: metastatic foci measuring <0.2 cm involving five or fewer central compartment lymph nodes (Sung *et al.*, 2017).
[b]Proposed criteria for minimal N1b disease: metastatic foci measuring <3 cm and involving 10 or fewer lateral compartment or superior mediastinal lymph nodes (Sung *et al.*, 2017).

cancer that appears to correlate well with the risk of persistent/recurrent disease (**Table 2**) (Francis *et al.*, 2015; Lazar *et al.*, 2016; Sung *et al.*, 2017).

Initial Management

The approach to initial management and follow-up of thyroid nodules and follicular cell-derived thyroid carcinoma in children is similar to that in adults.

Surgery

Thyroid nodules that are cytologically indeterminate or suspicious for malignancy are resected to obtain a histopathologic diagnosis. Cytologically benign nodules may be observed with periodic ultrasounds to detect growth or other changes concerning for malignancy, or they may be resected if they are very large (>4 cm) or cause symptoms.

For malignant thyroid nodules, the goal of initial surgery is resection of all clinically detectable thyroid cancer in the neck. Near-total thyroidectomy is generally recommended for all children with thyroid cancer and appears to reduce the risk of recurrence (Hay *et al.*, 2010), perhaps because of a higher incidence of bilateral disease in children (30%) than in adults (Francis *et al.*, 2015). While recent consensus guidelines in adults endorse more limited surgery (some as lobectomy) for low-risk thyroid carcinomas (Haugen *et al.*, 2016), the safety of this approach in children is not yet clear (Kluijfhout *et al.*, 2017). Cervical lymph node metastases are resected at initial surgery if possible.

The rate of complications of thyroid surgery, including hypoparathyroidism and recurrent laryngeal nerve injury, are higher in children than in adults (Wang *et al.*, 2009). Because complications rates of thyroid surgery are lower in the hands of more experienced surgeons (Adam *et al.*, 2017), whenever possible surgery for children with thyroid cancer should be performed by a high-volume thyroid surgeon capable of operating on pediatric patients.

^{131}I Therapy

The goal of postoperative ^{131}I treatment is to reduce the risk of thyroid cancer recurrence and potentially of mortality. The rationales for ^{131}I treatment are similar in children to adults, including ablation of the thyroid remnant to facilitate monitoring for persistent/recurrent disease using serum thyroglobulin, and ablation of likely or known residual thyroid cancer. Direct evidence is limited regarding the efficacy of ^{131}I in children with thyroid cancer, and practice is based largely on data from adults. ^{131}I treatment of known residual disease probably improves outcomes in children with thyroid cancer, particularly those with distant metastatic disease (Brink *et al.*, 2000; Chow *et al.*, 2004; Hay *et al.*, 2010). Whether ^{131}I is beneficial in children without known residual disease or in those with low-risk tumors remains unclear. In addition, ^{131}I treatment may increase the future risk of other secondary malignancies (Sawka *et al.*, 2009), a concern that is accentuated in children due to their greater sensitivity to radiation (Hay *et al.*, 2010; Marti *et al.*, 2015). Therefore, ^{131}I therapy is generally recommended for children with known or high risk of residual disease (including pulmonary metastases) that cannot be surgically resected (Francis *et al.*, 2015). Performing a diagnostic whole-body ^{123}I scan and measurement of the serum thyroglobulin concentration prior to

treatment often helps guide decisions of whether to treat with ^{131}I and the specific dose of ^{131}I to be given. A posttreatment ^{131}I whole body scan is obtained 4–7 days after ^{131}I therapy and may reveal iodine-avid disease that was not detectable on the pretreatment ^{123}I scan.

Children are usually prepared for ^{131}I by withdrawal of levothyroxine treatment to achieve a TSH concentration above 30 mIU/L. Children require less time ($\geq$14 days) to achieve adequate TSH elevation than do adults and generally tolerate hypothyroidism very well (Kuijt and Huang, 2005). There are few data on the use of recombinant human TSH to prepare pediatric patients for ^{131}I treatment, but it may be required in patients who cannot achieve TSH elevation (central hypothyroidism) or who cannot tolerate hypothyroidism. A low-iodine diet is recommended for 2 weeks prior to ^{131}I therapy.

Levothyroxine Therapy

The growth of thyroid follicular cells, including most follicular cell-derived thyroid carcinomas, is enhanced by the action of TSH on these cells. Therefore, suppression of serum TSH concentrations using supraphysiologic doses of levothyroxine is often used to treat thyroid carcinomas by depriving them of this stimulus for growth. TSH suppression appears to improve disease-free survival and mortality in adults with advanced thyroid cancer (Haugen *et al.*, 2016). Although minimal data exist on the efficacy of TSH suppression in pediatric patients with thyroid cancer, based on adult data TSH suppression ($<$0.1 mIU/L) is generally recommended for children with known or high risk of residual thyroid carcinoma after initial surgery. Milder TSH suppression (0.1–0.5 mIU/L) may be considered for patients with intermediate-risk disease.

Surveillance and Follow-Up

Ultrasonography

Periodic physical examinations and neck ultrasounds are a critical part of surveillance for persistent or recurrent thyroid cancer in the neck. Ultrasounds may be performed 6–12 months after initial treatment and every 6–12 months thereafter, depending on the severity of initial disease and risk of recurrence (Francis *et al.*, 2015).

Thyroglobulin Monitoring

Monitoring the serum concentration of thyroglobulin is another important part of thyroid cancer surveillance. Thyroglobulin is a protein synthesized only by thyroid follicular cells, whether normal or neoplastic. Therefore, the serum thyroglobulin concentration estimates the amount of thyroid tissue (normal or neoplastic) present in the patient and should be negligible after near-total thyroidectomy and ^{131}I treatment. Detection of thyroglobulin after thyroidectomy and ^{131}I, or rising thyroglobulin levels in any patient, raise concern for the presence of persistent or recurrent thyroid cancer and require imaging to localize the tumor. Because thyroglobulin synthesis is stimulated by TSH, thyroglobulin concentrations must be interpreted in the context of the serum TSH concentration at the time. The presence of circulating antibodies to thyroglobulin can confound measurement of serum thyroglobulin concentrations (Spencer *et al.*, 1998), so thyroglobulin antibodies should be measured in every sample sent for thyroglobulin analysis. Thyroglobulin antibodies are more common in children than in adults (40% vs. 20%–30%), but about half of children with such antibodies clear them within 2 years, particularly if the initial antibody titer is low (Wassner *et al.*, 2017). Based on data from adults, rising titers of thyroglobulin antibodies are considered an indicator of possible thyroid cancer recurrence, although no pediatric-specific data supporting this are available.

Additional Imaging

Whole body scintigraphy with ^{123}I may be employed to detect iodine-avid persistent or recurrent thyroid cancer in children in whom such disease is known to be present or was previously treated with ^{131}I. ^{123}I scintigraphy may also detect iodine-avid disease in children with abnormal or rising thyroglobulin concentrations but no sonographically detectable disease in the neck. If scintigraphy does not reveal the tumor location, CT or MRI scanning of the neck and chest may be helpful. Few pediatric data are available on the use of positron emission tomography (PET) in this setting.

Treatment of Persistent or Recurrent Disease

Persistent or recurrent thyroid cancer in the neck that is clinically detectable by ultrasound may be resected surgically if feasible, particularly if the disease is of significant size ($>$1 cm), is progressing, or is in an anatomically sensitive location. Cervical disease that is iodine-avid and not amenable to surgery may be treated with ^{131}I. Pulmonary metastases in children are frequently iodine-avid, and in this case may also be treated with ^{131}I if they are progressing. However, pulmonary metastases in children may follow an indolent course and remain stable for long periods, so repeated treatments with ^{131}I should be used with caution and only when necessary, to minimize the risks of radiation exposure. In rare cases of children with progressive disease that is not responsive to ^{131}I, systemic therapy with certain of the kinase inhibitors used for adults with thyroid cancer (e.g., sorafenib, lenvatinib) may be considered, although pediatric data are limited.

Long-Term Surveillance

In adults with thyroid cancer, a patient's response to initial treatment has been shown to significantly modify the risk of recurrence from the initial risk assessed at diagnosis based on tumor stage (Tuttle *et al.*, 2010). This approach of dynamic risk stratification therefore is used in adults to modify surveillance strategies over time based on the patient's response to therapy (Haugen *et al.*, 2016). Dynamic risk stratification is less well studied in children with thyroid cancer, but preliminary data suggest that it may be applicable to pediatric patients as well (Lazar *et al.*, 2016; Sung *et al.*, 2017). Nevertheless, in light of the high risk of recurrence of pediatric thyroid cancer even decades after diagnosis, lifelong surveillance is recommended for children with a history of thyroid cancer.

Medullary Thyroid Carcinoma

Medullary thyroid carcinoma (MTC) is rare in children and accounts for only 2% of pediatric thyroid cancers. The etiology, presentation, diagnosis, and management of pediatric MTC are similar to that in adults. The main difference relates to the fact that many children are diagnosed with a genetic risk for MTC before developing the disease itself, which requires an approach to counseling and management of such patients. Consensus guidelines for the management of MTC, including in children, have recently been published (Wells Jr *et al.*, 2015).

Etiology

Most cases of MTC in children are caused by activating mutations in the *RET* proto-oncogene on chromosome 10q11.2, which encodes a tyrosine kinase. Some cases of MTC are sporadic, but many are due to inherited germline *RET* mutations that cause the syndrome of multiple endocrine neoplasia type 2 (MEN2). In addition to a nearly 100% lifetime risk of developing MTC, MEN2 is associated with development of pheochromocytomas and either hyperparathyroidism (MEN2A) or mucosal neuromas and Marfanoid habitus (MEN2B). A minority of MTC in children is familial but occurs without a detectable *RET* mutation.

Diagnosis

MTC presents similarly to other thyroid cancers as an asymptomatic thyroid nodule, or with cervical lymphadenopathy due to locally metastatic disease. The diagnosis can be confirmed cytologically by ultrasound-guided FNA. Because C cells produce calcitonin, the concentration of calcitonin is often elevated in FNA aspirates of MTC as well as in the patient's serum. Preoperative evaluation of suspected MTC should include imaging of the cervical lymph nodes to detect possible local lymph node metastasis, which is present in about 15% of patients (Machens *et al.*, 2016). Any patient diagnosed with MTC should receive genetic testing for a germline *RET* mutation, which may direct further genetic testing of potentially affected family members.

Management

The management of pediatric MTC is similar to that in adults, beginning with total thyroidectomy and removal of lymph nodes in the central compartment, as well as dissection of any other lymph node compartments clinically involved with MTC. Baseline serum concentrations of calcitonin and carcinoembryonic antigen (CEA) are obtained preoperatively, and higher concentrations are associated with a greater likelihood of metastatic disease. Calcitonin and CEA concentrations are monitored over time to assess the response to treatment and to detect progression of disease. For patients with progressive disease that is not amenable to surgery, other treatment modalities may include systemic tyrosine kinase inhibitors such as vandetanib (Kraft *et al.*, 2017), as well as external beam radiation or radiofrequency ablation, although there are limited data on the use of these treatments in children.

Counseling and Prophylactic Thyroidectomy

Genetic testing of family members diagnosed with MTC or MEN2 often leads to detection of a germline *RET* mutation in a child prior to the development of any clinical manifestations. The risk of developing MTC is nearly 100% in these individuals, and while thyroidectomy is curative if performed before MTC develops or while it remains localized to the thyroid gland, the prognosis worsens once MTC spreads beyond the thyroid. For this reason, prophylactic thyroidectomy is recommended in most patients with MEN2. However, the timing of prophylactic thyroidectomy may be individualized for each patient, balancing the probability of developing metastatic MTC at a given age against the need to minimize the surgical risks of thyroidectomy, which are higher in younger patients.

Factors that may influence the timing of prophylactic thyroidectomy include the specific *RET* mutation present and serum levels of calcitonin. In general, certain *RET* mutations are associated with earlier or later onset of MTC, and consensus guidelines categorize *RET* mutations as highest risk (M918T mutation, usually associated with MEN2B), high risk (mutations in codon 634 or 883), or moderate risk (other mutations) (Wells Jr *et al.*, 2015). Patients at highest risk may develop MTC in infancy and should undergo thyroidectomy within the first year of life. Patients with high-risk mutations generally should undergo thyroidectomy by

5 years of age, or earlier if serum calcitonin levels begin to rise. For patients at moderate risk, monitoring by neck ultrasound and serum calcitonin levels is recommended beginning at age 5 years, and thyroidectomy should be performed if calcitonin levels rise. In high- and moderate-risk patients, the timing of thyroidectomy may also account for the history of MTC onset in affected family members, but this factor should be weighed cautiously since the timing of MTC development can vary significantly among individuals with a given *RET* mutation, even within the same family. Finally, the timing of surgery may be influenced by other factors, such as a patient's or family's desire to avoid the potential burden and anxiety of prolonged monitoring. Prophylactic thyroidectomy should be performed by an experienced thyroid surgeon to minimize the risk of surgical complications, which are highest in the youngest patients. Patients with MEN2 should also have age- and mutation-appropriate screening for pheochromocytoma and hyperparathyroidism prior to thyroid surgery. Overall, identifying individuals at genetic risk of MTC and performing prophylactic thyroidectomy improves outcomes in patients with MEN2, many of whom are have C cell hyperplasia (a premalignant condition) or frank MTC at the time of prophylactic thyroidectomy (Machens *et al.*, 2016; Bussieres *et al.*, 2017).

Physiology of Fetal and Neonatal Calcium Metabolism

Jeremy Allgrove, Great Ormond Street Hospital NHS Foundation Trust, London, United Kingdom

Introduction

In post-natal life, the concentration of calcium is controlled principally by two factors: parathyroid hormone (PTH) and 1,25dihydroxyvitamin D ($1,25(OH)_2D$), the active form of vitamin D. A calcium-sensing receptor (CaSR) is responsible for determining the "set" concentration of calcium and principally determines the secretion of PTH in response to changes in plasma calcium which remain very steady once they have been established in the few days after birth. Fibroblast growth factor 23 (FGF23), is now known to be the "phosphotonin" that had long been suspected to control phosphate metabolism. There is a classic negative feedback mechanism between plasma phosphate and FGF23 secretion although it is not clear what the sensing mechanism for this is. It would appear to be rather more complex than that of calcium since plasma phosphate concentrations vary throughout life, particularly in childhood.

Two other hormonal factors are also involved. Calcitonin (CT) is a circulating hormone but probably plays little part in maintaining plasma calcium although its effect is generally opposite to that of PTH. Parathyroid hormone-related peptide (PTHrP), does not circulate in significant quantities during postnatal life but is an important paracrine factor in cartilage development in the growth plate.

The full-term fetus contains approximately 30 g of calcium and 17 of phosphate. Most of this mineral is accumulated during the last trimester. The mechanisms whereby placental transport of calcium is maintained are complex and very efficient such that, in the event of premature delivery, it is very difficult to maintain calcium accumulation post-natally as well as it would have been in utero. Bone disease of prematurity is therefore primarily a condition associated with mineral deficiency.

Fetal Physiology

Studies, many of which go back to the 18th century, in which aborted fetuses were weighed and the calcium and phosphate content measured after the corpses were "ashed," have demonstrated that the calcium and phosphate content of fetuses is very closely related to body weight. The relationship between calcium and body weight is defined by the equations (Allgrove, 1984):

$$Ca = 0.00075 \times BWt^{1.3093}$$

And for phosphate as:

$$PO_4 = 0.00037 \times BWt^{1.2409}$$

Given the known increments in fetal body weight, it is possible to calculate the rate at which calcium and phosphate are normally accumulated during fetal life.

However, calcium flux across the placenta is not a one-way process, and the flows are bi-directional. This is true of all placental mammals, although the relationship between the forward-flow (i.e., from mother to fetus) and backward-flow is dependent on the number of placental layers—in the haemo-chorial human placenta, in which three layers are present, the ratio is approximately 6/5. Given that the net flow of calcium in favor of the fetus is more than 300 mg/day towards the end of gestation (Sparks, 1984), approximately 1800 mg has to flow from mother to fetus whilst 1500 mg is returned to the mother.

Calcium is unusual amongst substances that cross the placenta in that, unlike most others, there is a positive gradient that is, calcium concentrations in the fetus are greater than those in the mother by about 0.25–0.5 mmol/L. There is therefore active transport across the placenta, in contrast, for instance, to vitamin D in which facilitated transport results in 25-hydroxyvitamin D (25OHD) concentrations in the fetus that are about two thirds those of the mother. Positive gradients for both phosphorus and magnesium are also present in the fetus.

The mechanism by which the gradient for calcium is maintained was first suggested by studies of biologically active PTH-like activity which was shown to be present in cord blood, despite the fact that immunoassays of PTH suggested that concentrations were low (Allgrove *et al.*, 1985). Furthermore, the concentration of bio-active PTH was shown to have a direct relationship with the placental gradient of calcium. Further studies showed that this PTH-like activity was caused by a previously unknown hormone, parathyroid hormone-related peptide (PTHrP), also called PTH-like peptide (PTHLP). PTHrP normally has little role as a true hormone in post-natal life but is now known not only to be involved in maintaining the calcium gradient across the placenta but also as a paracrine factor in cartilage development in the growth plate, and also as one of the causes of malignancy-induced hypercalcaemia.

Factors involved in fetal mineral homeostasis

1. PTHrP

   PTHrP is a 141 amino acid peptide with similar bioactivity to PTH but with substantial structural differences from PTH, hence the bioactivity without immunoreactivity. It is equipotent with PTH in its actions on the Type 1 PTH receptor (PTH1R) but has little action on the PTH2R, present mostly in brain (Orloff *et al.*, 1994).

   In fetal life it is primarily responsible for the transport of calcium across the placenta. The fetal concentration of calcium is

 doi:10.1016/B978-0-12-801238-3.65420-X

"set" at a higher level than in post-natal life (David and Anast, 1974) although what constitutes the sensor for PTHrP is not fully understood, but is different from that for calcium. The maternal calcium concentration determines the activity of PTHrP which increases in the presence of maternal hypocalcaemia and is suppressed by maternal hypercalcaemia. Thus it is not the gradient, but rather the absolute value of calcium that is maintained.

The source of PTHrP in the fetus is not entirely clear. Much of it is probably secreted by the placenta, but there may also be small quantities produced by the fetal parathyroids.

2. PTH

PTH is secreted by the fetal parathyroid glands from about 9 weeks gestation but only in low concentrations normally. The relationship between calcium and the calcium-sensing receptor is present during fetal life but, because calcium concentrations are higher than after birth, PTH secretion is largely suppressed. It is not known by which stage of gestation the positive gradient is established, although it is present by 15 weeks.

PTH and PTHrP probably work together to maintain the calcium gradient although PTHrP is the principal factor. Circulating concentrations of PTHrP are about 10–15 times higher than those of PTH.

3. The calcium-sensing receptor (CaSR)

This is present in the fetus. The same sigmoid relationship between calcium and PTH secretion is present. However, because calcium concentrations are higher than in post-natal life because of the effects of PTHrP, PTH secretion is largely suppressed. However, if the fetus carries a heterozygous inactivating mutation of the CaSR, particularly if this is a new mutation or it is inherited from the father, or if the mutation is homozygous, neonatal severe hyperparathyroidism may result since the "set point" of calcium is even higher than normal, resulting in fetal hyperparathyroidism.

Nevertheless, it seems that a second sensor, related to PTHrP, is present which is responsible for regulating PTHRP secretion. The nature of this is not known but may be within the placenta.

Factors with minimal influence on fetal calcium homeostasis

1. Vitamin D

Vitamin D, in its circulating form, 25-hydroxy vitamin D (25OHD), readily crosses the placenta. This is a passive or facilitated process that results in 25OHD concentrations in the fetus that are only about 60%–80% those of the mother. Maternal vitamin D deficiency has little effect on fetal bone mineralization and individuals who have either 1α-hydroxylase or vitamin D receptor deficiency do not have rickets at birth and have normal mineralization. True congenital rickets is extremely rare and only occurs if maternal vitamin D is completely absent.

$(1,25(OH)_2D)$ concentrations are low in the fetus and play little part in promoting calcium transport across the placenta.

In contrast, concentrations of 24,25-dihydroxyvitamin D $(24,25(OH)_2D)$, an inactive metabolite of vitamin D, are high.

2. Calcitonin

Calcitonin (CT) also plays little part in fetal mineral homeostasis. CT deficiency does not result in mineral defects. There is some evidence to suggest that CT may play a part in embryonic implantation.

3. Fibroblast growth factor 23 (FGF23)

FGF23 is normally associated with increased excretion of phosphate by the kidney post-natally. Circulating concentrations of FGF23 in the fetus are approximately one third of those in postnatal life, whilst those of its inactive fragments are approximately twice as high (Takaiwa *et al.*, 2010). The co-factor, Klotho, also circulates at about six times its concentration in post-natal life (Ohata *et al.*, 2011). The implications are not clear but FGF23 has little effect on transplacental phosphate transport.

Fetal organs and mineral homeostasis

1. The placenta

The placenta is the principal organ regulating mineral transport, mainly under the influence of PTHrP. PTH has a lesser effect. In contrast, neither, vitamin D nor FGF23 nor calcitonin has any significant effect in the placenta.

2. Fetal kidneys

The fetal kidneys are the principal source of amniotic fluid. Much of this is swallowed, so any minerals that are excreted into the amniotic fluid are likely to be reabsorbed. They play little part in fetal mineral homeostasis

3. Fetal intestines

Most of the minerals that are contained in amniotic fluid are reabsorbed. The process is independent of vitamin D and is dependent on the concentrations of mineral within the fluid.

Fetal Skeletal Mineralization

Most of the mineralization of fetal bone occurs during the last trimester. A fetus of 28 weeks weighing 1.2 kg contains approximately 8 grammes of calcium. By term the same fetus weighing 3.3 kg has accumulated a further 22 grammes—an average of 261 mg/day and, by term, this net accumulation is greater than 300 mg/day. Thus infants who are born prematurely miss out on the mineral accumulation that normally occurs during this period. The process of mineral transfer across the placenta is so efficient that, in these premature infants, it is very difficult to achieve the same rate of mineral gain post-

natally that would have happened had they remained in utero. This is particularly true of phosphate, and relative phosphate deficiency is one of the principal causes of bone disease of prematurity. Phosphate supplementation is usually necessary in very premature infants, especially if born before 28 weeks' gestation, in order to prevent this, particularly if they are being fed breast milk which contains less phosphate than formula feeds.

The increase in fetal skeletal mineral is accompanied by a very rapid bone turnover that allows bone growth and remodeling to occur in utero. Approximately 300 mg of calcium are exchanged between plasma and bone each day. This means that about 1% of the entire mineral content of the fetal skeleton is changed daily—approximately 100 times that in adults.

Neonatal Mineral Homeostasis

At birth, there is an immediate and complete cessation of calcium transport to the newborn as the umbilical cord is cut. This is not matched by an immediate change in bone mineralization so there is a physiological fall in plasma calcium in the neonate whilst the supply of calcium is replaced by milk intake and PTH secretion increases, and which has its nadir at around 48 h. This is not usually of any clinical significance. However, in premature infants this reduction in calcium is exaggerated and may be a cause of symptomatic hypocalcaemia. In addition, infants who are "sick" for any reason have greater difficulty in establishing normocalcaemia.

Factors involved in neonatal mineral homeostasis

1. PTH

   At birth, the newborn is in a state of relative hypoparathyroidism due to the suppression of PTH by the high fetal concentrations of calcium. Once the influence of PTHrP (and its attendant sensor) is removed after separation from the placenta, PTH becomes the prominent factor in maintaining calcium homeostasis. However, this takes a few days to become established. In term infants, transport of calcium does diminish somewhat and bone turnover decreases temporarily, which mitigates the hypocalcaemic stress following birth. However, it also takes a few days to establish calcium supplies from intestinal absorption as milk intake increases. The combination of these factors results in a transient fall in plasma calcium, usually to a nadir of about 2.0 mmol/L before increasing to post-natal values by the end of the first week. By this time the normal relationship between PTH and the CaSR is established.

   Infants, such as those with 22q Deletion syndrome, GCMB mutations or other causes of congenital hypoparathyroidism, who are deficient in PTH are at risk of developing symptomatic hypocalcaemia in the neonatal period.
2. $1,25(OH)_2D$

   In contrast to intrauterine life, $1,25(OH)_2D$ becomes an important factor post-natally. Concentrations rise in response to the increase in PTH and vitamin D receptors in the intestine contribute to calcium absorption from the diet.
3. 25OHD

   Vitamin D itself is important at this stage in providing a substrate from which $1,25(OH)_2D$ can be synthesized. If supplies are limited, PTH increases to try to stimulate $1,25(OH)_2D$ production in an attempt to increase calcium absorption. This results in increased phosphate losses in the urine which, in turn, causes relative hypophosphataemia. This is the principal cause of rickets. Any cause of hypophosphataemia may result in rickets. The speed at which it develops is determined by the severity of the deficiency. Infants who are very deficient in vitamin D may develop clinically obvious rickets within a few weeks whilst others who are less severely deficient or who have an inherited metabolic disorder may take several months for this to become apparent.
4. PTHrP

   Concentrations of PTHrP are high at birth but become undetectable in post-natal life. It is not clear how quickly they become suppressed, but they play little part as a true hormone after birth. PTHrP is, however, important as a paracrine factor in growth plate development and operates in conjunction with other growth plate factors such as Indian Hedgehog and RUNX2 to regulate cartilage development within the growth plate. Some patients who subsequently develop hypercalcaemia of malignancy do so because they start to secrete PTHrP from the malignant tissue. There are high concentrations of PTHrP in breast milk, but the significance of this is not clear.
5. FGF23

   FGF23 rises after birth. Its principal effect is to increase phosphate excretion by the kidneys. It also has a suppressive effect on 1α-hydroxylase, although this is probably more important if concentrations become supra-physiological. The normal feedback mechanism between plasma phosphate and FGF23 is gradually established post-natally and depends partly on the responsiveness of renal tubules to the effect of FGF23. Excess concentrations of FGF23 due to mutations in PHEX or FGF23 itself cause hypophosphataemic rickets but, although low phosphate values can be demonstrated within 2–3 weeks in some patients, clinical rickets does not usually develop until a few months after birth.
6. Calcitonin

   CT is secreted by the C-cells of the thyroid. Concentrations rise following birth but the significance of this is not clear. Whether or not its hypocalcaemic effect contributes to neonatal hypocalcaemia is uncertain. After a few days, CT falls back to normal post-natal values. In later life, CT can be used as a marker of C-cell carcinoma in patients with mutations in the RET proto-oncogene (MEN2).

Neonatal organs and mineral homeostasis

1. Parathyroid glands

   The parathyroid (PT) glands are largely suppressed during fetal life but start to function more effectively following birth to help restore plasma calcium to normal. They develop from the third and fourth branchial arches. This occurs under the influence of several genes including GCMB, GATA3, TBCE, TBX1 and a number of mitochondrial genes. Failure of any one of these genes to make its proper contribution to parathyroid gland development results in primary hypoparathyroidism which can manifest itself at or shortly after birth. There may or may not be other clinical manifestations.
2. Neonatal kidneys

   Renal function is poor at birth and renal blood flow is limited. It improves with time and allows responsiveness to PTH and FGF23 to develop. Thus phosphate excretion increases. At the same time, expression of the vitamin D receptor and CaSR also increase and post-natal homeostasis is achieved.
3. Neonatal intestine

   Calcium absorption in the newborn is initially passive and independent of vitamin D. Gradually, the vitamin D dependent mechanisms develop with increases in the vitamin D receptor and activation of TRPV6, the vitamin D-dependent trans-cellular calcium transport protein. Lactose and breast milk promote calcium absorption and, because breast milk has a lower concentration of phosphate, calcium concentrations tend to be higher and phosphate concentrations lower in breast-fed compared with formula-fed infants.
4. The neonatal skeleton

   At birth skeletal mineralization is still progressing at a rapid rate, although there is some slowdown towards the end of pregnancy. Bone turnover is also rapid and occurs largely without the influence of vitamin D which, in any case, probably has little direct effect on bone mineralization. Its principal effect is to promote calcium absorption in the intestine in order to ensure an adequate supply of calcium. This effect can be overcome by increasing calcium intake so that passive (para-cellular as opposed to trans-cellular) absorption can compensate. As time progresses, the normal post-natal influences ensue.

Summary

Mineral metabolism in the fetus is very different from that in post-natal life. The neonate is largely dependent on PTH and PTHrP for promoting transport of mineral across the placenta. Following birth, profound changes occur which initially result in transient hypocalcaemia but which, by the end of the first week, have largely settled down to a postnatal pattern which remains largely unchanged, at least in quality, if not quantity, during the remainder of life.

Because of this, defects in the various mechanisms may not necessarily have any significant effects prenatally but become more obvious post-natally.

Rickets and Osteomalacia

Suma Uday and Wolfgang Högler, Birmingham Women's and Children's NHS Foundation Trust, Birmingham, United Kingdom and IMSR, University of Birmingham, Birmingham, United Kingdom

Glossary

Calcipaenia Calcium deprivation in the body due to vitamin D and/or dietary calcium deficiency.
Craniosynostosis Premature fusion of skull sutures in an infant.
Diaphysis The long bone shaft formed from a primary center of ossification.
Epiphysis End of a long bone formed from secondary center of ossification which is initially separate from the body of the long bone and later unites with it through ossification.
Hypocalcemia Low serum calcium concentration.
Hypophosphataemia Low serum phosphate concentration.
Hypophosphatasaemia Low serum alkaline phosphatase activity.
Metaphysis Growing part of the long bone which lies between the growth plate and the diaphysis.
Mineralization Integration of hydroxyapatite crystals into pre-formed osteoid, creates the bone matrix.
Ossification Transformation of a cartilage frame into bone tissue during bone development.
Osteoid Unmineralized, organic bone matrix component synthesized by osteoblasts.
Phosphopaenia Phosphate deprivation in the body.

Introduction

Rickets and osteomalacia occur as a consequence of defective mineralization of the skeleton. Such reduced mineralization results in soft bones, which deform and break more easily, and stunting of growth. The non-nutritional forms of rickets can be associated with raised intracranial pressure from craniosynostosis, and severe hypophosphatasia is associated with respiratory insufficiency from pulmonary hypoplasia secondary to insufficient chest growth. Dental manifestations are a frequent association due to impaired mineralization of enamel.

Defective mineralization occurs due to (1) lack of mineral supply to mineralization sites (calcium or phosphate), (2) lack of the mineral supplier calcitriol (hormone synthesized from vitamin D) which controls their intestinal absorption, and (3) less commonly due to lack of the tissue non-specific alkaline phosphatase enzyme which facilitates mineralization.

The leading cause of rickets worldwide is dietary calcium deficiency and/or vitamin D deficiency (Munns *et al.*, 2016). Dietary calcium deficiency predominates in low income countries with often abundant sunshine due to poor dietary intake whereas vitamin D deficiency predominates in dark skinned individuals residing in high latitude countries with poor ultra violet B (UVB) penetration and reduced skin synthesis of vitamin D. The recent refugee crisis and immigration of dark skinned individuals from low income countries into high latitude regions has led to the resurgence of nutritional rickets in high income countries (Högler and Munns, 2016).

A basic understanding of the physiology of bone growth, structure and mineralization is essential to differentiate and manage various forms of rickets and osteomalacia, and their fundamental difference to osteoporosis. Recent advances in the understanding of the pathophysiology of certain forms of rickets has led to the emergence of new therapeutic agents such as monoclonal antibody against fibroblast growth factor 23 in X-linked hypophosphatemic rickets (XLH) and enzyme replacement with asfotase alfa in hypophosphatasia (HPP).

Terminology Buster: Bone Formation, Mineralization, Ossification, Calcification

The bone tissue or matrix is composed of 50%–70% mineral (predominantly calcium and phosphate), 20%–40% organic material (predominantly type 1 collagen), 5%–10% water, and $<3\%$ lipids (Clarke, 2008). The three main types of bone cells are (1) osteoblasts which form new bone, (2) osteoclasts which resorb old bone and calcified growth plate cartilage, and (3) osteocytes which constitute 90% of the cells in the matrix and are responsible for biomechanical sensing and hormone production (Bellido *et al.*, 2014).

The term "bone formation" describes the process of synthesis of extracellular organic osteoid followed by its mineralization, with later integration of osteoblasts which transform into osteocytes. The term "mineralization" relates to the integration of hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ into osteoid. In contrast, the term "ossification" relates to the two major modes of bone development: intramembranous ossification is seen in flat bones such as the skull and endochondral ossification in long bones such as the femur (Gilbert, 2000). Physiological mineralization is restricted to bones, teeth, and growth plate cartilage (where it is also called calcification). Pathological mineralization or "calcification" in its true meaning is deposition of calcium-phosphate

 doi:10.1016/B978-0-12-801238-3.65426-0

crystals in extra-skeletal tissues (kidneys, skin, arteries, muscle, brain, tumors) and can lead to serious problems (Kirsch, 2012). Some of the conditions associated with pathological calcification include: Generalized arterial calcification of infancy, pseudoxanthoma elasticum, dermatomyositis and subcutaneous fat necrosis (Nitschke and Rutsch, 2017).

Endochondral ossification and mineralization merit more detailed discussion to be able to appreciate the pathogenesis and clinical features of rickets in children.

Endochondral Ossification

Longitudinal growth occurs through endochondral ossification in long bones. Condensation of mesenchymal cells to form cartilage precedes their differentiation into chondrocytes (Mackie *et al.*, 2008). These cells then secrete cartilage extracellular matrix components. The cartilage structure is invaded by cells to form the primary ossification center at the center (midshaft) followed by secondary ossification centers at the ends (epiphyses). The primary and secondary ossification centers are separated by the growth plate which is responsible for longitudinal growth and drives expansion of the primary ossification center (Mackie *et al.*, 2008). The articular epiphyseal growth cartilage is responsible for growth and shaping of the epiphyses and drives expansion at the secondary ossification center. The primary and secondary ossification centers encroach onto each other gradually replacing the cartilage with bone tissue except at the articular surface.

The chondrocytes in the growth plate are arranged in morphologically distinct zones. At the epiphyseal end of the growth plate is the reserve zone or resting zone. Cells in the resting zone then enter the proliferative zone where they undergo division and produce large amounts of extracellular matrix protein (Rauch, 2005). The proliferative cells lose their capacity to divide and then start to increase in size (pre-hypertrophic zone) until they are fully differentiated to form hypertrophic chondrocytes (in the hypertrophic zone) (Rauch, 2005). Intracellular calcium concentration continues to increase in the hypertrophic chondrocytes and at some point they start to mineralize the longitudinal septa in the surrounding matrix to form the zone of provisional calcification (Rauch, 2005). The final apoptosis of hypertrophic chondrocytes triggers mineralization of the matrix and vascular invasion (facilitating osteoblast invasion) at the metaphyseal/growth plate junction (primary spongiosa). Lack of phosphate supply at the growth plate (Tiosano and Hochberg, 2009) prevents apoptosis of hypertrophic chondrocytes and thus inhibits both mineralization and growth. Eighty percent of the longitudinal septa of the growth cartilage are rapidly resorbed in the metaphyseal zone immediately behind the invading blood vessels and the remaining longitudinal septa serve as scaffolds, on which osteoblasts deposit further bone matrix (secondary spongiosa) (Rauch, 2005).

The proliferation and differentiation of chondrocytes is regulated by a number of systemic factors (such as growth hormone, thyroid hormone, estrogen and cortisol) and a large number of still poorly understood locally secreted factors (such as Indian hedgehog, parathyroid hormone-related peptide, fibroblast growth factors) which act on receptors to effect intracellular signaling and activation of chondrocyte-selective transcription factors (Mackie *et al.*, 2008).

Mineralization

Bone is mineralized connective tissue. The most abundant minerals in bone matrix are calcium and phosphorus, present in the form of hydroxyapatite crystals [$Ca_{10}(PO_4)_6OH_2$]. The mineralization process therefore requires adequate supply of substrates, calcium and phosphate, which are supplied by calcitriol (1,25 dihydroxy vitamin D) through intestinal absorption.

The mechanism of initiation and regulation of cell mediated mineralization is not entirely clear, however several theories have been proposed (Huitema and Vaandrager, 2007). Matrix vesicles (MVs) protruding from osteoblasts play an important role in mineralization (Anderson, 1995). One theory suggests that MVs bud off the parental plasma membrane, another suggests that MVs represent the rearrangement of the apoptotic cell membrane (Cui *et al.*, 2016).

The first step in mineralization is the formation of hydroxyapatite in MVs of mature chondrocytes and osteoblasts (Cui *et al.*, 2016). During Phase I, there is increased activity of the MV phosphatases (including alkaline phosphatase, adenosine triphosphatase, pyrophosphatase and PHOSPHO1) which generate and transport phosphate; as well as calcium binding compounds such as the annexin family and phosphatidylserine (Anderson, 2003). Calcium and phosphate are attracted into the MVs by these compounds, until the threshold for their precipitation is reached (Anderson, 1995). In Phase II, the hydroxyapatite crystals penetrate the MV membrane and are elongated into the extracellular space (Anderson, 1995), which requires appropriate concentrations of calcium and phosphate outside the MVs. Tissue non-specific alkaline phosphatase (TNSALP) plays a crucial role in the formation of hydroxyapatite crystals by hydrolyzing inorganic pyrophosphate (PPi), an inhibitor of hydroxyapatite formation, to inorganic phosphorus (Pi) (Terkeltaub, 2001). The ratio of PPi to Pi is of critical importance in the promotion or indeed restriction of mineral in physiological tissues (Cui *et al.*, 2016). TNSALP, encoded by the *ALPL* gene, is abundant on the surface of MVs derived from osteoblasts and hypertrophic chondrocytes (Millán, 2013). Reduced TNSALP activity leads to hypomineralization as seen in HPP (Orimo, 2010).

The mineralization status of the bone matrix can be assessed by quantitative backscattered electron imaging and normative data on mineralization density distribution in iliac bone biopsies are available (Fratzl-Zelman *et al.*, 2009). Finally, it is important to highlight that the term "mineralization" used in radiology reports does not refer to the mineralization process described above and is erroneously used to report changes in bone mass, mineral content or areal bone density over time.

Bone Modeling and Remodeling

Bone metabolism in children differs from adults in that the bone undergoes longitudinal growth, metaphyseal inwaisting, modeling and remodeling during childhood and adolescence whereas in adults remodeling is the only active bone process (Clarke, 2008).

Modeling allows for bone growth in width by deposition of new bone on the periosteal surface by osteoblasts and resorption of old bone on the endosteal surface by osteoclasts (Rauch, 2007). Modeling allows for change in shape of bones in response to physiologic influences and mechanical forces (Frost, 1990).

Remodeling is the process by which old bone is replaced by new bone, essential for maintaining bone strength and removal of microcracks (Clarke, 2008). Unlike bone modeling where new bone formation and resorption occur on different surfaces (periosteal and endosteal respectively) allowing for increase in bone width, remodeling occurs in existing bone matrix. Osteoclasts dig tunnels and trenches and osteoblasts fill these with new bone (Allen and Burr, 2013).

Bone Strength

Bone tissue is a two-phase porous composite material composed primarily of collagen and minerals, with mechanical properties determined primarily by the amount, arrangement, and molecular structure of these primary constituents (Turner, 2006). Bone minerals provide stiffness or mechanical rigidity to the bone, in the absence of which bones become soft and pliable. Organic matrix on the other hand provides toughness enabling the bone to act as a shock absorber. Therefore, defective mineralization (rickets and osteomalacia) results in soft and pliable bones whereas defective collagen production (osteogenesis imperfecta) with excess minerals leads to overly stiff and brittle bones. Bone strength is compromised in both conditions rendering the bone susceptible to fractures (Chapman *et al.*, 2010; Rauch and Glorieux, 2004).

Definition

Rickets is the defective mineralization of the growth plate cartilage and adjacent primary and secondary spongiosa in the metaphysis ("new bone") and thus can only affect growing children with open epiphyses. Rickets is a radiological diagnosis.

Osteomalacia is the defective mineralization of newly formed osteoid in existing bone during remodeling ("old bone") and can affect humans of all ages, thus always co-exists with rickets in children. Osteomalacia is associated with musculoskeletal pain, causes leg bowing in children and Looser zone fractures in adults and children.

Osteoporosis is reduced bone mass and structural quality. It is not associated with reduced bone mineralization. Osteoporosis occurs when bone resorption exceeds bone formation (adults and children) or from reduced bone mass accrual (children). Increased bone resorption is typically secondary to chronic illness (inflammatory conditions, leukemia, poor nutrition), an effect of its treatment (glucocorticoids, anticonvulsants, chemotherapy) or due to sex hormone deficiency (hypogonadism, menopause) (Saraff and Högler, 2015; Högler and Ward, 2015; Kling *et al.*, 2014). Reduced bone mass accrual is typically secondary to muscle weakness (immobility, muscle atrophy/dystrophy conditions). Primary osteoporosis represents intrinsic skeletal defects and is commonly inherited (osteogenesis imperfecta, idiopathic juvenile osteoporosis) (Van Dijk and Sillence, 2014).

Pathogenesis and Classification of Rickets

Based on the primary pathology, rickets and osteomalacia can be classified broadly into defective mineral supply (calcipaenia, phosphopaenia) and defective mineralization (hypophosphatasia).

- Calcipaenia (deprivation of body calcium, most common cause is dietary calcium and/or vitamin D deficiency)
- Phosphopaenia (deprivation of body phosphorus, most common cause is renal phosphate wasting)
- Hypophosphatasia (lack of TNSALP, causing hypophosphatasaemia = low ALP)

Irrespective of the primary pathology, the underlying mechanism of all forms of rickets is low phosphate availability to the hypertrophic chondrocytes in the growth plate (Tiosano and Hochberg, 2009) resulting in lack of their apoptosis (Sabbagh *et al.*, 2005). The various causes of rickets and osteomalacia are detailed in **Table 1**.

Interestingly, some rare bone conditions have only been associated with osteomalacia and not rickets:

- Recessively inherited FAM20C mutations cause osteomalacia but not rickets in humans (Rafaelsen *et al.*, 2013; Whyte *et al.*, 2017). *FAM20c* associated rickets has only been noted in mice (Wang *et al.*, 2012) to date.
- Osteogenesis imperfecta type VI (OI6) caused by homozygous mutation (autosomal recessive inheritance) in the *SERPINF1* gene is characterized by excess accumulation of osteoid secondary to mineralization lag (Glorieux *et al.*, 2002).

Understanding the causes of rickets and osteomalacia based on the primary pathology (**Table 1**) aids in a structured diagnostic workup at presentation. In this article we focus on the most common and preventable cause of rickets worldwide; nutritional

Table 1 Classification of rickets based on the primary pathology

Calcipaenic rickets (nutritional rickets)	*Phosphopaenic rickets (hypophosphatemic rickets)*	*HPP rickets (hypophosphatasia)*
Calcium deficiency[a]	Renal phosphate wasting (non-FGF23 mediated)	Hypophosphatasia (*ALPL*)
• Dietary deficiency • Malabsorptive conditions: liver failure (hepatic osteodystrophy), coeliac disease, short gut syndrome, inflammatory bowel disease	• Hereditary hypophosphatemic rickets with hypercalciuria (*SLC34A3*) • Lowe's syndrome (*OCRL*) • Dent's disease (*CLCN5*) • Fanconi syndrome • Drug induced (i.e. valproate, aminoglycosides, cisplatin, ifosfamide)	• Prenatal benign • Perinatal • Infantile • Childhood • Adult • Odonto
Vitamin D deficiency • Decreased cutaneous synthesis: dark skin, covered clothing, sunscreen use, sunlight deprivation (latitude, cloud cover, pollution) • Dietary deficiency • Malabsorptive conditions (see above) • Increased degradation (*CYP3A4* enzyme-induction, i.e. rifampicin)	Renal phosphate wasting (FGF23 mediated) • X-linked hypophosphatemic rickets (*PHEX*) • Autosomal dominant hypophosphatemic rickets (*FGF23*) • Autosomal recessive hypophosphatemic rickets (*DMP1, ENPP1, FAM20c*[b]) • Tumor induced osteomalacia • Polyostotic fibrous dysplasia	
Defects in calcitriol synthesis or action • Genetic/vitamin D-dependent rickets (VDDR) – 25-Hydroxylase deficiency/VDDR 1B (*CYP2R1*) – 1-Hydroxylase deficiency/VDDR 1A (*CYP27B1*) – Vitamin D receptor defect/VDDR 2A (*VDR*) – Vitamin D response element binding protein defect/VDDR 2B – Enhanced vitamin D catabolism/VDDR 3 (*CYP3A4*) • Renal failure (renal osteodystrophy)	Poor intestinal absorption • Antacids contacting aluminum, magnesium, or calcium • Phosphate binders (i.e. Sevelamer)	
	Insufficient dietary intake (rare) • Osteopenia of prematurity	

[a]Calcium deficiency (calcium deprivation) is not equivalent to hypocalcemia. Secondary hyperparathyroidism maintains normal serum calcium by increasing bone resorption, 1-hydroxylase activity and renal reabsorption of calcium. Therefore, serum calcium is a very poor marker of calcipaenia.
[b]Mutations in *FAM20c* cause hypophosphatemic osteomalacia but not rickets.
For genetic conditions the affected gene is indicated in parenthesis.

rickets due to dietary calcium and vitamin D deficiency. We will also discuss inheritable conditions with emerging treatments such as XLH and HPP, to give the reader a broader view of different forms of rickets.

Calcipaenic Rickets

The leading causes of calcipaenic rickets worldwide are dietary calcium and/or vitamin D deficiency. Although calcipaenia (calcium deprivation) can very rarely occur due to defects in calcitriol synthesis or action, the commonest cause is reduced vitamin D synthesis in the skin from lack of UVB exposure. Vitamin D deficiency can very rarely occur due to dietary insufficiency, malabsorption or enhanced degradation induced by drugs such as rifampicin, a *CYP3A4* inducer (Wang *et al.*, 2013; Hawkes *et al.*, 2017). The main function of calcitriol is to maintain calcium homeostasis in the body by increasing intestinal absorption of the bone minerals calcium and phosphate (supplier function). Therefore, any decrease in dietary calcium or calcitriol action results in calcipaenia. Calcium deprivation in the body is sensed by the calcium sensing receptor in the parathyroid gland's chief cells which stimulate the release of parathyroid hormone (PTH) (Atapattu *et al.*, 2013). High PTH increases (1) osteoclastic bone resorption to release stored calcium, (2) renal calcium reabsorption and (3) 1-hydroxylase activity to maximize calcitriol synthesis. These three compensation mechanisms will keep serum calcium stable at the expense of high bone resorption (**Fig. 1**). Eventually, prolonged secondary hyperparathyroidism results in hypophosphatemia as it also reduces renal phosphate reabsorption. It is the hypophosphataemia that causes rickets and osteomalacia and not the hypocalcemia which occurs only once compensation fails. Hypocalcemia is frequently encountered in infants due to their smaller bone stores, higher mineral needs for rapid growth, and can cause seizures, cardiomyopathy and cardiac death. In children with chronic kidney disease, secondary hyperparathyroidism is triggered by reduced renal synthesis of calcitriol. This is the main mechanism involved in the pathophysiology of renal osteodystrophy (Wesseling-Perry, 2015; Bonthuis *et al.*, 2015).

phosphate reabsorption

Vitamin D and Calcitriol Synthesis

Vitamin D is biologically inert and merely serves as the substrate to calcitriol synthesis, in analogy to cholesterol being a precursor for cortisol synthesis. Calcitriol synthesis and metabolism is illustrated in **Fig. 1**. We would like to draw the readers' attention to the correct terminologies such as calciferol, calcidiol and calcitriol and discourage the use of the broad term "vitamin D" to refer to either calcidiol or calcitriol (Uday and Högler, 2017). Cholecalciferol (vitamin D3) is synthesized in the skin from 7-dehydrocholesterol following exposure to UVB in sunlight (290–315 nm) and is the main source of vitamin D in the body. Ergocalciferol (vitamin D2) and cholecalciferol can be obtained through certain dietary sources and both undergo 25-hydroxylation in the liver by the CYP2R1 enzyme to form 25 hydroxyvitamin D (25OHD; calcidiol). The stable but still inert 25OHD can be easily measured in human serum and best represents "vitamin D status." 25OHD then undergoes 1-hydroxylation by the CYP27B1 enzyme in the kidney (systemic production) and in the intestine (local production) (Gawlik *et al.*, 2015) to form the active hormone 1,25 dihydroxyvitamin D [1,25$(OH)_2$D; calcitriol]. Calcitriol then binds to its receptor, the calcitriol receptor, commonly referred to as the vitamin D receptor (VDR). The calcitriol-VDR complex heterodimerises with retinoid X receptor in the cell nucleus. This ligand-receptor complex targets specific vitamin D responsive elements (VDRE) on the genome to exert its action on various tissues.

Some of the rare, genetic forms of rickets caused by interrupted calcitriol metabolism or action are detailed in **Table 2** and illustrated in **Fig. 1**. The fact that rickets caused by severe inherited calcitriol receptor defects can be cured with high dose calcium points out the clinically negligible direct effect of calcitriol on bone tissue (Hochberg *et al.*, 1992; Tiosano *et al.*, 2011).

Nutritional Rickets (NR)

Nutritional rickets/osteomalacia (NR) is a major public health concern in low and middle income countries and has resurfaced in high income countries (Holick, 2006). Prevention of vitamin D deficiency and its associated complications in pregnancy, lactation and childhood is a global heath priority (Schoenmakers *et al.*, 2015). The spectrum of NR ranges from isolated dietary calcium or vitamin D deficiency to a combined deficiency (Pettifor, 2004). Calcium and vitamin D insufficiency or deficiency in isolation may not have any clinical consequences, however rickets and osteomalacia develop when both are deficient or insufficient (Munns *et al.*, 2016; **Fig. 2**).

Risk factors and epidemiology

The at-risk population includes: individuals with dark skin and those with reduced sunlight exposure (due to geographic location, predominant indoor living or covered clothing for cultural reasons), individuals with calcium restricted diets (malnutrition, medical or cultural reasons), babies not given vitamin D supplements, especially those of vitamin D deficient mothers and those breastfed for prolonged periods (Munns *et al.*, 2016).

Hypocalcemic complications and NR are only the tip of the iceberg and the true burden of hidden disease remains unidentified. The incidence of NR is on the rise even in developed countries, due to immigration of dark-skinned, high risk groups (Thacher *et al.*, 2016). NR due to dietary calcium deficiency predominantly affects individuals residing in low and middle income countries with abundant sunshine (Aggarwal *et al.*, 2012; Okonofua *et al.*, 1991; Fischer *et al.*, 1999) whereas vitamin D deficiency predominantly affects the dark skinned (immigrant and resident) population in high income countries (Callaghan *et al.*, 2006; Ward *et al.*, 2007; Munns *et al.*, 2012; Thacher *et al.*, 2013). Post-mortem studies from high latitude countries have demonstrated high prevalence of histological evidence of rickets (Scheimberg and Perry, 2014) and osteomalacia (Priemel *et al.*, 2010).

Clinical presentation

The clinical manifestations of calcipaenia occur as a consequence of Hypocalcemia in the short term and hypophosphataemia in the medium to long term. The clinical spectrum across the lifespan is wide and includes hypocalcemic seizures, life

Fig. 1 Vitamin D and calcitriol synthesis, metabolism, and interruptions in normal physiology resulting in disease states (rickets and osteomalacia). Cholecalciferol is synthesized in the skin from 7-dehydrocholesterol following sunlight exposure. Both cholecalciferol and ergocalciferol can be consumed through certain dietary sources or supplements. Calciferol undergoes 25-hydroxylation in the liver to calcidiol and then 1-hydroxylation in the kidney and gut to the hormone calcitriol or "active vitamin D." Calcitriol binds to the calcitriol receptor (vitamin D receptor, VDR) and the calcitriol-VDR complex heterodimerises with retinoid X receptor (RXR) in the cell nucleus. This ligand-receptor complex targets specific vitamin D responsive elements (VDRE) on the genome to exert its action on calcium homeostasis mainly through stimulating intestinal absorption of calcium and phosphate. Any lack of dietary calcium or decreased calcitriol action (nutritional or genetic) results in secondary hyperparathyroidism which maintains serum calcium concentrations by increasing bone resorption, renal calcium absorption and 1-hydroxylation. Disease states are indicated in red and include: nutritional rickets resulting from block of synthesis from sunlight or limited vitamin D in diet, vitamin D dependent rickets type 1B (VDDR1B) resulting from *CYP2R1* mutations blocking 25-hydroxylation in liver, VDDR1A resulting from *CPY27B1* mutations blocking 1-hydroxylation in kidney, VDDR2A resulting from *VDR* mutations, VDDR2B resulting from VDRE binding protein (VDRE-BP) defects and the recently described VDDR3 resulting from increased degradation of vitamin D metabolites due to activating mutations in *CYP3A4*.

Table 2 Genetics and treatment of rickets caused by defects in calcitriol synthesis or action, historically called vitamin D-dependent rickets (VDDR)

Type of vitamin D dependent rickets (VDDR)	*Description*	*Mutation and inheritance*	*Treatment*
VDDR1B (Cheng *et al.*, 2004)	25-Hydroxylase deficiency leading to low serum levels of 25 hydroxyvitamin D (25OHD)	*CYP2R1 gene* on chromosome 11p15.2. Autosomal recessive (AR) inheritance	Physiological doses of calcitriol
VDDR1A (Wang *et al.*, 1998)	1-Hydroxylase deficiency leading to low serum level of 1,25 dihydroxy vitamin D [$1,25(OH)_2D$]	*CYP27B1 gene* on chromosome 12q14.1. AR inheritance	Physiological doses of calcitriol or alfacalcidol
VDDR2A (Malloy and Feldman, 2011)	Vitamin D receptor (VDR) defect leading to increased serum level of $1,25(OH)_2D$. Most patients also have alopecia	*VDR gene* on chromosome 12q13.11. AR inheritance, rarely autosomal dominant	Pharmacological doses of calcitriol or alfacalcidol and high-dose calcium supplements. Severe cases (especially patients with alopecia) may warrant calcium infusions
VDDR2B (Giraldo *et al.*, 1995)	Abnormal expression of vitamin D responsive element-binding protein (Hewison *et al.*, 1993) interferes with the normal function of VDR	Mutation and inheritance not known	Pharmacological doses of calcitriol or alfacalcidol and calcium supplements
VDDR3 (Rodda *et al.*, 2017)	Enhanced hepatic inactivation of vitamin D metabolites leading to low serum 25OHD and $1,25(OH)_2D$	*CYP3A4 gene* on chromosome 7q22.1 (gain of function mutation). Inheritance not known	Pharmacological doses of cholecalciferol

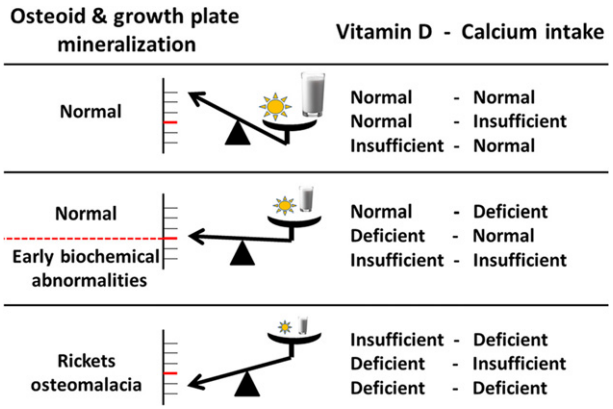

Fig. 2 Three stage classification of vitamin D status (symbolized by sun) and calcium intake (symbolized by glass of milk) in the pathogenesis of rickets. Serum 25 hydroxyvitamin D (25OHD) >50 nmol/L is classed as sufficient, 30–50 nmol/L as insufficient and <30 nmol/L as deficient. Reproduced from Högler, W. (2015) 'Complications of vitamin D deficiency from the foetus to the infant: One cause, one prevention, but who's responsibility?', Best Practice and Research Clinical Endocrinology and Metabolism, 29, 385–398.

threatening cardiac failure, rickets with osteomalacia, muscle weakness, musculoskeletal pain and fractures (Uday and Högler, 2017). The presenting feature depends on the age of the affected individual. All babies of vitamin D deficient mothers are born deficient, the most extreme scenario being congenital rickets in the newborn (Paterson and Ayoub, 2015). The majority of children present during phases of rapid growth: infancy and adolescence (Ladhani *et al.*, 2004; Robinson *et al.*, 2006; Callaghan *et al.*, 2006; Ahmed *et al.*, 2011). Infants can present in the first year of life with hypocalcaemic seizures (Basatemur and Sutcliffe, 2015; Robinson *et al.*, 2006; Callaghan *et al.*, 2006; Al-Atawi *et al.*, 2009), poor feeding, hypotonia and occasionally devastating hypocalcaemic, dilated cardiomyopathy resulting in cardiac failure and death (Elidrissy *et al.*, 2013; Yilmaz *et al.*, 2013; Uysal *et al.*, 1999; Maiya *et al.*, 2008; Scheimberg and Perry, 2014). Toddlers present with motor delay, muscle weakness (Fluss *et al.*, 2014) and leg bowing deformities (Robinson *et al.*, 2006). Adolescents usually present with hypocalcaemic seizures or proximal muscle weakness (Al-Said *et al.*, 2009). Late-effects of childhood rickets include obstructed labor (Konje and Ladipo, 2000), long-term leg deformities, disability and unemployment. In adults, osteomalacia is widespread but not easily diagnosed. Typical clinical signs are musculoskeletal pain and proximal muscle weakness, with increased falls and fractures. Postmortem studies suggest that 25% of adults from a non-risk population are affected by undiagnosed osteomalacia (Priemel *et al.*, 2010).

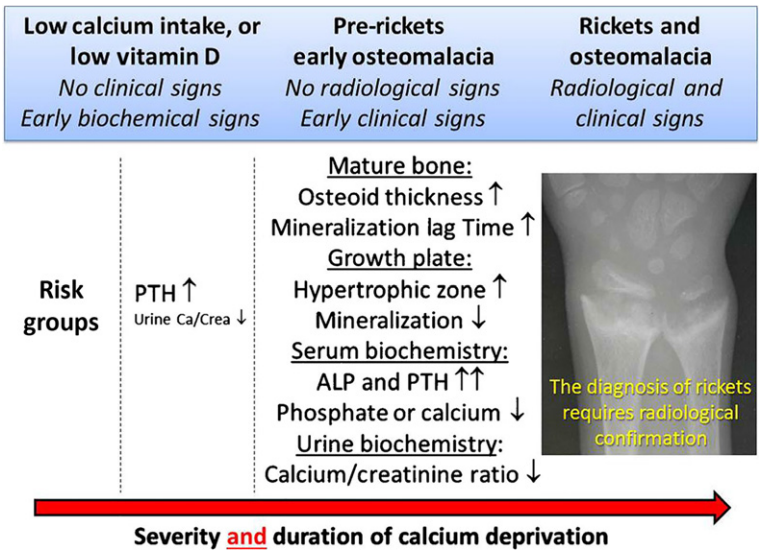

Fig. 3 Stages of progression of rickets ranging from asymptomatic at-risk individuals with calcium deprivation to histological/biochemical evidence of rickets and osteomalacia (pre-rickets) to overt rickets on radiographs. Reproduced from Uday, S. and Högler, W. (2017) 'Nutritional Rickets and Osteomalacia in the Twenty-First Century: Revised Concepts, Public Health, and Prevention Strategies', Current Osteoporosis Reports, 15, 293–302.

Diagnosis of nutritional rickets

The diagnosis of NR/osteomalacia is based on clinical (leg bowing deformities, enlarged wrists and rachitic rosary; seizures and heart failure), biochemical and radiological signs. The diagnosis requires radiographic confirmation, showing the typical radiological signs: cupping, splaying and fraying of metaphyses and widened growth plates. However, these signs only occur in late stages of the disease (**Fig. 3**; Uday and Högler, 2017). In contrast, osteomalacia in adolescents and adults cannot be diagnosed by X-ray. However, rickets and osteomalacia have the same typical biochemical signs (raised ALP and PTH) which appear before any radiological signs. Post-mortem studies in children have improved our understanding of the disease process, demonstrating typical rickets abnormalities at the growth plate (increased height of hypertrophic zone) in the absence of radiological signs (Scheimberg and Perry, 2014; Cohen *et al.*, 2013). Hence, the clinical diagnosis of NR is only made at a very late stage in the disease process and a state of pre-rickets exists before rickets becomes evident on radiographs (Högler, 2015; **Fig. 3**).

Treatment of nutritional rickets and osteomalacia

Treatment should address both vitamin D and calcium deficiency and combined treatment improves outcome (Thacher *et al.*, 1999). The treatment recommendations from the global consensus (Munns *et al.*, 2016) are detailed below:

- Daily oral vitamin D for a minimum of 3 months is recommended in a minimum dose of 2000 IU if <12 months, 3000–6000 IU if aged 12 months—12 years and 6000 IU if >12 years old; plus
- Minimum of 500 mg/day calcium via diet or supplements.
- Instead of daily doses, a single high dose of vitamin D in children aged >3 months can be considered in resource limited settings or suspected non-compliance. The recommended doses are: 50,000 IU if aged 3–12 months, 150,000 IU if aged 12 months—12 years and 300,000 IU if aged >12 years.
- Both cholecalciferol (vitamin D3) and ergocalciferol (vitamin D2) are equally effective for daily treatment, whereas cholecalciferol with a longer half-life is preferred for single high dose treatment.

Prevention of rickets and osteomalacia

For prevention of rickets, the minimum daily dietary intake for calcium is >500 mg/day for everyone except infants (0–6 months 200 mg/day and 6–12 months 260 mg/day) and the minimum supply for vitamin D is 400 IU (10 μg) for infants and 600 IU (15 μg) for anyone else (Munns *et al.*, 2016). Vitamin D and calcium deficiency can be overcome by ensuring adequate dietary intake and supplementation in at-risk populations. Calcium supplements from indigenous sources are preferred in low-income countries (Munns *et al.*, 2016).

Since the predominant source of vitamin D is from sunshine exposure and supply is rarely met through diet; supplementation or food fortification programs are essential to protect at risk populations. Most developed nations have vitamin D supplementation programs in place during pregnancy and infancy. However, poor policy implementation has led to the resurgence of rickets in certain European countries (Uday *et al.*, 2017). Evidence suggests that universal supplementation of all infants, monitoring during child surveillance visits, provision of information to new parents and financial incentives are effective implementation strategies (Uday *et al.*, 2017). Ultimately, fortification of food with vitamin D (Shakur *et al.*, 2014) and calcium (Ekbote

et al., 2011) will be necessary to increase uptake at a population level. Legislative authorities should consider the benefits of mandatory (Calvo and Whiting, 2013) versus voluntary fortification (Spiro and Buttriss, 2014) with vitamin D. More effort needs to be taken to introduce safe and efficient food fortification programs (Aguiar *et al.*, 2017). Such efforts are important to improve population bone health but may potentially have other beneficial effects, such as reduction in mortality (Gaksch *et al.*, 2017).

Phosphopaenic Rickets

Phosphopaenic, more commonly called hypophosphtemic, rickets commonly results from renal tubular phosphate wasting disorders (genetic or drug induced), less commonly from reduced gastrointestinal absorption and very rarely from insufficient dietary intake.

Phosphate homeostasis is closely regulated by the hormone fibroblast growth factor 23 (FGF23) which is produced by osteocytes and osteoblasts. FGF23 excess impairs renal phosphate reabsorption (Farrow and White, 2010) in the proximal renal tubule by:

- Down regulation of sodium–phosphate co-transporters (NaPi-2a and 2c) (Gattineni *et al.*, 2009) and
- Reduced synthesis of calcitriol through reduced 1-hydroxylase activity

hypophosphatemic rickets is classed as FGF23 mediated or non-FGF23 mediated (**Table 1**) depending on the underlying mechanism driving the renal phosphate wasting.

(1) Non-FGF23 mediated hyperphosphaturia can result:
   - From primary hereditary disorders of the renal tubule due to mutations in *SLC34A3* causing hereditary hypophosphatemic rickets with hypercalciuria (Lorenz-Depiereux *et al.*, 2006), *OCRL* causing oculocerebrorenal syndrome of Lowe' (Lin *et al.*, 1997), or *CLCN5* resulting in Dent's disease (Yamamoto *et al.*, 2000).
   - From Fanconi syndrome, either through respective genetic defects or drug effects (e.g., sodium valproate, cisplatin).

(2) FGF23 mediated hyperphosphaturia is seen in:
   - X-linked hypophosphatemic rickets (XLH) due to *PHEX* mutations, which represents the leading cause of phosphopaenic rickets and will be discussed in more detail here.
   - Autosomal dominant hypophosphatemic rickets (ADHR) secondary to *FGF23* mutations (White *et al.*, 2000)
   - Less common autosomal recessive forms caused by inactivating mutations of dentin matrix protein 1 (*DMP1*) (Feng *et al.*, 2006) and Ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*) (Levy-Litan *et al.*, 2010). Recessive *FAM20c* mutation causes osteomalacia but not rickets.
   - Tumor-induced osteomalacia and fibrous dysplasia

X-Linked hypophosphatemic Rickets (XLH)

XLH is the most common form of phosphopaenic rickets with an approximate prevalence of 1 in 20,000. Its X-linked inheritance means that boys always inherit the condition from their mothers and girls can inherit it from either parent. XLH results from inactivating mutations in the *PHEX* gene (phosphate-regulating gene with homologies to endopeptidases on X-chromosome) located at locus Xp22.11. PHEX regulates FGF23 cleavage, in the absence of which FGF23 accumulates and consequently inhibits renal phosphate reabsorption and down-regulates 1-hydroxylase activity.

Clinical presentation

Clinical features vary in affected individuals with majority presenting as toddlers with bowing deformities of long bones and short stature, or referred due to a positive family history. Other manifestations include craniosynostosis (Vega *et al.*, 2016) and dental anomalies (abscesses, reduced enamel). Enthesopathy (calcification of tendons and ligaments) and painful osteoarthritis are frequently seen in adults.

Diagnosis and differentials

Establishing the diagnosis of XLH and excluding other causes of hypophosphataemia is important. Given the various forms of hypophosphatemic rickets (**Table 1**), a thorough clinical evaluation is necessary to guide diagnosis and genetic testing. A positive family history and presence of clinical features from birth suggests a genetic cause rather than acquired. Additional clinical features may be more suggestive of certain specific syndromes such as: short stature, disordered development and ocular signs in Lowe's syndrome (*OCRL*), presence of hearing loss in autosomal recessive hypophosphatemic rickets type 2 (*ENPP1*) and presence of café-au-lait skin pigmentation or polyostotic fibrous dysplasia in McCune–Albright syndrome. Biochemical features that aid in diagnosis include: hypercalciuria in hereditary hypophosphatemic rickets with hypercalciuria (*SLC34A3*), proteinuria, nephrolithiasis and progressive renal failure in Dent's disease (*CLCN5*); proteinuria and glycosuria in Fanconi syndrome.

Measurement of phosphate and creatinine concentrations in serum and urine in the fasting state is required to calculate the percent tubular reabsorption of phosphate (TRP) and the tubular threshold maximum for phosphate (TmP) to glomerular filtration rate (GFR) ratio (Walton and Bijvoet, 1975). The hallmark of FGF23-mediated hypophosphatemic rickets is decreased serum phosphate, TRP and TmP/GFR with low or inappropriately normal $1,25(OH)_2D$ concentrations (**Table 3**). XLH can be

Table 3 Clinical, biochemical and radiological features distinguishing nutritional rickets, X-linked hypophosphatemic rickets and hypophosphatasia

	Nutritional rickets (NR)	*X-linked hypophosphatemic rickets (XLH)*	*Hypophosphatasia (HPP) rickets*
Pathogenesis	Calcipaenia secondary to dietary calcium and/or vitamin D deficiency	Phosphopaenia due to renal phosphate wasting	Hypophosphatasaemia due to defective TNSALP
Distinguishing features	Presence of risk factors (i.e. dark skin, covered clothing, indoor living, high latitude or reduced dietary intake of calcium or lack of vitamin D supplementation)	Family history of hypophosphatemic rickets, rarely *de-novo* mutations can occur Usually present with bowing deformities of the legs	Most severe forms present at birth with respiratory failure due to pulmonary hypoplasia, seizures and hypotonia. Older children have early tooth loss
Biochemical features	↔↓ Serum calcium, phosphate ↑ Alkaline phosphatase (ALP) ↑ Parathyroid hormone (PTH) ↓↔ 25OHD	↓ Serum phosphate ↑ ALP ↔ Calcium, PTH, 25OHD ↓/↔ 1,25 Dihydroxy vitamin D (inappropriately low) ↑ FGF23 ↓ TMP/GFR	↑↔ Serum calcium, phosphate ↓ ALP ↔/↓PTH ↔ 25OHD ↑ Serum PLP ↔↑ Urinary calcium ↑ Urinary PEA
Radiological features			
	Growth plate widening, metaphyseal cupping and fraying. Generalized hypomineralization and periosteal elevation due to hyperparathyroidism	Fraying and widening of metaphyses	Generalized hypomineralization, irregular zone of calcification; later tongue like radiolucent areas at the metaphyses

differentiated from conditions of non-FGF23 mediated renal phosphate wasting which show appropriately elevated $1,25(OH)_2D$ concentrations and accompanying tubulopathies (glycosuria, hyperaminoaciduria, hypercalciuria). Presence of normal or high TmP/GFR indicates an intake or absorption problem. Molecular genetic testing aids in confirming the diagnosis and counseling of family members. The diagnosis of hypophosphatemic rickets cannot be made when 25OHD is low.

Management and outcome

The mainstay of medical treatment currently is multiple daily dosing of phosphate supplements combined with active vitamin D metabolites (alfacalcidol and calcitriol) (Carpenter *et al.*, 2011), however promising therapeutic agents such as anti-FGF23 monoclonal antibodies which inhibit FGF23 action are under investigation (Imel *et al.*, 2017). The aims of treatment include: reducing bone deformities and improving height velocity (Linglart *et al.*, 2014). Early treatment ensures optimal growth (Mäkitie *et al.*, 2003).

Treatment is monitored and tailored to maintain normal serum concentrations of ALP and PTH, which requires considerable experience. Under-treatment inevitably results in short stature and leg deformities necessitating corrective surgery. Over-treatment with phosphate results in unpleasant gastrointestinal symptoms and secondary hyperparathyroidism; over-treatment with active vitamin D metabolites results in hypercalciuria and nephrocalcinosis. A multi-disciplinary team approach involving pediatric metabolic bone specialists, dentists and orthopedic surgeons is crucial. Also essential is appropriate transition of young patients to adult bone specialists for on-going treatment of hypophosphatemic osteomalacia and management of typical adult complications of XLH.

Hypophosphatasia (HPP)

Hypophosphatasia is an inborn error of bone mineralization caused by loss of function mutations in the *ALPL* gene encoding TNSALP. The name-giving hallmark biochemical feature of HPP is the low serum ALP activity, or hypophosphatasaemia (Whyte, 1994). The prevalence of severe and moderate HPP in the European population is estimated to be 1/300,000 and 1/6370, respectively (Mornet *et al.*, 2011).

The TNSALP enzyme on the surface of osteoblasts and brain cells hydrolyses extracellular substrates such as inorganic pyrophosphate (PPi) and pyridoxal-5′-phosphate (PLP, a vitamin B6 vitamer) and phosphoethanolamine (PEA). Reduced TNSALP activity therefore results in accumulation of these substrates. Accumulation of PPi inhibits mineralization (skeletal and dental), resulting in HPP-rickets, osteomalacia and early tooth loss. PLP is the activated form of vitamin B6 which is required as a co-factor in the production of inhibitory neurotransmitters, a process facilitated by TNSALP's extracellular dephosphorylation of PLP to pyridoxal (PL) which then crosses the cell membrane. Severely affected infants with HPP therefore can have seizures which are pyridoxine responsive (Baumgartner-Sigl *et al.*, 2007). The physiological function of PEA remains unclear.

Clinical Classification and Presentation

The clinical presentation varies depending on the age at presentation, ranging widely from stillbirth, severe rickets, atypical fractures in late adulthood to isolated premature tooth loss. The severity of the clinical phenotype of HPP reflects the magnitude of TNSALP deficiency in bone (Fallon *et al.*, 1984). Based on the age at presentation and severity, six distinct clinical forms of HPP have been identified (Fraser, 1948; Whyte *et al.*, 2015) but the disease variability has been considered a continuum as it evolves throughout life (Linglart and Biosse-Duplan, 2016).

Prenatal benign

Evidence on this rare form is limited (Wenkert *et al.*, 2011). The terminology "benign" is probably not justified but in the context of timing of presentation it is understood to mean "non-lethal."

Perinatal

This most severe form of HPP is diagnosed before or at birth. Short long bones are usually noted in utero, as well as reduced chest circumference and polyhydramnios (Shohat *et al.*, 1991). At birth, the skeleton is severely hypomineralized, often with an underdeveloped chest with pulmonary hypoplasia, muscular hypotonia, bony spurs in the mid-portion of forearms and lower legs and neonatal pyridoxine-responsive seizures. High serum levels of calcium, phosphate, PLP and very low ALP activity are typical. In the absence of treatment these infants do not survive, with majority dying in the first few days of life from pulmonary hypoplasia and respiratory insufficiency (Leung *et al.*, 2013).

Infantile

Affected infants may not have any clinical features at birth but develop symptoms in the first 6 months of life. They can have rachitic chest deformities and respiratory compromise due to rib fractures, muscular hypotonia and seizures. Development of functional craniosynostosis can lead to manifestations of increased intracranial pressure, even in the presence of an open fontanelle. Hypercalcaemia and hyperphosphataemia occur, manifesting with irritability, poor feeding, vomiting, failure to thrive,

polyuria and polydipsia (Mornet, 2007). Nephrocalcinosis secondary to hypercalciuria is typical. Survival in the era predating asfotase alfa was 50% (Whyte *et al.*, 2016b).

Childhood

Although less severe than the infantile forms, the clinical presentation of childhood HPP is widely variable. Children usually present around 2–3 years of age with delayed walking, early tooth loss, bony deformities, musculoskeletal pain, fractures and radiological features of rickets (Fallon *et al.*, 1984). Typically, most of them experience early loss of deciduous teeth *with intact roots*. More severe cases may present with craniosynostosis and intracranial hypertension, and detailed clinical history often uncovers early or subtle signs of disease in infancy such as delayed milestones.

Adult

Adults with HPP present with musculoskeletal pain and incidental or atypical fractures (Berkseth *et al.*, 2013). There may be a history of premature loss of deciduous teeth.

Odonto

The classic finding of HPP is premature loss of teeth. However, this feature also exists as an isolated condition, representing premature loss of deciduous teeth without skeletal involvement (Beumer *et al.*, 1973). However, individuals with dental manifestations may go on to develop skeletal features later in life and it may be impossible to distinguish odonto HPP from other forms of HPP (adult or childhood) at initial presentation. The natural history of this form of the disease remains unknown and longitudinal studies are required.

Diagnosis

Biochemical

The biochemical hallmark of HPP is a persistently low ALP activity. A low ALP for age in itself is not diagnostic and other causes should be excluded prior to further evaluation (Macfarlane *et al.*, 1992). Especially in the presence of clinical features of HPP and low serum ALP, further biochemical testing, radiographic imaging and genetic tests are indicated (Saraff *et al.*, 2016). Additional biochemical features of HPP include elevated serum PLP and urinary PEA. Unlike other forms of rickets, serum phosphate and calcium are normal or elevated, possibly with hypercalciuria (Whyte, 2016). In the presence of hypercalciuria or hypercalcaemia, PTH and 1,25 $(OH)_2D$ are appropriately suppressed (**Table 3**).

Radiological

Radiological features include generalized hypomineralization and rickets-like features (HPP-rickets). The most important diagnostic radiographs to be taken in infants and children are the knee (rickets) and skull (craniosynostosis). Childhood-HPP is associated with typical tongue like radiolucent areas in the metaphyses (**Fig. 4**). The skull is often dolicocephalic, copper-beaten and undermineralized (Whyte, 2016). Adults can have metatarsal stress fractures, subtrochanteric femoral pseudofractures, vertebral fractures and chondrocalcinosis (Berkseth *et al.*, 2013). Low bone mineral density on dual energy X-ray absorptiometry scans is reported but not specific to HPP (Fallon *et al.*, 1984). A natural history study reported no significant difference in mean/median spine bone mineral density (BMD) *z* scores in individuals through the disease course except in odonto HPP where significant spontaneous improvement was noted (Whyte *et al.*, 2016c). The final height-corrected spine BMD *z*-scores, although below average, remain in the normal range in infantile, odonto and childhood HPP (Whyte *et al.*, 2016c).

Fig. 4 Serial left knee radiographs of a 5-year old child with infantile onset hypophosphatasia. The metaphyseal tongue-like lucencies and low bone mass seen at baseline (pre-treatment) have progressively improved on asfotase alfa treatment on images taken at 5, 22 and 40 months of therapy.

Genetic testing

HPP can be diagnosed based on clinical, biochemical and radiological features (Fallon *et al.*, 1984) where genetic testing is not readily available. The *ALPL* gene is located on chromosome 1 (Greenberg *et al.*, 1990). To date, 349 mutations (http://www.sesep.uvsq.fr/03_hypo_mutations.php) resulting in HPP have been identified, the majority being missense mutations. Genetic testing can be useful in counseling family members, however the disease displays a high phenotypic variability (Hofmann *et al.*, 2014) limiting the prediction of the disease course. The extremely high phenotypic heterogeneity is attributed to variable residual enzymatic activities (Zurutuza *et al.*, 1999).

Management and Outcome

Asfotase alfa, a bone-targeted recombinant human TNSALP, is approved for treatment of pediatric HPP (perinatal, infantile and juvenile onset) by the US Food and Drug Agency (FDA) and the European Medicines Agency (EMA). Asfotase alfa improves skeletal disease manifestations and pulmonary and physical function in infants and young children with life-threatening HPP (Whyte *et al.*, 2012) and substantially improved survival in infantile and perinatal HPP (Whyte *et al.*, 2016b). **Fig. 4** demonstrates serial radiographs with healing of HPP-rickets following asfotase alfa treatment in a child with infantile onset HPP. The drug is administered as a subcutaneous injection in the licensed dose of 2 mg/kg three times per week, or 1 mg/kg six times per week, but individual dose requirements vary. The treatment is reported to be well tolerated with very few side effects except for mild to moderate injection site reactions (Whyte *et al.*, 2016b).

Neonates with severe form of the disease are usually managed in intensive care units in tertiary centers with support from specialized teams (Linglart and Biosse-Duplan, 2016). A multi-disciplinary approach to management is essential to address: ventilation, pain management, nutrition, reflux, hypotonia and positioning and neurological symptoms (Linglart and Biosse-Duplan, 2016). In older children and adults, involvement of dentists, orthopedic surgeons, physiotherapists and occupational therapists and pain management is necessary depending on the clinical features.

Long-term post-marketing studies are required, including global collaboration in a HPP registry to better understand the condition, treatment monitoring and development of complications. Treatment monitoring guidance is preliminary at present (Kishnani *et al.*, 2017).

Osteogenesis Imperfecta

Nick Bishop, Sheffield Children's NHS FT and University of Sheffield, Sheffield, United Kingdom

Definition

Osteogenesis imperfecta (OI) is a term that is applied to inherited bone diseases characterized clinically by bone fragility with accompanying bone pain, deformity and reduced stature. Patients often have altered scleral hue, typically blue or blue/gray; may have ligamentous laxity and sarcopenia (Veilleux *et al.*, 2014) resulting in easy fatiguability and reduced endurance; and develop deafness (Kuurila *et al.*, 2002) and aortic root dilatation with increasing age (McNeeley *et al.*, 2012). Dentinogenesis imperfecta—the dental equivalent of OI—with translucent and/or discolored teeth is present in up to 58% of more severely affected individuals, but a minority (13%) of those mildly affected (Lindahl *et al.*, 2015). At a tissue level, the material quality of bone is altered, resulting in the bone being brittle, that is, it bends less and fails sooner under load (Bishop, 2016). The spectrum of severity in OI is large—some individuals may go through life unaware that they have the disorder at all, whilst some infants perish in utero or soon after birth.

The classification of OI is a cause of continuing debate; the classification which was first proposed by Sillence *et al.* (1979), originally had four and now has five types. Since the discovery of multiple new genetic origins for the condition, some favor the attribution of successive "types" according to the date of discovery; Forlino and colleagues proposed such an extended classification first in Forlino *et al.* (2011) and Marini *et al.* (2017). Some forms/types of OI have characteristic clinical features that are important to recognize as they have implications for medical and surgical management (see below). Understanding the genetic origins of bone fragility is clearly of importance in terms of counseling families.

The genes whose mutations are known to result in bone fragility and their associated phenotypic details are shown in **Table 1**. Some inherited forms of bone fragility are not regarded as being OI; tissue hypermineralization is generally regarded as a differentiating factor, but again debate around these fine points continues. About 5% of inherited bone fragility cases still do not have their genetic origin defined.

Genetics

The vast majority of cases of OI—at least 85%—result from mutations in the genes encoding type I collagen. The COL1A1 and COL1A2 genes encode the α1 and α2 chains of the type I collagen molecule respectively; mutations result in dominantly-inherited OI. Each type I collagen molecule is comprised of three collagen chains—two α1 and one α2 chains coil tightly around each other to create the "Type I collagen" molecule, also known as "tropocollagen." The tight coiling is possible because every third amino acid in each chain is a glycine, the smallest amino acid.

In the main, mild OI is due to null alleles in the COL1A1 gene that result in a reduced amount of collagen production, with some abnormal, misfolded proteins incorporated into the matrix. The more severe forms result from missense mutations, exon skipping or splice site mutations in the collagen genes that result in the production of an abnormal protein and its subsequent incorporation into the bone matrix material. Most of the missense mutations result in a glycine being replaced by an amino acid that is more bulky, or charged, or with altered hydrophobicity. In general, the more different the amino acid is to what should be there, the more pronounced the effect.

There are multiple genes where either homozygous or compound heterozygous mutations result in OI (see **Table 1**). These are genes that affect collagen processing, transport, and stability; genes affecting endoplasmic reticulum functioning; genes that affect osteoblast maturation and skeletal patterning; and genes affecting mineralization primarily and collagen secondarily.

The other dominantly inherited form of OI is caused by a single point mutation in 5′-untranslated region of IFITM5/BRIL. This specific form of OI is recognized as distinct in both classification systems as "Type V" (Glorieux *et al.*, 2000).

Tissue Phenotype: Bone Material Properties in OI

The tissue characteristics of OI are spread across all scale levels, from the whole skeletal to the molecular level. Working from the smallest scale level upwards, alterations in the three-dimensional structure of the α1 and α2 chains of the type I collagen molecule result in retention of the chains within the endoplasmic reticulum and over-modification of the heterotrimeric tropocollagen molecule, further compromising three dimensional structure (Chang *et al.*, 2012; Andriotis *et al.*, 2015). The exported tropocollagen proteins do not then form the closely packed quasihexagonal microfibrils (Orgel *et al.*, 2006) (see **Fig. 1**) comprising five overlapping tropocollagen molecules in the "quarter stagger array" that results in the characteristic banding pattern on electron microscopy (Bailey *et al.*, 1998).

 doi:10.1016/B978-0-12-801238-3.65413-2

Table 1 Genotype, phenotype and classification details for inherited bone fragility syndromes

Gene	*Silence type*	*Barnes/Marini type*	*Protein*	*Phenotype(s)*
Collagen molecule				
COL1A1	I-IV	I-IV	Type 1 collagen α1 chain	Mild-lethal OI (Forlino and Marini, 2016) High bone mass in C-propeptide cleavage site defects (Lindahl *et al.*, 2011) Caffey disease with defect at p.Arg1014Cys (Gensure *et al.*, 2005)
COL1A2	I-IV	I-IV	Type 1 collagen α2 chain	Mild-lethal OI (Forlino and Marini, 2016) High bone mass in C-propeptide cleavage site defects (Lindahl *et al.*, 2011)
Collagen folding				
CRTAP	III	VII	Cartilage associated protein	Severe-lethal OI; (Barnes *et al.*, 2006; Morello *et al.*, 2006) Cole-Carpenter features (Balasubramanian *et al.*, 2015)
LEPRE1	III	VIII	Prolyl-3-hydroxylase	Severe-lethal OI (Cabral *et al.*, 2007)
PPIB	III	IX	Cyclophilin B	Moderate-lethal OI (van Dijk *et al.*, 2009)
Collagen stability				
FKBP10	III	XI	FKBP65; 65kD FK506-binding protein	Moderate-severe OI; Bruck syndrome (OI with contractures); (Schwarze *et al.*, 2013) Kuskokwim syndrome (contractures alone) (Barnes *et al.*, 2013)
PLOD2	N/A	N/A	Lysyl hydroxylase 2	Bruck syndrome (Ha-Vinh *et al.*, 2004)
SERPINH1	III	X	Heat Shock Protein 47	Severe OI, pyloric stenosis, skin bullae, renal stones (Christiansen *et al.*, 2010)
SPARC	III	XVII	Secreted protein, acidic, cysteine-rich; osteonectin	Notable sarcopenia (Mendoza-Londono *et al.*, 2015)
Collagen processing/cleavage				
BMP1	III	XIII	Bone morphogenetic protein 1; tolloid	High bone mass, hyperosteoidosis (Pollitt *et al.*, 2016; Hoyer-Kuhn *et al.*, 2013; Asharani *et al.*, 2012)
Wnt-signalling pathway				
WNT1	III	XV	Wingless-type MMTV integration site family, member 1	Homozygous—severe OI; some have brain malformation; autism, learning difficulties in some. (Fahiminiya *et al.*, 2013) Heterozygous—early onset osteoporosis, normal growth (Keupp *et al.*, 2013)
Mineralisation regulation				
IFITM5/ BRIL	V	V	Interferon-induced transmembrane protein 5, or, bone-restricted IFITM5-like	Severe OI; metaphyseal dysplasia and sclerosis, hypertrophic callus, interosseous membrane calcification. (Rauch *et al.*, 2018; Balasubramanian *et al.*, 2013; Semler *et al.*, 2012; Cho *et al.*, 2012)
SERPINF1	III	VI	Pigment epithelium derived factor	Slowly progressively worsening OI; osteoid mineralization defect (no endochondral defect) (Al-Jallad *et al.*, 2015; Becker *et al.*, 2011; Glorieux *et al.*, 2002)
Osteoblast lineage				
SP7/OSX	III	XII	Specificity protein 7; Osterix	Typical OI features (Lapunzina *et al.*, 2010)
Developmental/patterning				
TAPT1	III	Not assigned	Transmembrane anterior posterior transformation-1 protein	Complex lethal osteochondrodysplasia with multiple fractures; also have brain, cardiorespiratory and renal defects (Symoens *et al.*, 2015)
ER-related				
P4HB	III	Not assigned	Prolyl 4-hydroxylase; protein disulfide isomerase	Cole-Carpenter syndrome; craniosynostosis, ocular proptosis, hydrocephalus (Rauch *et al.*, 2015)
TMEM38B	III	XIV	Trimeric intracellular cation channel type B; TRIC-B	Severe osteopenia and limb fractures without vertebral fractures (Shaheen *et al.*, 2012)
CREB3L1	III	XVI	Old astrocyte specifically induced substrate—OASIS	Severe OI; cardiac failure (Symoens *et al.*, 2013)
SEC24D	III	Not assigned	Component of COPII complex	Cole-Carpenter syndrome; craniosynostosis, ocular proptosis, hydrocephalus (Garbes *et al.*, 2015)
MBTPS2	III	XVIII	Site-2 metalloproteinase S2P	Regulated intramembrane proteolysis of transcription factors such as OASIS x-linked moderately-severe OI (Lindert *et al.*, 2016)
Linker enzyme deficiency				
XYLT2	III	Not assigned	Xylosyltransferase II	Vertebral fractures, cataracts, heart defects (Munns *et al.*, 2015)
Bone fragility, not clearly OI				
LRP5/6	N/A	N/A	Lipoprotein receptor-related protein 5/6	Homozygous—osteoporosis pseudoglioma syndrome; (Gong *et al.*, 2001) Heterozygous—osteoporosis and/or vitreoretinopathy (Hartikka *et al.*, 2005)

Table 1 Continued

Gene	*Silence type*	*Barnes/Marini type*	*Protein*	*Phenotype(s)*
NBAS	N/A	N/A	Neuroblastoma amplified sequence	Early onset osteoporosis, recurrent acute liver failure, developmental delay(Balasubramanian *et al.*, 2017; Capo-Chichi *et al.*, 2015)
Osteocyte dysfunction				
PLS3	N/A	N/A	Plastin 3	X-linked early onset severe osteoporosis without other OI features (van Dijk *et al.*, 2013)

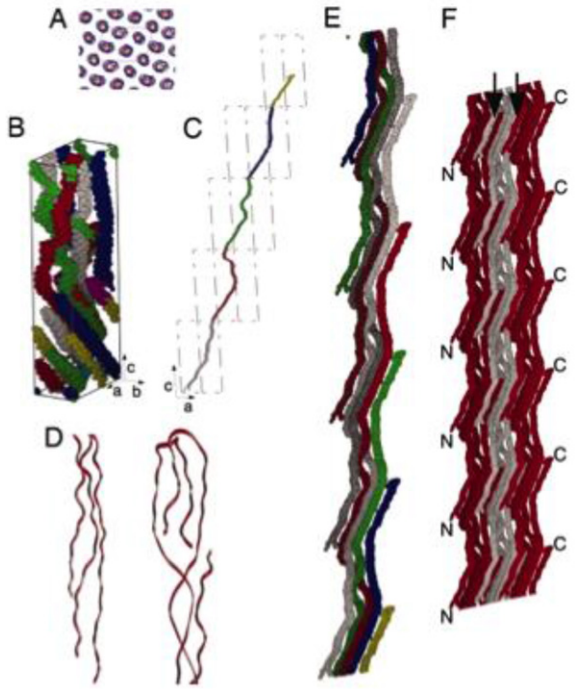

Fig. 1 Collagen organization and structure. The collagen segments are labeled as follows for *B*, *C*, and *E*: 1, *gray*; 2, *red*; 3, *green*; 4, *blue*; 5, *yellow*. Part of segment 1 is colored *cyan* (the N terminus), and part of segment 5 is colored *magenta* (the C terminus) to allow easier identification in *B*. The *c*-axis has been compressed five times for *B*, *C*, and *E*. (*A*) Electron density and model showing the quasihexagonal packing of the molecular segments. The approximate outline of the unit cell (*a* and *b* sides) is marked with black lines. (*B*) Cα carbons rendered as line spheroids showing the conformation of the *D*-staggered collagen segments within a single unit cell (cell axis shown). (*C*) Molecular path of a collagen molecule through successive unit cells in the *a*–*c* plane. (*D*) Enlarged view of the telopeptides of type I collagen, showing N-telopeptide (left and bottom of *C*) and C-telopeptide (right and top of *C*). Both have been rotated with respect to *C* for clarity of display. (*E*) Taking several 1D staggered collagen molecules from the collagen packing structure (single molecule shown in *C*), it is possible to represent the collagen microfibril. The collagen molecules progress from bottom to top (N to C terminus) and are colored as previously (except that chains starting in successive *D*-periods are darker equivalent colors). A clear right-handed twist can be seen, particularly between segments 2 and 3 (which is roughly at the midpoint of each collagen molecule). The noncrystallographic symmetry that relates the collagen molecules within the microfibrillar structure is a simple fractional translational function (*N* u, 0v, *N* w) where *N* is an integer. Five successive *D*-repeats of the microfibril can be visualized with nine copies of the coordinates (A–E1) of a single collagen molecule by applying the following translations. (A) 0, 0, 0. (B) −1, 0, −1. (C) −2, 0, −2. (D) −3, 0, −3. (E) −4, 0, −4. (B1) 1, 0, 1. (C1) 2, 0, 2. (D1) 3, 0, 3. (E1) 4, 0, 4. (*F*) Three microfibrils are shown side by side to indicate the probable binding relationship. The N-terminal segment of each collagen molecule is bound to two other collagen molecules (one inter- and one intramicrofibrillar) and a single crosslinked partnership at the C-terminal telopeptide (one intermicrofibrillar link). N- and C-terminal areas are marked. Note the positions (arrows) where the molecules belonging to one microfibril interdigitate with that of its neighbours. From Orgel, J. P., Irving, T. C., Miller, A. and Wess, T. J. (2006). Microfibrillar structure of type I collagen in situ. *Proceedings of the National Academy of Sciences of the United States of America* **103**, 9001–9005.

The fine detail of how cross-linking within and between microfibrils occurs is still being worked out; enzymatic cross-linking is normal and helps bone tissue to remain strong as well as elastic under load but nonenzymatic cross-linking, more evident in OI and other conditions such as diabetes, increases tissue brittleness (Poundarik *et al.*, 2015). The excessive spacing of tropocollagen within microfibrils, and possibly between microfibrils, is thought to contribute to the excessive deposition of mineral platelets (Fratzl-Zelman

et al., 2014), resulting in increased tissue mineralization density and increased tissue brittleness. Noncollagenous proteins are thought to have roles in tissue stability and the mineralization process; mutations in three specific areas of the tropocollagen molecule are associated with lethal phenotypes (Marini *et al.*, 2007), suggesting that key tropocollagen–noncollagen interactions are taking place at those sites. Moving up the scale, testing of fibrillar mechanics in the *oim* mouse model suggests decreased tissue mass that is reduced in toughness and less able to absorb and dissipate externally imposed loads (Vanleene *et al.*, 2012).

In most forms of OI, mineralization appears to proceed normally; however, in type V OI resulting from mutations in IFITM5/BRIL and type VI OI resulting from mutations in SERPINF1, altered mineralization is observed at clinical and tissue levels. Infants with type V OI initially display a rickets-like appearance at the metaphyses (Arundel *et al.*, 2011), and in later life develop interosseous membrane calcification of the forearm and lower leg, along with hyperplastic callus formation at fracture and osteotomy sites (Glorieux *et al.*, 2000). The tissue phenotype in type OI VI is osteomalacic, with grossly expanded osteoid thickness and an odd "fish scale-like" appearance under polarized light microscopy (Glorieux *et al.*, 2002). In type V, detailed molecular studies have found altered osteoblastic collagen secretion, which likely contributes to the bone fragility phenotype (Reich *et al.*, 2015). Type VI patients have very high tissue mineralization density, with altered orientation of collagen fibrils in perilacunar areas (Fratzl-Zelman *et al.*, 2015). Mineral platelets in OI have altered chemical composition, are thinner and reduced in size, contributing to the increased packing density that results in overall higher bone mineralization density distribution (Fratzl *et al.*, 1996).

Increased cross-linking and higher mineralization density contribute to reduced ability to absorb and dissipate energy from external loads. Fracture-toughening mechanisms that deflect energy along branching cracks and use other features such as sacrificial bonds and platelet sliding appear less effective in OI (Fantner *et al.*, 2007). In addition, increased cortical porosity allows a propagating fracture to "jump" from one pore to another, reducing the resistance of the whole.

At a whole bone level, the total amount of bone is reduced; cortical pores are larger and more numerous; trabeculae are thinned or lost and disconnected; cortical thickness is reduced; and bones are narrower (Rauch *et al.*, 2000). OI severity is most clearly reflected in overall stature—the shorter the patient, the more severely their disease has affected them. Put together the alterations in material properties, architecture and mass, it becomes readily apparent why bone fragility is such a prominent component of the clinical phenotype in this condition.

Bone Cell Activity

Bone cells fall broadly into two groups—those of mesenchymal lineage, and those of hematopoietic lineage. The bone forming cells—osteoblasts—are found as quiescent lining cells across all bone surfaces except where active remodeling is underway (Amizuka *et al.*, 2014). Osteoblasts are incorporated into the bone matrix during the mineralization process and become entombed within the lacunar-canalicular network as osteocytes (Prideaux *et al.*, 2012). Osteoclasts, by contrast, are formed from mononuclear precursors during the process of removal of bone tissue (Boyle *et al.*, 2003). The coordinated action of replacing existing old bone tissue with new bone is known as remodeling. During this process, bone lining cells appear to lift and form a tent or canopy under which the remodeling events proceed (Hauge *et al.*, 2001). The factors controlling the site-specific removal of bone—the timing, the quantity, the speed of removal—are still not fully elucidated. It is clear however that the initiation of remodeling is likely to be an osteoblast/osteocyte activity (Rumpler *et al.*, 2012); that the removal of bone mineral and some bone matrix protein is largely accomplished by osteoclasts (Sakamoto and Sakamoto, 1986), with the remainder of the matrix being removed by osteoblast lineage "reversal" cells (Andersen *et al.*, 2013) and then replacement of bone material by osteoid secreting and mineralising osteoblasts. The coordination of osteoclast and osteoblast activity may involve other hematopoietic lineage/immune cells (Andersen *et al.*, 2013).

All the defects that have been identified so far as giving rise to OI have occurred in mesenchymal lineage cells. The net effect at a tissue level is an increase in bone turnover, with increased osteocyte density (Blouin *et al.*, 2017), and reduced osteoblast cell effectiveness in terms of bone forming activity (Rauch *et al.*, 2000). In normal growing bone, each remodeling event results in a 4% increase in bone at the remodeling site; in OI this is reduced to 1% (Rauch *et al.*, 2000). Thus over time, the bone accrual in a child with OI deviates progressively from that expected for the normal skeleton, adding to the increased risk of fracture both during childhood and later in life.

Molecular Pathways

Recent years have seen elucidation of key pathways regulating and coordinating bone cell activity. In OI, two pathways/areas are currently receiving significant attention as potential treatment targets; endoplasmic reticulum stress (Ishida and Nagata, 2009) and the consequential effects on the unfolded protein response and autophagy, and the TGFβ signaling pathway (Grafe *et al.*, 2014).

In relation to ER stress, the misfolding and subsequent accumulation of abnormal protein within the ER might be expected to trigger the ER-associated degradation (ERAD) pathway (Horiuchi *et al.*, 2016). In fact, recent evidence suggests that ERAD is not the main process in OI, but that the misfolded collagen aggregates are removed by autophagy (Ishida and Nagata, 2009). ER stress causes impaired osteoblastic differentiation and may eventually result in osteoblast apoptosis (Symoens *et al.*, 2013).

TGFβ signaling is overactive in some murine models of OI (Grafe *et al.*, 2014); the mechanisms by which such excessive signaling might result in the observed phenotype are less clear, but in other settings such as Camurati–Engelmann syndrome

excessive TGFβ signaling results in increased bone turnover, bone pain and diaphyseal sclerosis (Janssens *et al.*, 2006). Anti-TGFβ antibody treatment of the crtap $-/-$ and G610C models described below showed restoration of bone architecture and mass, but not alteration in tissue material properties (Grafe *et al.*, 2014).

Recently it has been suggested that inflammatory processes may contribute to the OI phenotype; these suggestions are based on both the finding of elevated inflammatory markers and splenomegaly in the *oim* mouse model (Matthews *et al.*, 2017), and the demonstration of a right-shift in platelet counts in moderately-severely affected children.

Preclinical Models

Both mouse and zebrafish models of OI have been created; the mouse models cover a range of severity from relatively mild (Mov-$13^{/+}$) (Jaenisch *et al.*, 1983) to severe (crtap $-/-$) (Morello *et al.*, 2006). The murine model harboring the COL1A1 $+/$ $G610C^{Neo-}$ mutation recapitulates the human phenotype associated with the same mutation in an Amish population (Daley *et al.*, 2010). Zebrafish have a different bony architecture to mice or humans, and have heterotrimeric as opposed to heterodimeric tropocollagen molecules (Fisher *et al.*, 2003), but many of the pathways of collagen folding, processing, and transportation are similar. For instance, the "*frilly fins*" zebrafish (Asharani *et al.*, 2012) harbors a mutation in Bmp1 that provided insights into the molecular mechanisms of action relevant to the form of OI caused by loss of function in the human gene, whilst the "*Chihuahua*" mutant is caused by a heterozygous missense mutation in *Col1a1a* and has a clinical phenotype resembling moderately-severe OI with deformed vertebrae and frequent fractures (Fisher *et al.*, 2003).

The availability of these model systems is key both to understanding mechanism and for preclinical assessment of novel interventions.

Clinical Manifestations

The clinical manifestations of OI vary considerably. The most consistent feature bringing the patient to medical attention is bone fragility, manifested either as fractures occurring with little or no apparent trauma, or recurrent fractures. Fractures are not uncommon in childhood—up to 40% of children will have had a fracture by age 16 years (Landin, 1983); pelvic, hip, and vertebral fractures are uncommon at age any during childhood (Cooper *et al.*, 2004). The International Society of Clinical Densitometry Pediatric Position Statements on Osteoporosis Definition suggest that two fractures by age 10 years, or three fractures by age 19 years in association with low bone mass for body size, should raise suspicions of osteoporosis (Bishop *et al.*, 2014). In addition, one or more vertebral crush fractures in the absence of known significant trauma, should suggest osteoporosis.

In mild OI, bone density may be within the normal range and vertebral crush fractures may not be present initially; clinical experience indicates that the majority of even mildly affected cases will however develop vertebral crush fractures at some point. The most severely affected infants may have crush fractures at birth. More severely affected infants tend to have crumpled long bones, or femurs that look as though the shaft has expanded and then exploded. Maintenance of normal bone shape is a good prognostic indicator in our experience.

Children with type V disease have some characteristic radiological features including metaphyseal dysplasia/rickets-like changes at birth (Arundel *et al.*, 2011), which change over a period of weeks to sclerotic metaphyseal bands; dense wedge-like inclusions in the anterior vertebral wall, seen on lateral imaging of the spine (Arundel *et al.*, 2011); and the development of interosseous membrane calcification and associated radial head dislocation with limitation of elbow range of movement, particularly pronation and supination (Fassier *et al.*, 2007). Children with type VI disease rarely present before 12 months of age; they have a gradually progressive deforming disease course and are relatively insensitive to interventions using conventional antiresportive agents (Hoyer-Kuhn *et al.*, 2014).

Children with mutations in FKBP10 have a very variable clinical phenotype—at the Kuskokwim end of the spectrum, no fractures occur, in contrast to those with Bruck syndrome where fractures accompany contractures (Barnes *et al.*, 2013).

Fractures result in bony deformity in many cases of OI, but this is not sufficient to account for the degree of growth retardation that accompanies the more severe clinical phenotypes, which remains unexplained currently. Sarcopenia is a frequent finding in OI (Veilleux et al., 2014, 2017); alongside the bone pain that may reflect increased bone turnover, ligamentous laxity, muscle weakness, and fatigue contribute to the musculoskeletal pain in OI that for many is the most debilitating aspect of their disease on a daily basis.

Vertebral deformity can contribute to earlier presentation with scoliosis; restoration of vertebral size and shape through medical therapy (see below) does not necessarily prevent scoliosis, but likely delays the age at which it is first clinically manifested in more severely affected children (Sato *et al.*, 2016). Basilar invagination, one of the most feared complications of OI with advancement of the odontoid peg through the foramen magnum, is relatively uncommon in our experience (2%–3% over the last 20 years across all types, unpublished). Spondylolysis and spondylolysthesis can cause chronic pain, particularly in the lower back.

It is increasingly apparent that pulmonary disease is also present in the moderately-severely affected; manifested as a chronic oxygen requirement in severely affected infants that can persist for months, it is also present in older children and adults. Scoliosis in later years can be present and is associated with reduced pulmonary function (Wekre *et al.*, 2014) but scoliosis correction does not necessarily improve lung function.

Dentinogenesis imperfecta can result in teeth chipping and cracking; the altered appearance of the teeth can be distressing for some patients with tooth discoloration ranging from gray through yellow to brown. Accelerated wear occurs, with rapidly

progressive dental caries in some. Aortic root dilatation has been reported in adults; there are several reported cases of aortic dissection, two being fatal (McNeeley *et al.*, 2012). Combined conductive and sensorineural hearing loss occurs in up to 50% of cases (Kuurila et al., 2002, 2000).

Differential Diagnosis and Investigation

In older children presenting with osteoporosis, the urgent differential to exclude is any malignancy. Osteoporosis can occur secondary to a variety of inflammatory, immobilizing, hematological, and endocrinological disorders, as well as secondary to the treatments used, particularly steroids. In routine clinical practice, one of the most common "occult" causes we have seen is celiac disease.

Biochemical investigations would reflect the need to address both primary and secondary causes of bone fragility and include targeted testing for the groups of conditions mentioned above. Radiological imaging usually includes dual energy X-ray absorptiometry (DXA) for those able to lie still (typically 4 years and older) and where there is data to interpret the DXA outputs, along with lateral spine imaging to assess vertebral size and shape.

Bone biopsy can be helpful in distinguishing OI from other forms of osteoporosis in older children; OI is characterized by high turnover and increased numbers of osteocytes (24). Typical appearances under direct light, polarized light, and ultraviolet light are shown in **Fig. 2**.

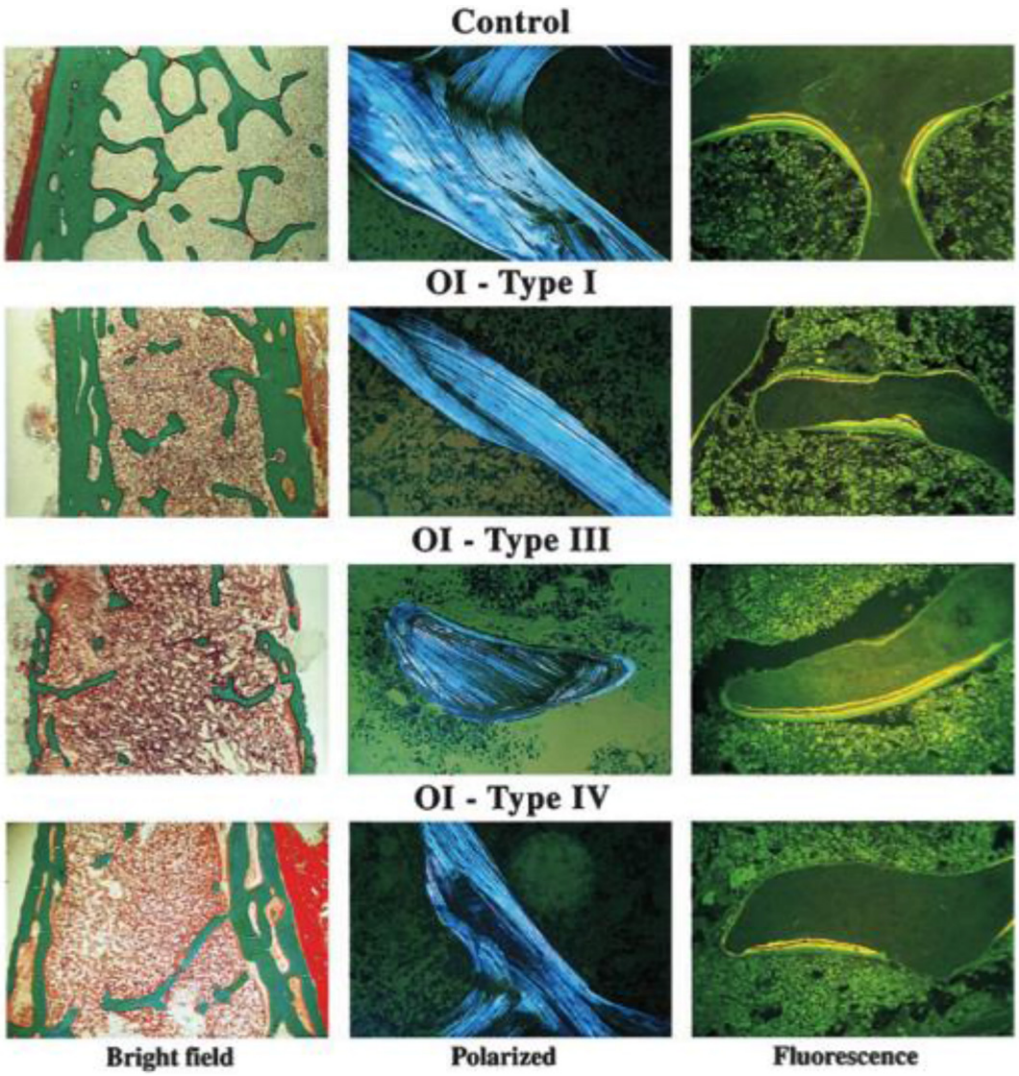

Fig. 2 Typical sections of biopsies from a control subject (boy, 9 years) and OI patients (type I: girl, 5 years; type III: boy, 9 years; type IV: boy, 13 years). Original magnifications: left column, ×32, middle column, ×200; right column, ×200. From Rauch, F., Travers, R., Parfitt, A. M. and Glorieux, F. H. (2000). Static and dynamic bone histomorphometry in children with osteogenesis imperfecta. *Bone*, **26**, 581–589.

If there is doubt about the genetic origin of the OI, targeted Next Generation Sequencing using an "OI panel," followed by whole genome sequencing, would be our way forward.

The issue of unexplained fractures in the context of suspected nonaccidental injury as opposed to bone fragility/mild OI is a thorny one. Our experience has been that infants with mild OI tend to present with a single fracture; those with more severe disease tend to have more than one fracture, and often have altered vertebral shape even in infancy. Those presenting with multiple fractures whose skeletons are later regarded as normal on repeat imaging and without evidence of other disturbances in skeletal homeostasis (e.g., rickets) are much less likely to have an underlying genetic cause for bone fragility, if indeed any bone fragility was ever present. Metaphyseal "corner" fractures are highly suggestive of nonaccidental injury and are vanishingly rare in OI, possibly because the tight adherence of the periosteal membrane at the metaphysis actually results in a stronger overall bone there, compared to the diaphysis, in OI.

Current Management

Management of OI is best undertaken by a multidisciplinary team that includes physicians, surgeons, dentists, nurses, physio- and occupational therapists, psychologists and social workers. The role of the physician is to make the diagnosis and direct management in terms of pain relief and any bone-targeted pharmacological therapy. For children, that therapy currently is essentially limited to one class of drugs, the bisphosphonates. For adults, other drugs have been used with limited evidence of efficacy.

Bisphosphonates are widely used in the treatment of both adults and children with OI. At a tissue level, the inhibition of osteoclastic bone resorption by bisphosphonates reduces trabecular loss at the growth plate, increasing trabecular number but not trabecular thickness (Rauch *et al.*, 2002). Cortical thickness increases due to reduced endosteal resorption, whilst periosteal apposition continues. Cortical porosity reduces with continuing therapy. In those treated intravenously, metaphyseal lines appear, parallel to the growth plate. These are bands of bone and calcified cartilage; the calcified cartilage is gradually remodeled to bone over time, as judged by the proportion of calcified remnants seen in bands of differing ages from transphyseal bone cores (Rauch *et al.*, 2004).

Bisphosphonates have been used in OI for three decades (Devogelaer *et al.*, 1987); although regarded as "standard of care," there is limited evidence for their efficacy in reducing fracture risk outside of those more mildly affected by OI (Dwan *et al.*, 2014). In part this may reflect the difficulty of undertaking randomized, controlled trials of intravenous therapy in children with severe bone disease. In trials of oral therapy (olpadronate, risedronate) in primarily mild disease, fracture risk reduction of around 50% has been demonstrated (Sakkers *et al.*, 2004; Bishop *et al.*, 2013). Oral therapy in more severely affected children using alendronate did not demonstrate such a reduction, however (Ward *et al.*, 2011).

Pamidronate and zoledronic acid are the most widely-used intravenous preparations and are generally used as first line therapy in more severely affected children. Cohort studies consistently report increased bone mineral density, improved vertebral size and shape and in some studies improved grip strength and mobility. Anecdotally, children and parents report that treatment with bisphosphonates reduces pain and fatigue and improves endurance; this has been difficult to demonstrate in clinical trials, but this difficulty may reflect the fact that until recently there has been no OI-specific assessment tool available to make such an evaluation (Hill *et al.*, 2014). Concerns have been expressed regarding the possibility of fracture nonunion in association with prolonged bisphosphonate use, but these have not been supported by data from longitudinal cohort studies (Munns *et al.*, 2004), although delay in healing for more than 12 months after osteotomy is observed in around 40% (Anam *et al.*, 2015). Based on experience in adults, concerns have also been expressed about the possibility of atypical femoral fractures and osteonecrosis of the jaw. A recent longitudinal review of femoral fractures in children with OI found no relationship of bisphosphonate administration with fractures that were similar to those described as "atypical" in non-OI adults (Trejo *et al.*, 2017). There have been no reported cases of osteonecrosis of the jaw in childhood.

Bisphosphonate and PTH therapy in adults has been largely ineffective in reducing fracture risk, although bone density measured by DXA is increased with both interventions (Orwoll *et al.*, 2014). Clinical trials with interventions focussed on increasing bone mass and reducing fracture incidence using both antiresorptive (anti-RANK-ligand antibody), anabolic (anti-sclerostin antibody), and combination therapy (zoledronic acid and PTH) are underway.

Surgical interventions include the placing of intramedullary rods to provide long bone stability, often using an expanding or telescopic system in the growing skeleton (Saldanha *et al.*, 2004), along with guided growth through the use of epiphysodesis. Scoliosis surgery using pedicle wires rather than screws may be needed for curves that continue to progress beyond 50 degree. Fusion of adjacent vertebrae can help in spondylolysthesis with a grade 2 or worse slip.

It is important that surgeons know if a child has type V OI before undertaking osteotomies—hypertrophic callus formation can occur around the osteotomy. Treatment with nonsteroidal antiinflammatory drugs may help prevent this.

Dental inputs include capping primary molars, crack, and fissure sealants and veneers that can improve cosmesis. The secondary dentition is generally stronger than the primary.

Therapy inputs are vital for muscle strength and range of movement, maintaining activities of daily living and providing aids to mobility (Marr *et al.*, 2017). Small changes can often make a big difference. Therapists and nurses often liaise with schools and primary care teams to ensure that all aspects of care are "joined up." Psychology inputs are important in any chronic disease.

Future Directions

The Holy Grail for OI therapy is gene correction—but that seems some way off. Fetal mesenchymal stem cell therapy has been used in two cases (Chan and Gotherstrom, 2014; Gotherstrom *et al.*, 2014); however, although the results appear encouraging, there is no evidence that the low level of engrafted cells has actually been responsible for the formation of new bone with improved tissue material properties, and the assessment of efficacy is hampered by the difficulty in making accurate assessments in utero. Anti-TGF pathway therapy may be possible in future, as may interventions targeting the ER stress and autophagy pathways. The latter have the possibility, alone amongst the available noncellular interventions, of altering bone material properties through the removal of excess misfolded proteins (Mullan *et al.*, 2017). The improvements in health outcomes and quality of life for those with OI should be expected to continue.

Hypercalcemia

Justin H Davies and Rebecca J Moon, Southampton Children's Hospital, Southampton, United Kingdom

Introduction

Hypercalcemia is rare in children, but if untreated can result in life-threatening end-organ damage including renal failure and neurological impairment. In adulthood malignancy and primary hyperparathyroidism are the most common causes of hypercalcemia, whereas in children the possible etiologies are more diverse, may be age-specific and many have an underlying genetic basis. Establishing the correct diagnosis will enable the most appropriate treatment to be given. When investigating hypercalcemia a key consideration is the accompanying PTH level at the time of hypercalcemia which delineates the etiology as either a PTH-dependent or PTH-independent cause (Davies and Shaw, 2012).

Definition of Hypercalcemia

A definition of hypercalcemia in childhood has not been established due to the paucity of pediatric laboratory reference data for normal calcium levels in healthy individuals during childhood and puberty. The clinical significance of the degree of hypercalcemia and how it relates to long term morbidity is unknown. A multicentre study of healthy children in Canada from birth to 18 years of age was used to develop assay, age and sex-specific reference ranges for analytes including calcium. Calcium levels were found to be assay dependent and there was no sex difference. Levels were higher in children compared to adults, likely reflecting greater bone turnover in children (Colantonio *et al.*, 2012). Thus age and assay-appropriate reference ranges should be used when interpreting serum calcium levels in children.

Frequency of Hypercalcemia

Hypercalcemia is rare in children (McNeilly *et al.*, 2016). A retrospective study of laboratory data from a tertiary unit showed that only 0.33% of over 61,000 pediatric serum samples were hypercalcemic (defined as serum calcium >2.9 mmol/L). Of the samples that were hypercalcemic, 41% of cases were taken in the first 28 days of life, 24% in 28 days to 1 year, 16% in 1–5 years, 12% 6–12 years and 7% in 13–17 years. These frequencies also reflect the likelihood of blood sampling at different ages, which is most frequent in the neonatal period, thus serendipitous discovery of hypercalcemia is more likely during biochemical screening for unrelated conditions. The severity of the hypercalcemia was classified as: 84.7% mild (2.9–3.1 mmol/L), 9.9% moderate (3.2–3.5 mmol/L), and 5.4% severe (>3.5 mmol/L). In a hospital setting, sustained hypercalcemia (i.e., a calcium >2.9 mmoL/L for two consecutive days) was observed in 1 in 500 children (McNeilly *et al.*, 2016).

Pathophysiology of Hypercalcemia

Plasma calcium is maintained by the interplay of three dynamic processes: tubular reabsorption from the kidneys, absorption from the small intestine and bone remodeling. The two main calciotropic hormones are parathyroid hormone (PTH) and 1,25-dihyroxyvitamin D [$1,25(OH)_2D$]. The calcium sensing receptor (CaSR), which is expressed on the surface of the parathyroid cell, is also a critical regulator of plasma calcium levels by directly influencing PTH release in response to circulating calcium levels.

PTH usually maintains plasma calcium levels in a narrow range between 2.1 and 2.6 mmol/L (ionized calcium, 1.1–1.4 mmol/L). Elevated plasma calcium suppresses PTH secretion but additional increases in calcium levels will not suppress PTH further. A low PTH leads to reduced activity of 1-α hydroxylase in the proximal tubule of the kidney and consequently reduced synthesis of $1,25(OH)_2D$ and reduced renal tubular calcium reabsorption. Low $1,25(OH)_2D$ results in reduced intestinal calcium absorption. Reduced osteoclastic activity from low PTH and $1,25(OH)_2D$ leads to reduced mobilization of calcium and phosphate from bone (Davies and Shaw, 2012). In the setting of hypercalcemia in individuals with normal counter-regulatory systems these changes result in a lowering of the serum calcium level.

Clinical Assessment of Hypercalcemia

Hypercalcemia may be found as a coincidental finding during investigation for an unrelated disorder and with no associated clinical features. This is common in infants in whom 60% of cases of mild hypercalcemia resolve spontaneously. However, persistence of hypercalcemia, hypercalciuria, or nephrocalcinosis occurs in 30% (Koltin *et al.*, 2011).

Symptomatic hypercalcemia has variable clinical features and there may be an insidious onset. Features include lethargy, hypotonia, anorexia, weight loss or failure to thrive, polydipsia, polyuria, vomiting, bone pain, constipation and abdominal pain. Polyuria results from a renal concentrating defect secondary to a tubular interstitial injury from calcium deposits in the medulla and down-regulation of aquaporin-2 water channels (calcium-induced renal AVP-resistance). In severe cases, renal failure, pancreatitis, and reduced consciousness may occur.

The clinical assessment should focus on features of malignancy, drug history including complementary alternative medicines, family history (hypercalcemia, renal stone formation, parathyroidectomy, tumors, multiple endocrine neoplasia). The examination should evaluate the degree of hydration, signs of malignancy, syndromic features, bone pain, fractures, growth and presence of subcutaneous calcification.

Investigations of Hypercalcemia

Prompt establishment of the underlying cause for the hypercalcemia is a key management step as this will influence subsequent investigations and treatment options. Investigations should be taken at the time of hypercalcemia to ascertain whether there is a PTH-dependent or PTH-independent cause (**Table 1**) (Hind *et al.*, 2007). Erroneous omission of investigations at this time is common, especially PTH and 25-hydroxyvitamin D [25(OH)D] measurements (Koltin *et al.*, 2011; McNeilly *et al.*, 2016). Adding $1,25(OH)_2D$ and CaSR mutation analysis to the initial investigations may increase diagnostic yield (Koltin *et al.*, 2011).

PTH-Dependent Causes of Hypercalcemia

PTH-dependent causes of hypercalcemia are usually associated with an elevated PTH (**Table 1**). Occasionally early onset primary hyperparathyroidism (PHPT) may be associated with a normal PTH.

Primary Hyperparathyroidism

PHPT during childhood is rare with an incidence of 2–5 per 100,000 (compared with 1 in 1000 in adults). There is an equal sex distribution (Roizen and Levine, 2012) with presentation most often during adolescence (Mallet, 2008). PHPT is characterized by autonomous secretion of PTH, which may occur secondary to parathyroid hyperplasia, adenoma or, rarely, carcinoma. Genetic abnormalities are more common with childhood presentations (Starker *et al.*, 2012). At initial presentation, PHPT may be isolated or occur in association with other disease. It is important to recognize that multiple endocrine neoplasia (MEN) type 1 and hyperparathyroid jaw-tumor syndrome may have no other manifestations at the time of diagnosis of PHPT in children.

Children are usually symptomatic at presentation of PHPT. Only 15% of cases are asymptomatic and detected coincidentally (Roizen and Levine, 2012). The non-specific symptoms often result in a delayed diagnosis and end-organ damage is common at presentation. Skeletal and renal complications occur in 75% and 45%, respectively (Roizen and Levine, 2012). Renal complications include nephrolithiasis, nephrocalcinosis and renal failure. Skeletal findings include sub-periosteal resorption, osteopenia, slipper upper femoral epiphysis, pathological fractures and osteolytic cysts (Brown's tumors), which resolve following parathyroidectomy. Bone pain, arthropathy and muscle aches may induce gait abnormalities. Calcium deposits in the eye (band keratopathy) may be observed at diagnosis.

The biochemical features of PHPT include an elevated or inappropriately normal level of PTH in the setting of a high-normal or elevated serum calcium concentration. Urine calcium concentrations are usually high but may be low if there is associated vitamin D deficiency. Accompanying hypophosphatemia is usual (Mallet, 2008). In very rare cases of parathyroid adenoma, elevated levels of an aberrant PTH molecule may not be detected by the standard intact PTH assays (Benaderet *et al.*, 2011). In the early stages of PHPT, there may be asymptomatic hypercalcemia with a PTH at the upper-end of the normal range. These biochemical features

Table 1 Investigation of hypercalcaemia in childhood

First line (at the time of hypercalcaemia)	
PTH	25-Hydroxyvitamin D
Calcium	Bicarbonate
Phosphate	Chloride
Alkaline phosphatase	Magnesium
Electrolytes	Urine calcium: creatinine ratio
Creatinine	Renal ultrasound scan
Second line (guided by initial results)	
$1,25(OH)_2D$	Serum ACE
PTHrP	DNA for genetic analysis
Skeletal survey	Parathyroid gland: ultrasound scan, SestaMIBI scan
Investigate parents: calcium, phosphate, PTH, 25-hydroxyvitamin D, urine calcium: creatinine ratio	

may be indistinguishable from familial hypocalciuric hypercalcemia (FHH) and genetic investigation may be helpful to avoid unnecessary parathyroidectomy. Magnesium levels may be helpful to distinguish these conditions as levels may be elevated in FHH, but are normal in PHPT.

Preoperative assessment of parathyroid adenomas is required either by use of Doppler ultrasound and/or 99 m Tc-SestaMIBI scintigraphy. A SestaMIBI is scan is more helpful for investigation of a single adenoma rather than more generalized hyperplasia and identifies approximately 60%–80% of parathyroid adenomas. Single-photon emission computed tomography may increase the diagnostic yield for small parathyroid adenomas or ectopic adenomas (Roizen and Levine, 2012). Parathyroidectomy is usually required as treatment for PHPT (see later).

Specific Causes of Primary Hyperparathyroidism

Familial isolated primary hyperparathyroidism

In a child presenting with apparently isolated PHPT and a family history of PHPT, MEN types I, IIa and IV as well as hyperparathyroid jaw-tumor syndrome should be considered in the differential diagnosis. Familial isolated primary hyperparathyroidism (FIPH) may also be associated with abnormalities at the chromosome locus 2p14-p13.3. Mutations in the PTH gene, PRAD1, may cause some sporadic cases (Hemmer *et al.*, 2001). These genes are thought to be oncogenes or tumor suppressor genes. In sporadic cases, a "single hit" mutation affecting a proto-oncogene such as PRAD1 can result in preferential growth of a single cell line. Thus familial forms of the condition are autosomal dominant. In the familial syndromes, a germline "first hit" mutation affects a tumor suppressor gene and makes the parathyroid (and other) glands susceptible to a "second hit" (Bastepe *et al.*, 2003). Tumors that arise in familial hyperparathyroidism are usually the result of hyperplasia whilst those occurring in sporadic cases are adenomas. However these can be multiple and it is sometimes difficult to distinguish between the two.

Multiple endocrine neoplasia

MEN types I, IIa, and IV are all associated with PHPT. MEN type 1 is an autosomal dominant condition caused by inactivating mutations of the MEN1 gene, located on chromosome 11q13. This gene encodes the tumor suppressor protein MENIN. PHPT is usually the first clinical manifestation of MEN type 1, with 75% of cases developing PHPT before 21 years of age (Goudet *et al.*, 2015). Ninety percent of cases of PHPT secondary to MEN type 1 occur after 10 years of age, but it has been reported below the age of 6 years. Most cases are now discovered during biochemical surveillance with $<20\%$ presenting with symptomatic hypercalcemia (Goudet *et al.*, 2015). Genetic counseling should be offered if a MEN1 gene mutation is detected.

MEN type IIa results from mutations in the *c-ret* proto-oncogene located on chromosome 10cen-10q11.2. Parathyroid tumors are observed in 20% of cases. MEN type IV is caused by mutations in the CDKN1B gene and PHPT is typically observed in adulthood.

Hyperparathyroid jaw-tumor syndrome

Hyperparathyroid Jaw-Tumor (HPT-JT) syndrome is an autosomal dominant condition caused by activating germline mutations in the CDC73 (formally HRPT2) gene. It is associated with parathyroid tumors causing PHPT. The phenotype observed in HPT-JT is highly variable due to incomplete gene penetrance, and ranges from apparent sporadic parathyroid carcinoma, FIPH with or without parathyroid cancer to full expression of HPT-JT syndrome. Although jaw tumors feature in the name of the condition, less than half of affected individuals have this symptom. Other tumors are commonly seen including both benign and malignant uterine and renal tumors, and regular surveillance should be undertaken in affected individuals.

Parathyroid carcinoma

Although parathyroid carcinoma typically presents in the fifth decade it has rarely been observed in children (Shane, 2001). Most cases are associated with mutations in the CDC73 gene and can occur in the same families as those with parathyroid adenomas in HPT-JT syndrome. Parathyroid carcinoma is difficult to distinguish from parathyroid adenoma both clinically and histologically, but carcinoma tends to present with more aggressive hypercalcemia.

Tertiary hyperparathyroidism

Following a prolonged hypocalcemic stimulus causing sustained release of PTH, autonomous functioning of the parathyroid gland can occur. This is termed tertiary hyperparathyroidism. Chronic renal failure is the commonest cause and parathyroidectomy may be necessary. Treatment of any hypovitaminosis D may also help to lower PTH levels and avoid the need for surgery.

Tertiary hyperparathyroidism may also occur with chronic secondary hyperparathyroidism associated with vitamin D deficiency. In this scenario the plasma calcium may remain normal in the presence of severe rickets until treatment with vitamin D is commenced, at which stage hypercalcemia becomes manifest.

Neonatal severe hyperparathyroidism

Neonatal severe hyperparathyroidism (NSHPT) is caused by a homozygous inactivating mutation of the CaSR. Newborns are typically critically ill at presentation. Clinical features include hypotonia, thoracic deformities, feeding difficulties and respiratory distress (Mallet, 2008). Skeletal complications are severe and include multiple fractures, demineralisation, metaphyseal

irregularities, cortical dualisation, sub-periosteal erosion and bell-shaped thoracic deformation. Biochemically, severe hypercalcemia with very high PTH levels are observed. Measurement of PTH and calcium in both parents will help confirm the diagnosis in advance of CaSR analysis as both parents will usually have FHH. Milder phenotypes associated with homozygous CaSR mutations have been described in adults with normal renal function (Chikatsu *et al.*, 1999).

Preoperative medical management of hypercalcemia is directed at stabilization prior to surgery and includes hyperhydration with diuretics, bisphosphonate administration and a calcium-poor diet. Vitamin D deficiency will further aggravate the elevated PTH levels and should be treated. A trial of cinacalcet may be merited as a successful reduction in PTH and calcium has been observed (Wilhelm-Bals *et al.*, 2012), although not all cases are responsive. It is possible that in vitro studies will be used in the future to predict the sensitivity of specific CaSR mutations to cinacalcet (Mayr *et al.*, 2016).

The definitive treatment for neonatal cases is a total parathyroidectomy (Mallet, 2008; Ghirri *et al.*, 1999; Rodd and Goodyer, 1999). Postoperatively these infants may have a "hungry bone" syndrome and require large quantities of calcium to avoid hypocalcemia until the bones have healed sufficiently. Recurrence of hyperparathyroidism has been observed when total parathyroidectomy was combined with auto-transplantation. Following surgery treatment is with lifelong calcium and active vitamin D. The aim is to avoid symptoms of hypocalcemia but whether the therapeutic goal should be to keep calcium levels within or above the normal range is unknown as long-term outcome data are unavailable.

Neonatal hyperparathyroidism

Neonatal hyperparathyroidism is a distinct condition from NSHPT and is most commonly caused by a heterozygous CaSR mutation. It is unclear why some heterozygous CaSR mutations cause neonatal hyperparathyroidism and others cause FHH (Glaudo *et al.*, 2016). A case of neonatal hyperparathyroidism associated with parathyroid hyperplasia and hypercalciuria but without a mutation in the CaSR has been reported. In this case, a mutation in SLC12A1, the cause of antenatal Bartter syndrome type 1, was identified (Li *et al.*, 2016).

Presentation of neonatal hyperparathyroidism is usually with symptomatic hypercalcemia in the neonatal period, but it may present later during investigations for developmental delay. There is moderate to severe symptomatic hypercalcemia, elevated PTH, parathyroid bone disease (including demineralisation, rib cage instability), and respiratory distress (Toke *et al.*, 2007; Reh *et al.*, 2011). Hypercalcemia may spontaneously improve over time without the need for surgery and the phenotype subsequently resembling FHH. Early analysis of the CaSR is helpful to differentiate the condition from neonatal severe hyperparathyroidism where surgery is invariably required.

Treatment should initially be aimed at managing the hypercalcemia, which might avoid the need for surgery. Cinacalcet may be a useful temporizing measure to reduce PTH levels until the hyperparathyroidism resolves. Patients treated in this way have demonstrated good catch up growth and development (Reh *et al.*, 2011; Fisher *et al.*, 2015).

Gestational maternal hypocalcemia

Maternal hypocalcemia should be considered in the differential diagnosis for infants with persistent hypercalcemia. Investigation of neonatal hypercalcemia should include a measurement of plasma calcium in both parents. Chronic maternal hypocalcemia (from undiagnosed or under-treated hypoparathyroidism or pseudohypoparathyroidism) may cause secondary fetal hyperparathyroidism from reduced materno-fetal calcium transfer in order to maintain adequate plasma calcium levels in utero. The hypercalcemia may take several weeks to resolve but does not require surgical intervention (**Table 2**).

Table 2 Causes of PTH-dependent hypercalcaemia in children

- Neonatal causes
  - Neonatal severe hyperparathyroidism
  - Neonatal hyperparathyroidism
  - Mucolipidosis type II (I-cell disease)
  - Gestational maternal hypocalcaemia
- Primary hyperparathyroidism
  - Parathyroid adenoma
  - Parathyroid hyperplasia
  - Parathyroid carcinoma
- Specific causes of primary hyperparathyroidism
  - Multiple endocrine neoplasia types I, IIa, IV
  - Hyperparathyroid jaw-tumor syndrome
  - Familial isolated primary hyperparathyroidism
- Other causes
  - Tertiary hyperparathyroidism
  - Prior radiation to neck

PTH-Independent Hypercalcemia

The causes of PTH-independent hypercalcemia are diverse (Table 3). These conditions cause hypercalcemia associated with a suppressed, low or inappropriately normal PTH level. Selected examples of PTH-independent hypercalcemia are discussed below.

PTH-independent Hypercalcemia Associated With Normal (Unsuppressed) PTH Levels

Hypercalcemia associated with normal or unsuppressed PTH levels suggests a defect in the CaSR.

Familial hypocalciuric hypercalcemia

Familial hypocalciuric hypercalcemia (FHH) is an autosomal dominant disorder. Most affected individuals are asymptomatic and do not require treatment although rarely recurrent pancreatitis and chondrocalcinosis have been described in adults.

Table 3 Causes of PTH-independent hypercalcaemia

Normal (unsuppressed) PTH levels
- Familial hypocalciuric hypercalcaemia types I, II, III
- Early onset primary hyperparathyroidism

Low or suppressed PTH levels
- Malignancy
  - Acute lymphoblastic leukemia
  - Acute myeloid leukemia
  - Lymphoma
  - Ovarian dysgerminoma
  - Medulloblastoma
  - Hepatoblastoma
  - Rhabdomyosarcoma
  - Hepatic sarcoma
- Drug-induced
  - Vitamin D intoxication
  - Vitamin A intoxication
  - Thiazides
  - 13-*Cis*-retinoic acid
  - Inadequate phosphate supplementation in parenteral nutrition
  - Following discontinuation of denosumab
- Acute immobilization
- Genetic
  - Williams–Beuren syndrome
  - Jansen's metaphyseal chondrodysplasia
  - Down syndrome
  - Hypophosphatasia
  - IMAGe syndrome
- Idiopathic infantile hypercalcaemia of infancy
  - CYP24A1 mutation
- Granulomatous disease
  - Subcutaneous fat necrosis
  - Tuberculosis
  - Sarcoid
- Endocrine
  - Hyperthyroidism
  - Addison disease
  - Phaeochromocytoma
  - Congenital hypothyroidism
  - Diabetic ketoacidosis
- Inborn errors of metabolism
  - Congenital lactase deficiency
  - Bartter syndrome
  - Blue diaper syndrome
  - Disaccharide intolerance
- Renal
  - Distal renal tubular acidosis
  - Multicystic renal dysplasia
  - Renal failure
- Ketotic diet

There are three types of FHH, which are classified based on the location of the genetic abnormality. FHH type 1 is secondary to a heterozygous loss of function mutation of the CaSR gene, a G protein-coupled receptor. FHH type 2 is caused by a loss of function mutation in the GNA11 gene that encodes for $G\alpha_{11}$, which is involved in calcium-receptor signaling. This mutation likely impairs GDP release (Nesbit *et al.*, 2013). FHH type 3 results from heterozygous mutations of the adaptor-related protein complex 2, sigma 1 subunit (AP2S1) gene and causes defective endocytosis and recycling of the CaSR (Fujisawa *et al.*, 2013). Two-thirds of cases of FHH are caused by CaSR gene mutations and approximately 20% from AP2S1 mutations and 10% from GNA11 mutations (Nesbit *et al.*, 2013; Fujisawa *et al.*, 2013; Hendy *et al.*, 2014). In the absence of gene mutations, autoantibodies directed at the CaSR may also cause hypocalciuric hypercalcemia (Marx *et al.*, 1978).

The biochemical features of FHH include lifelong hypercalcemia associated with inappropriately low urinary calcium excretion (80% of cases) but with a normal (unsuppressed) or slightly high PTH level (Marx *et al.*, 1978), indicative of parathyroid and renal resistance to suppression of PTH. However, hypercalciuria can occasionally occur in FHH types 1 and 3 (Fujisawa *et al.*, 2013; Hendy *et al.*, 2014). This is more common in infancy, with hypocalciuria developing over time. The serum phosphate is usually at the lower end of the normal range and there may be hypermagnesemia. The biochemical features may be indistinguishable from PHPT and investigation for genetic causes of FHH may be useful in some cases of suspected PHPT to avoid unnecessary parathyroidectomy.

The use of cinacalcet to treat symptomatic FHH is evolving, but will only be effective if the function of the mutated CaSR protein can be enhanced. Cinacalcet has been used to treat symptomatic FHH type 1 and type 3 in children and adults. The data are currently limited but with apparently good effects in the 10 out of 12 treated patients to date (Mayr *et al.*, 2016). The reasons for treatment initiation in these cases included symptomatic hypercalcemia, pancreatitis, poor wound healing, psychosis, and muscle cramps.

PTH-Independent Hypercalcemia Associated With Low or Suppressed PTH Levels

Childhood malignancy

The incidence of hypercalcemia in childhood malignancy is $<1\%$ whereas it occurs in up to 30% of adult cancer patients (Stewart, 2005; McNeilly *et al.*, 2016; Jick *et al.*, 2017). It is most commonly observed at diagnosis in children, and, unlike in adults, is not predictive of a poor prognosis. Hypercalcemia secondary to childhood malignancy is associated with a low or suppressed PTH, except in parathyroid carcinoma where PTH levels will be elevated.

The mechanism leading to hypercalcemia varies depending on the tumor type (Stewart, 2005). In acute leukemia and lymphoma an increase in osteoclastic bone resorption mediated by cytokines in areas surrounding malignant cells in the marrow space results in hypercalcemia secondary to local osteolysis (Niizuma *et al.*, 2007). Humoral hypercalcemia of malignancy is caused by direct tumor secretion of either PTH-related peptide (PTHrP) (childhood acute lymphoblastic leukemia (Shimonodan *et al.*, 2005), rhabdomyosarcoma, medulloblastoma, hepatic sarcoma and hepatoblastoma (Dharmaraj *et al.*, 2006; Lakhdir *et al.*, 1994)) or $1,25(OH)_2D$ (ovarian dysgerminoma, lymphoma). Similarly to PTH, PTHrP increases bone resorption and enhances renal retention of calcium (Hibi *et al.*, 2008). Hypercalcemia from ectopic secretion of PTH is a very rare and has been reported in association with rhabdomyosarcoma (Brooks *et al.*, 2018). 13-*Cis*-retinoic acid is used to treat neuroblastoma and hypercalcemia is a known side effect.

Williams–Beuren syndrome

Williams–Beuren syndrome (WBS) is a multisystem disorder with an incidence of 1 in 20,000 births and is caused by a microdeletion on chromosome 7, resulting in the loss of 26–28 genes. Clinical features include a characteristic facial appearance, specific neurocognitive profile and congenital heart disease, most commonly supravalvular aortic stenosis. Additionally there is an increased risk of hypercalcemia during infancy, childhood, and adolescence.

The cause of hypercalcemia is unknown although endocrine, gut and renal abnormalities have been described. Elevated levels of $1,25(OH)_2D$ have been observed in some infants and some have hypothesized increased sensitivity to normal circulating levels. Others suggest that hypercalcemia results from abnormal function of a multi-protein complex (WINAC) that interacts with the Williams syndrome transcription factor and augments recruitment of the vitamin D receptor causing increased sensitivity to vitamin D (Kitagawa *et al.*, 2003).

The lifetime prevalence of hypercalcemia in WBS is 15%, and the prevalence is highest in infants (17%) and toddlers (26%). Hypercalcemia is usually mild and requires no intervention, but approximately 6% of cases are symptomatic and require management of calcium levels. This is more frequent in younger children (5% of infants and 10% of toddlers) (Sindhar *et al.*, 2016). Those requiring intervention for hypercalcemia are more likely to have associated nephrocalcinosis and hypercalciuria. A transient shortening in the QTc interval associated with hypercalcemia has not been associated with arrhythmia, seizure or death. Screening calcium levels does not predict which individuals go on to develop actionable hypercalcemia; however calcium levels should be checked at diagnosis and symptom-based testing is appropriate thereafter (Sindhar *et al.*, 2016). In older children other medical conditions should be excluded before attributing hypercalcemia to the syndrome.

Individuals with WBS should avoid vitamin D supplementation. If hypercalcemia supervenes, a calcium-restricted diet including low calcium milk may be helpful with later re-introduction of a standard healthy diet. Hypercalcemia is amenable to standard treatments if necessary.

Jansen's metaphyseal chondrodysplasia

Jansen's metaphyseal chondrodysplasia is a rare skeletal dysplasia characterized by abnormal endochondral bone formation and hypercalcemia associated with low levels of PTH. Clinical features include micrognathia, arched palate, hypertelorism, waddling gait, bowed tibiae and kyphoscoliosis. Short stature becomes more apparent with increasing age with skeletal disproportion. Affected individuals typically have short limbs without significant shortening of the torso.

Hypercalcemia results from constitutive activity of PTH/PTHrP receptor in bone and is associated with hypophosphatemia and with a normal or undetectable serum PTH or PTHrP. Biochemical abnormalities are usually apparent by 3 months of age and following completion of linear growth calcium levels typically fall but still remain elevated (Schipani *et al.*, 1999). Overt hypercalcemia is not always observed, and the same mutation may cause severe hypercalcemia in some affected individuals but not others within the same family (Nampoothiri *et al.*, 2016). Bisphosphonates have been used in adults to reduce the rate of bone turnover and control hypercalciuria (Onuchic *et al.*, 2012).

Idiopathic infantile hypercalcemia

Idiopathic infantile hypercalcemia (IIH) presents with hypercalcemia in the first year of life, typically after 6 months of age. Non-progressive subclinical nephrocalcinosis may occur and remain persistent into childhood (Huang *et al.*, 2006). Behavioral problems and deficits in performance IQ have been reported in children with IIH (Udwin *et al.*, 1986).

Recessive and dominant mutations in the 24-hydroxylase gene (CYP24A1) have been identified as the cause for some cases of IIH (**Fig. 1**). 1,25$(OH)_2$D, is normally inactivated by CYP24A1, which also promotes the metabolism of 25(OH)D to the inactive metabolite 24,25-dihydroxyvitamin D3, thus reducing stores of 25(OH)D (**Fig. 1**). The activity of CYP24A1 is regulated by 1,25$(OH)_2$D, serum calcium and PTH. Inactivating mutations of CYP24A1 reduce the degradation of 1,25$(OH)_2$D resulting in symptomatic hypercalcemia, especially in those given vitamin D supplements. The PTH is suppressed and serum 1,25$(OH)_2$D and 25(OH)D may be elevated or normal (Pronicka *et al.*, 1997). 24,25-Dihydroxyvitamin D [24,25$(OH)_2$D] levels may be low or undetectable. Typically hypercalcemia in IIH resolves over time. Homozygous CYP24A1 knockout mice have decreased expression of CYP27B1, which encodes the 1-α hydroxylase enzyme in the kidney (Masuda *et al.*, 2005) and long-term compensatory down-regulation may explain the improvement in hypercalcemia over time.

Milder phenotypes may occur with biallelic CYP24A1 mutations, either homozygous or compound heterozygous, with chronic mild hypercalcemia or normocalcemia associated with low or normal PTH levels, hypercalciuria, renal stones, nephrocalcinosis and absence of hypophosphatemia (Schlingmann *et al.*, 2011; Tebben *et al.*, 2012; Jacobs *et al.*, 2014; Carpenter, 2017). Serum 1,25$(OH)_2$D may be elevated in some cases. Circulating 24,25$(OH)_2$D is low and the molar ratio of circulating 25(OH)D: 24,25$(OH)_2$D may be a good indicator of CYP24A1 function (Kaufmann *et al.*, 2014).

Treatment of IIH includes dietary calcium and vitamin D restriction and reducing cutaneous vitamin D synthesis using clothing and sunscreen. Ketoconazole and fluconazole are inhibitors of CYP27B1 and have been used to reduce 1,25$(OH)_2$D synthesis (Tebben *et al.*, 2012; Sayers *et al.*, 2015), but the risk of serious hepatotoxicity limits the long-term use of these agents. Rifampicin, which induces CYP3A4, an alternative vitamin D metabolite degradation pathway, has also been used to reduce serum 1,25$(OH)_2$D and normalize serum and urinary calcium concentrations in two patients with IIH (Hawkes *et al.*, 2017). The safety of long-term usage however needs to be established, but as a number of foods (e.g., starfruit, pomegranate, white grapefruit) and medications (e.g., macrolide antibiotics, fluoxetine, verapamil, steroids) are known to inhibit CYP3A4, avoidance of these in patients with CYP24A1 mutations should be recommended.

Renal failure

Both acute and chronic renal failure can cause hypercalcemia, but the mechanisms by which this occurs differ. The oliguric phase of acute renal failure (ARF), particularly when associated with rhabdomyolysis, is often associated with hypocalcemia.

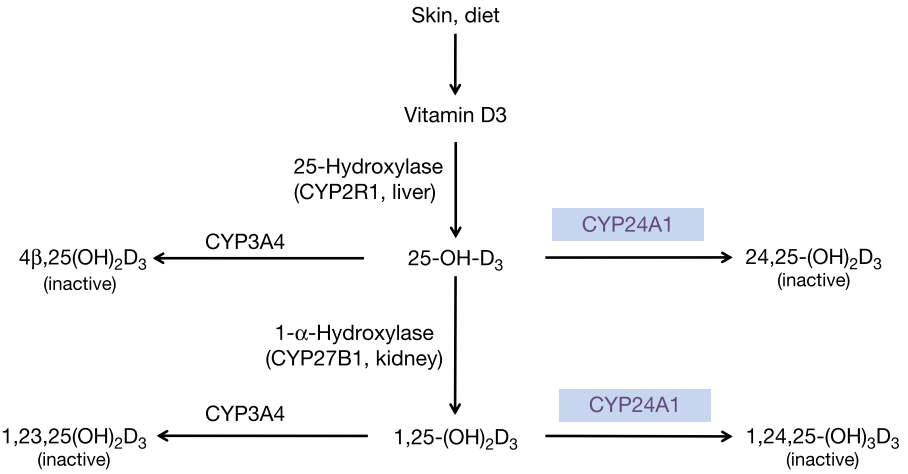

Fig. 1 Activation and inactivation pathways of vitamin D.

Hypercalcemia typically occurs later during recovery of renal function and the ensuing diuresis. A number of mechanisms have been proposed for this: firstly, during the hypocalcemic phase of ARF, skeletal resistance to PTH occurs resulting in deposition of calcium in soft tissue. Mobilization of these calcium deposits can occur as the ARF resolves. Secondly, in ARF secondary to rhabdomyolysis, both serum 25(OH)D and $1,25(OH)_2D$ are elevated during the diuretic phase of recovery. It is postulated that 25(OH)D is released from damaged muscle, thereby increasing substrate availability for conversion to $1,25(OH)_2D$ by renal 1α-hydroxylase as renal function improves (Akmal *et al.*, 1986).

Hypercalcemia occurs in up to 20% of patients with chronic renal failure, and persistence of hyperparathyroidism following renal transplantation is common. Several mechanisms lead to hypercalcemia. Secondary hyperparathyroidism occurs in response to hyperphosphatemia, hypocalcemia and reduced $1,25(OH)_2D$ levels. In some patients, despite treatment of secondary hyperparathyroidism with phosphate restriction, calcium binders and calcitriol, the PTH levels remain elevated and results in tertiary hyperparathyroidism. These patients have increased parathyroid gland mass from hyperplasia and proliferation of parathyroid cells may lead to somatic mutations and monoclonal expansion of the type seen in parathyroid adenomas. Slow involution of the hyperplastic parathyroid glands following transplantation results in hypercalcemia, which can persist for several years. Hypervitaminosis A, which is commonly seen even in early chronic kidney disease and particularly in children on supplemental feeds, has also been associated with hypercalcemia (Manickavasagar *et al.*, 2015).

Immobilization hypercalcemia

Acute immobilization, for example, head injuries, fractures or spinal cord injuries, is often associated with hypercalcemia. Serum calcium, hypercalciuria, and the incidence of hypercalcemia increase with the duration of immobilization (Yusuf *et al.*, 2013), and whilst commonly asymptomatic, typical symptoms of hypercalcemia have also been reported. Uncoupling of bone remodeling with a reduction in osteoblastic activity and increased osteoclastic activity occurs during immobilization, and thus is more commonly associated with hypercalcemia in children than adults due to the higher bone turnover during growth. Calcium and phosphate release from the skeleton can result in disuse osteoporosis, and fractures and renal stone formation may also occur. Serum PTH and $1,25(OH)_2D$ levels are suppressed and hypercalcemia and hypercalciuria typically resolve with the onset of weight bearing.

Drug-induced hypercalcemia

Vitamin D intoxication

Vitamin D intoxication can occur secondary to excessive milk fortification, prescribing or manufacturing errors of vitamin D formulations, or due to accidental overdosing or overzealous usage of either prescribed or self-administered vitamin D supplements (Kara *et al.*, 2014; Vanstone *et al.*, 2012; Vogiatzi *et al.*, 2014). Supraphysiological doses of vitamin D result in hypercalcemia as a result of both increased intestinal calcium absorption and enhanced bone resorption due to increased osteoclastic activity. It is postulated that at very high serum levels, 25(OH)D is also able to act on the vitamin D receptor, in addition to being converted to the active $1,25(OH)_2D$ metabolite (Jones, 2008). Hypercalciuria and nephrocalcinosis occurs in up to 25% of cases, and vitamin D intoxication should be considered in the differential diagnosis when these features are present (Vogiatzi *et al.*, 2014). In severe cases life-threatening dehydration and cardiac arrhythmias may occur (Nimesh *et al.*, 2015).

The dose of vitamin D required to cause intoxication is large, but highly variable, ranging from 240,000 to 4,500,000 (or 40,000 to 560,000 IU/kg) and resulting in serum 25OHD concentrations typically >625 nmol/L. Genetic variation in genes involved in the vitamin D metabolism pathway, including CYP24A1 (Schlingmann *et al.*, 2011), may alter an individual's predisposition to vitamin D intoxication and account for some of this variability.

Vitamin D_2 and vitamin D_3 preparations can both cause vitamin D toxicity. Importantly, 25(OH)D has a half-life of 2–3 weeks and its lipophilic nature allows for storage in adipose tissue. As such, vitamin D intoxication may take several weeks to resolve and require prolonged treatment, although is typically amenable to standard therapies for hypercalcemia. In contrast, hypercalcemia secondary to ingestion of short acting vitamin D analogues (alfacalcidol, calcitriol) tend to cause less severe intoxication and of shorter duration due to the shorter half-life.

Others drugs

Vitamin A toxicity has been associated with hypercalcemia (Kimmoun *et al.*, 2008; Nagasawa and Okawa, 1994). Vitamin A analogues such as *cis*-retinoic acid are used as a treatment for acne and other retinoic acids are used in the treatment of certain malignancies. The mechanism of hypercalcemia is unclear but vitamin A has direct effects to stimulate bone resorption. Thiazide diuretics may cause hypercalcemia by increasing renal tubular reabsorption of calcium. This is particularly evident in individuals with PHPT.

Granulomatous disorders

Subcutaneous fat necrosis

Subcutaneous fat necrosis of the newborn (SCFN) is a transient panniculitis characterized by hard indurated violaceous nodules and plaques with ill-defined overlying erythema on the trunk, arms, buttocks, thighs and cheeks. It typically presents within the first 6 weeks of life, and the majority of infants with SCFN have a history of perinatal stress and/or maternal morbidity, such as diabetes (gestational or pre-existing diabetes mellitus) (Del Pozzo-Magana and Ho, 2016). A history of treatment with therapeutic hypothermia is also commonly reported in infants who develop SCFN (Del Pozzo-Magana and Ho, 2016).

Hypercalcemia occurs in approximately 60% of neonates with (SCFN) (Del Pozzo-Magana and Ho, 2016), and is often the presenting feature, but delayed onset of hypercalcemia up to 6 months after onset of the skin lesions has also been reported (Norwood-Galloway *et al.*, 1987). Biopsies taken from the skin lesions have revealed copious expression of 1-α hydroxylase in the inflammatory infiltrate which is thought to result in excessive endogenous synthesis of $1,25(OH)_2D$ and the ensuing hypercalcemia (Farooque *et al.*, 2009). Initial treatment is with rehydration and glucocorticoids, and pamidronate may be considered if hypercalcemia is refractory (Alos *et al.*, 2006; Lombardi *et al.*, 2009). Low-calcium formula may be required for weeks following the initial treatment to prevent rebound hypercalcemia. Hypercalcemia may be present for 1–2 years and nephrocalcinosis persists in the majority of infants with hypercalcemia seconding to SCFN, although renal function is not usually affected (Shumer *et al.*, 2014).

Other granulomatous disorders

Sarcoidosis and other granulomatous diseases such as tuberculosis can occasionally give rise to hypercalcemia. The mechanism is thought to be similar to that of SCFN.

Endocrine causes of hypercalcemia

Some endocrines diseases cause hypercalcemia (**Table 3**). Hypercalcemia may occur at the presentation of an adrenal crisis due to abnormal vitamin D metabolism from glucocorticoid deficiency and also volume depletion from mineralocorticoid deficiency. Thyrotoxicosis can cause mild hypercalcemia by T3-induced stimulation of osteoclastic bone resorption. Hypercalcemia has also been reported at presentation of diabetic ketoacidosis which is likely secondary to a combination of metabolic acidosis, hypophosphatemia, rhabdomyolysis with acute renal failure and immobilization (Makaya *et al.*, 2013).

Hypophosphatemia

Hypophosphatemia can cause hypercalcemia as low phosphate levels suppress circulating FGF23 levels with subsequent disinhibition of 1-α hydroxylase and increased synthesis of $1,25(OH)_2D$. Inadequate phosphate provision in preterm milk or parenteral nutrition may cause hypercalcemia. Increasing phosphate content to match higher calcium content in preterm parenteral nutrition may reduce the incidence of and severity of hypercalcemia (Mulla *et al.*, 2017).

Treatment of Hypercalcemia

Treatment of hypercalcemia is aimed at both lowering serum calcium concentration and correcting the underlying disease. General measures include minimizing calcium concentration in enteral and parenteral feeds and discontinuation of oral calcium supplements and drugs known to cause hypercalcemia. Weight bearing activity should be increased and, when relevant, withdrawal of sedatives to promote mobility.

Increase Urinary Calcium Excretion

Intravenous hydration is the mainstay of emergency hypercalcemia treatment. Children with severe hypercalcemia are usually dehydrated due to both decreased fluid intake and hypercalcemia-induced nephrogenic diabetes insipidus. Furthermore, hypovolemia exacerbates the hypercalcemia as it allows greater calcium resorption in the kidney.

In the kidney, filtered calcium is principally reabsorbed in the proximal tubule and the ascending loop of Henle in a passive process. Active resorption of calcium occurs in the distal loop of Henle under the influence of PTH and to a lesser degree $1,25(OH)_2D$. Proximal tubular reabsorption of calcium is inhibited by volume expansion. Intravenous saline infusion is recommended for rehydration as the increase in sodium reduces calcium reabsorption in the ascending loop of Henle. Administration of a loop diuretic, such as furosemide, similarly reduces calcium reabsorption in the ascending loop of Henle, whereas thiazide diuretics should not be used due to a hypocalciuric effect. However, caution should be taken in long term loop diuretic use as they have been associated with an increased risk of nephrocalcinosis.

Reduce PTH Secretion

In cases where excess PTH secretion is a cause of the hypercalcemia, it may be possible to reduce secretion of the hormone. Cinacalcet is a calcimimetic agent that acts to sensitize the CaSR on the parathyroid gland and thus reduces PTH synthesis and secretion. Cinacalcet has been successfully used in neonatal hyperparathyroidism to prevent the need for parathyroidectomy, and to treat hypercalcemia in NSHPT, although variability in the response to cinacalcet is observed and might reflect the residual function of the CaSR (Mayr *et al.*, 2016; Fisher *et al.*, 2015). In chronic renal failure and post-renal transplantation, cinacalcet has been shown to reverse hyperparathyroidism. Treatment of vitamin D deficiency will also help to lower PTH levels.

Adverse effects of cinacalcet include hypocalcemia, hypotension, nausea, vomiting, paresthesiae, and eye palpitations. The death of a 14-year old was associated with cinacalcet administration, although no clinical details are available. The medication is

not licensed for those under 18 years of age thus the decision to treat should be individualized with strict clinical monitoring for side effects.

Decrease Intestinal Calcium Absorption

If hypercalcemia is caused by raised levels of $1,25(OH)_2D$, glucocorticoids might be useful as they inhibit 1α-hydroxylase and thereby reduce the conversion of 25OHD to $1,25(OH)_2D$. Glucocorticoids have been used to treat hypercalcemia for granulomatous conditions such as tuberculosis, sarcoid and subcutaneous fat necrosis.

Inhibit Bone Resorption

Bisphosphonates

Bisphosphonates are extremely effective in children with moderate to severe hypercalcemia (Niizuma *et al.*, 2007). The most commonly used agent is pamidronate, which is safe to use even in patients with renal dysfunction, but there are increasing reports of zoledronate being equally effective for treating hypercalcemia associated with malignancy and neonatal SCFN (Park *et al.*, 2016; Di Bari *et al.*, 2017). Potential benefits of zoledronate include greater potency, a longer duration of action and shorter infusion time. Both pamidronate and zoledronate lead to a reduction in serum calcium 12–48 h after administration, but a sustained period of hypocalcemia requiring additional calcium supplementation can occur and warrants monitoring of calcium levels. An acute-phase reaction with flu-like symptoms is commonly seen following first exposure to intravenous bisphosphonate.

Denosumab

Denosumab is an inhibitor of receptor activator of nuclear factor kappa-B ligand (RANKL). RANKL promotes osteoclast differentiation and activity, leading to increased bone resorption. Hence denosumab reduces bone resorption. Denosumab has been shown to be useful in the treatment of hypercalcemia of malignancy in adults but there is little data in children and rebound hypercalcemia has been observed in case reports and open-labeled studies in children, which may limit its use in the treatment of hypercalcemia (Boyce, 2017).

Calcitonin

Calcitonin reduces calcium absorption in the gut, inhibits calcium reabsorption in the kidney and reduces osteoclast activity. Synthetic calcitonin can be effective in reducing plasma calcium and has a rapid onset of action but short duration of effect. It is generally only used in an acute situation and when other treatment options have been unsuccessful.

Dialysis

In resistant, life-threatening hypercalcemia, hemodialysis against a low-calcium dialysate is more effective than peritoneal dialysis at lowering calcium levels.

Parathyroidectomy

Surgery is required for primary hyperparathyroidism and should be undertaken by an experienced pediatric endocrine surgeon. In most cases of NSHPT total parathyroidectomy is required and will render the child hypoparathyroid. The decision to operate for milder forms depends on the degree of hypercalcemia, symptoms and potential for renal damage. Pamidronate may be required preoperatively in those with severe or symptomatic hypercalcemia. Rapid peri-operative PTH measurements can be undertaken to determine whether or not parathyroidectomy has been effective. Following parathyroidectomy, replacement with maintenance calcium and vitamin D should be commenced. Immediately following surgery, hypocalcemia secondary to a "hungry bone" syndrome may develop despite maintenance treatment. Serial calcium measurements should therefore be taken following surgery and additional calcium supplementation given if appropriate. If severe hypocalcemia develops, intravenous calcium may be required.

Summary and Conclusions

Hypercalcemia is rare in childhood and requires proper assessment and diagnosis before correct treatment can be given. The spectrum of disease is rather wider than that found in adults with the emphasis less specifically on hyperparathyroidism and malignancy and encompassing a wide range of conditions, many of them genetic in origin. Once a correct diagnosis has been made, it is usually possible to offer effective treatment.

A Review of Skeletal Dysplasias for the Pediatric Endocrinologist

Sarah M Nikkel, University of British Columbia, Vancouver, BC, Canada
Leanne Ward, University of Ottawa, Ottawa, ON, Canada and Children's Hospital of Eastern Ontario, Ottawa, ON, Canada

Introduction

A skeletal dysplasia is defined literally as a condition where the bones are abnormally formed. Bones can be shorter than typical, unusually shaped, more fragile or even missing. To date there have been over 400 genetic skeletal conditions described with 300 + genes known to be associated with these conditions. A nosology group regularly reviews the medical literature and provides a document that categorizes the different dysplasias. The last was published 2015 (Bonafe *et al.*, 2015). The conditions are grouped by different characteristics such as by the genes involved (i.e., *FGFR3*, *COL2A1*), radiologic findings (i.e., metaphyseal dysplasias), and clinical presentation (i.e., bone fragility syndromes). The clinical presentation can be quite variable depending upon the gene and even the specific mutation or mutations within the gene(s). Many of the lethal skeletal dysplasias will demonstrate features during the second trimester of pregnancy on a fetal ultrasound. Other dysplasias may not be diagnosed until an x-ray demonstrates an incidental finding. The majority of dysplasias present sometime in childhood due to some atypical finding, including short stature, a common reason for referral to a pediatric endocrinologist.

The term dwarf is used to describe an individual with short stature who is typically disproportionate in his or her growth parameters. Little person is also an acceptable term, although usage of such terms can vary depending upon the region. However, not all skeletal dysplasias result in short stature.

One should also consider the difference between a skeletal dysplasia and a syndromic condition where there are skeletal features. For example, Cornelia de Lange syndrome is associated with short stature and limb anomalies, but is not typically considered a type of dwarfism. However, as more and more conditions are being better characterized, and many skeletal dysplasias are associated with issues in other body systems, the distinction between the two is blurred.

How an Individual With a Skeletal Dysplasia may Present to an Endocrinologist (Table 1)

Short Stature

An endocrinologist may be the first specialist to suspect a skeletal dysplasia, commonly in a child who is referred with short stature. In one series of patients published by Flechtner *et al.* (2014), they found that a significant proportion of patients referred for idiopathic short stature and small for gestational age had mutations in *FGFR3* or *SHOX*, once genetic and syndromic diagnoses were excluded. This individual may have always had growth parameters below the curve or had measurements that are falling off the normative curves. With further measurements, disproportion may be detected. Thus accurate and historic measurements may demonstrate a pattern that is key to making a diagnosis.

Growth Plate Abnormalities Mimicking Rickets

Vitamin D deficiency remains prevalent the world over (Munns *et al.*, 2016) despite international guidelines for its prevention through vitamin D supplementation in at-risk groups and, in some countries, food fortification. As it is a treatable condition, it should always be ruled out; fortunately, the diagnosis is often suggested on the history alone. Clinically these children may present in the first few months of life with the textbook features of rachitic rosary, splaying of the distal metaphyses, hypocalcemic seizures, delayed developmental milestones, abnormal dentition, enlarged fontanelles and craniotabes (softening of the skull). They may also present later with "normal" childhood bowing of the legs not resolving in the typical manner and bone pain due to fractures. There are other pathway disruptions that also present with rickets such as hypophosphatemia, so a broad approach should be considered in the work-up. The morphology of the growth plate is similar to that of a metaphyseal dysplasia; individuals with this diagnosis are sometimes presumed to have rickets, but do not respond to vitamin D and calcium in the expected way. Children with metaphyseal dysplasias also do not have the classical biochemical features associated with vitamin D deficiency rickets. On the other hand, those with Jansen metaphyseal chondrodysplasia have biochemical perturbations including hypercalcemia and hypophosphatemia without intrinsic parathyroid gland abnormalities as the genetic etiology is a mutation in the parathyroid hormone receptor-1 gene (*PTHR1*).

Delayed Bone Age

The bone age is calculated by the maturation of the epiphyses of the left hand via radiograph. A delayed bone age in an otherwise healthy individual most likely indicates delayed physical maturation within the spectrum of normal development (constitutional

Table 1 Most common reasons or signs prompting for referral to an endocrinologist and associated diagnoses

Clinical feature	*Diagnoses*
Short stature	*FGFR3* related conditions: achondroplasia and hypochondroplasia
	Leri-Weill/*SHOX* mutations
	COL2A1 related conditions: spondyloepiphyseal dysplasia congenital
Growth plates resembling rickets	Metaphyseal dysplasias (Shwachman–Diamond, Schmid metaphyseal chondrodysplasia, cartilage-hair hypoplasia)
	Hypophosphatemic rickets (X-linked and recessive types)
Delayed bone age	Multiple epiphyseal dysplasia (*COMP, COL9A1, COL9A2, COL9A3, MATN3, SLC26A2, CANT1*)
	TRPV4 related conditions (brachyolmia, spondylometaphyseal dysplasia—Kozlowski type)
Fractures	Osteogenesis imperfecta
Abnormal bone density/ mineralization	Cleidocranial dysplasia
	Osteopetrosis (various types)
	Camurati–Engelmann
	Endosteal hyperostosis (various types)
	Hypophosphatasia

delay). One does need to rule out endocrine causes like hypothyroidism, pathologically delayed puberty and chronic illnesses. There are also a number of genetic syndromes associated with delayed bone age, which are suggested by congenital anomalies in the individual. One such example is Floating-Harbor syndrome, which is a short stature syndrome with a very characteristic facial appearance and significant expressive language impairment. However, a delayed bone age may indicate that the patient has an epiphyseal dysplasia and upon examination of the other epiphyses, these tend to be smaller, with the proximal femoral epiphyses being the most affected. There may also be an abnormal pattern in the ossification of the carpal bones that is reported as delayed bone age, but is actually a sign that the bones overall have not developed in the typical way. It is upon further x-rays that differences in other bones may be demonstrated, such as the platyspondyly seen in brachyolmia.

Fractures

When a child presents with multiple fractures, the common question that arises is whether the fractures represent nonaccidental injury or a form of osteogenesis imperfecta (OI). This is obviously a critical distinction. Often a careful history will determine which is the most likely. The *COL1A1* and *COL1A2* genes account for the majority of cases of OI, and other features such as blue sclera, Wormian bones of the skull, vertebral fractures, hyperlaxity and long bone deformity assist in the diagnostic process. However, a few patients with type I collagen mutations or the more rare OI types do not have discoloration of the sclera or Wormian bones (Bardai *et al.*, 2017), but the radiographs and nature of the factures (including the presence of vertebral fractures) may suggest that the individual has an underlying bone disorder. At present, there are close to two dozen genes implicated in congenital bone fragility, recently reviewed in articles on the management of osteoporosis in children (Ward *et al.*, 2016; Trejo and Rauch, 2016).

Differences in Bone Density

Bone mineral density studies are not commonly done as a routine investigation in children with a suspected skeletal dysplasia unless there is a history of fractures, but x-rays may suggest the individual has osteopenia or a sclerosing bone disorder. In an infant with sclerotic bones, the diagnosis could be an infantile form of osteopetrosis, which may quickly progress, resulting in cranial nerve entrapment. The ability to respond to hematopoietic stem cell transplantation (HSCT) in osteopetrosis is dependent upon the causative genetic change (Palagano *et al.*, 2018); therefore, identifying the molecular basis for the phenotype expediently, guides clinical care. Often the endocrinologist is charged with managing osteopetrorickets (treating the hypocalcemia and hypophosphatemia, a feature of malignant infantile osteopetrosis due to mutations in *TCIRG1*) (Nour and Ward, 2013) and also taking leadership on the child's coordination of care so that HSCT can be carried out as quickly as possible.

Investigating a Child With a Suspected Skeletal Dysplasia

History

The family may provide key information during the diagnostic process. Parents, when available, should always be measured to calculate mid-parental heights and to determine if one of them may have the same diagnosis as the proband. If there is any disproportion in the patient (i.e., macrocephaly, mesomelia, upper to lower extremity disproportion), this should also be assessed in both parents. Similar features in a parent may suggest that the condition is autosomal dominant, while an affected sibling with

unaffected parents suggests autosomal recessive inheritance. Advanced paternal age at conception may indicate a new dominant condition as de novo mutations are associated with a paternal age effect.

One should note the ethnicity of the family and if there is consanguinity or if the parents are from a limited geographic area. Some autosomal recessive skeletal conditions are more common in certain populations, such as cartilage – hair hypoplasia in individuals of Amish and Finnish ancestry.

Growth curves and plotting of historic measurements will provide a pattern of growth that may suggest or exclude a particular diagnosis. Those with pseudoachondroplasia have length measurements that are typically on the average curve until age 2, when there is a decrease in growth velocity (Horton *et al.*, 1982), while individuals with achondroplasia are short at the time of term delivery. Individuals with hypochondroplasia tend to be of average length at birth, and it may be only when the child starts school that short stature and disproportion are noticed. Individuals with hypochondroplasia and achondroplasia also do not appear to have a pubertal growth spurt. The differential diagnosis may be narrowed if skeletal differences were noted during third trimester ultrasounds (i.e., prenatal onset of short stature).

Physical Examination

As for any patient, a careful examination is important. Height, weight, arm span, sitting height and head circumference are standard measurements. One should use normative values appropriate for their population. Additional measurements, such as hand length, may be indicated if the size looks disproportionate to the rest of the individual. The handbook of Physical Measurements (Gripp *et al.*, 2013) is a good resource for the average curves for a number of different measurements, which can help sort out if a result is significant or not. Head circumference is often missed, but is it an important clue. Occipitofrontal circumferences (OFC) at or above the 95th percentile makes one consider an *FGFR3* condition. Short stature with an average OFC can also narrow the differential. When the head circumference is at a lower percentile in an individual with extreme short stature, this raises the possibility of a type of primordial dwarfism (Seckel syndrome or microcephalic osteodysplastic primordial dwarfism, type II).

The arm span to height ratio can indicate the type of disproportion that is present. If the arm span is significantly lower than the standing height, this suggests that the limbs are more affected than the spine. Conversely, if the arm span is much greater, then the spine could be involved. In childhood, the arm span is less than height and approaches a ratio of 1:1 around the time of puberty. It is also normal for arm span to be greater than height in certain populations, especially those of African ancestry. One also does need to take into account if a scoliosis is present when interpreting these results.

It is often difficult to measure limb segments in an active child. A quick way of determining if there is rhizo- or mesomelia of the upper limb is to flex the arm at the elbow and observe the location of the wrist crease relative to the shoulder. If the crease is at or above the shoulder, there is rhizomelia. If the crease is at the mid-shaft of the humerus, then mesomelia is present.

The hands can provide important clues in regards to a diagnosis. There is the classic trident appearance of the fingers in achondroplasia, where it is difficult for the digits to touch from base to tip. In spondyloepiphyseal dysplasia congenital (SEDC–*COL2A1*), the hands can appear unremarkable and be average in size despite marked upper to lower extremity disproportion due to the platyspondyly. The flexibility of the digits should also be noted. In cartilage – hair hypoplasia (*RMRP*), the hands are small and the joints are very hypermobile. Conversely, the digits in some of the mucopolysaccharidoses (Hunter, Hurler) lose their mobility and have a "claw" appearance. Acromicric dysplasia is characterized by small hands and resembles a storage disorder in that the digits are very stiff.

One should note the range of motion in all the joints. Typically individuals with achondroplasia are unable to fully extend their elbows. Other diagnoses may have limited movement of the hips due to positioning of the femoral head. Bony synostoses or dislocations may also limit mobility of a joint.

Some of the dwarfing conditions have a characteristic facial appearance, and this can help with making the diagnosis. The bodies of individuals with achondroplasia and pseudoachondroplasia can look very similar, but those with pseudoachondroplasia have an unremarkable facial appearance, while those with achondroplasia typically have macrocephaly with frontal bossing.

Radiographs

Plain x-rays are still the most useful diagnostic imaging test in diagnosing a skeletal dysplasia. Three dimensional reconstructions via computed tomography can be helpful in visualizing the morphology of the bones and MRI is extremely important in determining if there is nerve compression secondary to the boney anomalies, especially if there are vertebral differences. Radiologists are accustomed to reviewing x-rays and should be consulted during the diagnostic process; skeletal dysplasia textbooks are also an excellent resource (Spranger *et al.*, 2012; Lachman, 2007). One should try to obtain the films prior to bone maturation, as after the growth plates fuse important information is lost; postepiphyseal plate fusion, it is harder to note if there are epiphyseal or metaphyseal changes.

Many radiology requisitions from pediatric centers will have a tick box for a "skeletal survey." However, not all centers include the same films, so it is important to note what films are done when a box is checked. Watson *et al.* surveyed a number of specialists in skeletal dysplasias to generate a list of the minimum films that should be included (**Table 2**) (Watson *et al.*, 2015). However they recognized that for some conditions under consideration more specific films may be necessary. For example, if one suspects

Table 2 Standardized x-ray images in the diagnosis of a patient with a skeletal dysplasia

AP* and lateral of skull
Lateral of thoracolumbosacral spine
AP of chest
AP of pelvis
AP of one upper limb
AP of one lower limb
Dorsopalmar of left hand

AP*—anteroposterior.

that a child has spondyloepiphyseal dysplasia congenital, there is a high likelihood of atlantoaxial instability, so neck extension/flexion films should be carefully done. Unless there are management issues, it is not helpful to repeat the films with a frequency of less than 1 year.

Many dysplasias are categorized by which aspects of the bones are involved, the category of dysplasia (D) (Fig. 1). If the differences mostly involved the epiphyses (E), then a multiple epiphyseal dysplasia must be considered. If metaphyseal (M) flaring and irregularities are the prominent feature, then conditions like Schwachman-Diamond, cartilage-hair hypoplasia, and Schmid metaphyseal chondrodysplasia are on the differential diagnosis. There are diagnoses that affect the spine (S) primarily like brachyolmia. Also, there are conditions that combine these aspects of the bones; for example, there are different types of spondyloepimetaphyseal dysplasias (SEMDs) and spondyloepiphyseal dysplasias (SEDs).

Biochemical and Hormone Investigations

As mentioned earlier, there are a number of treatable conditions that affect bone and growth plate, and these should be ruled out if the clinical presentation indicates that they could be a possibility. If there are epiphyseal changes and/or delayed bone age, thyroid stimulating hormone (TSH) should be ordered to ensure that there is no hypothyroidism. Individuals with a multiple epiphyseal dysplasia may be of average stature, so short stature may not always be a clue. A "rickets work-up" that includes 25-hydroxyvitamin D, 1,25-dihydroxyvitamin D, parathyroid hormone, serum phosphorus, calcium, alkaline phosphatase, and urinary calcium, phosphorus, and creatinine should be performed when the x-rays predominantly show metaphyseal changes. While alkaline phosphatase is invariably high in rickets and osteomalacia, a low alkaline phosphatase for age and gender suggests another condition with radiographic features that are similar to rickets, hypophosphatasia. Hypophosphatasia can be distinguished from the radiographic features of rickets by the presence of characteristic "metaphyseal tongues," consistent with the patchy sclerosis that results from the unique mineralization defect in this condition.

Molecular Studies

Next-Generation or whole-exome sequencing (WES) technology has provided clinicians the opportunity to simultaneously test a number of possible candidate genes for a given clinical presentation. These panels can be quite broad and may include all genes associated with a bone phenotype, or may target the most common genes associated with a dysplasia. There are also, for example,

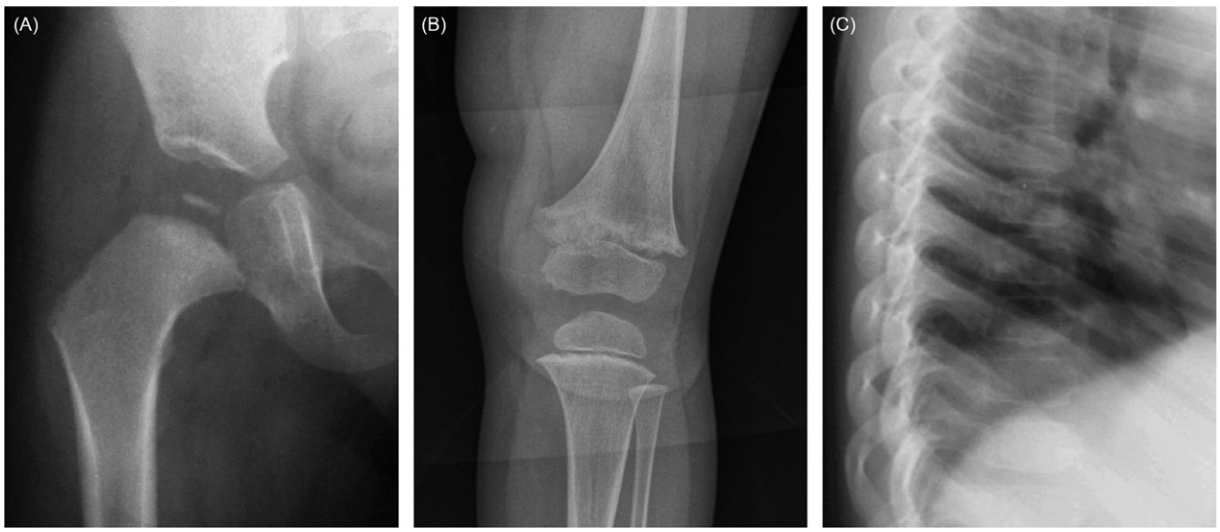

Fig. 1 (A) Epiphyseal anomaly; (B) metaphyseal anomaly; (C) spondyle anomaly.

dense bone (including osteopetrosis) and osteogenesis imperfecta panels. The quality of the panels can vary from the laboratory doing the testing, depending on the coverage of the critical portions of the gene and whether dosage studies are included. Some conditions may be due to a deletion in part of the gene, and sequencing alone will not always pick this up. The laboratory is also dependent upon the clinician ordering the appropriate investigation and providing accurate phenotype information so that the data generated can be properly interpreted. The costs of such testing have decreased over time, turning WES into one of the frontline investigations.

A clear molecular diagnosis early on in the work-up of a suspected skeletal dysplasia has multiple benefits. There are management guidelines that are tailored for particular diagnoses, the information allows for prognostication and recurrence risk counseling for families, and it should prevent the individual from undergoing investigations that are not necessary.

There are conditions where the genetic basis has yet to be elucidated, so a panel that does not reveal a pathogenic mutation does not exclude a genetic condition. To date there are a number of spondyloepiphyseal dysplasias where a causative gene has yet to be determined. For these rare conditions, collaborative sharing of phenotypes and WES data may reveal the etiology.

Putting the Information All Together

The diagnosis of a skeletal dysplasia may be simple if the individual has classic features, both on examination and radiographically, and a well-characterized gene change, such as the one that accounts for achondroplasia over 99% of the time (p. Gly380Arg in the *FGFR3* gene). However, sometimes all the pieces need to be considered, especially if a gene change has not been reported before in the literature and the laboratory categorizes it as a variant of unknown significance, or a second mutation is not found in a recessive condition. There are number of reports of ciliary chondrodysplasias, comprising of such conditions as asphyxiating thoracic dysplasia (ATD), Sensenbrenner, and Ellis–van Creveld, where only one heterozygote mutation is found (Baujat *et al.*, 2013). However, if the clinical presentation is that of shortened long bones, narrow thorax, polydactyly, and there is involvement of the kidneys, liver and retinas with a single previously reported change in the *DYNC2H1* gene, one can be confident that the likely diagnosis is that of ATD.

Management

Parents often ask how they can "fix" a child with a skeletal dysplasia. It is important to remember that these individuals are not "broken", and as care providers, the focus should be on functionality of the child. Limb lengthening does have its place, such as to correct limb length discrepancy or if it improves the ability to perform activities of daily living. The Medical Advisory Board of the Little People of America (LPA) issued a position statement in 2006, which provides a number of factors that should be considered prior to undergoing a lengthening procedure (available on the LPA website—lpaonline.org). The most important point is that the person who is considering this surgery needs to be able to understand the possible consequences and be able to consent him/herself. The statement is very clear that it does not advocate for or condemn such procedures, but encourages individuals and families to be thoughtful in their decision making and to carefully consider the risks (i.e., nerve injury/foot drop, infection, angulation, increased risk of contractions and late onset osteoarthritis, etc.) in light of the perceived benefits. It is appropriate to discuss with families that such lengthening surgeries exist, but one must also state that an improvement in height, does not decrease the likelihood of the other health issues associated with the underlying diagnosis (i.e., someone with spondyloepiphyseal dysplasia is still at risk for retinal detachment).

Most individuals with a skeletal dysplasia will need a care team, as multiple systems are often involved. Most commonly orthopedics has a role as there can be limb alignment issues, abnormal joints, or fractures. They are also the service that can provide appropriate counseling regarding limitations on physical activity and/or the type of sports to be avoided. Many individuals with a skeletal dysplasia may require surgery with careful attention to peri-operative issues such as anatomy of the airway, respiratory status, size of the patient impacting medication dosage, positioning of the individual among others; best practices to manage these issues in the skeletal dysplasia setting have been suggested (White *et al.*, 2017). Otolaryngology is often consulted in view of potential airway issues such as laryngomalacia. Both sensorineural and conductive hearing loss is common and regular audiometry is suggested (Tunkel *et al.*, 2012). Respirology is needed when the chest is small and to interpret sleep studies in regards to central versus obstructive apneas. Ophthalmologists will follow individuals with *COL2A1* mutations due to the risk of retinal detachment and those with ciliopathies for retinitis pigmentosa. Medical Geneticists typically play a role in the diagnostic process, provide counseling for the family, and in some centers provide longitudinal care. Endocrinologists are often asked to take leadership in care coordination given their expertise in discussing short stature and treating patients with fractures. The specialty to take leadership on the care coordination of children with skeletal dysplasia should be openly discussed, so that families are clear on their care pathways and contacts within the medical system.

Allied health professionals are also very important to this patient group. Physiotherapists can assist in regaining mobility after an orthopedic procedure. Occupational therapists can provide suggestions regarding adaptive devices to assist in activities of daily living like toileting. Dieticians can help the individual and family determine what are appropriate portion sizes for food. Obesity is a common problem in individuals with short stature and it is important that families provide calories tailored to the individual, especially if mobility is also an issue. Excessive weight can exacerbate mobility issues further.

The Role of an Endocrinologist in the Management of a Skeletal Dysplasia

Endocrinologists typically have a solid understanding of bone growth, strength and metabolism, thus it is often this group that manages conditions that affect biochemical and/or hormonal pathways. Bisphosphonates are well known to this specialty in their treatment of osteoporotic features of skeletal dysplasias. Given the benefit of intravenous bisphosphonates to pain control, muscle strength along with vertebral fracture prevention and reshaping in the osteogenesis imperfecta conditions (Dwan *et al.*, 2016; Trejo and Rauch, 2016), such treatment is often organized by the endocrinologist and has been reviewed extensively (Ward *et al.*, 2016).

The use of growth hormone (GH) is indicated where there is growth hormone deficiency as evidenced by abnormal secretory status (i.e., classic growth hormone deficiency confirmed on biochemical testing and an abnormal pituitary on MRI) or a mutation causing haploinsufficiency of the *SHOX* gene (Leri-Weill dyschondrosteosis) (Benabbad *et al.*, 2017), with *SHOX* being one of the genes implicated in the short stature of Turner syndrome. Growth hormone has been tried in other conditions where there is short stature. Short-term treatment has demonstrated that there is improvement in mean growth velocity in individuals with achondroplasia and hypochondroplasia (Tanaka *et al.*, 2003; Hertel *et al.*, 2005). The benefits to final adult height in those with achondroplasia were found to be around 3.5 cm in males and 2.8 cm in females (Harada *et al.*, 2017). However, the numbers of individuals who were recruited for these studies were relatively few and long-term information regarding the benefits and complications is lacking in this population. There are also no clear guidelines regarding the dose of GH and the timing and duration of treatment.

Individuals with skeletal dysplasias are also at risk for all the potential complications of GH use, including avascular necrosis of the capital femoral epiphysis and slipped capital femoral epiphyses. In individuals who have a dysplasia involving the epiphyses, these risks may be much greater. Scoliosis is also a potential side effect of growth hormone therapy and for conditions that have involvement of the spine, GH use may cause further complications. Taken together, GH therapy is not typically prescribed nor recommended for treatment of short stature in the context of skeletal dysplasias. Gonadal suppression has also been considered in this population in order to enlarge the window for growth; however, controlled studies have not shown benefit to increasing final height (Harada *et al.*, 2017).

We now have a much better understanding of the biological mechanism of many of the skeletal dysplasias. This has allowed researchers to proceed to the next step of trying to modify/treat dysplasias by introducing different molecules to bypass the faulty pathways. Enzymatic treatment so far has been the most successful, as conditions that are due to a flawed ongoing process are in theory easier to treat than conditions that are due to abnormalities of structural proteins that are already in abundance once the child is born. The treatment of infantile and juvenile/childhood hypophosphatasia with asfotase alfa has been shown to be life-saving in those with the severe infantile form; improved linear growth, muscle strength, and bone pain have also been observed (Whyte *et al.*, 2016a, b). Unique properties of asfotase alfa allow the enzyme to get into the affected tissues. This is the reason why the treatment of Morquio syndrome (mucopolysaccharidosis IV) with elosulfase alfa has had limited benefits, as some of the tissues involved, such as the heart valves and cartilage, are avascular (Tomatsu *et al.*, 2015). The cost of developing such treatments for rare disorders is also very expensive and unfortunately this translates to challenges in funding the high costs for providing such care to the individual with the condition. There have been a number of review papers published (Jelin *et al.*, 2017; Yap and Savarirayan, 2016) that discuss the current and emerging therapies for the skeletal dysplasias. Many of these therapies are still in the trial phase, so the utility of them has yet to be proven.

Support Groups

Support groups are a great resource for those living with and caring for individuals with a skeletal dysplasia. Many of these groups have annual meetings, but for those individuals who are unable to travel, the internet has allowed connections to occur that previously were impossible. The groups are well informed, as often there is a medical advisory group associated with them. They also provide excellent advocacy for their membership, thus clinicians should direct their patients to these societies as often as possible (**Table 3**).

Conclusions

Skeletal dysplasias are comprised of a diverse group of conditions with both skeletal and extraskeletal effects. The approach to management of each should be tailored to the individual in order to optimize function and quality of life. In some instances, the ability to define these conditions on molecular grounds has led to the discovery of novel treatments which better address the

pathobiology of the condition. Endocrinologists are often involved in the care of patients with skeletal dysplasias, either in a supportive role by providing input on aspects of skeletal dysplasia management such as short stature or osteoporosis treatment, or a leadership role including care coordination among multiple disciplines.

Acknowledgments

The authors would like to acknowledge the patients, families and colleagues who have helped them develop an appreciation of the issues for individuals living with skeletal dysplasias. Dr. Ward is supported by a University of Ottawa Research Chair Award in Pediatric Bone Health.

Premature Adrenarche☆

Antonis Voutetakis, Catherine Dacou-Voutetakis, Maria Dracopoulou, and Sarantis Livadas, University of Athens, Athens, Greece

Glossary

Adrenarche Initiation of function of the reticular zone of the adrenal gland.

Congenital adrenal hyperplasia A disorder resulting from enzymatic defects in the pathway of cortisol synthesis.

CYP21A2 A gene encoding the steroidogenic enzyme 21-hydroxylase.

Gonadarche Initiation of function of the hypothalamic–pituitary–gonadal axis.

Premature pubarche Pubarche occurring prior to age 8 in girls and 9 in boys.

Definition

Premature adrenarche refers to the premature activation of the zona reticularis (ZR) of the adrenal gland, clinically manifested by pubic hair development.

Introduction

Although more than 60 years have passed since the endocrinologist F. Albright coined the term adrenarche, the mechanisms underlying the functional initiation of the reticular zone (ZR) of the adrenal gland have not yet been unraveled. While studying girls with gonadal dysgenesis, a natural experimental model of agonadism, Albright observed that pubic hair can develop under the influence of adrenal androgens and in the absence of gonadal hormones. He was thus the first to distinguish between gonadal and adrenal puberty (gonadarche and adrenarche, respectively). Subsequent studies of other clinical prototypes such as hypogonadotrophic hypogonadism, isolated premature thelarche and others confirmed Albright's observations. Dissociation between adrenal androgens and cortisol secretion has also been documented by demonstrating that a rise in dehydroepiandrosterone sulfate (DHEAS) during puberty is not accompanied by a rise in cortisol. Moreover, the rise in adrenocorticotropin hormone (ACTH) and cortisol in Cushing's syndrome occurs without an analogous increase of DHEAS (Parker Jr, 1999).

Adrenarche

Definition

Adrenarche refers to the activation of the ZR of the adrenal gland, biochemically marked by a rise in dehydroepiandrosterone (DHEA) and DHEAS but not in other androgens. The clinical manifestation of adrenarche has been assigned the eponym pubarche and is characterized by the development of pubic hair with or without axillary hair growth or apocrine odor. The decline in the function of the ZR, later in life, is termed adrenopause.

Phylogenetic Data on Adrenarche

Adrenarche and adrenopause appear to be phenomena unique to the highest order of primates and, therefore, represent a recent evolutionary development. The serum levels of DHEA, DHEAS and Δ_4–adrostenedione (Δ_4A) remain unchanged during sexual maturation in rats, hamsters, guinea pigs, sheep, pigs, goats, horses, and cows. Modest (twofold) changes of DHEA are observed in rabbits and dogs only after their sexual maturation. With regard to primates, the phenomenon of adrenarche is observed only in the chimpanzee but not in others (e.g., the rhesus monkey) (Ibanez *et al.*, 2000).

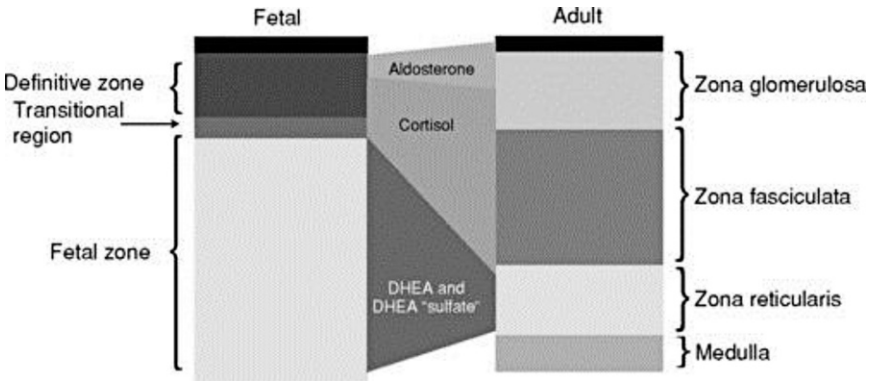

Fig. 1 The zones in fetal and adult adrenal gland.

Ontogenetic Data on Adrenarche

The adrenal gland originates from the mesodermal ridge at the fourth gestational week. Multiple transcription factors, acting at various developmental stages, direct the adrenogonadal primordium into the adrenal cortex, kidney and the bipotential gonad. The human fetal adrenal (HFA) consists of three zones; the centrally located inner zone, so called fetal zone (FZ), the outer definitive zone (DZ) and the transitional zone (TZ) lying between the FZ and DZ (Fig. 1).

During embryonic life the FZ secretes adrenal androgen precursors (AAPs) primarily DHEA and DHEAs which are used by the placenta to form estrogens. Specifically, fetal adrenal steroidogenesis begins at about 7–8 weeks post fertilization. The fetal adrenal expresses 3bHSD2 encoded by the HSD3B2 gene and produces cortisol at week 8–10. Nevertheless, HSD3B2 expression and consequently cortisol synthesis wane thereafter. Past week 12, the fetal zone is morphologically distinct, lacks 3bHSD2 but expresses CYP11A1, CYP17A1, CYB5 and the steroid sulfotransferase (SULT2A1). As a result of this enzymatic profile high levels of DHEA and DHEAS are present in the fetal circulation. The fetal adrenal also expresses 17bHSD5 which forms testosterone from androstenedione. As previously mentioned, DHEA and DHEAs are converted to estriol by the placenta.

Following birth and specifically during the first postnatal month, the FZ regresses by apoptosis and the levels of AAPs (DHEA and DHEAs) decrease and remain low until adrenarche. It seems that an important repressor function is exerted by SF1 stimulation and DAX1 during the physiological cessation of fetal adrenal and the resultant involution of the postnatal fetal cortex. It is of interest to mention that nature's spontaneously occurring knock-out paradigms (i.e., patients with specific mutations in which the fetal zone is not expected to function normally), indicate that fetal adrenal steroidogenesis may not be a sine qua non for fetal development and survival as well as for parturition. However "hidden" effects may exist, possibly important for other physiological functions.

Adrenarche could result from an increase in 17,20-lyase activity of P450c17, secondary to high levels of cytochrome *b*5 expression, in conjunction with low 3bHSD2 expression and an increase in the expression of SULT2A1 in the ZR. The steroid profile resulting from these enzymatic alterations leads to the production of adrenal androgens by the ZR. Additionally, P450 oxidoreductase (POR) serves as an obligatory electron donor for P450c17 and cytochrome *b*5 acting as an allosteric factor promoting the 17,20-lyase reaction (Bird, 2012).

Moreover, it has been shown that Kisspeptin, a protein with an important role in initiating secretion of GnRH at puberty, significantly increases DHEAS production from human fetal adrenal (HFA) cells during the second trimester of pregnancy. It has been established that the Kisspeptin receptor (KISS1R) is expressed in the adrenals (especially, in the FZ) starting from the 8th gestational week and up to term. It seems that Kisspeptin–KISS1R signaling plays an important role as a regulator of HFA development, steroidogenesis and the function of the feto-placental unit especially, during the second trimester of pregnancy (Katugampola *et al.*, 2017).

It must be underlined that the cortisol and androgen producing part of the adrenal and the adrenal medulla are related ontogenetically, anatomically, and functionally suggesting a possible link between adrenomedullary function and adrenarche (Ross and Louw, 2015).

Postnatal Development of the Reticular Zone

During the first postnatal months in humans the fetal zone regresses and almost disappears. At the age of 3 years, focal islands of the ZR are noted in the adrenals while a continuous ZR starts to develop at the age of 6, an age at which adrenal C19 steroids begin to rise. Adrenarche is initiated at about the age of 6 in girls and 7 in boys and this is reflected in a gradual rise of the adrenal androgens DHEA and DHEAS. The driving force of these evolutionary events has not been determined.

The serum levels of DHEA and DHEAS start to rise approximately 2 years prior to the gonadal activation (gonadarche) reaching their peak value at 20–25 years. Thereafter, the serum concentrations of the adrenal androgens gradually decline and in elderly people are 10%–20% of those encountered in young adults (adrenopause). The DHEAS reduction in the elderly is coupled with a decrease in the width of the ZR without an impact in the size of the rest of the adrenal cortex. The values of cortisol and aldosterone do not show analogous changes. This observation strongly indicates that the events described herein are unique to the ZR. Some of the mechanisms involved in these alterations of the ZR will be outlined herein. A histological study of adrenal samples from individuals, aged from 4 months to 56 years, showed a decrease in the enzymatic activity of 3β-HSD in the ZR, beginning at the age of 8–13 months with a further progressive decline up to the age of 25–26 years. Longitudinal clinical data obtained from subjects aged 2.9 to 12.3 years have demonstrated a progressive, age-related increase in the DHEAS values (about 22%/year) in parallel with an increased activity of 17,20 lyase and decreased activity of 3β-HSD (an enzymatic profile encountered in both the fetal and the adult reticular zones). These changes are already evident at the preadrenarcheal stage of development. It can thus be deduced from this study that adrenarche is not the result of a sudden change in the activity of adrenal enzymes, at a particular period of time; it rather reflects a gradual maturational process that begins in early childhood. When controlled for chronological age, no association was evident between weight, body mass index (BMI) and DHEAS (a marker of adrenarche). Nevertheless, changes in the nutritional status, measurable by changes in BMI, have been suggested as an important physiological regulator of adrenarche (Miller and Auchus, 2011).

Origin, Regulation, and Biological Significance of Adrenarche

Origin and regulation

The extra or intra adrenal factors involved in the development and function of the ZR, have not been fully elucidated. It has long been postulated that a distinct pituitary factor (Adrenal Androgen Stimulating Hormone, AASH), conducts the development and function of the ZR, but this factor has not been isolated.

Studies of natural human models have provided valid data with respect to the putative developmental and/or functional factors that influence the ZR. Among these we may mention the anencephalic fetuses, patients with congenital adrenal hypoplasia (ACTH receptor defect), combined pituitary hormone deficiency, hypogonadotropic hypogonadism, isolated premature thelarche and subjects with precocious gonadarche on gonadotropin releasing hormone analog (GnRHa) suppression (Palmert *et al.*, 2001). The study of adrenal androgens in these models suggests that DHEA and DHEAS synthesis and secretion are dependent upon an intact corticotropin releasing hormone (CRH)–ACTH axis, in the latter part of pregnancy as well as postnatal life. It is most probable that the CRH–ACTH complex exerts a permissive effect and acts in synergy with a putative extra-adrenal factor to successfully orchestrate the development and function of the ZR. Adrenarche could result from an increase in 17,20 lyase activity of P450c17 secondary to high levels of cytochrome b expression in conjunction with low 3bHSD2 expression and an increase of SULT2A1 in the ZR. The steroid profile resulting from these enzymatic alterations leads to the production of adrenal androgens by the ZR.

An interesting model in which low DHEAS levels have been detected, despite the normal ACTH-adrenal axis, is the pituitary insufficiency associated with Prop1 gene defects. The low DHEAS in these patients possibly indicate that the pituitary transcription factor Prop1 is necessary for the normal synthesis of the putative factor (AASH) that initiates adrenarche. Alternatively, the low DHEAS in patients with Prop1 gene defect could simply represent an early marker of incipient ACTH insufficiency, which is known to occur later in life in a number of these patients (Voutetakis *et al.*, 2001).

Besides CRH/ACTH and the putative AASH, other extra-adrenal factors have also been implicated in the development and function of the ZR: prolactin, estrogens, the epidermal growth factor, angiotensin, gonadotropins, pro-opiomelanocortin (POMC) related peptides, growth hormone (GH), and insulin growth factor 1 (IGF1), insulin, and possibly adipose tissue factors. None of these factors, however, have been conclusively shown to regulate androgen secretion by the adrenal gland (Voutilainen and Jääskeläinen, 2015).

Age-related alterations in the expression of the adrenal enzymes have also been proposed as a mechanism for the development and function of the ZR (intraadrenal factors). These changes not only refer to the relative activity of the adrenal enzymes but also to their responsiveness to ACTH. It must be stressed, however, that these biochemical changes alone cannot fully explain the initiation of adrenarche.

Biological significance of adrenarche

Since a human model of isolated absence of the ZR has not thus far been identified, the exact biological role of the ZR and the implications of its absence or insufficiency still remain enigmatic. A small, transient increase in growth rate occurring around the age of 7 years (mid-childhood spurt) has been attributed to the initiation of adrenarche. However, a cause–effect relationship between adrenarche and mid-childhood growth spurt has been disputed. It has also been shown that adrenarche is not a sine qua non for gonadarche since gonadal puberty proceeds normally in clinical entities in which adrenarche is absent.

The decline of DHEA coincides with signs of aging and has therefore been interpreted to indicate that aging is, at least in part, a DHEA deficiency syndrome. This observation has prompted studies on the effect of DHEAS replacement in the elderly and in young subjects with DHEAS deficiency of various etiologies, with equivocal results.

Premature Adrenarche–Pubarche

Definitions

Premature adrenarche (PA) and premature pubarche (PP) are frequently used interchangeably. Nevertheless, they are not synonymous. PA refers to premature activation of the ZR of the adrenals and is marked by levels of DHEA and DHEAS, which are high for the chronological age (CA) but appropriate for the stage of pubic hair development. PP is the term applied to characterize the clinical expression of PA, namely the appearance of pubic hair, usually at the labiae, with or without axillary hair growth or increased apocrine odor, in the absence of other secondary sexual characteristics, prior to age 8 in girls and 9 in boys. This age cut-off point has recently been questioned but is still accepted.

It has been shown that the prevalence of phenotypic expression of adrenarche is higher in girls than in boys whereas biochemical adrenarche is more frequent in boys than in girls (Mäntyselkä *et al.*, 2014). The risk of presenting clinical signs of adrenarche increases with higher body fat in boys and higher serum DHEAS in girls. This gender dimorphism of adrenarche might be attributed to sex-dependent differences in peripheral androgen metabolism or action that are modified by adiposity, knowing that AAPs (DHEA and DHEAS) are weak androgens and their peripheral metabolism is required for the efficient androgen receptor activation and clinical androgenic signs. Factors that have been suggested to mediate the effect of obesity in AAP synthesis include IGF1, insulin and leptin. Additionally, the conversion of AAPs to active androgens in adipose tissue may be enhanced by obesity (Williams *et al.*, 2015).

The term "exaggerated adrenarche" or amplified or pronounced has been coined to describe a form of PP in which DHEAS levels, basal or post ACTH stimulation, are above the range expected for the pubertal stage (Likitmaskul *et al.*, 1995).

Etiology of Premature Pubarche

The etiologic factors of the PA phenotype may act at multiple levels by (1) activating the maturation of AAP synthesis, (2) accelerating the peripheral conversion of AAPs to testosterone and DHT and (3) increasing the sensitivity of the androgen receptor.

Premature pubarche may be caused by: (1) premature activation of the ZR without any apparent pathological condition (idiopathic), (2) congenital adrenal hyperplasia (CAH), (3) virilizing adrenal or ovarian tumor, and (4) increased end organ sensitivity to androgens.

In idiopathic PP, increased BMI or a sudden rise in BMI may constitute a trigger factor for its induction. Nevertheless, BMI and leptin levels only partially explain the increased DHEAS values. The GH/IGF1 axis and especially hyperinsulinism, as a consequence of insulin resistance, have been implicated in androgen production by the ZR and generally in the mechanism of PP initiation.

The most frequent pathological condition underlying PP, and the one, usually creating diagnostic dilemmas, is the defective adrenal steroidogenesis and, in particular, nonclassical CAH (NC CAH). This aspect of PP has been quite controversial. Based on the determination of basal and ACTH stimulated adrenal androgen levels, defective steroidogenesis, indicative of the NC form of CAH (caused by 21-hydroxylase or 3βHSD deficiency) ranges from 0% to 54% in the various published series. These huge differences are probably due to the variety of criteria used for recruitment and evaluation of the subjects participating and, most importantly, due to lack of confirmation by molecular analysis (Witchel *et al.*, 1997). In one of our studies, 48 consecutive cases of PP were evaluated by molecular analysis of the CYP21 gene as well as by basal and ACTH stimulated 17OH progesterone (17OHP) values. A significantly increased incidence of mutations in the CYP21 gene was detected in the PP children in comparison to the general population (heterozygous 37.5% and homozygous 8.3%). The 17OHP values on the ACTH test showed an overlap between carriers and noncarriers. The application of the ROC curve in this study showed that the sum of basal plus 60 min value of 17OHP was the best indicator of heterozygosity. For children over a cut-off point of 5 ng/mL (15 nmol/L), there is a 76.5% certainty of heterozygosity for a CYP21 mutation (Dacou-Voutetakis and Dracopoulou, 1999). By using the nomogram proposed by New *et al.*, the heterozygote's values fell in the expected area, but this was also the case for the majority of normal values. A value of 17OHP 60 min post ACTH stimulation equal to or >10 ng/mL (30 nmol/L) was indicative of a homozygous mutation and occurred in 8.3% of the cases. The latter finding is accepted by most investigators. An increased incidence of CYP21 heterozygosity in either PP or functional hyperandrogenism in adolescents has also been reported by Witcell *et al.* and has been postulated by Knorr *et al.*, based on hormonal evaluation. Contrary to these findings, Potau *et al.* did not find higher incidence of CYP21 carriers in Spanish subjects with a history of PP. Based on current data, it is not possible to determine whether or not PP CYP21 heterozygote subjects have a higher probability of manifesting hyperandrogenism and the clinical syndrome related to this entity than PP girls who are not CYP21 carriers. Only long-term follow-up of such cases will provide a definitive answer to these important questions. Mutations in the 3βHSD gene have also been detected in girls with PP, though infrequently. The new hormonal criteria for the diagnosis of 3βHSD deficiency in children with PP are the following: (a) baseline 17OH pregnenolone (17P) and 17P/cortisol ratio >29 nmol/L and >103, respectively and (b) ACTH stimulated 17P and 17P/cortisol ratio >294 nmol/L and 363, respectively (Voutilainen and Jääskeläinen, 2015).

Inactivating mutations in the gene encoding 11β-hydroxysteroid dehydrogenase (CYP11B1) causing the NC form of CAH have been described in cases of premature pubarche. NC11OHD may be missed if standard steroid profiles are used (Reisch *et al.*, 2013). Moreover, apparent cortisone reductase deficiency due to inactivating mutations in the exose 6-phosphate dehydrogenase (H6PDH) gene may be the cause of ACTH-driven adrenal hyperandrogenism due to reduced peripheral conversion of cortisone to

cortisol (Lavery *et al.*, 2013) as well as apparent DHEA sulfotransferase deficiency. A rare genetic defect in adrenal androgen metabolism leading to PA is that of inactivating mutations in the PAPS53 gene encoding for a cofactor (PAPS synthase 2) which is needed for SULT2A1 enzymatic action. Hormonally this entity is characterized by high DHEA and low DHEAS levels.

Androgen producing tumors of the adrenals or ovaries are rarely a cause of PP, but they should be considered in the differential diagnosis, especially if pubarche is noted prior to the age of 3 years.

Finally, in some children with PP no androgen excess for either CA or pubertal stage is detected and the pubic hair growth is attributed to increased end organ sensitivity to androgens (Utriainen *et al.*, 2015).

Long-Term Consequences of Premature Adrenarche–Pubarche

Growth and pubertal development

Children with PP show, at presentation, an acceleration of linear growth and skeletal maturation. In some children, the difference between their bone age (BA) and CA (ΔBA-CA) can be up to 2 years, while in others the BA is comparable to CA. Long-term follow-up of children with PP has not shown impaired growth potentials: the final height (FH) attained being comparable to their target height (TH). It seems that the linear growth pattern in children with PP is modified in that height velocity in the period preceding PP diagnosis is higher than that of controls, peak height velocity occurs at an earlier age, and growth during puberty is compromised.

It has been reported that the combination of PA and obesity may be associated with significant advancement of bone age resulting in a final height less than the target height. Thus, despite reports indicating good FH prognosis, the physician must individualize the approach for each child with PP and closely watch patients with the so called "exaggerated adrenarche" and/or those who have BA advancement greater than 1 year, for the possibility of an unfavorable effect of PP on growth potentials, namely a predicted height below the TH. The age of gonadarche and menarche in children with PP is not different than in the general population (Gurnurkar *et al.*, 2014).

Functional Ovarian Hyperandrogenism (FOH) and Polycystic Ovarian Syndrome (PCOS)

In a percentage of girls with PP, functional ovarian hyperandrogenism (excessive response of androgens to GnRHa), along with an increased incidence of anovulation, hirsutism, and menstrual irregularities (characteristics of PCOS) have been reported to occur already in late adolescence. It seems that girls with an exaggerated response of 17OHP to ACTH at the time of PP diagnosis are more prone to develop FOH and/or PCOS. Raised values of AMH have been reported in girls with PA, possibly indicating advanced follicular development.

Insulin resistance, hyperinsulinism, and the metabolic syndrome

Acanthosis nigricans, decreased insulin sensitivity, and consequent hyperinsulinism and dyslipidemia have been found in a number of girls with PA. Pertinent data in boys are inconsistent. In certain studies, hyperinsulinemia is already evident at the prepubertal stage, possibly conferring a higher risk for later development of diabetes mellitus type 2 (DM 2). Contrary to the above findings, other investigators found no differences in glucose tolerance, insulin resistance indices or lipid values between PP and control girls, studied 5 years after menarche. It is quite possible that the stated differences reflect differences in the population (ethnic) groups studied and this must be seriously considered in the study and follow-up of PP girls. The contribution of intrauterine growth retardation (IUGR) to the occurrence of later adverse consequences, and especially FOH in girls with PP, is highly controversial, most authors not finding such an association (Williams *et al.*, 2015).

Does PA Represent a Pathologic Condition?

The question whether or not PP is a benign condition, simply reflecting premature activation of the ZR without long-term adverse consequences, cannot be convincingly answered at present. A number of girls with PP later present insulin resistance and hyperinsulinism, low sex hormone binding globulin (SHBG), FOH, increased hirsutism, acne or PCO like syndrome with possible later occurrence of DM 2 or the metabolic syndrome. Pertinent data in boys are not consistent (Livadas *et al.*, 2009).

At this point, no specific features at PP diagnosis have been identified to predict the child at risk for developing these pathological entities. Nevertheless, it seems that some of the late consequences are, to a large extent, restricted to certain population (ethnic) groups. Besides the ethnic group, other factors, such as obesity and a family history of DM 2, might contribute to the occurrence of adverse consequences. "Exaggerated adrenarche" as well as low SHBG (an index of insulin resistance and free androgen levels) and glucose/insulin ratio < 4.5 at the time of PP diagnosis, might confer a higher risk for the later development of FOH and/or the metabolic syndrome in children with PP (Paterson *et al.*, 2010).

Psychological implications of premature adrenarche

The impact of PA on brain function and psychology has not been adequately evaluated. However, recent reports indicate that early adrenarche associated with relatively high levels of DHEAS is associated with mental health and behavioral problems. The study of the effect of early adrenarche on affection brain function as well as on symptoms of psychopathology in late childhood has

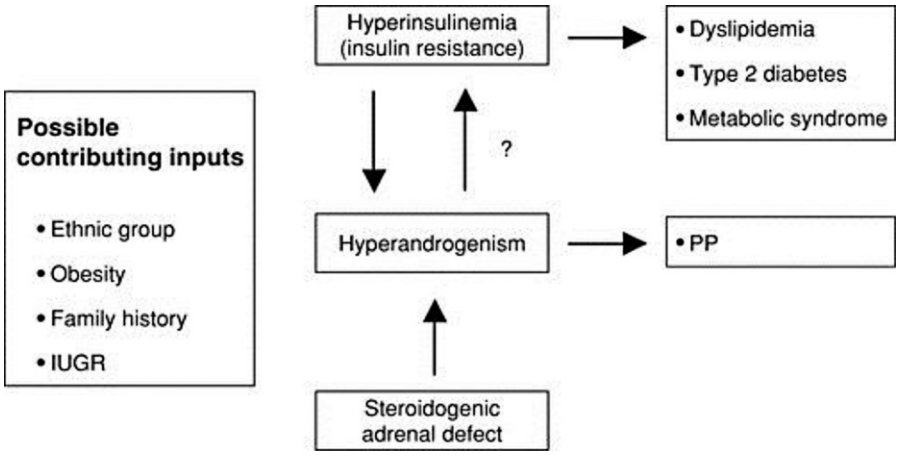

Fig. 2 Possible pathogenetic mechanisms of premature pubarche.

revealed that higher DHEA levels were associated with decreased activity of affect related brain in boys and girls. The investigators concluded that the timing of adrenarche constitutes an important moderator of affect related brain function (Whittle *et al.*, 2015). The same group using a whole-brain voxel-based morphometry analysis on MRI scans found reduced frontal white matter volume (WMV) in the left corona radiata in children with earlier adrenarche. They concluded that early adrenarche may be associated with differences in the development of frontal white matter tracks (Delany *et al.*, 2016).

Evaluation, Management, and Follow-Up of the Child With PP

Clinical evaluation

The clinical evaluation of a child with PP at presentation should include measurements of height, weight, waist circumference, BMI estimation, BA determination, and recording of relevant family history. Predicted height, TH and the stage of pubertal development should also be assessed. The presence of acne, hirsutism or virilization (clitoral enlargement) should be noted. If ΔBA-CA is less than 1 year and the predicted height falls within the height range expected from parental height (TH), the possibility of isolated premature activation of the ZR is quite high (**Fig. 2**).

Hormonal determinations

If basal values of 17OHP, $\Delta_4$androstenedione, testosterone, 11 deoxycortisol and DHEAS taken at 8 am, fall into the range expected for the pubertal stage, the diagnosis of idiopathic PP is fairly well confirmed. If basal adrenal androgen levels are higher than the levels for the corresponding pubertal stage and are accompanied by advanced BA (ΔBA-CA > 1), the main possibilities are: (a) exaggerated adrenarche, (b) defective adrenal steroidogenesis, or (c) virilizing tumor (adrenal or ovarian). In such cases an IV Synacthen test (ACTH) is carried out (250 μg or 150 μg/m^2 or 10 μg/m^2, the latter being infrequently used). Blood samples, primarily for 17OHP and 11 deoxycortisol determination, are obtained at 0 and 60 min. A 60 min value of 17OHP > 10 ng/mL strongly suggests a homozygous mutation of the CYP21 gene (NC form) and CYP21 gene analysis should be considered (**Fig. 3**). There is a 75% probability of existence of heterozygosity if the sum value of 0 and 60 min post Synacthen of 17OHP is > 5 ng/mL (15 nmol/L). Obviously, the latter information is of no immediate practical significance and may only be of value for genetic counseling. Determination of glucose/insulin value, SHBG, and ovarian sonography might constitute a good baseline record but should not be regarded as necessary diagnostic tools. It must be stated that an increased prevalence of sonographic findings of PCOS has been reported in girls with PP at the prepubertal stage, but the diagnostic and prognostic value of such a finding remains unclear. The dexamethasone suppression test or some form of imaging study is rarely indicated for the remote possibility of a virilizing tumor. This latter possibility is much higher if pubarche occurs very early (< 3 years of age) and there is an increased level of serum testosterone (Idkowiak *et al.*, 2011).

It must be underlined that steroid metabolome determination possibly constitutes a very good methodological approach in children with PA not only for the evaluation of the particular child but also for uncovering novel deficiencies in steroidogenesis (Rege and Rainey, 2012).

Management and follow-up

The therapeutic approach for children with PP will be determined by the pathogenetic mechanism involved and the clinical findings. In most cases however, drug intervention is not required. A follow-up of children with PP must be assured, especially during puberty and the immediate postpubertal years. In general, both the child and the parents should be notified of the good prognosis of most cases. Instructions concerning dietary habits and exercise should be given in cases with borderline or elevated BMI or positive family history of DM2.

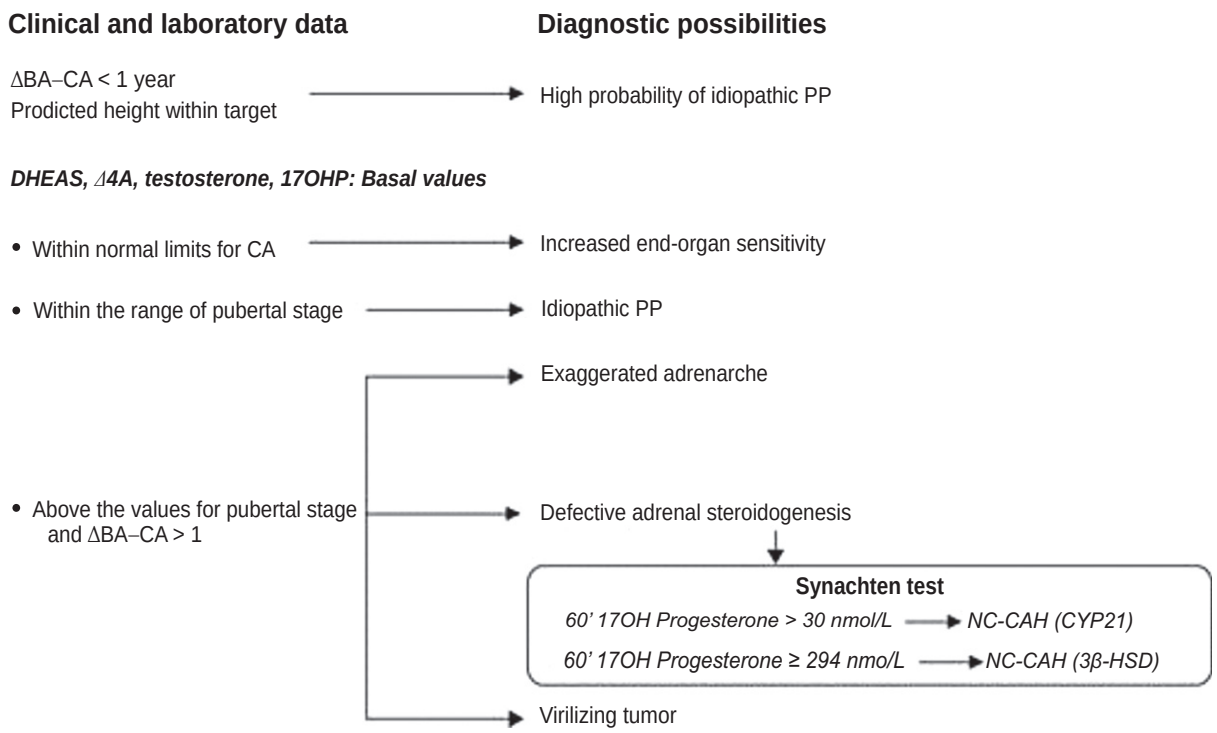

Fig. 3 Premature pubarche: diagnostic steps.

The physician should be aware of the possible long-term consequences of PP and should individualize the care and follow-up keeping in mind that PP, in certain cases, might not represent an innocent temporal deviation of sexual maturation but, possibly, an early manifestation of a complex metabolic abnormality. Fasting glucose/insulin ratio < 4.5, low SHBG values and/or exaggerated adrenarche might constitute early markers conferring an increased risk for later development of FOH, PCOS, DM 2 or the metabolic syndrome. However, it must be underlined that such recommendations are not strictly evidence based and they rather constitute extrapolation from still controversial published data. Moreover, data related to long-term consequences seem to apply to certain population (ethnic) groups. The physician in charge, being aware of the current trends concerning prognosis of PP, will determine the diagnostic studies necessary at presentation of the patient, as well as the frequency and duration of the follow-up visits.

The recent findings of an effect of PA in the neuro-psychological function should be taken into consideration and appropriate intervention must be included in the holistic management of the child, if indicated by the data of the patient under consideration.

21-Hydroxylase Deficiency: Clinical and Biochemical Aspects

Anna Nordenström and Svetlana Lajic, Karolinska Institute at Karolinska University Hospital, Stockholm, Sweden

Introduction

21-Hydroxylase deficiency is the most common form of congenital adrenal hyperplasia (CAH). It is caused by mutations in one of the enzymes, CYP21A2, involved in the synthesis of cortisol and aldosterone in the adrenal cortex. The cortisol deficiency, and subsequent loss of negative feedback, triggers increased release of CRH from the hypothalamus and ACTH from the pituitary gland. The enzymatic block results in increased levels of precursors, mainly 17-hydroxyprogesterone (17-OHP) that are shunted through alternative adrenal biosynthetic pathways and converted into adrenal androgens (El-Maouche *et al.*, 2017; Speiser and White, 2003; Merke and Bornstein, 2005) (**Fig. 1**). The androgen excess is present early on during fetal development and causes virilization of the external genitalia in fetuses with 46,XX karyotype to a varying degree (Merke and Bornstein, 2005; Parsa and New, 2017). There is a broad phenotypic variation, with a continuous spectrum of disease severity ranging from salt losing crises and risk of death in the neonatal period in the most severe forms to increased androgen production and infertility in adult age in the milder forms. Individuals, especially men, with the mildest forms may escape clinical diagnosis altogether (Parsa and New, 2017; Falhammar and Nordenstrom, 2015).

Genetics

The molecular genetics of *CYP21A2* has been studied extensively. The inheritance pattern is autosomal recessive. The gene is located on chromosome 6p21.2, in the HLA region, in tandem with a pseudogene *CYP21A2P*, which is 98% homologous with the active gene, but contains a number of inactivating mutations. This structural arrangement of the genes is the explanation for why a limited number of mutations are the most common ones all over the world. Microconversion and misalignment during meiosis and unequal crossing over can result in transfer of sequences from the pseudogene to the active *CYP21A2* gene or a deletion of the active gene. As a result, 10 pseudogene derived mutations and deletions constitutes more than 90% of all mutated alleles with some frequency variations in different populations (Wedell *et al.*, 1992; Wedell, 2011); (Krone and Arlt, 2009; Speiser *et al.*, 1992a; Krone *et al.*, 2013). In the remaining 5%–10% more than 200 rare mutations have been identified (Human Gene Mutation Database, HMG, www.hgmd.cf.ac.uk, and Human Cytochrome P450 (CYP) Allele Nomenclature Committee, http://www.cypalleles.ki.se/vyp21.htm). The limited number of mutations involved has made genotype–phenotype correlations possible. The clinical severity can be predicted from the *CYP21A2* genotype, where the mildest allele determines the severity (genotype group), with very few exceptions (**Fig. 1**). This is useful in the clinical situation, for predicting the clinical symptoms and making treatment decisions (Krone *et al.*, 2013; New *et al.*, 2013; Wedell, 2011).

Historically 21-hydroxylase deficiency has been divided into two classical and more severe forms of CAH (salt-wasting, SW, and simple virilizing, SV CAH) and a nonclassical form with no risk of salt crisis. The most severe form, the null genotype

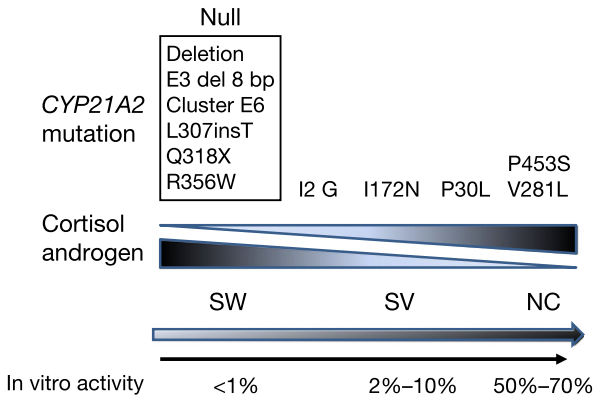

Fig. 1 The *CYP21A2* genotype groups in relation to the enzyme in vitro activity, cortisol, and androgen synthesis, and clinical phenotype are shown. The clinical phenotype can be predicted from the *CYP21A2* genotype, where the mildest allele determines the severity. The null genotype group has completely abolished enzyme activity, the lowest cortisol production and most prenatally elevated androgens.

 doi:10.1016/B978-0-12-801238-3.65208-X

group, which is homozygous for mutations completely abolishing the enzyme activity and the genotype group with the I2G mutation, with less than 1% residual in vitro activity, typically present with the salt-wasting form, SW CAH. The I2G mutation shows however a variation in clinical symptoms with some patients presenting with a considerably less severe phenotype with no salt crises (Gidlof *et al.*, 2013; New *et al.*, 2013). The I172N and P30L mutations have higher residual activities and form the SV genotype group with prenatal virilization in females and about 10% risk of developing salt crisis in particularly stressful situations (Wedell, 2011; Krone and Arlt, 2009). The common nonclassical mutations, V281L, and P453S, typically lead to signs of androgen excess over time and no risk of salt loss.

About 70% of the diagnosed patients have been reported to have the classical form of the disease with a worldwide incidence ranging between 1/10,000 and 1/20,000 in most populations. The nonclassical, late-onset form has been reported to have an incidence of as high as 1/1000 in some populations (New *et al.*, 2013; Speiser *et al.*, 1992b, 2010; Witchel, 2017).

Steroid Synthesis

Cortisol and aldosterone synthesis requires 21-hydroxylase activity. In 21-hydroxylase deficiency the metabolite before the block, 17-hydroxyprogesterone (17-OHP), is markedly elevated and is used as an indicator of the disorder (**Fig. 2**). The increased levels of DHEA and androstenedione result in increased testosterone and dihydrotestosterone production. In addition, the 17-OHP can be converted to dihydrotestosterone (DHT), through an alternative route, the so-called back door pathway (**Fig. 1**), not via androstenedione and testosterone. DHT is a more potent androgen than testosterone and is required for the masculinization of external genitalia (Miller and Auchus, 2011; Turcu and Auchus, 2015a).

Aldosterone is normally present in the circulation in concentrations of about 1% of that of cortisol. Clinically relevant aldosterone deficiency is therefore only seen in severe CYP21A2 deficiency.

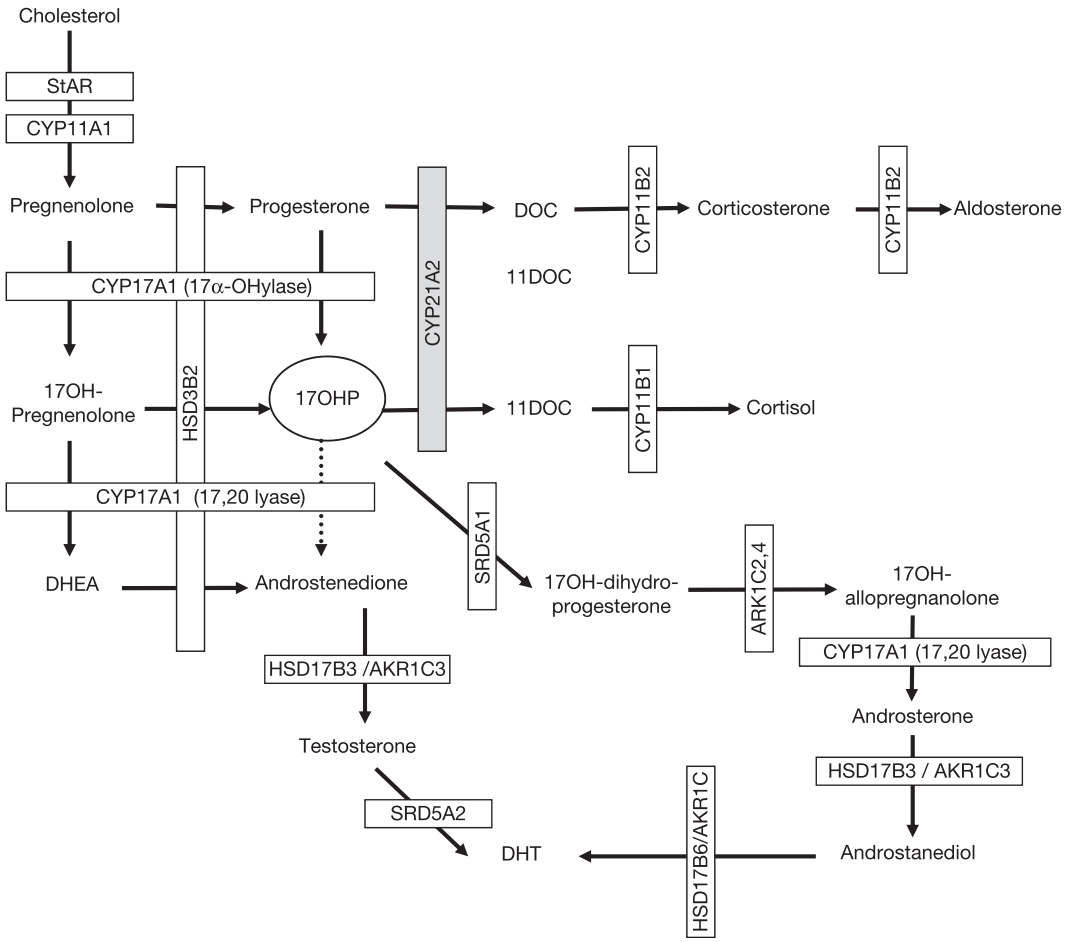

Fig. 2 The major steroid synthesis pathways are shown, including the back-door pathway leading to synthesis of DHT via androsterone. Not all intermediate steps are depicted.

Clinical Signs and Symptoms

Undiagnosed patients of both sexes with the salt losing form of CAH, will develop symptoms of failure to thrive, poor weight gain, and vomiting in the neonatal period (Speiser and White, 2003; Speiser *et al.*, 2010; Auchus *et al.*, 2010; Witchel, 2017; Merke and Bornstein, 2005). The aldosterone deficiency causes hyponatremia, hyperkalemia, acidosis and the concomitant development of circulatory collapse, hypotension, and shock. The adrenal crisis, which untreated will be lethal, typically occurs during the second or third week of life (Hindmarsh, 2009).

The excess production of androgens starts already early on during fetal life (Hindmarsh, 2009) and causes varying degrees of virilization of the external genitalia in fetuses with 46,XX karyotype and classical forms of CAH. The enlargement of the clitoris, fusion of the labia majora and formation of a urogenital sinus result in ambiguous genitalia and uncertainty of sex assignment at birth. The degree of virilization is classified according to the Prader score, (**Fig. 3**) (Prader and Gurtner, 1955). The posterior fusion of the labia majora is related to the degree of prenatal androgen exposure. It has been suggested that measurements of the anogenital distance, that is, to the scrotum or la fourchette, can be used to estimate prenatal androgen exposure, which may prove to be especially useful in unclear cases (Callegari *et al.*, 1987; Priskorn *et al.*, 2017). The increase in DHT from androsterone, via the back door pathway (**Fig. 2**), plays an important role in the prenatal virilization of the external genitalia (Kamrath *et al.*, 2012a,b) and may explain the potent androgen effects seen in *CYP21A2* deficiency. Among patients with SV CAH and the same genotype there is considerable variation in the degree of virilization ranging from uncertainty of sex assignment at birth to not being noted at birth. This variability might be explained by other modulating factors (Krone and Arlt, 2009). The results regarding differences in androgen receptor sensitivity due to variations in the length of the CAG repeat are however, conflicting (Rocha *et al.*, 2008; Welzel *et al.*, 2010).

In newborn boys the diagnosis is far more difficult since the clinical signs may not be obvious before the development of the adrenal crisis, although affected males may have increased pigmentation of the genitalia and a larger phallus (Hindmarsh, 2009). The diagnosis has to be suspected from the combination of the unspecific clinical signs of poor weight gain in the neonatal period and sodium loss preceded by increased potassium (Thil'en *et al.*, 1998).

During childhood, severe infections and stressful events may trigger an overt cortisol deficiency in undiagnosed patients with SV and NC forms of the disease. However, they typically come to diagnosis when they develop signs of excess androgen production such as acne, pseudo pubertas praecox with apocrine body odor, axillary and pubic hair, and growth acceleration (Witchel and Azziz, 2011). A thorough clinical evaluation will show advanced skeletal maturation, no signs of central puberty, low gonadotropins and no increase in testicular size in boys. In girls clitoral enlargement can be seen (Witchel and Azziz, 2011). Patients with late-onset, nonclassical CAH come to diagnosis later during childhood or adolescence or even as adults (Turcu and Auchus, 2015a; Witchel, 2017; Hindmarsh, 2009). In adolescents and adults, typical symptoms may be acne, hirsutism, oligomenorrhea or infertility. In studies on children with premature adrenarche 4%–25% were diagnosed with CAH (Armengaud *et al.*, 2009; Skordis *et al.*, 2015). On the other hand, regarding the reverse clinical question of how likely it is that a person with NC CAH would be diagnosed due to androgen excess, studies have shown that in 92% of the children diagnosed before age 10 and 8% in the age group 10–19 years this was their presenting symptom (Moran *et al.*, 2000; Carmina *et al.*, 2017) (**Table 1**).

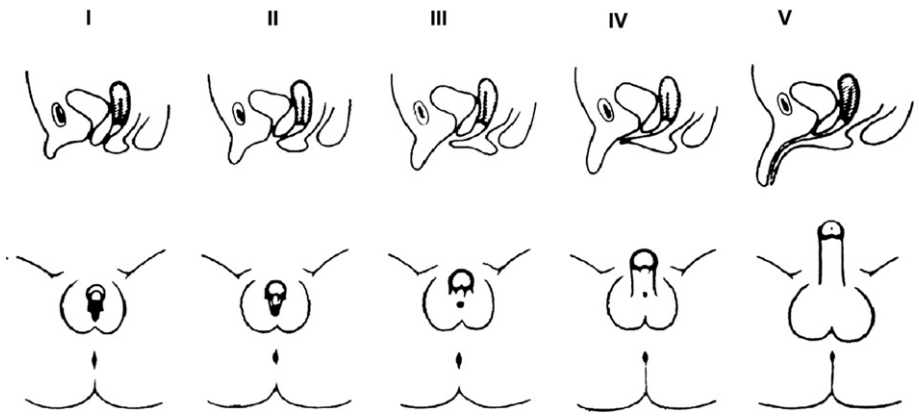

Fig. 3 The Prader scoring, showing the degree of virilization on a five point scale, from mild clitoral enlargement, 1, to clitoromegaly with the urethral opening at the tip of the glans and high confluence between the urethra and vagina, 5. Modified from Prader, A. and Gurtner, H. P. (1955). The syndrome of male pseudohermaphrodism in congenital adrenocortical hyperplasia without overproduction of androgens (adrenal male pseudohermaphrodism). *Helvetica Paediatrica Acta* **10**, 397–412.

Table 1 Schematic description of the clinical presentation in different forms of 21-hydroxylase deficiency, according to age at presentation

Age at presentation	*SW CAH*	*SV CAH*	*Nonclassic CAH*
Neonatal period	Ambiguous genitalia (F) Failure to thrive, salt loss Hypoglycemia	Ambiguous genitalia (F)	–
Early childhood, <5 years of age	–	Apocrine body odor, axillary and pubic hair Increased growth Enlarged clitoris (F)	–
School age	–	Axillary and pubic hair Increased growth Enlarged clitoris (F) Enlarged penis (M) Pseudopubertas precox (M)	Acne, increased growth
Adolescence	–	TART (M)	Delayed menarche, irregular menses, acne, hirsutism Clitoral enlargement (F)
Adult		Androgen symptoms Infertility, TART, (M)	Acne, hirsutism, irregular menses, infertility (F), infertility (TART), (M)

F, Female; M, male; TART, testicular adrenal rest tumor.

Diagnosis: Laboratory and Clinical Investigations

Ambiguous genitalia and the absence of palpable testis should alert the physician to perform further investigations (Speiser *et al.*, 2010; Hindmarsh, 2009). Elevated 17-OHP, 46,XX karyotype and the presence of a uterus or even hyperplastic adrenals on ultrasound gives the diagnosis of 21-hydroxylase deficiency.

In addition to an increase in serum 17-OHP, the marker of the disorder, androstenedione and testosterone are typically elevated. In SW CAH the plasma renin is increased. Urinary pregnanetriol, the metabolite of 17-OHP, in 24 h profile, or spot urine is elevated (Kamrath *et al.*, 2016; Miller and Auchus, 2011).

The serum 17-OHP level reflects the severity of enzyme deficiency. Individuals with morning values of 17-OHP above the reference range should be investigated further. A Synachten/cosyntropin stimulation test results in elevated levels of 17-OHP and subnormal cortisol in patients and heterozygous carriers of CYP21A2 mutations (Turcu and Auchus, 2015a; Parsa and New, 2017). Patients with classic CAH typically have stimulated levels above 300 nmol L^{-1} (10000 ng dL^{-1}) while those with nonclassic CAH have morning values above the reference range that do not increase above 300 nmol L^{-1} (Turcu and Auchus, 2015a). The diagnosis can be confirmed by *CYP21A2* mutations analysis, which also enables prediction of disease severity and guidance in clinical treatment decisions.

Neonatal Screening

Neonatal screening for CAH is aimed at avoiding salt losing crises and neonatal death, most often seen in the boys. In addition, a secondary outcome is that the screening improves growth and development in children with milder forms of CAH by enabling early detection and treatment to prevent the symptoms of androgen excess during childhood (White, 2009; Gidlof *et al.*, 2014).

Screening was first started in the 1970s (Pang *et al.*, 1977) when it was shown to increase the noted prevalence among the Yupik Eskimos from 1/490 to 1/280. National and regional programs are now performed in more than 30 countries all over the world including many countries in Europe, and screening is mandatory in all states in the United States (White, 2013). Measurements of 17-OHP on filter paper cards using DELFIA (dissociation enhanced lanthanide fluorescence immunoassay) is used (White, 2009). Despite the use of birth weight or, more effective, gestational age related cut-off levels (Gidlof *et al.*, 2014; van der Kamp *et al.*, 2005) the false positive rate has been relatively high compared to other types of screening programs (White, 2013; Gidlof *et al.*, 2014). The recall rate is especially high among preterm infants, due to immature adrenal steroid production and varies between 1.2% and 0.02% (Gidlof *et al.*, 2014; Coulm *et al.*, 2012).

The cut-off level for17-OHP differs in the different screening programs and has to be adjusted depending on the day the sample is taken since 17-OHP increases just after birth and decreases during the first week of life. In patients with CAH the 17-OHP level increases over time and is related to the severity of CAH (Nordenstrom *et al.*, 1999). On the other hand, the sample has to be taken early enough for the result to be ready before the child develops a salt crisis. Severely ill and stressed infants have more elevated 17-OHP levels, which contribute to a relatively high false positive rate (Torresani and Biason-Lauber, 2007; Sarafoglou *et al.*, 2014; Hayashi *et al.*, 2017). The detection rate for SW CAH is high but efficiency of the screening programs varies from 100% to less than 70% detection of SW CAH (Sarafoglou *et al.*, 2012; Gidlof *et al.*, 2014; Coulm *et al.*, 2012).

A second tier analysis using the ratio of 17-OHP androstenedione and cortisol determined by tandem mass spectrometry has been used but has not proved to be as useful as expected, since 1/3 of the infants with SW CAH were missed (Sarafoglou *et al.*, 2012). In the future, genetic testing may be applied as a second tier procedure in some screening programs (White, 2013; Sarafoglou *et al.*, 2014).

In order for the screening to be effective, a good follow-up is important, and should include a confirmatory sample and immediate start of treatment if markedly elevated 17-OHP or if the child has clinical signs such as failure to thrive or virilization of the external genitalia. In equivocal cases a Synachten/cosyntropin stimulation test or genetic investigations must be performed to confirm the diagnosis.

It should be understood, that the aim of the screening programs is to detect infants at risk of salt crisis and neonatal death, and in order not to increase the false positive rate the cut-off level is set in such a way that the individuals at risk are detected but the milder forms, mainly nonclassic CAH, are not detected (Gidlof *et al.*, 2013, 2014; White, 2009). This implies that pediatricians have to identify children and adolescents with symptoms of androgen excess clinically.

Hormonal Treatment

The treatment is, in theory, straightforward. The glucocorticoid and mineralocorticoid deficiencies are replaced and the hormonal balance is restored. In practice, this has turned out to be considerably more complicated. The treatment goals are to obtain linear growth, normal bone maturation, and timing of puberty, good self-esteem and a good quality of life.

In children, hydrocortisone is the first choice of treatment since prednisolone and dexamethasone have more negative effects on growth and possibly weight (Punthakee *et al.*, 2003). A normal cortisol production rate has been reported to be 7–8 mg m^{-2} and day (Hindmarsh, 2009). However, treatment requires a higher dosing especially in CAH since one of the aims is to decrease the production of metabolites before the block. That is, 17-OHP and other androgenic compounds. The total hydrocortisone dose varies between 7 and 15 mg m^{-2} and day and usually given three or four times per day. Not only the total dose but also how it is divided over the day is of importance. Most clinicians seem to agree today that mimicking the circadian rhythm by giving the highest dose in the morning is preferred to giving the highest dose in the evening. The dose has to be individualized since there are individual variations in uptake and half-life of hydrocortisone (Hindmarsh and Charmandari, 2015; Miller and Auchus, 2011). Impaired ability to reactivate cortisone to cortisol (via 11betaHSD type 1), results in requirement for more frequent dosing in addition to a higher total dose (Nordenstrom *et al.*, 1999).

The treatment strategies differ depending on the child's age. The first year of life and the puberty seem to be vulnerable periods with regard to growth and growth potential. Specific issues of importance to consider for the different developmental periods are discussed below.

The Neonatal Period and First Year of Life

Hydrocortisone treatment is initiated at diagnosis. The dose should be sufficient for replacement, but 17-OHP during the first year of life should be allowed to be elevated. During the first month, a dose of 1 mg given three times per day is often sufficient. A doubled or even higher dose may be required during the first week in order to effectively suppress the adrenal hyperplasia and over activity (Speiser *et al.*, 2010).

Fludrocortisone in a dose of 100–150 μg/ m^{-2} or day or even higher doses may be required during the first months of life (Hindmarsh, 2009). In the small children, the fact that fludrocortisone has a glucocorticoid effect equal to about 1–1.5 mg of hydrocortisone should be taken into account. In addition to the fludrocortisone treatment, extra salt (sodium chloride) is important during the first year of life. The normal sodium requirement in a small child is 1 mmol kg^{-1} per day, but since children with CAH have an increased natriuresis 2–3 mmol kg^{-1} per day may be necessary to prevent deficit, and 2 mmol kg^{-1} per day (1–2 g day^{-1}) is recommended in SW CAH (Mullis *et al.*, 1990; Speiser *et al.*, 2010).

It is known that sodium is important for normal growth (Kuhnle *et al.*, 1983). Studies comparing patients with and without salt supplementation during the first year showed that the group that received sodium chloride during the first year of life achieved a higher final height, also when corrected for the target height (van der Kamp *et al.*, 2002).

Childhood

The hydrocortisone dose required for replacement is usually between 8 and 12 mg/m^2 per day in order to achieve adequate suppression of the pituitary ACTH production and maintain a normal growth rate. Undertreatment and advanced bone age during the prepubertal period results in attenuated height gain during the pubertal spurt (van der Kamp *et al.*, 2002; Balsamo *et al.*, 2003). As the child gets older physical activity including sports activities can vary considerably between days and weeks. Extra dosing can be required during excessive activities such as sports camps but not for normal training. In general, extra doses are not recommended for psychologically stressful events although in rare individual cases this may be needed before special occasions such as traveling or on the child's birthday.

Table 2 Rules of thumb for stress dosing with hydrocortisone

Oral stress dosing
Fever above 38°C—double hydrocortisone dose
Fever above 39°C—triple hydrocortisone dose
Fludrocortisone should be kept unchanged
If injection of hydrocortisone is given, the child should be taken to the hospital emergency department
If injection of hydrocortisone is given fludrocortisone should not be given since it will only increase the risk of hypertension

The fludrocortisone dose after 2 years of age is usually 100 μg/ m^2 in SW CAH and in adults rarely over 100 μg per day (Hindmarsh, 2009). After the first year of life salt is given ad libidum. Also in SV CAH a small dose of mineralocorticoid replacement is beneficial and allows for a lower total hydrocortisone dose (Witchel, 2017).

Adolescence

The treatment of teenagers/adolescents can be challenging in many ways (Merke and Poppas, 2013). Compliance and timing of the dosing, especially in the morning may by particularly difficult. However, it is important to be aware that the doses often need to be increased considerably.

The pharmacokinetics of cortisol is influenced by hormonal changes during puberty that necessitate increases in the hydrocortisone doses. During the pubertal development sex hormone production is increased as well as growth hormone production and IGF-1. The enzyme 11beta-hydroxysteroid dehydrogenase type 1 (HSD11B1) that reactivates cortisone to cortisol becomes less active, due to inhibition by the increased IGF-1 levels (Charmandari *et al.*, 2001). The increased cortisol clearance is more marked in females (Charmandari *et al.*, 2004). Hence the need for higher doses of hydrocortisone, in spite of good compliance, may thus be needed during the pubertal years. In young girls long standing androgen excess during puberty may not only result in increased hirsutism but also in a lowered timbre of the voice which is irreversible and can be experienced as a problem in everyday life (Nygren *et al.*, 2013).

It is, of course, important to keep the everyday doses as low as possible and allow some increase in 17-OHP during puberty in order to normalize growth but all aspects of development must be considered. Doses above 17 mg/m^2 should be avoided since this has been shown to affect the growth negatively (Bonfig *et al.*, 2009; Jaaskelainen and Voutilainen, 1997).

Monitoring

The child should be seen for regular check-ups every 3–6 months, from the second year onwards and more often during the first year and during puberty.

There is no single parameter that can be used alone for monitoring treatment in CAH. Height and weight development are the most important clinical parameters. Also small changes in height velocity should be considered in treatment decisions, and dosing. In preschool children, oily skin and acne are important signs of increased androgen production. Bone age is frequently used but it is more a reflection of the situation in the past and it is not informative to perform bone age evaluations more often than once a year.

Serum 17-OHP, androstenedione, and testosterone are often analyzed but it is not clear what levels should be obtained for adequate hormonal control (Kamrath *et al.*, 2017). Measurements of pregnanetriol in 24 h urine samples have been widely used. It has recently been shown that 11-oxygenated metabolites of adrenal androgens, mainly 11β-hydroxyandrosterone, was the dominating urinary adrenal androgen in treated patients with CAH (Kamrath *et al.*, 2017). Similarly, using liquid chromatography tandem mass spectrometry 11oxygentated metabolites were shown to be markedly elevated also in serum in patients with CAH, and may even be the more clinically relevant adrenal androgen. 11keto-testosterone is a potent androgen. Urine is difficult to collect in newborns and small children, serum samples are therefore often preferred.

During the past decade, it has become increasingly common to use 24 h 17-OHP profiles either performed with patient admitted to the hospital or on filter paper samples collected by the patients in the home (Schwartz, 1999; Bode *et al.*, 1999; Wieacker *et al.*, 2015). The circadian rhythm of the 17-OHP follows the ACTH production and the 17-OHP profile gives an indication of the hormonal situation over the day and guidance as to which dose should be changed. The optimal 17-OHP levels for patients at different ages and sex still need to be determined but completely suppressed 17-OHP levels indicate overtreatment.

The mineralocorticoid effect is followed with measurements of renin with the goal to maintain the plasma renin in or just above the normal range (Witchel, 2017; Hindmarsh, 2009). The blood pressure should be measured at every clinic visit.

Table 3 Stress dosing with injections of im or iv hydrocortisone

Weight (kg)	*Hydrocortisone (mg)*	*Injection*
Below15	25	iv or im
15–25	50	iv or im
25–50	75	iv or im
Above 50	100	iv or im

Stress Dosing

It is important to keep the everyday dose low to avoid side effects in the long-term perspective, but during acute illness or significant physical stress it is important that the dose is sufficiently increased (Hindmarsh, 2009). The hydrocortisone dose should be at least doubled if the patient has a fever above 38°C and tripled if it is above 39°C (**Table 2**). It is important to spread the dose more evenly over the 24 h especially when the everyday dose is considerably higher in the morning. In case of vomiting, intravenous or intramuscular injections of Solu–Cortef should be given. Admission to hospital and treatment with intravenous glucose and sodium chloride may be required.

It is imperative, that all parents and patients have appropriate information about stress dosing, both oral and for intramuscular injections, and the situations in which the different stress dosing should be given (**Table 3**). If intramuscular hydrocortisone is given the patient should be taken to the emergency department (Hindmarsh, 2009). Those who had received written information and instructions on how to give hydrocortisone intramuscularly had a higher level of self-efficacy (Fleming *et al.*, 2011).

The patient should have an emergency kit with a supply of injectable hydrocortisone and carry medical information as well as information on dosing and an ID card (Speiser *et al.*, 2010). However, one study showed that 40% of patients in an American survey did not follow these instructions (Fleming *et al.*, 2011). This is especially concerning in the light of the high mortality rate also in diagnosed patients. The mortality is increased for CAH with a hazard ratio of 3.2, and of 2.6 if the children under 1 year of age were excluded (Falhammar *et al.*, 2014). In a study in the United Kingdom the all-cause mortality was 3 times that expected, while it was 18 times higher in children under 4 years of age (Swerdlow *et al.*, 1998).

In preparations for surgery an i.v. acute dose of hydrocortisone (see **Table 2**) should be given 1 h before the start of the procedure, followed by an i.v. infusion of 2–3 mg m^{-2} per hour during the operation, or the same total dose but given every 4 h. Hydrocortisone (Solu–Cortef) can be diluted in 50–1000 mL Glucose 50 mg mL^{-1} with 80 mmol Na/1000 mL. During the days following the operation the dose should be tapered off; day two 40 mg m^{-2}, day three 30 mg m^{-2}, or faster after smaller procedures.

Hypoglycemia and Adrenal Crisis

In addition to the cortisol synthesis the epinephrine production is compromised in patients with CAH, resulting in an increased risk of salt crises and hypoglycemia.

This was demonstrated in a follow up of 102 children, below 6 years of age, 28 had been hospitalized, 22 with salt-losing crises, 25 with hypoglycemia (7 with both), and 13 children developed seizures during these events (Odenwald *et al.*, 2016). Adrenal crisis typically occurs during acute illness with inappropriate emergency treatment. Hypoglycemia is most often seen during infections but also when the glucocorticoid dose is tapered too quickly after a longer period of illness with high fever or vomiting but it may occur unexpectedly, often in the morning (Odenwald *et al.*, 2016). The epinephrine and metanephrine production has been shown to be compromised (Merke *et al.*, 2000a) and the degree of deficiency is related to the severity of the CYP21A2 deficiency (Charmandari *et al.*, 2002). This not only increases the risk of developing hypoglycemia but also attenuates the symptoms that we are using as signs of hypoglycemia, such as paleness and tremor. Hypoglycemic episodes are therefore likely to be more common than they were previously thought to be (Keil *et al.*, 2010). The families should be informed early on, in order for the preventive measures and treatment to be given in time. In addition to stress dosing with hydrocortisone an adequate intake of carbohydrates should be given, this seems to be especially important in the younger children (Keil *et al.*, 2010; Odenwald *et al.*, 2016; Kim *et al.*, 2014).

Development of Novel Therapies

Today treatment considerations have focused on more frequent dosing optimization and individualization of therapy (Webb and Krone, 2015). Slow release preparations with different profiles have been and are under development (Turcu and Auchus, 2015b; Mallappa *et al.*, 2015). In children for whom it is particularly difficult to obtain hormonal control the possibility of using an infusion pump, has been tested successfully (Hindmarsh, 2014). Flutamide (an antiandrogen) in combination with testolactone (an aromatase inhibitor) has been tried (Merke *et al.*, 2000b), and a more experimental treatment with

Abiraterone (a CYP17A1 inhibitor) has been tried in adult women (Auchus *et al.*, 2014). Growth hormone in combination with a gonadotrophin analog has been reported to have positive effect in some cases (Lin-Su *et al.*, 2011). Routine use of such experimental therapies to promote growth and delay puberty is however not generally recommended by the Endocrine Society guidelines (Speiser *et al.*, 2010).

Growth

Birth weight has been reported to be higher in CAH, However, the gestational age of a child with CAH is related to the severity of CAH, that is, the SW form results in longer gestation and BW corrected for gestational age was not increased in CAH (Gidlof *et al.*, 2007; Miles *et al.*, 2010). Hence, this speaks against the idea that prenatal growth would be influenced by androgens. In line with this is the observation that neither the growth velocity, nor the bone age was affected in children 1 year of age or younger with elevated 17-OHP levels and increased androgen production (Bonfig *et al.*, 2011). Similarly, retrospective studies on children with late diagnosed forms of the disease showed that the growth acceleration did not start until after the children were older than 1.5 years of age (Thilen *et al.*, 1995; Bonfig *et al.*, 2011). These findings have prompted the clinical practice to allow for more elevated 17-OHP in this age group in order not to compromise growth. If the hydrocortisone dose is increased to normalize the laboratory parameters the growth is suppressed. It is however important that the dose is sufficient to avoid hypoglycemia and to promote general well-being.

Throughout childhood and adolescence treatment has been proven to be a difficult balance between under- and over-treatment. Many studies on growth in CAH include heterogeneous cohorts including both early and late diagnosed patients which makes predictions in neonatally screened populations more difficult. Metaanalyses have shown that patients with CAH as a group lose about 1.4 SDS in final height, and -1 SDS in final height corrected for target height (Eugster *et al.*, 2001; Muthusamy *et al.*, 2010). There are differences between studies and countries but the height outcome was not significantly associated with gender, age at diagnoses, age at puberty, type and dose of glucocorticoid used. Patients with mineralocorticoid supplementation had a significantly better outcome in the more recent metaanalysis (Muthusamy *et al.*, 2010).

Undertreatment during childhood associated with an advanced bone age will result in an attenuated height gain during the pubertal growth spurt (van der Kamp *et al.*, 2002; Bretones *et al.*, 2016; Bonfig, 2017). It should be noted that final height predictions using bone age are difficult in CAH (Balsamo *et al.*, 2003; Bonfig and Schwarz, 2012). Mineralocorticoid treatment and sufficient salt supplementation are important for growth in all classic forms (Kuhnle *et al.*, 1983; van der Kamp *et al.*, 2002; Balsamo *et al.*, 2003; Bonfig, 2017). Moreover, in patients with SV CAH a low dose of fludrocortisone facilitates limiting the glucocorticoid dose (Witchel, 2017). Patients with an early diagnosis had a better final height (Balsamo *et al.*, 2003).

In conclusion, growth during the first year of life and pubertal growth seem to be most vulnerable (Speiser, 2010). It is important to keep the everyday doses as low as possible and allow some increase in 17-OHP during the first year of life and during puberty in order to optimize growth. Hydrocortisone doses above 17 mg m^{-2} or prednisolone should be avoided (Bonfig *et al.*, 2009; Jaaskelainen and Voutilainen, 1997; Punthakee *et al.*, 2003). In the future, it is likely that early diagnosis through screening and more individualized and lower doses of hydrocortisone in combination with the use of fludrocortisone in all patients with classical forms will improve the growth and final height in individuals with CAH.

Weight

High doses of glucocorticoid induce weight gain. As a group, patients with CAH have a slightly higher BMI than the reference population (Volkl *et al.*, 2006a). However, there are considerable individual variations. The risk of developing obesity was reported not to be related to the glucocorticoid dose per se, but was related to familial predisposition (Moreira *et al.*, 2013). The relative risk of developing obesity was increased more than four times if one of the parents had a BMI over 30 (Volkl *et al.*, 2006a). Obesity increases the insulin resistance and results in increased levels of insulin that will stimulate androgen synthesis in both the adrenals and ovaries (Charmandari *et al.*, 2004). In addition, increased insulin lowers the levels of SHBG and potentiate the androgen effects. Overweight in patients with CAH is therefore difficult to treat. Clinicians should be aware of this and take preventive measures when indicated.

Pubertal Development

Untreated patients with SV or NC CAH may enter puberty earlier than average in the general population, in which case this also affects final height, and result in short stature. Also treated patients have been reported to have an earlier start of puberty and often an attenuated growth spurt (Balsamo *et al.*, 2003; van der Kamp *et al.*, 2002; Hargitai *et al.*, 2001; Bretones *et al.*, 2016; Bonfig, 2017). In a study of 92 children (57 F, 35 M) the mean age at menarche (13.5 $\pm$ 1.6) did not differ from that of the reference population while an earlier increase in testicular volume was seen in boys with SV CAH (9.6 + 2.5) and SW (11.0 + 1.3 years) (Bonfig *et al.*, 2009).

Testicular adrenal rest tumors (TARTs) are formed from testicular adrenal rest cells located in the testis and are activated by an increased ACTH drive. TARTs develop over time and are more prevalent in men with severe forms of CAH (Stikkelbroeck *et al.*, 2004; Auchus, 2015). TARTs can be identified with high resolution ultra sound assessment early in life and the prevalence increases with the onset of puberty (Claahsen-van der Grinten *et al.*, 2014). The TARTs increase in size with insufficient hormonal control, which may cause pain.

In addition, secondary effects on gonadotrophins and the gonadal axis can be seen in both sexes. Undertreatment and increased androgens result in pituitary inhibition and lower FSH and LH levels. In men the resulting decreased testicular production of testosterone, may be one of the causative factors with negative effect on sperm production. A ratio between testosterone and androstenedione may be used as an indication whether the androgens are of adrenal or testicular origin (Auchus, 2015). In women elevated adrenal androgen production will cause irregular menstruations, and affect ovulation and hence, fertility (Witchel, 2017; Strandqvist *et al.*, 2014). Women may have a positive effect on the androgen synthesis if a contraceptive pill is used since it decreases the androgen production from the ovaries (Carmina *et al.*, 2017).

Surgery in Girls With CAH

The Endocrine Society Guidelines from 2010 emphasize that early single-stage genital repair for severely virilized girls, should be performed by experienced surgeons (Speiser *et al.*, 2010). The outcome of feminizing surgery has been disappointing in several follow-up studies (Crouch *et al.*, 2004, 2008; Gastaud *et al.*, 2007; Nordenskjold *et al.*, 2008; Johannsen *et al.*, 2010; Nordenstrom *et al.*, 2010; Nordenstrom, 2011) and has as a result of this been questioned. The possibility of obtaining informed consent from the individual concerned is also discussed from a human rights perspective (The UN rapporteur of torture 2012 and the EU Council resolution 2191 (2017) (http://assembly.coe.int/nw/xml/XRef/Xref-XML2HTML-en.asp?fileid=24232&lang=en). There has been a tendency towards performing early surgery less often (Michala *et al.*, 2014), however, a change in praxis needs to be evaluated since the psychological outcome of early versus late genital surgery has not been investigated. A recently published feasibility study, reported that no obvious discomfort or anxiety related to the genitals was observed in the clinical setting in seven girls, aged 1–8 years, who had not had early surgery (Bougneres *et al.*, 2017). The risk of urinary infections if surgery is not performed does not seem to be increased (Nabhan *et al.*, 2006).

Long Term Risks, Metabolic Aspects

Blood pressure has been reported to be elevated in younger children with CAH, in 45% during the first year of life and then decreasing to 15% at 4 years of age (Bonfig and Schwarz, 2014). A registry study on a larger cohort of 716 patients aged 3–18 years showed that elevated blood pressure was seen in 18%, and the blood pressure correlated with the BMI but not with the hydrocortisone dose (Bonfig *et al.*, 2016). A small study on six patients showed that giving the higher hydrocortisone dose in the evening attenuated the nightly dip possibly an independent risk factor for cardiovascular disease (Liivak and Tillmann, 2009).

There is an increased risk of obesity and of elevated blood pressure (Subbarayan *et al.*, 2014; Volkl *et al.*, 2006b). In addition, an epidemiological registry study showed an increased cardiovascular morbidity in adult patients with CAH (Falhammar *et al.*, 2015). Obesity, but also other factors such as how the glucocorticoid dose is divided over the day and the mineralocorticoid dose may be of importance.

Psychological Aspects

It is important to support the family and the child/teenager. Information and understanding of the disorder and its treatment have been shown to strengthen the coping ability (Pasterski *et al.*, 2014). Actively finding ways to communicate with the parents of the small children, and later on with the child and teenager is the foundation for a situation where all issues can be discussed between the healthcare professionals and the patient and parents but also between the family members (Nordenstrom and Thyen, 2014; Nordenstrom, 2015).

It has been shown repeatedly that girls and women with CAH have gender atypical interests and behavior (Berenbaum and Beltz, 2011; Hines, 2010) and that this is related to the extent of prenatal androgen exposure, that is, the severity of the disorder (*CYP21A2* genotype) (Nordenstrom *et al.*, 2002; Frisen *et al.*, 2009) that is, the level of prenatal androgen exposure rather than a threshold effect. Importantly in all the Swedish follow up studies, women in the null genotype group were considerably more affected by the disease, also compared to the I2G group, while in the clinic these two groups are often treated the same (Nordenstrom *et al.*, 2002, 2010; Frisen *et al.*, 2009; Strandqvist *et al.*, 2014; Engberg *et al.*, 2015).

There is much less known about what determines a persons' gender identity. The current practice is to raise children with 46,XX karyotype as girls but this has been challenged for the most severely virilized cases (Speiser *et al.*, 2010; Lee and Houk, 2010). Girls with CAH were shown to have more cross-gender identification, and gender role behavior compared to controls (Pasterski *et al.*, 2015) but these entities are independent of each other. In a gender identity questionnaire, the girls made more cross-gender statements but it is not known if this caused distress in the girls.

In a nationwide epidemiological registry study, girls with SW CAH were less likely to complete primary school than their controls (Strandqvist *et al.*, 2014). This could not be explained by hypoglycemia or adrenal crises since it was not seen in the boys with SW CAH: therefore, psychological aspects are likely to be of importance. Cognition is normal in CAH but short-term memory has been reported to be affected (Collaer *et al.*, 2016; Karlsson *et al.*, 2017; Hampson and Rovet, 2015; Agoston *et al.*, 2017). In the Swedish national cohort men and women with CAH had a doubled risk of receiving a psychiatric diagnosis of misuse or stress and adjustment disorder (Engberg *et al.*, 2015; Falhammar *et al.*, 2014), indicating that these patients are vulnerable to stress.

There is emerging evidence for and a focus on psychological counseling as an important part of the team approach to the care for these patients (Hindmarsh, 2009); (Nordenstrom, 2015; Speiser *et al.*, 2010). The patient's well-being should be addressed in a wider perspective. Over time the care for patients with CAH has evolved from rescuing patients with a lethal disorder by glucocorticoid and mineralocorticoid treatment to a multidisciplinary team approach where in addition the patients and the families' well-being is in focus in a more general perspective (Gidlof *et al.*, 2013; Speiser *et al.*, 2010).

Prenatal Diagnosis and Treatment of Congenital Adrenal Hyperplasia

Svetlana Lajic and Anna Nordenström, Karolinska University Hospital, Stockholm, Sweden

Introduction

Congenital adrenal hyperplasia (CAH) comprises several enzymatic defects that disrupt adrenal steroidogenesis and cortisol production in the adrenal cortex (El-Maouche *et al.*, 2017; Speiser *et al.*, 2010). They are all inherited in an autosomal recessive manner and the lack of cortisol stimulates the hypothalamic–pituitary–adrenal-axis (HPA-axis) to increase the ACTH production. In some of the enzymatic defects (21-hydroxylase deficiency, 21OHD; 11β-hydroxylase deficiency, 11βOHD; 3β-hydroxy steroid dehydrogenase deficiency, 3βHSD; P450 oxidoreductase deficiency, POR), excessive ACTH stimulation of the adrenal gland will lead to over-production of adrenal androgens that virilize the female fetus.

CAH due to 21-hydroxylase deficiency (21OHD) is the most common variant affecting 1:10,000–1:15,000 live births (classic forms, salt-wasting CAH, SW CAH and simple virilizing CAH, SV CAH) (Speiser *et al.*, 1985; Wedell, 2011; White and Speiser, 2000) but milder adult onset forms of 21OHD (nonclassic CAH, NC CAH) are even more frequent ($\sim$1:1000) (Speiser *et al.*, 1985; Therrell *et al.*, 1998).

The other virilizing forms of CAH are rare, incidence 1:100,000 in 11βOHD and even less frequent in 3βHSD and POR (El-Maouche *et al.*, 2017). The focus of this paper will therefore be on 21OHD and the state of the art regarding prenatal diagnosis, prenatal treatment and the outcome of such interventions.

Clinical Aspects of CAH

In classic CAH, the early prenatal excess of adrenal androgen precursors (DHEA/DHEA-S, androstenedione) and their conversion to testosterone and dihydrotestosterone (DHT) will virilize the female fetus. The so called backdoor pathway descending from 17-hydroxyprogesterone lead to additional synthesis of androgens (androsterone and androstanediol) that are converted to DHT thus further aggravating in utero virilization in girls with 21OHD (Auchus, 2004; Hanley and Arlt, 2006; Miller and Auchus, 2011; Kamrath *et al.*, 2017a,b).

Virilization may lead to difficulties in sex assignment and a need for plastic surgery in the more severe cases. The degree of virilization is classified according to the five stages of Prader, where stage 1 is defined as almost normal female external genitalia with minor clitoral enlargement and stage 5 resembles male external genitalia with posterior labial fusion, formation of a urogenital sinus, hypertrophy of the clitoris and a phallic urethra (Prader and Gurtner, 1955).

SW CAH leads to prenatal virilization of the external genitalia Prader score 3–4 with very few exceptions. In SV CAH there is a wide range in virilization, from ambiguous genitalia at birth to clitoris enlargement and posterior fusion that may not be noted initially.

Ten common mutations are found in over 95% of all CAH cases (**Fig. 1**) and, in total, over 280 CYP21A2 alleles have been identified. There is a strong genotype and phenotype correlation for 21OHD, with the mildest allele determining the severity of the disorder (Krone *et al.*, 2013; Nordenstrom *et al.*, 2002; New *et al.*, 2013). However, there is also a contribution from the other allele, such that a patient with one mildly and one severely affected allele (compound heterozygote) will generally present with a more severe phenotype than one who carries two mild alleles. An in vitro analysis can be used as a complement in disease

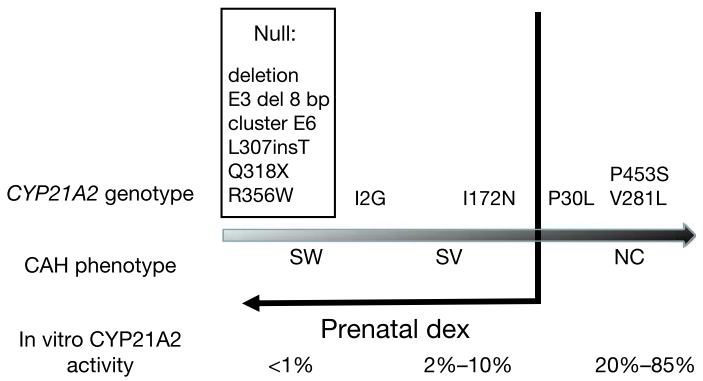

Fig. 1 Mutations giving rise to 21OHD in relation to clinical severity and enzyme activity in vitro. A group of completely inactivating mutations (Null), together with the I2G and I172N mutations, are associated with classic CAH that is, salt-wasting (SW) or simple virilizing (SV) disease. Prenatal DEX treatment is restricted to families segregating these mutations.

classification, especially for rare mutations, where large groups of patients are not available for clinical investigation (Barbaro *et al.*, 2015). Prediction of phenotype is possible from the *CYP21A2* genotype and in vitro studies and improves genetic counseling and clinical management. (Barbaro *et al.*, 2004, 2015; de Paula Michelatto *et al.*, 2016). Computational and structural modeling may also be used for predicting the phenotype of novel mutations (Haider *et al.*, 2013). Families with mutations that give rise to NC disease should never be subjected to prenatal treatment, whereas families carrying the more deleterious mutations may be offered prenatal treatment in a subsequent pregnancy (see below and **Fig. 1**).

Females with CAH have an increased risk of negative outcomes regarding sexual function, reproductive potential and psychosocial and cognitive aspects, especially in the more severe cases (the null genotype group), but it is unclear if this is the result of the degree of prenatal virilization or other factors related to the disease and postnatal treatment (Nordenstrom *et al.*, 2010; Miller, 2015; Strandqvist *et al.*, 2014; Karlsson *et al.*, 2017; Crouch *et al.*, 2008; Johannsen *et al.*, 2006; Nordenskjold *et al.*, 2008; Nordenstrom, 2011).

Prenatal Diagnosis and the Protocol for Prenatal Treatment of CAH

The molecular genetic diagnosis is more complicated for 21OHD than for other monogenic disorders due to the location and variability of the genomic region (White *et al.*, 1986; Miller and Auchus, 2011; Hannah-Shmouni *et al.*, 2017). There may be several *CYP21/C4* repeat units present on the same chromosome and one allele may harbor more than one mutation in the *CYP21A2* gene. Mutated alleles in a proband must be segregated in the parents to investigate their presence in different alleles and to verify de novo mutations.

Sanger sequencing is the gold standard for detecting point mutations and small gene deletions or insertions. It is used today by most centers in combination with MLPA (Multiplex ligation-dependent probe amplification) to detect mutations and large gene rearrangements/copy number variations in affected individuals (Concolino *et al.*, 2009). Prenatal diagnosis of a fetus at risk of CAH is performed during the late first trimester (around gestational week (GW) 10 postconception) when it is possible to perform a chorionic villous biopsy and extract DNA from cultured fetal cells for genotyping of mutations in *CYP21A2* using the methods mentioned above. There is also an option of using allele-specific PCR and other related techniques (Wedell *et al.*, 1994; White and Speiser, 2000). However, with this approach, the diagnosis of a fetus will not be established prior to the timing when prenatal treatment has to be initiated in order to be effective. Early prenatal genotyping is therefore warranted in order to be able to introduce treatment in only those cases that may benefit from it. In addition to the CVS method, it is possible to isolate fetal DNA for genotyping via amniocentesis performed in the second trimester (GW 12–14) or measure hormones in the amniotic fluid (17OH-progesterone, 21-deoxycortisol, androstenedione, and testosterone) (Forest *et al.*, 1993). This will, however, delay the diagnostic results and prolong the time the fetus is exposed to dexamethasone (DEX).

The use of DEX, a synthetic glucocorticoid for prevention of prenatal virilization in girls with classic CAH was first described by David and Forest in the mid-1980s (David and Forest, 1984). The protocol is depicted in **Fig. 2**. To be effective, the treatment has to be initiated before gestational week 7 in order to prohibit the fusion of the labio-scrotal folds and the formation of the urogenital sinus. The dose used is 20 μg/kg of the maternal prepregnancy weight and is divided into three doses per day (maximum 1.5 mg/day). Treatment can be offered to mothers who previously had a child with a variant of classic CAH expected to result in severe virilization in a female fetus.

Only girls with CAH are treated during the entire gestation, from week 6–7, while treatment in all boys and in girls without CAH is stopped when the genotype of the fetus is known, usually at the beginning of the second trimester (**Fig. 2**).

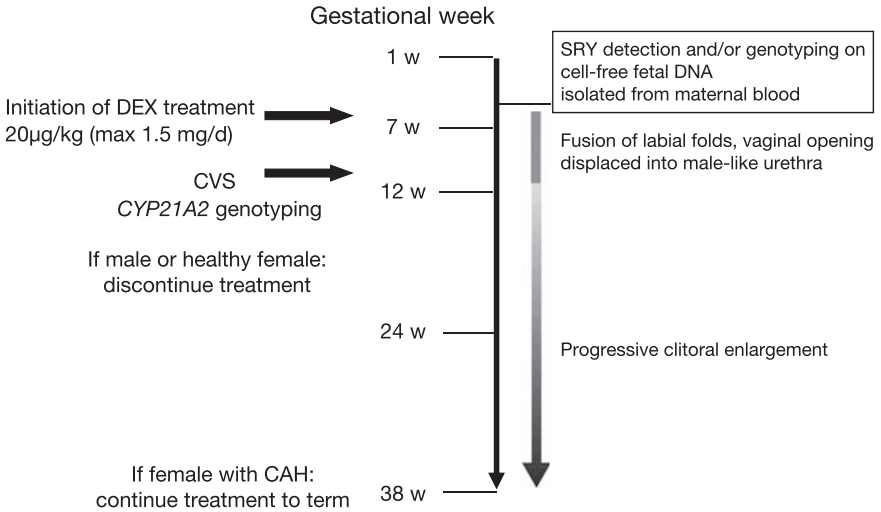

Fig. 2 The protocol for the prenatal treatment of CAH.

In women treated until term, the efficiency of the treatment is monitored with measurements of maternal serum cortisol and DHEAS (from GW 7) and estriol (from GW 16). Low levels of cortisol and DHEAS indicate adequate maternal adrenal suppression and compliance while a low level of estriol is a marker for fetal adrenal suppression (David and Forest, 1984). The mother should be followed throughout pregnancy with analysis of blood pressure, weight, glucosuria, proteinuria, and symptoms of edema, striae and other adverse effects (Lajic *et al.*, 1998). Discontinuation of DEX treatment should be tapered, in both short-term and long-term-treated women. The treatment strategy involves the dilemma that seven out of eight fetuses will be needlessly subjected to high doses of glucocorticoids during early embryonic life.

Noninvasive prenatal sex typing (SRY detection) can be performed using PCR amplification of cell-free fetal DNA in maternal blood as early as week 6–9 (Lo *et al.*, 1997; Bischoff *et al.*, 2005). The methodology has been applied by Tardy-Guidollet and colleagues in the diagnostic procedures for CAH as early as at 4 weeks and 5 days postconception and avoided prenatal treatment in 68% of the males (Tardy-Guidollet *et al.*, 2014). The method does not, however, change the fact that, with early sex typing of the fetus, three out of four cases will still be treated for a period of time for the benefit of others.

New *et al.* have recently succeeded in treating only the affected females using targeted massive parallel sequencing of cell-free fetal DNA in maternal plasma (New *et al.*, 2014). Fourteen expectant families at risk of having a child with classic CAH were recruited and fetal inheritance of parental haplotypes was determined (in one case, as early as 5 weeks + 6 days). The method is based on the detection of SNPs linked to the active *CYP21A2* gene and specific for either the maternal, paternal, or proband haplotypes. The technique is promising, but it still is not freely available as part of routine clinical care because it requires highly trained personnel and expensive equipment.

The preimplantation genetic diagnosis (PGD) is another methodology that can be applied for the diagnosis of genetically defined disorders (Simpson, 2010). Only embryos not having the disorder will be implanted in the uterus. In many countries, PGD is available for families at risk of having a child with a severe genetic condition. Three approaches are used to obtain DNA for PGD: (1) polar body biopsy, utilizing oocytes; (2) blastomere biopsy, utilizing the 3-day 6- to 8-cell cleavage stage embryo; and (3) trophectoderm biopsy, utilizing the 5- to 6-day blastocyst that contains about 120 cells. In PGD of the first polar body, the procedure is performed before fertilization occurs and the analysis offers the unique possibility of *preconceptional* diagnosis. The disadvantage for CAH and other single-gene autosomal recessive disorders is of course that the transmission of the paternal allele is not taken into account. The blastocyst is therefore the preferred biopsy approach in PGD (Simpson and Rechitsky, 2017).

DEX is efficient in preventing virilization in girls with CAH, but long-term evaluations of the treatment risks are still limited and have been the focus of debate for more than a decade (Seckl and Miller, 1997; Miller, 1999; Lajic *et al.*, 2008, 2011; Hirvikoski *et al.*, 2012). The safety aspects of the prenatal treatment have been discussed in the light of the fact that the majority of the treated children do not benefit from it (Hirvikoski *et al.*, 2012). Even with the new diagnostic approaches, unnecessary treatment in healthy girls during the first trimester of pregnancy is still a fact and also in girls with CAH undergoing DEX treatment, a risk benefit assessment is crucial.

Due to the safety issues it has been concluded by several authors and international societies that prenatal DEX treatment of children at risk of CAH should only be carried out in centers where a follow-up of treated individuals can be achieved (LWPES/ESPE, 2002; Miller, 2015; Hirvikoski *et al.*, 2012). Since 1999, all prenatally treated cases in Sweden have been followed according to a structured protocol within the framework of the PREDEX study (Hirvikoski *et al.*, 2012) and, since 2010, no additional cases at risk of CAH have been treated in Sweden due to the accumulating reports of long-term sequelae after prenatal DEX therapy.

Negative Consequences for Health in Animals and in Humans Attributable to Prenatal Glucocorticoid Excess

Glucocorticoids (GCs) are important for the differentiation and maturation of fetal tissues. They are used in the treatment of pregnancies at risk of preterm delivery to induce pulmonary maturation and prevent intraventricular cerebral hemorrhage. Glucocorticoids affect growth, including a dose-dependent inhibition of prenatal growth leading to lower birth weight and inhibition of neuronal proliferation (Norberg *et al.*, 2011; Samarasinghe *et al.*, 2011). The effects of GCs on fetal development are time- and dose-dependent with different outcomes in early versus late gestational treatment (Hauser *et al.*, 2008; Davis and Sandman, 2010). It is, however, important to be aware of the fact that it may be difficult to distinguish between effects of pre- versus postnatal treatment and adversities related to the preterm birth itself or to the underlying genetic defect.

According to the Barker hypothesis, the in utero milieu predisposes the child to a range of diseases later on in adult life (Barker *et al.*, 2002; Seckl and Holmes, 2007). The placental enzyme 11-beta-HSD type 2 protects the fetus from excess glucocorticoid by inactivation of cortisol to cortisone. The levels of cortisol in the fetus are normally ~1/5–1/10 of the levels in the mother (Chapman *et al.*, 2013). DEX and other synthetic glucocorticoids are not inactivated by 11-beta-HSD and the dose of DEX used in prenatal treatment of CAH will result in excess fetal GC levels that are estimated to be up to 60 times higher than the normal hormonal level (Miller, 2015; Busada and Cidlowski, 2017). It is therefore important to raise the question of whether in utero treatment with GCs comes with a cost.

Investigations in different animal models have shown that high levels of GCs during early- or late fetal life have effects on cognition, behavior and metabolism. In general, good animal models for obtaining information about the possible side effects of prenatal treatment in the context of CAH are scarce. Most animal studies have been designed to mimic the treatment in preterm infants, that is, treatment after mid-gestation.

Rodents are more GC-sensitive than primates and the teratogenic effects seen in rodent models are not observed in humans. Every species has its own characteristics, but several common mechanisms can be identified. Studies in rats have demonstrated low birth weight and smaller litter size after prenatal DEX exposure (Bakker *et al.*, 1995; Emgard *et al.*, 2007). As adults, rodents develop a status similar to the metabolic syndrome with hypertension, hyperinsulinemia, and hyperglycemia, as well as hyperactivity of the HPA-axis and altered affective behavior and altered stress reactivity (Celsi *et al.*, 1998; Drake *et al.*, 2010; Hauser *et al.*, 2008, 2009; Nyirenda *et al.*, 2006; Wyrwoll and Holmes, 2012; Zeng *et al.*, 2015). Similar effects have been observed in guinea pigs in the form of an abolished diurnal cortisol rhythm and male animals had a lower cortisol response (increased negative feed-back) to stress compared to female animals (Iqbal *et al.*, 2012).

On the other hand, early gestation, low-dose DEX treatment of pregnant ewes (20 μg/kg per day) did not affect blood pressure or renal function in 2 year-old offspring (Dodic *et al.*, 2003). Sloboda *et al.* showed that, in sheep treated with betamethasone during fetal life, the HPA-axis changed as the sheep matured and the adrenals became increasingly ACTH-resistant since the ACTH levels rose and the cortisol levels decreased with age (Sloboda *et al.*, 2000, 2002, 2007). A recent study from the same group, again using DEX during early pregnancy in the same animal model, presented evidence of an increased apoptosis in placenta with increased pro-apoptotic- (*Bax, p53*) and reduced antiapoptotic (proliferating cell nuclear antigen) markers and less placental binucleate cells (Braun *et al.*, 2015). This was associated with a temporarily decreased fetal growth in female off-spring (Braun *et al.*, 2015). In nonhuman primates, such as the Rhesus macaque, high levels of prenatal DEX during the last trimester resulted in offspring with elevated levels of basal- and stress-stimulated cortisol at the age of 10 months. In addition, there was an induced degeneration and depletion of hippocampal neurons with a 30% reduction of hippocampal volume (Uno *et al.*, 1994). In the African vervet monkey, high-dose DEX exposure (120 or 200 μg/kg) from mid-gestation until term caused an increased cortisol response to stress at 12 months of age (prepubertal animals). This reflects an increased drive of the HPA-axis, contrary to the rodent models. Nevertheless, by the age of 8 months the animals exhibited metabolic changes similar to those seen in rodents, that is, hypertension, impaired glucose tolerance, and hyperinsulinemia and the pancreatic β-cell mass was decreased by approximately 25% (de Vries *et al.*, 2007). In the common marmoset monkey, early DEX treatment resulted in reduced sociability in infants and increased motivation for palatable reward in the adolescent animal (Hauser *et al.*, 2008). Late DEX treatment resulted in a mild transient increase in knee-heel length in infants and an enhanced reversal learning of stimulus reward association in adolescents (Hauser *et al.*, 2008).

In a follow-up study of children who had been treated prenatally with GCs, but were born full term, there was an increased cortisol response to psychosocial stress, indicating an imprinting effect on the HPA-axis also in humans and with a greater effect being seen in girls (Alexander *et al.*, 2012). Effects on cognition have also been studied in preterm infants exposed to synthetic glucocorticoids, but there are difficulties in defining the exact cause of the negative effects since adversities directly related to the preterm birth may also play a role (Alexander *et al.*, 2016). The situation is further complicated by the fact that there seems to be individual differences in the vulnerability to GC exposure due to genetic differences in genes involved in GC signaling and prereceptor metabolism, as well as to sex differences, where girls seem to be more vulnerable than boys (Alexander *et al.*, 2012; Wallensteen *et al.*, 2016; Ragnarsson *et al.*, 2014). Additional postnatal treatment with GCs in the case of patients with CAH may also add to the effects of the initial prenatal treatment. Women with CAH and exposed to DEX antenatally had a worse cognitive outcome than non-prenatally treated women with CAH (Karlsson *et al.*, 2017). In patients with Cushing's syndrome in remission there was an association between a polymorphism in the *NR3C1* gene and worse visual attention and visual working memory, and a polymorphism in the gene encoding 11-beta-HSD1 and auditory working memory, processing speed, and reading speed (Ragnarsson *et al.*, 2014). In rats, GC treatment induces the 11-beta-HSD1 activity in the hippocampus, increasing action in that part of the brain (Low *et al.*, 1994). Certain SNPs in the genome may thus increase the GC exposure in the brain and affect cognitive functions long-term. Effects on the future fertility of the fetus may also be a risk, and maybe even transgenerational effects, since a study where 8–11 week old human fetal ovaries were incubated with DEX resulted in a reduced number of germ cells due to an increased rate of apoptosis (Poulain *et al.*, 2012).

In the following, we will focus on the published results from studies in humans regarding the outcome after prenatal dexamethasone therapy in the context of CAH. A large number of individuals have already been treated and can therefore be evaluated. The studies conducted up to now give important information regarding the safety of the treatment and the effects on the somatic and behavioral outcomes.

Maternal Outcome and Effects on Pre- and Postnatal Growth

The maternal side effects of DEX treatment are not negligible. Approximately 50% of the mothers treated during early pregnancy and all mothers treated until term experienced some type of side effect that can be attributed to DEX (edema, weight gain, cutaneous striae, sleep disturbances, and mood swings) (Lajic *et al.*, 1998; Forest *et al.*, 1993; Mercado *et al.*, 1995). The side effects usually disappeared after the treatment was discontinued. The incidence of hypertension or gestational diabetes was not increased in DEX-treated women and the incidence of miscarriage was comparable to that in the general population or in the control groups, although the total numbers of mothers were small (Lajic *et al.*, 1998). Studies conducted in France and the USA have reported that nearly all the mothers were willing to undergo the treatment again in the event of another pregnancy, while about one third of the Swedish mothers reported that they would not (Forest *et al.*, 1993; Forest and Dörr, 2003; Mercado *et al.*, 1995; Carlson *et al.*,

1999; New *et al.*, 2001; Lajic *et al.*, 1998). It is important to inform the women in advance about possible side effects if treatment is initiated.

Most of the children show normal pre- and postnatal growth, although several adverse events involving failure to thrive have been observed in both short-term and full-term-treated cases (Lajic *et al.*, 1998). Birth weight, even though nominally normal, was reduced in some studies on children with CAH and treated with DEX (Forest *et al.*, 1993; Forest and Dörr, 2003; Mercado *et al.*, 1995; Carlson *et al.*, 1999; New *et al.*, 2001; Lajic *et al.*, 1998). Reduced birth weight may be a risk factor for the development of chronic disorders later in life (Barker, 1995, 1998; Harris and Seckl, 2011).

Effects on Cognition and Behavior

In humans, memory deficits have been found after prolonged postnatal exposure to elevated glucocorticoids, such as in Cushing's syndrome and pharmacological glucocorticoid treatment (Sapolsky, 2000; Lupien *et al.*, 2007; Stuart *et al.*, 2005). Cushing's disease has irreversible effects on the brain, that is, persistent effects also after treatment, including both structural differences as seen in MRI and fMRI studies and negative effects on cognition (Andela *et al.*, 2015; Tiemensma *et al.*, 2010). As mentioned above, some of these effects may be a consequence of different vulnerability among individuals due to genotypic differences in the *NC3R1* and *11-beta-HSD1* genes (Ragnarsson *et al.*, 2014).

The glucocorticoid receptor (GR) is widely distributed throughout the brain, while the mineralocorticoid receptor (MR) is mainly expressed in the limbic structures. Both MR and GR are expressed at high levels in neurons in the amygdala, hippocampus, and the prefrontal cortex (Colciago *et al.*, 2015; Matsusue *et al.*, 2014; de Kloet *et al.*, 2005) areas important for executive function, emotional regulation, and memory (LeDoux, 2000; Funahashi, 2001; Opitz, 2014). These areas of the brain are thus vulnerable to high doses of GC.

The GC effect on the human brain is not only harmful since mechanisms of long-term memory formation are dependent on and influenced by glucocorticoids and other hormones (for a review, see (Colciago *et al.*, 2015). Epigenetic modifications and BDNF expression are the molecular mechanisms responsible for the synaptic plasticity that occurs in learning and formation of long-term potentiation and memory consolidation (Colciago *et al.*, 2015). Specific patterns of DNA methylation and histone modifications are established during learning in specific neurons in different areas of the brain involved in memory formation and long-term storage (amygdala, hippocampus, and prefrontal cortex). Chronic exposure to excess GC and early life events may thus alter these processes. Activation of the glucocorticoid receptor by DEX may cause inhibition of proliferation of neural progenitor cells (Samarasinghe *et al.*, 2011). Neural progenitor cells are important throughout life since they form the basis for adult neurogenesis in the dentate gyrus of the hippocampus and olfactory bulb (Aimone *et al.*, 2011; Zhao *et al.*, 2008). Factors that modulate memory formation such as stress, depression and environmental processes induce epigenetic modifications in the brain and influence cognitive functions beside the epigenetic changes seen in basic memory formation (Fischer *et al.*, 2007; Hunter *et al.*, 2009).

The first pilot study indicating long-term behavioral effects of prenatal exposure to DEX was published in 1995 by Maria New and Heino Meyer-Bahlburg (Trautman *et al.*, 1995). Since then, the behavioral and cognitive outcome has been the most studied area of research regarding long-term effects of prenatal treatment of CAH (Trautman *et al.*, 1995; Meyer-Bahlburg *et al.*, 2004, 2012; Hirvikoski *et al.*, 2007, 2008; Frisen *et al.*, 2009; Wallensteen *et al.*, 2016, Karlsson *et al.*, 2017).

In the Swedish cohort of prenatally DEX-treated children, there were no differences in parent-reported behavioral problems (using CBCL). However, in the parental assessments, DEX-treated children were reported to be more sociable (EAS scale), while more social anxiety was reported by the children themselves (SASC-R) (Hirvikoski *et al.*, 2007, 2008). Data from the same cohort of patients indicated that there may be some effects on gender role behavior also in prenatally treated boys since DEX-treated boys without CAH exhibited more neutral behaviors compared to controls (Hirvikoski *et al.*, 2011). In an extended follow-up study on healthy children at risk of CAH and treated with DEX during the first trimester, no significant negative behavioral effects were observed, but it should be noted that treated girls had the highest scores on measures of anxiety (Wallensteen *et al.*, 2016, Hormones and Behavior (YHBEH_4299)). Moreover, DEX treatment had long-lasting effects on cognition, which was observed as poorer performance in verbal working memory tasks (Hirvikoski *et al.*, 2007). In a more recent follow-up study of children exposed to DEX but without CAH, these effects seemed to be sex-dimorphic, since treated girls exhibited more pronounced cognitive deficits than treated boys. In addition to negative effects on executive functions, the girls showed broader effects on cognition, observed as poorer performance in a test assessing verbal intelligence (Wallensteen *et al.*, 2016).

Data from women with CAH treated with DEX prenatally suggest that this sex-dimorphic effect may also be present in adult age (Karlsson *et al.*, 2017). When short-term treated healthy individuals were re-tested as adults, there was a catch-up in executive function performance compared to their performance during childhood (Karlsson, *personal communication*).

The aforementioned American research group could not identify differences in the general development of children up to 6 years of age (Meyer-Bahlburg *et al.*, 2004). More recent data on long-term-treated girls with CAH indicate a slower cognitive processing in DEX-exposed individuals (Meyer-Bahlburg *et al.*, 2012). Contradictory results are reported in a Polish report which showed that prenatal DEX may have a negative effect on cognitive abilities in girls without CAH and a positive effect on girls with CAH (Maryniak *et al.*, 2014). A pilot study, using parental questionnaires as the method of assessment, indicated that prenatally DEX-exposed preschool children showed more shyness and emotionality, as well as less sociability (Trautman *et al.*, 1995). The mothers also reported more internalizing problems in a questionnaire measuring behavioral problems in children who were

between 2 and 5½ years of age (Trautman *et al.*, 1995). All of the above-mentioned studies are relatively small, which limits the possibility to detect smaller effects and emphasizes the need for additional national and international longitudinal follow-ups. Future studies should also investigate potential effects on metabolism, brain morphology, and functional networks in the brain to complement the neuropsychological assessments.

Studies regarding effects on the fetal programming of the HPA-axis are lacking in the context of prenatal treatment of CAH. There are, however, a few reports regarding prenatal glucocorticoid treatment of children at risk of preterm birth where treated children have an altered HPA-axis activity (Reynolds and Seckl, 2012; Seckl, 2004; Davis *et al.*, 2011). Furthermore, there is evidence that treated girls are more susceptible to altered programming since late prenatal glucocorticoid treatment resulted in increased cortisol responses to psychosocial stress, with a greater effect observed in girls (Alexander *et al.*, 2012). A similar effect was also identified with neonatal DEX-treatment in children at risk of bronchopulmonary dysplasia (Ter Wolbeek *et al.*, 2015). The DEX-treated girls showed increased levels of ACTH and increased cortisol responses in a stress test, further reinforcing the view that early life exposure to elevated glucocorticoids affects the HPA-axis and that these effects may be sex-dimorphic (Ter Wolbeek *et al.*, 2015).

Metabolic, Cardiovascular, and Immunological Effects

In general, there has been very little research on the cardio-metabolic outcome after prenatal glucocorticoid exposure in humans. However, in a report describing the metabolic effects after prenatal treatment with betamethasone during late gestation, the prenatally exposed individuals exhibited insulin resistance 30 years after exposure and the effects were more pronounced in women (Dalziel *et al.*, 2005). Antenatal glucocorticoid treatment in preterm infants is associated with increased aortic arch stiffness and altered glucose metabolism in early adulthood (Kelly *et al.*, 2012). The observed increased aortic stiffness was equivalent to that of term adults a decade older (Kelly *et al.*, 2012). Another study examining children and young adults (age 14–26 years) found no effect on BMI, blood pressure, blood lipids, cortisol levels, or insulin resistance in the group prenatally treated with betamethasone, compared to controls (Norberg *et al.*, 2013). Although no statistical differences could be found in arterial stiffness there was larger number of individuals who had received multiple GC doses than there where nontreated individuals in the group of subjects with the highest arterial stiffness (Norberg *et al.*, 2013).

The function of the immune system may also be affected by prenatal DEX-treatment since treatment is initiated during a period of gestation when the fetal thymus is formed and the first lymphocyte gene rearrangements occur (GW 7–12) (Veru *et al.*, 2014). There is evidence that children exposed to prenatal maternal stress (PNMS), and plausible high levels of cortisol, have programming effects that may have long-lasting consequences on the immunity (Veru *et al.*, 2015). PNMS altered the levels of cytokines, reduced the number of CD4 + T-cells and induced a shift of the T-helper cell population favoring Th2 cells (Veru *et al.*, 2015). Long term outcome regarding other biological functions in these children showed a pattern consistent with excessive glucocorticoid exposure, that is, PNMS was positively associated with a higher insulin secretion and a higher BMI during adolescence (Dancause *et al.*, 2013).

Suggestions for Future Research

Altered DNA methylation is a mechanism involved in adapting genomic programs for long-lasting effects on human health after exposure to stress/GCs or traumatic events. Most studies concerning glucocorticoid exposure have, however, investigated alterations on the single gene level and changes in gene promoters. There is a need for additional investigations in this area of research using techniques with more extensive coverage, such as microarrays and bisulphite next-generation sequencing.

It is possible that alterations in DNA methylation are involved in and the cause of, the fetal programming seen after prenatal DEX-treatment for CAH. There are a few animal studies pointing in that direction. A trans-generational effect of the epigenetic changes has also been proposed. The second generation off spring of guinea pigs treated during pregnancy with multiple doses of betamethasone showed reduced methylation of genomic DNA globally and of specific genes involved in the methylation process per se (Crudo *et al.*, 2012; Iqbal *et al.*, 2012).

Summary

In summary, the long-term outcome of prenatal DEX treatment on behavior and cognition has been investigated and most of the evidence points towards a negative effect on executive functions, with girls appearing to be more vulnerable than boys. Behavior is mostly unaffected in treated subjects and the children are well adapted. Cardiovascular and metabolic functions are still areas that need to be investigated. Epigenetic alterations may be the cause of the long-lasting effects of prenatal glucocorticoid exposure by interacting with genomic programs that affect human health. Whether such changes take place in the context of prenatal DEX treatment in humans remains to be investigated.

Steroidogenic Factor 1 (SF-1; NR5A1)

Ken McElreavey and Anu Bashamboo, Institut Pasteur, Paris, France

The orphan nuclear receptor steroidogenic factor 1 (SF-1, also called Ad4BP, encoded by the *NR5A1* gene located on Chr 9q33.3 in human) is an essential regulator of endocrine development and function.

Structure of SF-1

NR5A1 belongs to the subfamily of transcription factors known as nuclear receptor subfamily 5 (group A, member 1; NR5A1), which is highly conserved in vertebrates. With a striking homology to the Drosophila nuclear receptor fushi tarazu factor (Morohashi *et al.*, 1992), the 461 amino acid long SF-1 protein consists of a DNA-binding motif composed of two zinc-chelating modules that coordinate the interaction between the receptor and hormone response element (Schimmer and White, 2010). SF-1 binds DNA as a monomer, with DNA-binding stabilized via a 30 amino acid extension to the DNA-binding domain (Ftz-F1 or A box) and has a high affinity for the region 5′YCAAGGYCR′3 (where Y = T/C, R = G/A) (Wilson *et al.*, 1993). The C-terminal ligand-binding domain (LBD) encompasses an AF-2 domain that cooperates with a proximal activation domain (AF-1) and is required for maximal biological activity with coactivators such as NCOA1 (SRC-1). Post-translational modification plays an important role in modulating SF-1 activation and repressor functions. Phosphorylation of Ser203 within the LBD enhances the interaction of the cofactors Tif2 (Grip1/Ncoa2) and Smrt (Ncor2/Trac1) with the AF-1 and AF-2 motifs. Strong transcriptional repression requires sumoylation of lysine residues 119 and 194, which increases interactions with DEAD box proteins including Ddx20. SF-1 binds phospholipids with a phosphatidylinositol (PI) head-group, in particular PI(3,4)P2 and PI(3,4,5)P3 (Hammer *et al.*, 1999).

SF-1 Expression in Embryonic and Adult Tissues

The localization of SF-1 in embryonic and adult tissues in mammals has been explored in humans, mice and rats (Ikeda *et al.*, 1994; Morohashi *et al.*, 1995; Hanley et al., 1999, 2001). In developing embryos, SF-1 marks the earliest populations in the developing adrenal gland and the urogenital ridge. In later embryonic development, SF-1 is expressed in the steroid secreting cortical zones of the adrenal gland, testicular Leydig and Sertoli cells. In mice and rats, ovarian expression of SF-1 is turned off as development proceeds and does not resume until just before birth. In contrast, the expression of human SF-1 is similar in the developing ovary and testis with expression observed in granulosa cells (Bashamboo *et al.*, 2016). SF-1 is also expressed in the fetal spleen (Morohashi *et al.*, 1999) and in the prosencephalon (Ikeda *et al.*, 1994).

In the adult, SF-1 is expressed in the major steroidogenic tissues, including the adrenal cortex, Leydig and Sertoli cells, the ovarian interstitium, theca cells, granulosa cells, and, to a lesser degree, corpus luteum (Morohashi *et al.*, 1994; Morohashi, 1999; Ramayya *et al.*, 1997). It also is expressed in pituitary gonadotrophs where it regulates the expression of the gonadotropins and the GnRH receptor (Barnhart and Mellon, 1994; Ingraham *et al.*, 1994). Apart from these tissues, SF-1 expression is limited to neurons in the dorsomedial portion of the ventromedial hypothalamus (VMH) that are distinct from those expressing GnRH, to the endothelial linings of the venous sinuses and pulp veins in the spleen (Ramayya *et al.*, 1997), and to a subset of neurons in the hippocampus that coexpress steroidogenic acute regulatory protein (StAR) and aromatase (Wehrenberg *et al.*, 2001).

Biological Function of SF-1

SF-1 regulates the expression of genes involved in differentiation and control of the hypothalamus–pituitary–adrenal axis via cAMP/PKA signal pathway that transmits the signal from extracellular stimuli to the nucleus (Val *et al.*, 2003). SF-1 is activated by phosphorylation at a single Serine residue (Ser203) by mitogen-activated protein kinase (MAPK) (Hammer *et al.*, 1999) and acetylation (Chen *et al.*, 2005), whereas conjugation by a small ubiquitin like modulator (SUMO) leads to the repression of SF-1 activity (Chen *et al.*, 2004). Inhibition of histone deacetylase cause increased ubiquitination of SF-1, leading to its degradation resulting in reduction of steroid secretion (Chen *et al.*, 2007).

SF-1 localizes to both the nucleus and centromere within the cell and depending on its intracellular localization it impacts on cell growth and differentiation. When acetylated, SF-1, together with RNA polymerase II and coactivators, is present in transcriptionally active loci of the nucleus. On the contrary SUMOylation relocates SF-1 to nuclear speckles that contain transcriptional repressors like PML proteins that repress its activity. In the centrosome, SF-1 regulates centrosome homeostasis by preventing

 doi:10.1016/B978-0-12-801238-3.65242-X

aberrant DNA-PK activation. The absence of SF-1 causes centrosomes to over-duplicate leading to multiple spindle poles during mitosis followed by genomic instability resulting in a reduction of cell numbers (Chia-Yih *et al.*, 2013).

XY mice lacking SF-1 have gonadal dysgenesis resulting in male-to-female sex-reversal with a female phenotype and persistence of Müllerian structures (uterus), highly reduced corticosterone levels, elevated adrenocorticotrophic hormone levels due to adrenal insufficiency, underdevelopment of the spleen and impaired clearance of abnormal red blood cells (Luo *et al.*, 1994). *Nr5a1*$^{-/-}$ mice do not express luteinizing hormone (LH) or follicle-stimulating hormone (FSH) from the gonadotroph cells in the pituitary, and the VMH is disorganized (Büdefeld *et al.*, 2011). VMH specific knockout of *Nr5a1* show high fat diet-induced obesity and increased anxiety-like behavioral patterns (Kim *et al.*, 2011). Nr5a1 haploinsufficiency results in aberrant adrenal architecture and reduced gonad weight, whereas granulosa cell specific ablation of Nr5a1 results in reduced ovarian reserve in females (Bland *et al.*, 2000; Pelusi *et al.*, 2008).

Clinical Phenotypes Associated With *NR5A1* Mutations

In the human, mutations involving *NR5A1* are associated with a wide range of reproductive anomalies including adrenal insufficiency and 46,XY gonadal dysgenesis, ambiguous genitalia, hypospadias, micropenis, spermatogenic failure with normal genitalia and primary ovarian insufficiency and TDSD/OTDSD in females.

Adrenal Insufficiency

The first human mutation in *NR5A1* was reported in a 46,XY girl with complete gonadal dysgenesis with persistent Müllerian structures and primary adrenal failure, similar to that of mouse model lacking *Nr5a1* (Achermann *et al.*, 1999). This girl carried a de novo heterozygous mutation (p.G35E) localized in "P"-box of the first zinc finger of SF-1, a region crucial for recognizing DNA-binding sequence on target genes. Another homozygous mutation (p.R92Q) was identified soon after in a 46,XY girl, from a consanguineous family, presenting with complete sex-reversal and primary adrenal insufficiency (Achermann *et al.*, 2002). The mutation p.R92Q localizes in the "A"-box within the FtzF1 domain of SF-1, which is involved in stabilizing monomeric binding through an interaction with the DNA minor groove. Although the mutations in SF-1 were initially identified in children with adrenal insufficiency, mutations in patients with an adrenal phenotype are rare (Biason-Lauber and Schoenle, 2000; Lin *et al.*, 2006).

Although the initial search for *NR5A1* mutations focused on the children with phenotypes consistent with that of the mouse model, the past 15 years have seen an exponential increase in reports describing pathogenic changes in *NR5A1* and as well as the phenotypes associated with those changes. More than 200 individuals and families are now described in the literature.

46,XY DSD

Heterozygous mutations in *NR5A1* are one of the most frequent (approximately 15%) causes of 46,XY DSD with normal adrenal function at the date of examination although some cases may have mildly elevated ATCH levels. The most common phenotype is a 46,XY child with ambiguous genitalia, with or without Müllerian structures. These mutations are associated with variable degrees of testicular dysgenesis, ranging from partial to complete. This is associated with low levels of testosterone, inhibin B and anti-Müllerian hormone (AMH), and an elevation of follicle-stimulating hormone. On the other hand, there are also some cases reported with low levels of AMH at birth but without apparent Müllerian structures. In rare children there may be adequate testosterone production in the newborn, which may lead to a misdiagnosis of partial androgen insensitivity syndrome (Coutant *et al.*, 2007; Wu *et al.*, 2013). There are also reports of with *NR5A1* mutations associated with progressive androgen production in 46,XY girls with virilization at adolescence, resembling the phenotypes associated with 5 alpha-reductase or 17 beta-hydroxysteroid dehydrogenase deficiency (Cools *et al.*, 2012; Tantawy *et al.*, 2012). Mullerian derivatives are present in approximately a quarter of all 46,XY DSD cases harboring *NR5A1* mutations suggesting that in most cases the fetal Sertoli cell function has been at least partially preserved. However, an impairment of Sertoli cell function in following pubertal age is indicated by elevated FSH levels in all patients studied. Around 30% of all children with 46,XY DSD inherit a heterozygous change from their mother in a dominant manner although rare recessive mutations have been reported.

NR5A1 and Spleen Development

A rare heterozygous nonsense mutation was reported in a girl with polysplenia and her father, who had hypospadias and asplenia (Zangen *et al.*, 2014). A homozygous missense mutation (R103Q) was reported in a child with severe 46,XY DSD and absent spleen. Precisely how SF-1 regulates spleen development is unclear, but mice lacking Nr5a1 show morphologic defects in the spleen vascular system that are associated with a decrease in the proportion of hematopoietic cells, although differentiation of these cells was not affected significantly (Morohashi *et al.*, 1999). TLX-1 promoter is a homeodomain-containing transcription

factor critical for embryonic spleen development. The human R103Q mutation showed impaired transactivation of the *TLX1* promoter and this may provide a mechanism for the asplenia (Colson *et al.*, 2017).

Hypospadias and Undescended Testes

Although hypospadias is a common phenotype, only a small minority are associated with *NR5A1* mutations (Kohler *et al.*, 2009). The first case of a NR5A1 mutation associated with severe penoscrotal hypospadias was reported in a child who had small inguinal testes, partial gonadal dysgenesis, and reduced androgen synthesis. *NR5A1* mutations have been reported in around 5% of individual presenting with the most severe forms of penoscrotal hypospadias with a reduced penile length and at least one undescended testis. *NR5A1* changes in boys with the less severe forms of hypospadias have been reported but are much less common. In one boy with mild distal hypospadias a de novo p.Arg313Cys mutation was identified (Allali *et al.*, 2011), however, a 46,XY girl with complete gonadal dysgenesis was also reported with the same de novo p.Arg313Cys mutation (Mazen *et al.*, 2016). This suggests that the severity of the NR5A1 phenotype may be influenced by other genetic factors.

Bilateral Anorchia

A single heterozygous mutation in *NR5A1* was reported in an analysis of a cohort of 24 children with bilateral anorchia (vanishing testis syndrome). Although anorchia is often believed to reflect neonatal torsion or a vascular event, a small subgroup of bilateral anorchia may represent progressive late onset testicular dysgenesis, occurring after the external genitalia have formed (Philibert *et al.*, 2007).

Male Factor Infertility

In a study of 315 men with spermatogenic failure, heterozygous missense mutations in *NR5A1* were identified in seven men with either azoospermia or severe oligozoospermia (Bashamboo *et al.*, 2010). Testis histology in one man with azoospermia was suggestive of a mild form of testicular dysgenesis rather than Sertoli Cell Only Syndrome. In all cases the men carrying the NR5A1 mutations had normal development of the external genitalia. Other studies have confirmed these findings and current data indicate that around 3% of men with idiopathic spermatogenic failure carry mutations in the gene (unpublished data). In some of these *NR5A1* mutated cases the men had a history of cryptorchidism, which may influence the severity of the spermatogenic failure. Cryptorchidism may occur since SF-1 directly regulates the expression of *INSL3*, a Leydig cell product that is critical for testicular descend (Ferlin *et al.*, 2015).

Interestingly, one of the men described in the initial report showed gradual reduction in sperm numbers suggesting a progressive loss of testicular function associated with mutations in *NR5A1* (Bashamboo *et al.*, 2010). Therefore, children carrying *NR5A1* mutations with no apparent gonadal or adrenal phenotypes may merit long term monitoring to assess the retention of postpubertal testicular function.

Primary Ovarian Insufficiency (POI)

Research on the consequences of human *NR5A1* mutations focused 46,XY individuals since initial reports suggested the mutations mainly affected testis formation and development. Furthermore the report of a prepubertal girl with adrenal insufficiency and an *NR5A1* mutation without a gonadal phenotype led to the suggestion that mutations in *NR5A1* are pathogenic only in 46,XY chromosomal context (Biason-Lauber and Schoenle, 2000). This concept changed with the report of sisters or mothers of children with 46,XY DSD, who carried heterozygous *NR5A1* variants and showed an ovarian phenotype (Lourenco *et al.*, 2009). Like the testis, *NR5A1* mutations effects the ovary at multiple levels, including follicular recruitment and reserve, stromal development and the endocrine function. This is reflected in the gamut of clinical phenotypes seen in the 46,XX individuals carrying mutations that may range from gradual loss of ovarian reserve (premature menopause) to later loss of ovarian reserve/function (secondary amenorrhea) to complete early ovarian insufficiency (primary amenorrhea). Despite being one of the single most important monogenic cause of ovarian insufficiency, mutations in *NR5A1* are relatively rare (1.4%–1.6%) in women with sporadic idiopathic POI (Lourenco *et al.*, 2009; Camats *et al.*, 2012; Janse *et al.*, 2012; Voican *et al.*, 2013). However, there are also women carrying *NR5A1* mutations with no apparent clinical effect on ovarian development or function, indicating that *NR5A1* mutations have variable penetrance. Excessive anxiety and/or depression has been reported in two independent 46,XX women who were carriers of *NR5A1* mutations but this association needs to be confirmed by other studies (Suwanai *et al.*, 2013).

Testicular/Ovo-testicular DSD (TDSD/OTDSD)

Several studies report a specific recurrent point mutation in NR5A1 (p.R92W) in association with testis development in 46,XX individuals in multiple families of different ancestry (Bashamboo *et al.*, 2016; Baetens *et al.*, 2016; Igarashi *et al.*, 2017). All individuals lacked the testis-determining gene *SRY*. The p.R92 *NR5A1* mutation was described in twelve 46,XX DSD patient and it is absent from control databases indicating that the association with the phenotype is robust. However, the expressivity of the phenotype is variable ranging from female external genitalia with clitoromegaly, to male external genitalia with micropenis or penoscrotal hypospadias. Sex of rearing was female in nine cases and as male in the other three. In one family a 46,XY sib, who inherited the mutation, developed 46,XY partial gonadal dysgenesis and was raised as a girl. The families also show incomplete penetrance for the phenotype with in total, 12 apparently unaffected carriers of the mutation were reported (six XY men and six XX women). Although, these individuals are not reported to have either under or overvirilization it is unclear if the mutation is completely without effect in these carriers as other heterozygous *NR5A1* mutations cause a decline in sperm numbers in men and premature ovarian failure in fertile women (Lourenco *et al.*, 2009; Bashamboo *et al.*, 2010). Three families were from a 70 km radius of the Southern Netherlands and haplotype analysis indicated that this is a founder mutation in that region. The other families were of Japanese, American or South Asian ancestry and in at least two families the mutation was not carried by either parent and was de novo. A heterozygous p.Arg92**Gln** variant (not p.Arg92Trp) has also been reported in a child with 46,XX ovotesticular DSD of American-European ancestry (Bashamboo *et al.*, 2016). This variant was inherited from her unaffected father. How changes in the R92 amino acid influences cell fate to change from a granulosa to a Sertoli cells is unclear. This mutation does not show a phenotype when introduced into mice (Miyado *et al.*, 2016). This is most likely due to the fact that, unlike the human (Bashamboo *et al.*, 2016), *Nr5a1* is not expressed in the early developing (pre)-granulosa cell (Ikeda *et al.*, 1994). Not surprisingly, this amino acid change introducing a bulky tryptophan residue in the A-box region results in an inability of the mutated protein to bind to a consensus target DNA sequence (Bashamboo *et al.*, 2016). However, either directly or indirectly the *NR5A1* mutation must lead to the upregulation of *SOX9* expression, which is a key for the formation of Sertoli cells and a direct target for SRY. In theory, this could be performed in one of two ways, either by directly activating genes in the male pathway and/or impeding female genes from repressing the male pathway. Thus, derepression could lead to the upregulation of SOX9 expression. There is no evidence that NR5A1 p.R92W is directly upregulating "male" genes including SOX9. In vitro assays showed that the R92W protein lacked the ability to directly upregulate expression when using the *AMH* or *Cyp11A1* promoters or a testis-specific *Sox9* enhancer. It is emerging that at least one function of pro-ovarian pathways, such as R-spondin-1/WNT4 is to activate β-catenin. β-catenin has emerged as a key regular of sex development in mammals. Mice lacking Rspo1 exhibit partial female-to-male sex-reversal, a phenotype that can be rescued by stabilized β-catenin expression in the somatic cells of the ovary. On the other hand, the expression and stabilization of β-catenin in the gonads of XY mice is sufficient to disrupt the male pathway and promote ovarian development. SF-1 has the ability to physically interact with the β-catenin protein and upregulate the expression of a series of target genes (Hossain and Saunders, 2003). These include the *AMHR2*, *INHA*, *CYP19A1*, and *DAX-1/NR0B1*. The SF-1 R92W mutant shows a reduced ability to interact with β-catenin to synergistically activate reporter gene activity. This suggests that the p.R92W NR5A1 variant switches organ fate from ovary to testis through disruption of ovary-specific pathways that would normally oppose testis development, rather than by activating pro-testis pathways directly.

Overactivity of SF-1

Overexpression or overactivity of SF-1 may be implicated in certain clinical phenotypes. Duplication of the locus encoding SF-1 has been reported in a high proportion of pediatric adrenal carcinomas, and overexpression of SF-1 has been shown to be present in many adult adrenal tumors (Almeida *et al.*, 2010; Sbiera *et al.*, 2010). Overactivity of SF-1 has been proposed to be associated with endometriosis, where SF-1 expression in undetectable in normal endometrial stromal cells and highly expressed in endometriotic stromal cells. Similarly, in polycystic ovaries, androgens are mainly produced in the follicular theca cells that express high levels of SF-1 (Calvo *et al.*, 2001).

Genotype–Phenotype Correlations

All studies indicate that there is a poor correlation between the severity of the phenotype and the nature of the NR5A1 variant. Even within families there is evidence of variable expressivity of the phenotype including both highly variable endocrine values and in the phenotypic appearance (Werner *et al.*, 2017). In part this may be explained by di- or oligogenic inheritance of other factors that influence the phenotype (Mazen *et al.*, 2016; Hattori *et al.*, 2017). The severity of the phenotype has also been proposed to be modulated by interallelic association with a known and common p.Gly146Ala polymorphism. However, robust genetic associations to support this have not been reported. Furthermore, the type of the NR5A1 mutation does not inform patient outcomes including pubertal androgenization, risk of cancer development or gender assignment. Gonadal histology is also not consistent between NR5A1 mutated individuals, even for the same amino acid change. Since the clinical effects of SF-1 are wide ranging and variable, management plans must be tailored to individuals cases.

Glossary

Congenital adrenal hyperplasia (CAH) A group of autosomal recessive disorders caused by defects in various enzymes involved in adrenal steroidogenesis leading to defective glucocorticoid and/or mineralocorticoid synthesis.

Introduction

The 11β hydroxylase enzymes (CYP11B1 and CYP11B2) are responsible for catalyzing the final steps in synthesis of cortisol and aldosterone. Congenital adrenal hyperplasia (CAH) due to 11β hydroxylase deficiency (11βOHD) results from reduced or absent activity of CYP11B1 enzyme in the adrenal cortex (Bulsari and Falhammar, 2017). 21-Hydroxylase deficiency (21OHD) remains the most common cause of CAH accounting 90%–99% of CAH cases, followed by 11β hydroxylase deficiency (11βOHD) responsible for 0.2%–8% (Bulsari and Falhammar, 2017; El-Maouche *et al.*, 2017; Gidlof *et al.*, 2013).

Depending on severity of clinical manifestations and degree of loss of enzymatic activity, 11βOHD is classified as classic or non-classic (NC). The clinical manifestations of classic 11βOHD include features of androgen excess including virilization of external genitalia in females, peripheral precocious puberty and hyporeninemic hypokalemic hypertension due to mineralocorticoid excess (Bulsari and Falhammar, 2017; Khattab *et al.*, 2017). Although, hypertension is only found in two-third of the cases at time of diagnosis of classic 11βOHD (Rosler *et al.*, 1992), hyporeninemic hypertension remains a key differentiating clinical feature for 11βOHD from classic 21OHD. NC 11βOHD usually has no abnormalities at birth and occurs as a result of partial loss of enzyme activity. Individuals with NC phenotype present in later life with mild virilization, peripheral precocious puberty, hirsutism or menstrual irregularities resembling polycystic ovarian syndrome (Bulsari and Falhammar, 2017; Speiser and White, 2003; White, 2001). Hypertension is not a feature commonly found in NC 11βOHD (Zachmann *et al.*, 1983).

Epidemiology

The exact prevalence of classic 11βOHD in general population is not well documented. It has been claimed to be 1 in 100,000 in the general population and around 5%–8% of the CAH cases (White, 2001). However, based on recent studies from United Kingdom and Sweden, 0.2%–1.5% of all CAH cases had 11βOHD (Arlt *et al.*, 2010; Gidlof *et al.*, 2013) and only 1 case of 11βOHD was found in the national CAH registry in Sweden suggesting the prevalence to be 1 in 9,000,000 in the general population (Bulsari and Falhammar, 2017; Gidlof *et al.*, 2013). The higher prevalence in previous studies could be secondary to selection bias and ethnicity of the study population.

Certain geographical locations and ethnic populations such as Tunisia, Iran, Saudi Arabia, Turkey and Jews of Morocco and Israel have higher frequency of classic 11βOHD (al-Jurayyan, 1995; Kandemir and Yordam, 1997; Khattab *et al.*, 2017; Rosler *et al.*, 1992). The estimated incidence in an offspring of Moroccan Jews in Israel was 1 in 5000–7000 with a carrier rate of 1 in 35 to 1 in 42 and an overall estimated incidence in Israel was 1 in 30,000–40,000 (Rosler *et al.*, 1992). The higher prevalence in certain ethnic populations is believed to be due to founder effect and high rates of consanguineous marriages within these ethnic populations. In an international cohort study, 58% of patients were from consanguineous marriages and mostly confined to Middle East and North African nations (Khattab *et al.*, 2017).

The prevalence of NC 11βOHD again varies with geographical location and ethnicity of study population from 0.8% to 8% in women with hirsutism and hyperandrogenism, however, in none of these studies the diagnosis was confirmed with *CYP11B1* gene mutation analysis (Azziz *et al.*, 1991; Carmina *et al.*, 1988; Eldar-Geva *et al.*, 1990; Kelestimur *et al.*, 1996; Sahin and Kelestimur, 1997).

Physiology

The zona glomerulosa and zona fasciculata in the adrenal cortex behave as distinct glands with specific biological functions. In zona fasciculata, the cholesterol precursors are converted to cortisol through a series of enzymatic reactions. CYP11B1 plays crucial role in the final step of conversion of 11-deoxycortisol to cortisol as depicted in **Fig. 1**. This pathway is under the regulatory effect

 doi:10.1016/B978-0-12-801238-3.65823-3

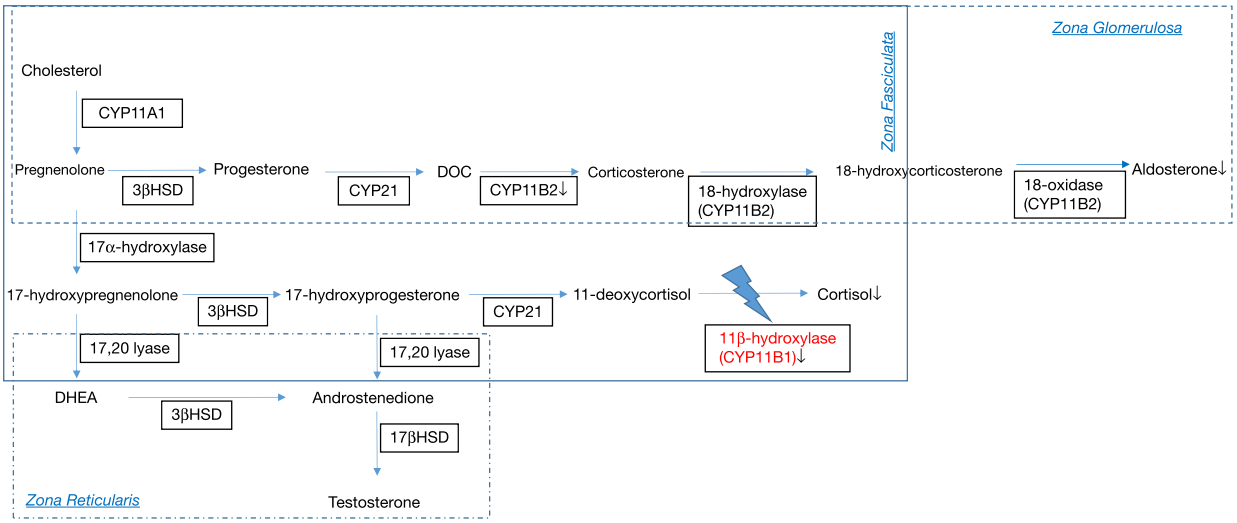

Fig. 1 Adrenal steroidogenesis. The classic pathways of aldosterone, cortisol, and androgen synthesis and the enzymatic steps from the precursor cholesterol are shown. Deficiency of 11β hydroxylase enzyme results in accumulation of 11-deoxycortisol, 11-deoxycorticosterone, 17-hydroxyprogesterone and progesterone in addition to androgens. The arrows demonstrate decreased synthesis of CYP11B1 and CYP11B2 in *zona fasciculata and zona glomerulosa*, respectively. The low aldosterone levels result from an excess of DOC, which is accumulated due to a blocked glucocorticoid pathway. As this metabolite possesses mineralocorticoid features, the renin angiotensin system is not activated as evidenced by the low renin concentration. This leads to a decreased synthesis of CYP11B2 and thus, to a decreased aldosterone production. 3βHSD, 3 beta hydroxysteroid dehydrogenase; 17βHSD, 17 beta hydroxysteroid dehydrogenase; CYP11B1, 11 beta hydroxylase; CYP11B2, 11 beta hydroxylase; 11DOC, 11-deoxycorticosterone; DHEA, dehydroepiandrosterone; DOC, 11-deoxycorticosterone.

of hypothalamic corticotrophin releasing hormone (CRH) and adrenocorticotropic hormone (ACTH) from the corticotroph cells of the pituitary gland.

In zona glomerulosa, the conversion of 11-deoxycorticosterone (DOC) to aldosterone requires three enzymatic reactions including 11β-hydroxylase, 18-hydroxylase, and 18-oxidase to convert DOC to corticosterone and subsequently to aldosterone (**Fig. 1**). This pathway is regulated by renin–angiotensin–aldosterone pathway and is independent of regulatory effect of ACTH. In vitro studies demonstrate CYP11B1 mediated conversion of DOC to corticosterone with inability to convert corticosterone to aldosterone. Hence, aldosterone is primarily produced in zona glomerulosa through the action of CYP11B2 (aldosterone synthase) which possesses 18-hydroxylase and 18-oxidase activities.

Pathophysiology

CYP11B1 mutations will result in defective 11β-hydroxylase enzyme and resultant defects in adrenal steroidogenesis. There is impaired conversion of 11-deoxycortisol and DOC to cortisol and corticosterone respectively in zona fasciculata (Bulsari and Falhammar, 2017; Krone and Arlt, 2009; Nimkarn and New, 2008; White, 2001). The low cortisol level results in activation of hypothalamic pituitary adrenal feedback system and increased ACTH production with resultant adrenal cortex hyperplasia (White and Speiser, 2000) and in occasional cases, adrenal tumor formation (Falhammar, 2014; Falhammar and Torpy, 2016; Jaresch *et al.*, 1992).

Blockade of cortisol secretion due to CYP11B1 enzymatic deficiency results in accumulation of precursor steroid metabolites which are shunted to androgen pathway (**Fig. 1**). DOC, and possibly other steroid precursors, possess mineralocorticoid activity and hence result in volume induced hypertension with resultant renin suppression and aldosterone deficiency. Elevated levels of androstenedione and testosterone levels due to shunting to androgen pathway result in symptoms of hyperandrogenism.

Cortisol appears to have important role in adrenomedullary organogenesis. Studies demonstrate significantly lower plasma epinephrine and urine metanephrine levels in patients with CAH and the degree of catecholamine deficiency appears to correlate with severity of adrenocortical dysfunction (Charmandari *et al.*, 2002; Falhammar *et al.*, 2011; Merke *et al.*, 2000; Tutunculer *et al.*, 2009).

Molecular Genetics

11β hydroxylase and aldosterone synthase are two homologous enzymes which are encoded by *CYP11B1* and *CYP11B2*, respectively in humans. *CYP11B1* gene is located on chromosome 8q24.3 (OMIM #202010), approximately 40 kb apart from the *CYP11B2* gene. There is 95% homology in coding regions and 90% homology in non-coding regions between *CYP11B1* and *CYP11B2*. The nine exons on CYP11B1 gene encode for 503 amino acids. More than 100 mutations including missense/nonsense,

small/gross deletions, insertions, splicing and complex rearrangements have been reported in various ethnic populations (www.hgmd.cf.ac.uk). Majority of mutations have been reported on exons 2, 6, 7, and 8 (Curnow *et al.*, 1993; Nimkarn and New, 2008).

Owing to the rarity of disease and significant variability in clinical presentations, it has been difficult to predict the actual disruptive effects of mutations and record genotype–phenotype co-relation until recently (Kandemir *et al.*, 2016). A recent international cohort study of 108 patients from 11 countries looked at clinical, genetic and structural effects of CYP11B1 gene mutations. This study noted certain specific mutations could be correlated to severity of 11βOHD, but this was not universally applicable (Khattab *et al.*, 2017). However, the majority of CYP11B1 gene mutations can distinguish between classic and NC 11βOHD (Bulsari and Falhammar, 2017).

Certain mutations occur with increased frequency in specific ethnic populations or geographical locations. In Jews of Moroccan origin, R448H, a point mutation is the most common mutation which was identified in 11 of 12 patients with 11βOHD (White *et al.*, 1991). On the other hand, c.945G>A splice site mutation was the most frequent mutation noted in a Turkish cohort (Kandemir *et al.*, 2016). This could be a result of high frequency of consanguineous marriages in specific populations with resultant founder effect.

Clinical Manifestations

Classic 11βOHD

Hyperandrogenism

In patients with 11βOHD, features of androgen excess can be detected from infancy to early adulthood.

In 46XX females, variable degree of virilization of external genitalia with intact functional gonads and internal genitalia derived from Mullerian structures has been noted. The severity of virilization is scored based on Prader staging system from stage zero to stage six. Females were diagnosed at a median age of 1.1 years with 80% females reported to have ambiguous genitalia at birth and incorrect gender assignment was common (Khattab *et al.*, 2017). In 46 XY males, enlarged penis with age appropriate testicular size may be noted during childhood or early adulthood. Untreated males may develop pubertal gynecomastia, Leydig cell hyperplasia (Rosler *et al.*, 1992) or testicular adrenal rest tumors (TARTs) (Oberman *et al.*, 1993).

Acne, premature adrenarche, hyperpigmentation of skins and nipples, peripheral precocious puberty, delayed menarche in females and poor spermatogenesis in males have been documented in 11βOHD as clinical signs of androgen excess (White *et al.*, 1994).

Other features of hyperandrogenism in both males and females include accelerated somatic growth, premature epiphyseal closure and resultant short adult stature. A retrospective study of 24 patients (15 girls, 9 boys) with 11βOHD were followed over a period of 15 years to assess growth and pubertal velocity (Hochberg *et al.*, 1985). Normal growth parameters of height, weight and bone age were noted for the first 4 months of life but accelerated by 11 months of life. Height was noted to be at a mean of 4 SDs above the mean for age between the ages of 2 and 5 years but the pubertal growth velocity was slower than normal. Final height was significantly compromised in all patients irrespective of age at diagnosis and therapeutic control. Precocious onset of puberty was noted in males but not in females.

Hypertension

Hypertension is a key differentiating feature from 21OHD. However, varying degrees of hypertension is observed in only two-thirds of the cases at time of diagnosis (Burren *et al.*, 1996; Rosler *et al.*, 1992). The recent international cohort study reported presence of hypertension in 59% of 11βOHD patients (Khattab *et al.*, 2017). The presence of excess DOC is thought to be responsible for hypertension, however, the mechanisms remain unclear (–see "Blood Pressure" section).

Electrolyte balance

Hypokalemia has been reported in a minority of patients with 11βOHD. It is believed to be due to excess mineralocorticoid precursors. In a study of 23 patients with 11βOHD, only six had overt hypokalemia (Rosler *et al.*, 1982). There appears to be no correlation between hypertension and hypokalemia. On the other hand, hypokalemic periodic paralysis has been reported as a presenting symptom of 11βOHD in teenage years (John *et al.*, 2009; Sathya *et al.*, 2012). Hence, 11βOHD should be considered as a differential diagnosis in a patient presenting with hypertension and hypokalemia or hypokalemic periodic paralysis (Falhammar *et al.*, 2013).

Salt-wasting is not a typical feature of 11βOHD unlike 21OHD. However, salt-wasting has been reported in the early neonatal period prior to treatment with glucocorticoids in patients with elevated basal DOC and renin levels. The mechanism is not well-understood but is possibly secondary to the natriuretic effect of 16-hydroxylated steroids, progesterone and pregnenolone from fetal adrenal tissue (Zachmann *et al.*, 1983). Therefore, it disappears in adult life and there are no reports of clinically significant salt-wasting in adults with 11βOHD. However, a minority of patients develop features of mineralocorticoid deficiency including hyperkalemia, hyponatremia, and hypovolemia during acute illness. Adequate dietary sodium intake and mineralocorticoid therapy may be required in such cases (Hochberg *et al.*, 1984; Liel, 1993). Rarely, glucocorticoid therapy may precipitate salt-wasting via suppression of DOC and resultant low mineralocorticoid activity (Zadik *et al.*, 1984).

Non-Classic 11βOHD

Patients with this milder form of 11βOHD usually have normal external genitalia at birth but present with peripheral precocious puberty in childhood or features such as acne, hirsutism and/or oligo-amenorrhea. Females are often misdiagnosed as polycystic

ovarian syndrome due to very similar clinical presentation. Hence, NC 11βOHD patients have similar clinical features as NC 21OHD (Falhammar *et al.*, 2008, 2015; Pall *et al.*, 2010). Patients with NC 11βOHD are usually normotensive or have borderline high-normal blood pressure at time of diagnosis (Parajes *et al.*, 2010; Reisch *et al.*, 2013; White, 2001).

The diagnosis of NC 11βOHD is based on either high basal or ACTH stimulated levels of serum 11-deoxycortisol level. NC 11βOHD should be considered as a differential diagnosis in cases of premature adrenarche, hirsutism, and menstrual irregularities.

Diagnosis

Reduced/absent activity of 11β-hydroxylase enzyme results in impaired production of cortisol and accumulation of steroid precursors (**Fig. 1**). Elevated basal levels of 11-deoxycortisol, DOC and 17-hydroxyprogesterone (17OHP) are noted in patients with 11βOHD. The increased 17OHP is then shunted to androgen pathway resulting in elevated androstenedione and testosterone. Accumulation of DOC results in suppression of renin–angiotensin system and hence reduced plasma renin and aldosterone levels are noted. These laboratory findings are summarized in **Table 1**.

Measurements of basal and ACTH stimulated 11-deoxycortisol and DOC aid in diagnosis of NC 11βOHD. Levels more than three times above the 95th percentile in normal population has been used for diagnosis in some clinical studies, however, it is not a specific marker (Azziz *et al.*, 1991; Kelestimur *et al.*, 1996; Sahin and Kelestimur, 1997).

Urinary steroid profile for tetrahydro-metabolites of steroid precursors such as tetrahydro-11-deoxycortisol (THS), tetrahydro-deoxycorticosterone (THDOC) can be helpful in diagnosis of 11βOHD and monitoring efficacy of treatment (Burren *et al.*, 1996).

Genetic profile and functional characterization of mutations is important in order to confirm the diagnosis as well as provide appropriate genetic counseling (Parajes *et al.*, 2010).

Complications

Mortality

Mortality has not been studied in detail in 11βOHD. However, it can be extrapolated from the data available in 21OHD patients which shows three times higher hazard ratio for mortality compared to controls (Falhammar *et al.*, 2014). The mortality rate in 11βOHD could be higher compared to 21OHD due to higher cardiovascular risk (Bulsari and Falhammar, 2017). However, the risk of adrenal crisis is believed to be lower in 11βOHD than 21OHD and hence the mortality might be reduced compared to 21OHD but is likely to be higher than the general population (Burren *et al.*, 1996).

Cardiovascular and Metabolic Complications

Blood pressure

As mentioned above, hypertension is the hallmark features of classic 11βOHD. It is assumed to be secondary to excess mineralocorticoid activity of DOC. However, there is no correlation between plasma levels of DOC and severity of hypertension (Khattab *et al.*, 2017; White *et al.*, 1994; Zachmann *et al.*, 1983). There is poor correlation between degree of virilization and features of mineralocorticoid excess (Rosler *et al.*, 1982, 1992). DOC has been shown to have weak mineralocorticoid activity

Table 1 Comparison of clinical features of three forms of CAH including 11β-hydroxylase deficiency, 21-hydroxylase deficiency, and 17-hydroxylase deficiency

	11β-Hydroxylase deficiency	*21-Hydroxylase deficiency*	*17-Hydroxylase deficiency*
Affected gene	*CYP11B1*	*CYP21A2*	*CYP17A1*
Prevalence (classic)	1 in 100,00 to 1 in 9,000,000[a]	1 in 15,000	1 in 50,000 to 1 in 9,000,000
Salt wasting	Rare	Common	Rare
Hypertension	Common	Rare	Common
Degree of virilization	Mild-severe	Mild-severe	Nil
11-Deoxycortisol	Elevated	Low	Low
Deoxycorticosterone	Elevated	Low	Elevated
17-Hydroxyprogesterone	Elevated	Elevated	Low
Progesterone	Elevated	Elevated	Elevated
Renin	Low	Elevated	Low

[a]Incidence in Caucasian population.

in vivo compared to 18-hydroxylated compounds which are hence, speculated to be the cause of hypertension in 11βOHD. Both inadequate dosing and over-treatment with glucocorticoids can contribute to hypertension. Suboptimal blood pressure control and over-replacement with glucocorticoids will have negative effects on cardio-metabolic profile. There are multiple reports of significant end-organ damage secondary to hypertension including left ventricular hypertrophy, hypertensive retinopathy, hypertensive nephropathy, encephalopathy, ischemic heart disease, cerebrovascular accidents and deaths in patients with 11βOHD (Chabre *et al.*, 2000; Glenthoj *et al.*, 1980; Hague and Honour, 1983; John *et al.*, 2009; Melcescu *et al.*, 2012; Rosler *et al.*, 1982, 1992).

Metabolic complications

There is wide variations in BMI in patients with classic and NC 11βOHD (Jermendy *et al.*, 1991; Menabo *et al.*, 2014; Parajes *et al.*, 2010; Polat *et al.*, 2014; Reisch *et al.*, 2013). Obesity is a well-known risk factor for adverse cardiovascular outcomes. The prevalence of type 2 diabetes in 11βOHD has not been reported except for two cases of type 2 diabetes in NC 11βOHD (Jermendy *et al.*, 1991).

Height and Bone Health

There is little information known in regards to height and bone health in patients with 11βOHD.

Final height

Advanced bone age has been well reported with males significantly exceeding females in terms of bone age (Khattab *et al.*, 2017). The mean final height was significantly lower in patients with 11βOHD compared to general population. The possible factors contributing to slow pubertal growth velocity and reduced final height include delay in diagnosis and over-replacement with glucocorticoids. However, there was poor correlation between age at diagnosis and efficacy of glucocorticoid therapy measured with clinical biochemical control and mean final height (Hochberg *et al.*, 1985). Hydrocortisone was superior to cortisone acetate and prednisolone in terms of growth velocity.

Bone health

There is no available information on bone mineral density (BMD) in patients with 11βOHD. However, as seen with 21OHD, long term glucocorticoid exposure is expected to have negative impact on BMD (Bulsari and Falhammar, 2017).

Adrenocortical Tumors

In 21OHD, chronically elevated ACTH levels result in stimulation of adrenal cortex and adrenal hyperplasia (Falhammar, 2014; Falhammar and Torpy, 2016; Jaresch *et al.*, 1992; Nermoen *et al.*, 2011). Similar studies in 11βOHD are lacking. However, there are reports of adrenal incidentalomas found in cases of classic and NC 11βOHD. None of these cases were confirmed with genetic testing (John *et al.*, 2009; Kacem *et al.*, 2000; Touitou *et al.*, 1989). In vitro enzymatic analyses and ACTH stimulation test in patients with functional adrenocortical tumors and nonfunctional adrenal incidentalomas have shown evidence of impaired 11β-hydroxylation activity (Dall'Asta *et al.*, 2002; Doerr *et al.*, 1987; Reincke *et al.*, 1997; Werder *et al.*, 1994).

Testicular Adrenal Rest Tumors

Testicular adrenal rest tumors (TARTs) mostly affect the rete testes on bilateral sides and are benign testicular masses. In 21OHD patients, functional studies have identified ACTH and angiotensin II (AII) receptors in addition to adrenal specific CYP11B1 and CYP11B2 enzymes. Histological studies revealed significant resemblance between TARTs and adrenocortical tissues along with presence of ACTH and AII receptors in the TART tissue (Claahsen-van der Grinten *et al.*, 2007). There was poor relationship between tumor growth and ACTH suppression as well as total TART volume and age, glucocorticoid dosing, plasma renin and ACTH concentrations (Falhammar *et al.*, 2012; Reisch *et al.*, 2010; Stikkelbroeck *et al.*, 2004).

Owing to its central location, TART tissue causes compression of seminiferous tubules with fibrosis and tubular hyalinization leading to obstructive azoospermia. Among five males with 11βOHD, 60% (three out of five) had TART identified on ultrasonography, indicating possible high prevalence (Aycan *et al.*, 2013). Complete disappearance to no response on high dose steroid therapy have been reported in cases with 11βOHD (Bulsari and Falhammar, 2017). Testis sparing surgery has been shown to improve fertility in some cases of 21OHD with persistent azoospermia or poor response to glucocorticoid therapy (Tiryaki *et al.*, 2005; Walker *et al.*, 1997). TART can be easily misdiagnosed as testicular malignancy and patients with CAH have undergone testicular surgery in the past (Arlt *et al.*, 2010; Falhammar *et al.*, 2012). Hence, it is an important differential diagnosis to be considered prior to testicular surgery in a patient with CAH (Falhammar and Thoren, 2012).

Given significant impact of TART on fertility, early diagnosis and treatment is important. Screening with scrotal ultrasound from early childhood to peripubertal period should be considered (Aycan *et al.*, 2013). We suggest scrotal ultrasound every 2–5 years or earlier if clinically indicated as there is lack of consensus guidelines to specify frequency of screening in adults.

Fertility

Male fertility

Azoospermia has been reported in majority of cases with 11βOHD. However, semen analyses results were available on in cases of TARTs giving a false impression of high rates of subfertility in males with 11βOHD (Aycan *et al.*, 2013; Kaynar *et al.*, 2014; Willi *et al.*, 1991). In addition to presence of TART, a multitude of sexual and psychosocial factors may play a role in male fertility (Falhammar and Thoren, 2012). Fertility was impaired in 221 males with 21OHD and it can be assumed to be similar in 11βOHD (Falhammar *et al.*, 2017).

Female fertility

There is limited information regarding female fertility in patients with 11βOHD. There are two case reports of successful pregnancy outcomes in patients with 11βOHD with no adverse maternal or fetal outcomes (Simm and Zacharin, 2007; Toaff *et al.*, 1975). Fertility outcomes for 11βOHD can be inferred to some extent from the currently available data on pregnancy and fertility in females with 21OHD. 21OHD patients had higher incidence of gestational diabetes and emergency or elective caesarean section compared to controls (Falhammar *et al.*, 2007; Hagenfeldt *et al.*, 2008). As dexamethasone is not metabolized by placental 11 beta hydroxysteroid dehydrogenase type II, it should be avoided during pregnancy (Speiser *et al.*, 2010).

Prenatal Diagnosis

The fetal status for 11βOHD can be assessed by molecular genetic analysis of CYP11B1 gene in the extracted fetal DNA by chorionic villus sampling (Bouchard *et al.*, 1989; Cerame *et al.*, 1999; Curnow *et al.*, 1993; Geley *et al.*, 1996). There is controversy regarding prenatal treatment with dexamethasone in case of an affected female fetus and such treatment should be considered only in research settings (Speiser *et al.*, 2010).

Gynecomastia

Pre-pubertal gynecomastia has been reported in 11βOHD (Bulsari and Falhammar, 2017). The mechanisms of gynecomastia remain unclear. There are two plausible explanations for gynecomastia. Firstly, there are high levels of circulating adrenal androgens which undergo peripheral aromatization to estradiol. Secondly, 11-deoxycortisol and DOC are potent mineralocorticoids with possible anti-androgen effect contributing to gynecomastia (Hochberg *et al.*, 1991). Treatment with glucocorticoids resulted in reversal of gynecomastia in patients with 11βOHD (Hochberg *et al.*, 1991; Maclaren *et al.*, 1975; Rosler *et al.*, 1992; Zachmann and Prader, 1975; Zachmann *et al.*, 1983; Zadik *et al.*, 1979).

Management

Medical Therapy

Glucocorticoid therapy and monitoring

The basic principle of therapy is to replace cortisol deficiency and hence, reduce excess production of adrenal androgens and mineralocorticoid precursors. Hydrocortisone in doses of 10–20 mg/m^2/day in two to three divided doses is the most commonly used glucocorticoid preparation. It has been reported to be effective in most patients with 11βOHD similar to in 21OHD (Burren *et al.*, 1996; Nimkarn and New, 2008; Peter, 2002). Hydrocortisone is preferred in children due to short duration of action and hence less potential for growth suppression (Hochberg *et al.*, 1985; Speiser *et al.*, 2010). During adulthood, intermediate acting and long acting glucocorticoids such as prednisolone (2.5–7.5 mg/day in divided doses) and dexamethasone (0.25–0.5 mg at bedtime or in divided doses), respectively have been used in 21OHD. Modified release hydrocortisone preparation has been studied in 21OHD with potential benefits, but not in 11βOHD (Quinkler *et al.*, 2015). In case of acute illness, stress doses of glucocorticoids are required in all patients with classic 11βOHD although, the risk of adrenal crisis is lower with 11βOHD compared to 21OHD patients (Burren *et al.*, 1996; Nimkarn and New, 2008; Peter, 2002).

The patients should be monitored at regular intervals for clinical assessment and documentation of virilization, growth parameters and control of hypertension (Rosler *et al.*, 1982). Adequate therapy should result in optimal blood pressure and control of hyperandrogenism features along with optimization of growth and fertility preservation (Nimkarn and New, 2008). Plasma 11-deoxycortisol, DOC and renin activity are useful to monitor adequacy of glucocorticoid therapy (Nimkarn and New, 2008; Rosler *et al.*, 1982). Patients on suboptimal doses will have high DOC levels with suppressed renin activity. The DOC levels and renin activity should normalize once appropriate glucocorticoid therapy is initiated. The glucocorticoid therapy has to be monitored and adjusted closely to reduce risk of iatrogenic Cushing's syndrome.

Control of hypertension

Despite adequate glucocorticoid dosing, blood pressure may remain elevated in certain cases. An additional anti-hypertensive agent should be added in such cases. The agents of choice are amiloride or spironolactone as monotherapy or in combination with

calcium channel blockers (White, 2001). Angiotensin converting enzyme inhibitors and angiotensin II receptor blockers should be avoided as the renin angiotensin system is suppressed in patients with 11βOHD. Due to the potential risk of hypokalemia with thiazide diuretics, they should be avoided or used in combination with potassium sparing diuretics.

Mineralocorticoid therapy

Patients with 11βOHD have elevated mineralocorticoid precursors prior to treatment with glucocorticoids. Initiation of glucocorticoid therapy can result in suppression of excess mineralocorticoid precursors and relative mineralocorticoid deficiency. Mineralocorticoid therapy has been shown to reduce glucocorticoid requirement and achieve better growth outcomes in a study where patients with 11βOHD had elevated renin activity despite optimal glucocorticoid doses (Rosler and Leiberman, 1984). However, patients need careful monitoring of blood pressure, urinary electrolytes and renin levels with mineralocorticoid therapy. Similarly, patients with acute illness and electrolyte imbalance may require mineralocorticoid therapy (Hochberg *et al.*, 1984; Liel, 1993; Zadik *et al.*, 1984). In the early neonatal period, salt-wasting has been reported as described earlier (Zachmann *et al.*, 1983). Hence, when the diagnostic test results are pending in early neonatal period, mineralocorticoid therapy should be considered in addition to glucocorticoid replacement to avoid renal salt-wasting. The mineralocorticoid therapy can be gradually withdrawn over the first year of life with close follow-up and monitoring.

Growth augmenting therapy

In children, close monitoring of growth velocity and bone maturation is an important aspect in management of CAH (Speiser *et al.*, 2010). As discussed earlier, children with 11βOHD have significantly lower final height irrespective of age at diagnosis and biochemical control. Hence, growth augmentation therapies have been trialed. There are case reports of using growth hormone, gonadotropin releasing hormone (GnRH) analogue and glucocorticoid combination therapy, aromatase inhibitor and growth hormone combination therapy in children with 11βOHD with improved final height outcome and no reported adverse events (Bulsari and Falhammar, 2017). There is lack of randomized trials and the long term effects of above therapy are unknown. Hence, such treatment is recommended only in research settings.

Surgical Therapy

Genital reconstruction/correction surgery

In addition to above medical therapy, corrective surgeries for genital abnormalities (e.g., vaginoplasty and clitoral reduction) have to be considered in 46XX patients with severe virilization. The appropriate timing of surgical intervention is not clear in currently available guidelines. The surgical treatment should be performed in specialized centers where medical, surgical and psychological expertise in CAH care is available (Nordenskjold *et al.*, 2008; Speiser *et al.*, 2010). Additional surgeries or vaginal dilatation may be required in adolescent life and hence, these patients require ongoing follow-up with the surgical clinic.

Adrenalectomy

Bilateral adrenalectomy has been described as a successful management option in five case reports of patients with 11βOHD. This has been implemented in cases with poorly controlled hypertension and end-organ damage, severe hypokalemia and extreme hyperandrogenism requiring high doses of glucocorticoid therapy (Chabre *et al.*, 2000; John *et al.*, 2009; Kacem *et al.*, 2009; Nasir *et al.*, 1996). Long-term outcome has been reported in one case followed up until 72 months post-operatively. The hypertension resolved rapidly within 15 days post-operatively. Interestingly, the 11-deoxycortisol levels remained elevated during follow-up with normal blood pressure and no focus of adrenal rest tissue (Kacem *et al.*, 2009).

The risks and benefits of bilateral adrenalectomy have to be weighed carefully. Due to lack of evidence and the increased risk of adrenal crisis, bilateral adrenalectomy should be considered only in selected cases.

Conclusion

11βOHD is a rare autosomal recessive disorder with only a few studies reported in the literature with limited number of patients included. Owing to relatively low prevalence and significant phenotypic variability, diagnosis of 11βOHD is usually delayed unless there is high index of clinical suspicion. 11βOHD is associated with multiple complications including adverse cardiovascular, final height and fertility outcomes. Early diagnosis and appropriate management of such cases are likely to improve long-term outcomes. Medical management of 11βOHD requires close monitoring and surveillance to avoid complications of over-replacement with glucocorticoids. Ongoing research and collaborative studies are of paramount importance to explore the underlying pathophysiology, molecular genetics and management strategies in patients with 11βOHD.

Human P450 Oxidoreductase Deficiency

Christa E Flück and Amit V Pandey, University of Bern, Bern, Switzerland

Introduction

P450 oxidoreductase deficiency (PORD, OMIM 613571) is a form of congenital adrenal hyperplasia (CAH) (Pandey and Flück, 2013; Burkhard *et al.*, 2017). CAH is defined as an inborn error of adrenal steroid biosynthesis affecting glucocorticoid production (**Fig. 1**) (Miller and Fluck, 2014; Fluck, 2017). The most common and first described form of CAH is steroid enzyme 21-hydroxylase deficiency, in which mutations of the *CYP21A2* gene lead to diminished or lacking glucocorticoid and maybe mineralocorticoid production, and thus compensatory androgen overproduction. POR is an essential redox partner for the catalytic activity of CYP21A2, but other than specific enzyme deficiencies of adrenal steroidogenesis involved in cortisol production, PORD manifests several symptoms in addition to the CAH phenotype. As a redox partner to dozens of cytochrome P450, effects of mutations in POR reach far beyond steroid biosynthesis and POR variants manifest with a very broad phenotype like a chameleon changing color depending on its surrounding.

Interestingly, the mouse knockout (KO) of *Por* −/− was created before the first human POR mutations were found. It was found to be embryonic lethal (Shen *et al.*, 2002; Otto *et al.*, 2003), and resembled the KO mouse of retinoic acid metabolizing *Cyp26a1* −/− (Sakai *et al.*, 2001). While the same phenotype was also observed with toxic embryonic retinoic acid exposure, retinoic acid lowering measures were able to mitigate the phenotype of *Por* −/− (Otto *et al.*, 2003; Lee *et al.*, 2004; Ribes *et al.*, 2007). By contrast, a conditional liver-specific KO model yielded normal, fertile mice with disrupted hepatic drug metabolism and lipid accumulation (Gu *et al.*, 2003; Henderson *et al.*, 2003).

Clinical Manifestation

The first clinical description of PORD patients was through the remarkable steroid profile combining characteristics of 21-hydroxylase and 17-hydroxylase deficiency, but no genetic mutations in the genes of *CYP21A2* and *CYP17A1* were found (Peterson *et al.*, 1985). The reported patient manifested at 6 months of age with a 46,XY disorder of sexual development (DSD) characterized by a female phenotype with ambiguous genitalia. Although the hypothesis that the underlying genetic cause might lie in redox partners POR or

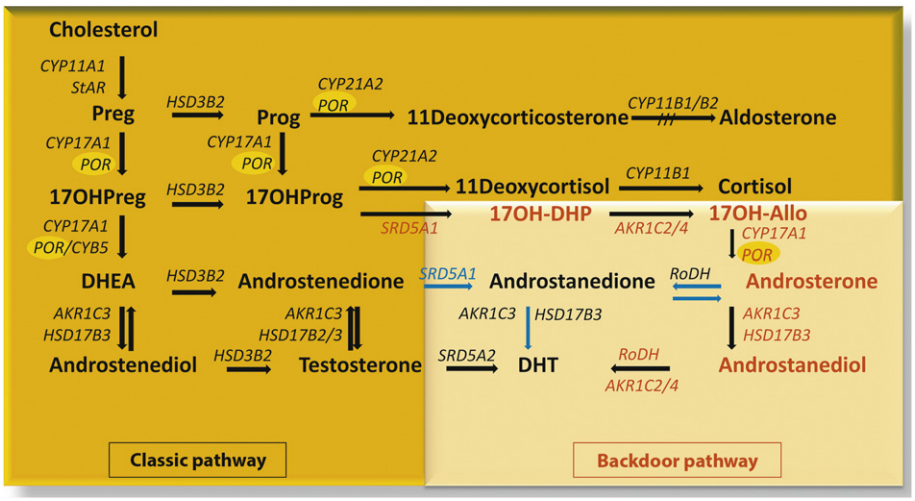

Fig. 1 Steroidogenesis of the human adrenal cortex. Mineralocorticoids, glucocorticoids, and adrenal sex steroids are produced from cholesterol through multiple catalytic reactions (shown as *arrows*) supported by specific steroid enzymes and cofactors such as P450 oxidoreductase (POR) (given in *italics*). The classic pathway for mineralocorticoid, glucocorticoid and androgen production is shown in *dark yellow*, while the alternative pathway for dihydrotestosterone (DHT) synthesis is shown in yellow. POR (shown in bright *yellow*) is essential electron transfer donor to CYP21A1 and CYP17A1 in several steps of adrenal steroidogenesis, and therefore causing a phenotype of congenital adrenal hyperplasia (CAH) as well as disordered sex development (DSD) in both males and females. *Preg*, pregnenolone; *17OHPreg*, 17-hydroxypregnenolone; *Prog*, progesterone; *17OHProg*, 17-hydroxyprogesterone; *DHEA*, dehydroepiandrosterone; *17OH-DHP*, 17-hydroxy-dihydroprogesterone; *17OH-Allo*, 17-hydroxy-allopregnanolone.

 doi:10.1016/B978-0-12-801238-3.64966-8

CYB5 was expressed in a letter ensuing the report (Miller, 1986), POR mutations were found many years later, when additional patients with similar unexplained phenotypes were found and sequenced for variations in the *POR* gene (Arlt *et al.*, 2004; Flück *et al.*, 2004; Miller *et al.*, 2004; Pandey *et al.*, 2004). In a first report three patients with POR deficiency (PORD) were described showing skeletal malformations with craniosynostosis known as Antley–Bixler syndrome (ABS) and genital anomalies at birth both in 46,XX and 46,XY subjects (Flück *et al.*, 2004). Mild adrenal insufficiency was diagnosed at follow-up upon stimulation testing. On the other hand, POR mutations were also found in a 23-year young women seeking help for primary amenorrhea with hypoplastic uterus and enlarged cystic ovaries, but normal breast development, and mild arterial hypertension (Flück *et al.*, 2004). She had otherwise no dysmorphic features. Concurrently, similar POR mutations were found in three other individuals (Arlt *et al.*, 2004). Two siblings were reported with PORD; the 46,XX girl had severe bone malformations and virilization of the external genitalia at birth, while her younger affected 46,XY brother showed a normal male phenotype at birth and had no ABS-like features (Arlt *et al.*, 2004). In addition, a 46,XX girl with POR mutations was found to have minor ABS features with ambiguous genitalia at birth, and developed large ovarian cysts during puberty leading to ovarian ruptures and therefore ovarectomy (Arlt *et al.*, 2004).

Over the last 15 years, more than 100 patients with PORD have been reported either in series or as case reports (**Table 1**). The manifesting phenotype remains very broad ranging from severely affected individuals showing an ABS with DSD at birth to being normal at birth, but having minor problems with steroid hormone production leading to pubertal disturbances, a polycystic ovary syndrome-like phenotype or fertility problems toward adulthood. There might be even asymptomatic carriers. Therefore, the clinical diagnosis of PORD is challenging. Genotype–phenotype and structure–function correlations may explain some observed characteristics, while others remain a conundrum.

Table 1 Characteristics of 120 reported patients with POR deficiency

			Phenotype			
Number of patients	Chromosomal sex 46,XX/46,XY	POR mutations	ABS features/skeletal anomalies	Abnormal genitalia	Abnormal steroids	References

[a]POR mutations not identified on all alleles.

[b]19 out of 32 patients with the ABS phenotype had POR mutations.

[c]Karyotype, description of genitalia or steroid profile not known for all patients.

[d]Additional heterozygote mutation Q798E in the androgen receptor gene.

[e]Prenatal diagnosis at 17, 22, 23 (Tzetis *et al.*, 2016), and 26 (Oldani *et al.*, 2015) weeks gestation with pregnancy termination.

Modified from Burkhard, F. Z., S. Parween, S. S. Udhane, C. E. Flück and A. V. Pandey (2017). "P450 Oxidoreductase deficiency: Analysis of mutations and polymorphisms." Journal of Steroid Biochemistry and Molecular Biology 165(Pt A), 38–50.

PORD and Pregnancy

Remarkably, mothers carrying a fetus with PORD may notice signs of virilization on their own body during pregnancy in 1/3–1/2 of cases (Arlt *et al.*, 2004; Flück *et al.*, 2004; Reisch *et al.*, 2013; Bai *et al.*, 2017). These include oily hair, acne, hirsutism, and deepening of the voice, and mostly disappear after delivery. This phenomenon is also observed in mothers carrying a fetus with aromatase (CYP19) deficiency or with pregnancy luteoma (Miller and Auchus, 2011). POR is the essential cofactor to CYP19 and CYP21, and therefore mutations of fetal POR may cause androgen excess in the fetal-placental unit. The suggested mechanism seems complex and is explained in more details in **Fig. 2** as well as in Reisch et al. (2013). In addition fetal sex development may be affected in both sexes leading to ambiguous genitalia detected in ultrasound screening. Furthermore, prenatal ultrasound may also reveal skeletal anomalies compatible with ABS including craniosynostosis, femoral bowing and bilateral radiohumoral synostosis (Reisch *et al.*, 2013; Oldani *et al.*, 2015; Tzetis *et al.*, 2016).

However, why some subjects with same POR mutations, even from same families/parents may present with different phenotypes, also with respect to maternal virilization, remains unexplained.

PORD and DSD

New born boys and girls with PORD may have a DSD phenotype due to disturbed intrauterine steroid hormone production according to the Chicago consensus DSD classification (Hughes *et al.*, 2006). This seems contradictive, given that most other forms of CAH associated with DSD result in either 46,XX DSD (e.g., CYP21 deficiency) or 46,XY DSD (e.g., CYP17 deficiency), with the exception of HSD3B2 deficiency, in which also both female virilization and male undermasculinization are observed. External genitalia of 46,XX girls may be significantly virilized (Prader III–V) at birth leading to male sex assignment. But unlike in CAH due to classic 21-hydroxylase deficiency, postnatal progression of virilization in affected girls does not occur, because circulating androgen levels are low after birth in both sexes. This intrauterine androgen excess, affecting the female phenotype only, can be explained by an alternative pathway for androgen biosynthesis from dehydroepiandrosterone (DHEA) that seems present merely in utero and in early postnatal life (**Fig. 2**) (Arlt *et al.*, 2004; Homma *et al.*, 2006; Williamson *et al.*, 2006). Noteworthy, this alternative androgen production does not seem to compensate for the classic sex steroid biosynthetic pathway in the male fetus. Therefore, external genitalia of 46,XY boys with PORD may be undervirilized at birth varying from micropenis and cryptorchidism to severe hypospadias due to PORD-related CYP17 deficiency (Flück and Pandey, 2017a,b). Its clinical and biochemical picture may be indistinguishable from isolated 17,20 lyase or cytochrome *b*5 deficiency (Hershkovitz *et al.*, 2008; Miller, 2012; Flück and Pandey, 2017a,b). However, to our knowledge complete sex reversal has not been described in 46,XY PORD so far.

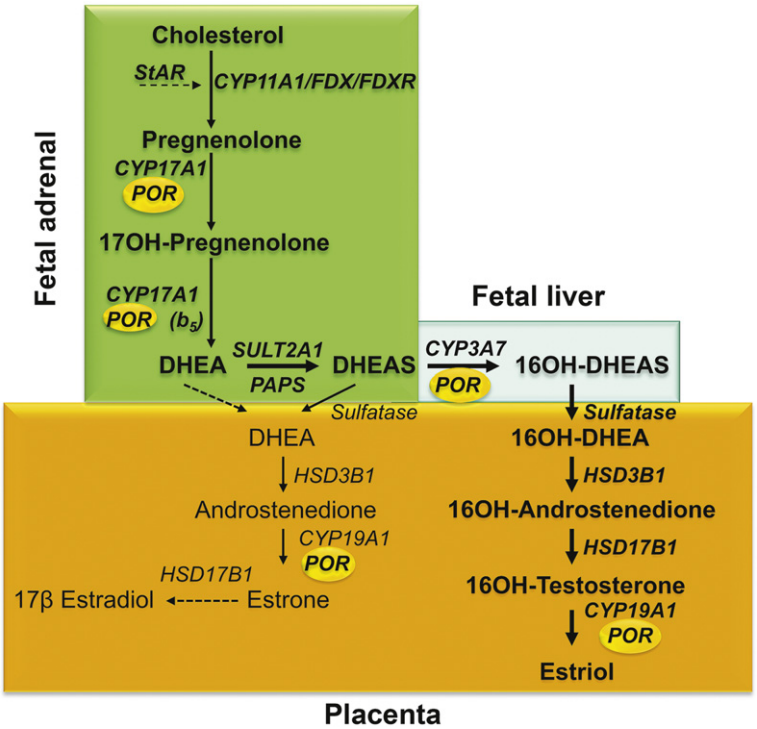

Fig. 2 Scheme of the fetal adrenal-placental steroid metabolism. Updated from Miller, W. L. and Fluck, C. E. (2014). Adrenal cortex and its disorders. In *Pediatric endocrinology*. M. A. Sperling, ed. Philadelphia: Saunders.

Adrenal Insufficiency/CAH and PORD

Although POR is needed for two catalytic reactions along the pathway for cortisol production from cholesterol (**Fig. 1**), overt adrenal insufficiency is rarely described in PORD. But adrenal insufficiency may be diagnosed at birth through neonatal screening established for CAH due to mutations in the *CYP21A2* gene using 17-hydroxyprogesterone as marker steroid. Thus several cases are reported that have been mis-diagnosed with CAH due to 21-hydroxylase deficiency, in whom no *CYP21A2* but *POR* mutations have been found (Fukami *et al.*, 2006; But *et al.*, 2010). Fortunately for them, this led to early protective steroid replacement therapy.

Asymptomatic adrenal insufficiency is often found in PORD with ACTH testing showing normal cortisol levels at baseline, but an inadequate rise in cortisol upon ACTH stimulation. CAH due to PORD has a mixed character of both 17- and 21-hydroxylase deficiency and causes therefore usually a mild glucocorticoid deficiency and a mild mineralocorticoid excess, which may lead to arterial hypertension with aging, similar as seen in patients with *CYP17A1* mutations. As mild adrenal insufficiency may not be relevant in healthy days, but life-threatening in sick days, it is important that all patients with an ABS phenotype or known POR mutations are tested for their adrenal function and individually advised for their need of glucocorticoid replacement therapy either continuously or at least in stress situations.

Pubertal Development and Gonadal Function in PORD

PORD affects CYP17 activity and thereby sex hormone biosynthesis. It may or may not lead to a DSD phenotype manifesting at birth (as described in section "PORD and DSD") and/or result in absent or insufficient pubertal development in both males and females. Several young females were diagnosed with PORD after medical work-up for primary amenorrhea or menstrual irregularities, normal breast development and (recurrent) large ovarian cysts complicated by spontaneous ruptures (Flück *et al.*, 2004; Fukami *et al.*, 2009; Sahakitrungruang *et al.*, 2009; Herkert *et al.*, 2011; Idkowiak *et al.*, 2011; Bai *et al.*, 2017). They presented with a hormonal profile of hypergonadotropic hypogonadism, elevated 17OHProg, but low or normal androgens and estrogens, and were successfully treated with estrogens/progestins and glucocorticoids. Ovarian cysts are frequently seen in females suffering from steroid biosynthetic disorders and may be seen even in early childhood (Idkowiak *et al.*, 2011). The pathomechanism of ovarian cysts in PORD may be mediated through (a) excessive ovarian LH stimulation caused by insufficient ovarian sex steroid production, (b) chronic anovulation, and (c) disrupted synthesis of meiosis-activating sterols (MAS) and metabolism essential for oocyte meiosis and maturation with onset of puberty (Grondahl *et al.*, 2000; Idkowiak *et al.*, 2011; Bai *et al.*, 2017). It is therefore conceivable that PORD may affect female fertility harder than other steroid biosynthetic defects, in which pregnancies have been achieved through personalized (hormonal) fertility techniques (e.g., CYP17 deficiency Bianchi *et al.*, 2016).

By contrast, males with PORD seem overall less affected in their pubertal development than females. However, while normal pubertal development and sexual function seem possible (Idkowiak *et al.*, 2011), infertility due to incomplete sexual development and azoospermia have also been reported (Armeni *et al.*, 2012). To date little is known on testis histology, fertility, and malignancy risk in 46,XY DSD patients owing to androgen biosynthetic defects in general, and in PORD specifically (Burckhardt *et al.*, 2015).

ABS and Skeletal Malformations With PORD

While 2/3 of patients with PORD have some (minor) skeletal anomalies, a severe ABS phenotype is less frequently observed. Craniosynostosis is observed in variable severity (e.g., cloverleaf skull) and may cause hydrocephalus necessitating surgical intervention. Craniofacial anomalies include midface hypoplasia and choanal atresia, low set ears and a pear-shaped nose. However, radiohumeral synostosis, clinodactyly, and arachnodactyly are more frequently observed with PORD, while femoral bowing can be observed already prenatally in rare cases causing neonatal fractures. Conversely, about 50% of children born with an ABS phenotype have accompanying genital anomalies (Reardon *et al.*, 2000), and are most likely to harbor severe autosomal recessive POR gene mutations (Huang *et al.*, 2005).

ABS is a rare craniosynostosis syndrome first described by Antley and Bixler (1975). It is characterized by craniosynostosis and radiohumeral synostosis, but can be associated with a wide range of bony malformations. Neonatal mortality is high in ABS due to respiratory failure and improves with age. ABS without genital anomalies and/or disordered steroidogenesis is caused by autosomal dominant, gain-of-function mutations in the fibroblast growth factor receptor 2 (*FGFR2*) gene (OMIM 207410), or by homozygous mutations in the *CYP26B1* gene (OMIM 614416) (Laue *et al.*, 2011). Thus severe PORD may reproduce skeletal malformations similar to ABS due to mutations in *FGFR2* or *CYP26B1*, but has broader consequences on steroidogenesis and beyond, which should not be missed.

Other Possible Clinical Features

In theory, POR is the essential electron donor to all type II microsomal P450s, which are involved in numerous body functions reaching far beyond steroidogenesis and bone formation (Nebert and Russell, 2002; Miller, 2005; Pandey and Flück, 2013). Other known functions include metabolism of drugs, xenobiotics, arachidonic acid and eicosanoids, synthesis and metabolism of cholesterol, bile-acids and hemoglobin, as well as retinoic acid hydroxylation (**Fig. 3**) (Pandey and Flück, 2013). Nonetheless, the exact function of some of these possibly interacting P450s remains still unsolved. Thus the currently known spectrum of PORD might just be the tip of the iceberg.

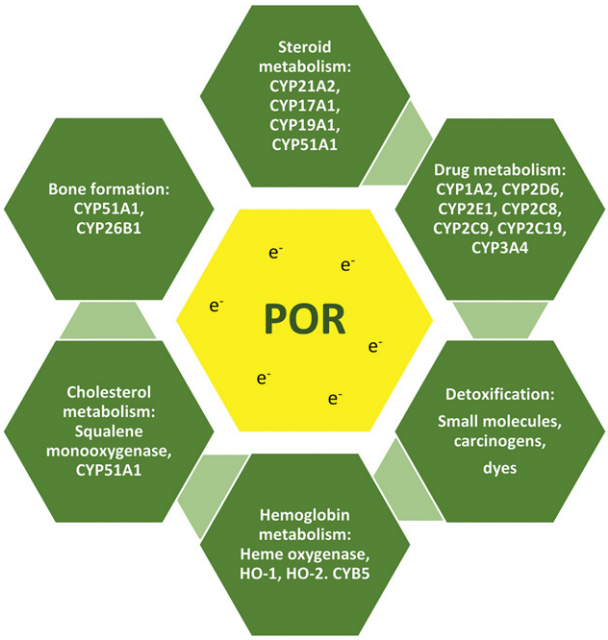

Fig. 3 Interacting redox partners of POR and their impact on life processes. The POR protein is a redox partner of many enzymes involved in both the drug as well as steroid metabolism. In addition POR can supply electrons to other proteins like cytochrome *b*5, heme oxygenase etc. POR can also directly metabolize several small molecules and drugs.

Concerning drug metabolism, prenatal fluconazole toxicity has been suggested in severely affected patients with ABS and DSD suffering from POR mutations, when mothers were treated with the drug during pregnancy (Reardon *et al.*, 2000). However, so far no clinically relevant, adverse drug events have been reported from PORD patients directly. However, drug-cocktail testing in a homozygous PORD patient and her heterozygous mother revealed diminished activities of several drug-metabolizing P450s (e.g., CYP1A2—caffeine, CYP2C9—tolbutamide, CYP2D6—dextrometorphan, CYP3A4—midazolan) (Tomalik-Scharte *et al.*, 2010). Nonetheless, several in vitro studies were able to show significant negative effects of many POR variants on drug metabolizing P450s (Pandey and Flück, 2013; Pandey and Sproll, 2014; Burkhard *et al.*, 2017; Udhane *et al.*, 2017).

Abnormal retinoic acid (RA) metabolism due to diminished CYP26 activity with PORD may not only lead to genital and skeletal malformation, but also cause anorectal and urinary anomalies as seen in the *por* KO model (Ribes *et al.*, 2007). Therefore, Fukami et al. investigated a group of 37 Japanese PORD patients for these specific anomalies and found imperforate anus in 11% and vesicoureteral reflux in 8% (Fukami *et al.*, 2010). Accordingly, plasma atRA levels were also found elevated in these patients.

Reduced HO-1 activity (*HMOX1*) has been assessed for several human POR variants (Pandey *et al.*, 2010) in vitro, and could cause oxidative neurotoxicity, anemia, growth retardation, and abnormal iron deposition in theory. Whether it is just a matter of time, and depending on close clinical follow-up of PORD patients before finding these hypothetical clinical consequences, remains to be seen.

Biochemical Characteristics of POR and PORD

The POR Protein and Its Electron Transfer Function

The reduced nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome P450 oxidoreductase (POR) is the obligate electron transfer partner for the cytochrome P450 proteins located in the endoplasmic reticulum (Pandey and Flück, 2013; Pandey and Sproll, 2014) (**Fig. 4**). Cytochrome P450s are responsible for metabolizing xenobiotics, drugs, and steroid hormones (Omura, 2010; Zanger and Schwab, 2013). In mammals and higher organisms there are two different types of cytochrome P450 proteins (Omura, 2010). Type 1 cytochromes P450 which metabolize steroids are localized in the mitochondria (Omura, 2006) and depend on adrenodoxin and adrenodoxin reductase as redox partners for their metabolic activities (Bernhardt and Urlacher, 2014; Zalewski *et al.*, 2016). The type 2 cytochromes P450 are located in the endoplasmic reticulum and depend on POR for supply of electrons for their catalytic activities (Lu *et al.*, 1969). Human POR is a flavoprotein that contains two flavin molecules, the flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) (**Fig. 5**). POR is a membrane associated protein that binds NADPH, causing a conformation change that brings NADPH and FAD close together to transfer electrons. Afterwards, further conformation changes cause a closing of the POR structure and bring FAD and FMN closer for electron transfer. The FMN binding domain of POR interacts with cytochrome P450 proteins and other redox partners through charge pair interactions. In addition to

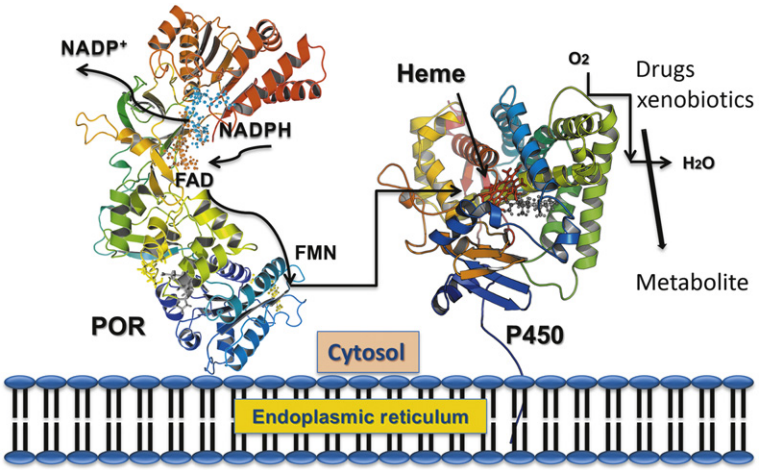

Fig. 4 Electron transfer from NADPH to redox partners of POR. NADPH binds to POR located into the endoplasmic reticulum, and donates electrons which are received by FAD. Electron transfer to FAD causes a conformational change that brings together the FAD and FMN domains and electrons are transferred from FAD to FMN. The FMN domain of POR interacts with the P450s and other redox partners and completes the final step of electron transfer. From Pandey, A. V. and P. Sproll (2014). "Pharmacogenomics of human P450 oxidoreductase." *Frontiers in Pharmacology* **5**, 103.

cytochromes P450 in the endoplasmic reticulum, POR supplies electrons to many other proteins and small molecules including heme oxygenase and cytochrome b_5 (Matsubara *et al.*, 1976; Nagao *et al.*, 1983; Guengerich, 2005).

Steroid Profile of PORD

POR supports three steroid enzymes for human glucocorticoid and sex steroid production in the adrenals and gonads, namely CYP21A1, CYP17A1, and CYP19A1. Changes of the steroid profile of PORD were first described as combined 21- and 17-hydroxylase deficiencies by Peterson et al. in a 6-months old 46,XY DSD baby (Peterson *et al.*, 1985). The detailed findings were specifically: (1) normal basal plasma cortisol and normal urinary excretion of cortisol metabolites, but high plasma ACTH levels, (2) high plasma 17α-hydroxyprogesterone and 21-deoxycortisol and increased urinary excretion of pregnanetriol, 17α-hydroxypregnanolone, and pregnenetriolone, (3) high plasma and urinary 5-pregnene-3β,20α-diol sulfate, (4) low plasma 21-hydroxy-pregnenolone and 5-pregnene-3β,17α, 20α-triol sulfate, (5) high plasma corticosterone and deoxycorticosterone and elevated urinary excretion of their metabolites, (6) high plasma progesterone and pregnenolone and increased urinary excretion of pregnanediol and pregnenediol, (7) low basal plasma levels of C19 steroids and their sulfates, without increase upon stimulation with human chorionic gonadotropin or ACTH, and (8) no urinary metabolites of C19 11-deoxy steroids, and decreased C19 11-oxosteroids.

In addition to these findings, low androgens and low-normal estrogen levels are common (in females) with PORD after puberty reflecting affected gonadal steroidogenesis (Idkowiak *et al.*, 2011). However, the spectrum of biochemical severity with PORD is extremely broad, and analysis of serum steroids alone can be misleading (Fukami et al., 2005, 2006; Williamson *et al.*, 2006). Therefore the diagnostic gold standard for PORD remains biochemical analysis by urinary gas chromatography mass spectrometry (GC–MS), which reveals accumulation of pregnenolone, progesterone, and 17OH-progesterone metabolites, but low androgens in the urine of affected individuals (Shackleton et al., 2004a,b). Calculation for specific POR-supported enzyme ratios may help to establish the diagnosis (Krone *et al.*, 2010). Interestingly, some specific alterations in urinary GC–MS profiling may be even seen in heterozygote POR subjects (Arlt *et al.*, 2004).

Similarly, diagnosis of PORD in a fetus may be made by prenatal GC–MS steroid profiling of maternal urine after 12 weeks gestation. Characteristic findings are (1) very low estriol levels (**Fig. 2**), combined with (2) increased excretion levels of epiallo-pregnanediol (a pregnenolone metabolite), and (3) androsterone (a 5α-reduced androgen **Fig. 1**) (Shackleton et al., 2004a,b; Reisch *et al.*, 2013). By contrast, low plasma estriol levels in pregnancy screening may be also attributed to other conditions of disturbed sterol and steroid biosynthesis besides PORD, such as steroid sulfatase deficiency (*STS*), Smith–Lemli–Opitz syndrome (*DHCR7*), aromatase deficiency (*CYP19A1*), as well as to several forms of severe congenital adrenal insufficiency (e.g., *NR5A1*, *NR0B1*, *CYP11A1*, *TBX19*).

Population Genetics of POR and PORD

After analysis of a large amount of sequencing data from 1000 Genome Project and other large sequencing studies we found the A503V variant of POR in different population has a minor allele frequency from 0.12 to 0.48 (Burkhard *et al.*, 2017). There are

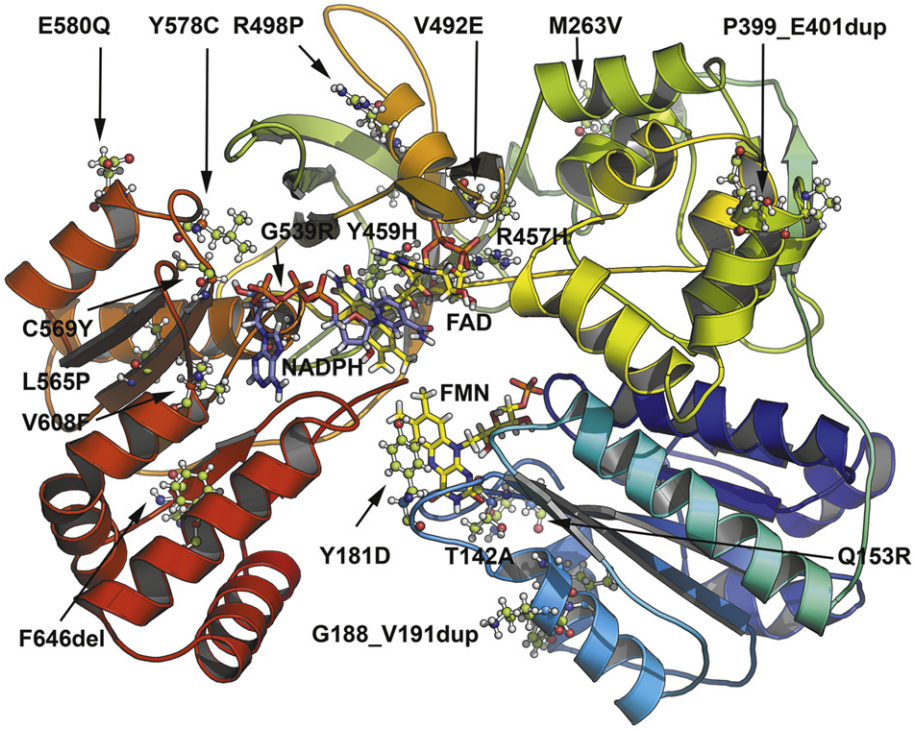

Fig. 5 Amino acid changes in POR identified in patients with PORD. A ribbons model of the human POR protein (Flück et al., 2009). The model is colored in rainbow colors with violet at the N-terminus and red at the C-terminus. The cofactors FMN, FAD and NADPH are shown as sticks. Mutations found in patients with PORD are shown as *ball* and *sticks*. Mutations that caused a truncation in the protein are not shown. Reproduced with permission from our earlier publication Pandey, A. V. and Flück, C. E. (2013). NADPH P450 oxidoreductase: Structure, function, and pathology of diseases. *Pharmacology & Therapeutics* **138**(2), 229–254.

some distinct trends that can be identified in different populations. The POR A503V allele frequency is 31% in Caucasian and hispanic populations, 48% in Pacific Islanders and 34%–39% in Asian populations. Among Japanese population the A503V is found in 40% of all alleles and in African Americans groups the POR A503V is found in less than 15% of alleles.

Many POR variants identified by sequencing of nonclinical populations had >40% of the enzymatic activities compared to WT in different assays. A sequencing study of POR from human livers added more amino acid variations (K49N, L420M, and L577P) (Hart *et al.*, 2008). The L577P variant of POR showed loss of activities several P450 assays utilizing drug metabolizing enzymes (Hart *et al.*, 2008). A study by group of Ulli Zanger on analysis of POR variations in human liver samples reported 43 variations that included 19 SNPs in protein coding regions (Gomes *et al.*, 2009). Some allele combinations (P228L + A503V and A503V + V631I) were also present and the common minor allele present was A503V (Gomes *et al.*, 2009).

Several new studies have analyzed the sequence of POR gene in specific populations (Burkhard *et al.*, 2017). A study of Japanese population (Saito *et al.*, 2011) identified four additional variants of POR (T29M, R550W, R570C, and A659T) found that minor allele frequency of A503V was 0.434. A study of POR variations in Jewish populations identified additional variants S102P, V164M, V191M, D344N, E398A, and D648N (Tomkova *et al.*, 2012). Most variants of POR are found in extremely rare cases and even with more than 5000 alleles, the numbers are still not conclusive for any definitive links to unique populations. However, some patterns have emerged from our analysis of the currently available sequencing data (Burkhard *et al.*, 2017). The variant T93I seems to be exclusive to South Asians, while A172T was prevalent in European populations. The variant P284T which shows almost complete loss of activity in functional assays was found exclusively in Africans. The variant T372M was linked to mixed American population and the G537R was found in Europeans. We have found that the mutations located in the NADPH binding site of the POR are more sensitive toward aromatase and availability of cofactors may further influence their effects on different partner protein activities.

Pathogenetic Mechanisms and Their Implications

On Steroidogenesis and Cholesterol Synthesis

PORD causes adrenal insufficiency/CAH through inhibition of CYP21A2 and CYP17A1, which are essential for glucocorticoid and androgen biosynthesis (**Fig. 1**) (Pandey and Flück, 2013). CAH in PORD thus combines the typical characteristics of CAH due to the 21-hydroxylase and the 17-hydroxylase deficiency (Miller and Fluck, 2014). Milder GC deficiency than with *CYP21A2* mutations is observed because many *POR* mutations have residual activity and because of the accompanying CYP17A1 inhibition that leads to

corticosterone accumulation, which also has GC properties. Therefore, the basal plasma cortisol levels are often normal in PORD, while basal ACTH is frequently elevated and the ACTH stimulation test is abnormal. In addition, POR-related CYP17A1 inhibition may also cause mild mineralocorticoid excess (with low renin and potassium), and thus arterial hypertension in some affected individuals.

PORD also affects gonadal steroidogenesis through the lack or insufficient support of partner enzymes CYP17A1 and CYP19A1 crucial for androgen and estrogen biosynthesis in the Leydig and the Theca/granulosa cells of testis and ovary respectively (Miller and Auchus, 2011). This may result in disturbed fetal sex development (DSD) and/or lack or insufficient pubertal development and/or hypergonadotropic hypogonadism and infertility in adult life. Many POR mutations have been shown to cause severe loss of the CYP19A1 activities. The CYP19A1 seems to be more sensitive to mutations in the NADPH binding regions of POR and is affected to a greater degree compared to other cytochrome P450s that depend on POR (Pandey *et al.*, 2007; Udhane *et al.*, 2016; Flück and Pandey, 2017a,b).

While DSD in severely affected 46,XY subjects with PORD mainly seems to result from the lack of androgen production by the fetal testis due to diminished CYP17A1 activity, DSD in severely affected 46,XX subjects seems more complex and more severe. Diminished CYP21A2 activity alone leads to androgen excess and virilization of the female external genitalia during the critical time window of 6–12 weeks gestation (Goto *et al.*, 2006). With PORD additional inhibition of CYP17A1 and CYP19A1 (Aromatase) activities contribute toward androgen excess (Arlt *et al.*, 2004; Flück *et al.*, 2004). Aromatase (CYP19A1) deficiency of the fetal-placental unit fails to convert fetal adrenal androgens to mainly estriol (**Fig. 2**), and thereby causes not only ambiguous genitalia in a 46,XX fetus, but also maternal virilization during pregnancy (Shackleton et al., 2004a,b; Reisch *et al.*, 2013). In addition, production of excess fetal adrenal androgen precursors lead to DHT production through an alternative backdoor pathway (**Fig. 1**), which is thought to be more readily used during fetal and early postnatal life (Auchus, 2004; Homma *et al.*, 2006; Flück *et al.*, 2011; Kamrath *et al.*, 2012; Biason-Lauber *et al.*, 2013). This alternative androgen biosynthesis pathway was first discovered in the tammar wallaby pouch young (Auchus, 2004). Interestingly, it was with studies of the urinary steroid profile of patients with PORD that its existence in humans was detected (Homma *et al.*, 2006). In this pathway, 17OH-progesterone is 5α-, 3α-reduced to yield specific metabolites, which are precursors for DHT production, without going through testosterone as intermediate product like in the classic pathway (**Fig. 1**). Early postnatally, metabolites 17-hydroxy-alloprogesterone (17OH-Allo; also known as 5α-pregnane-3α, 17α-diol-20-one) and androsterone of the backdoor pathway were found elevated in PORD, while metabolites of the classic pathway were either low or normal.

POR also supports the catalytic reactions of squalene monooxygenase (*SQLE*) and 14α-lanosterol demethylase (*CYP51A1*) (**Fig. 3**), which are important enzymes in sterol and cholesterol synthesis. In addition, sterols are involved in hedgehog-mediated regulation of fetal bone development, as well as oocyte meiosis and maturation (Byskov *et al.*, 1995; Grondahl et al., 1998, 2000). Women with PORD are prone to suffer from ovarian cysts (see section "Pubertal Development and Gonadal Function in PORD"), which might be in part due to insufficient production of meiosis-activating sterols (MAS); on the other hand due to high gonadotropins secondary to disrupted ovarian steroidogenesis and anovulation (Idkowiak *et al.*, 2011; Bai *et al.*, 2017). Likewise, testicular MAS may play a role in male fertility by affecting meiosis in spermatozoa (Byskov *et al.*, 1999), although such effect has not been implicated in PORD so far.

POR and Bone Formation

Skeletal malformations are found very frequently in PORD patients, when a careful clinical assessment is performed (see **Table 1** and Fukami *et al.*, 2009; Krone *et al.*, 2012; Flück and Pandey, 2013; Pandey and Flück, 2013). They can be of minor degree or very severe, and in its extreme form manifesting with an ABS phenotype (section "ABS and Skeletal Malformations With PORD").

The pathomechanism underlying the bony malformations with PORD is complex, but involves a role of POR in sterol and cholesterol biosynthesis on one hand, and on retinoic acid metabolism on the other. This includes inhibition of squalene monooxygenase and 14α-lanosterol-demethylase (*CYP51A1*) in the cholesterol biosynthesis pathway, which both depend on POR for electron transfer (Ono and Bloch, 1975), suggested to leading to abnormal activity and signal transduction of hedgehog proteins required for normal morphogenesis, bone formation and growth during embryogenesis (Gofflot *et al.*, 2003). Accordingly, *Por* KO in rat chondrocytes was found to induce apoptosis, reduce cholesterol levels and lower Indian hedgehog content, while all these effects could be rescued by cholesterol supplementation (Aguilar *et al.*, 2009). Interestingly, disruption of downstream processing of lanosterol by fluconazole (a known CYP51 inhibiting drug), resulted in similar skeletal abnormalities (Pursley *et al.*, 1996; Andersson *et al.*, 2002).

Similarly, the skeletal malformation phenotype of PORD resembles embryonic retinoic acid toxicity. Retinoic acid is metabolized by microsomal CYP26 enzymes, which receive electrons from POR for catalytic reactions. Conditional limb Por −/− KO mice were found to have excess retinoic acid levels, but low cholesterol and upregulated genes in the whole cholesterol biosynthetic pathway, (Schmidt *et al.*, 2009). Elevated plasma all-trans retinoic acid levels were also reported in some PORD patients manifesting with skeletal anomalies (Fukami *et al.*, 2010). Finally, human loss of function mutations in *CYP26B1* essential for retinoic acid degradation were recently found to produce a skeletal malformation syndrome with craniosynostosis just like ABS seen in PORD (Laue *et al.*, 2011).

Effects on Drug Metabolism by Mutations in POR

Here we are reviewing only the effects of mutations found in patients (**Fig. 5**) and major common minor allele of POR, the A503V (POR*28), while a detailed review of the POR variations could be found in our earlier publications (Pandey and Flück, 2013;

Pandey and Sproll, 2014; Burkhard *et al.*, 2017). Initially the focus of POR variation studies was on characterization of effects on steroid metabolism, but soon afterwards, a range of redox partners including drug metabolizing cytochrome P450s and heme oxygenase were also studied (Agrawal et al., 2008, 2010; Flück *et al.*, 2010; Nicolo *et al.*, 2010; Pandey *et al.*, 2010). Sequencing studies from many different genome sequencing projects as well as targeted gene sequencing across various population subgroups have identified may variations in the POR gene (Gomes *et al.*, 2008; Huang *et al.*, 2008; Gomes *et al.*, 2009; Sim *et al.*, 2009; Agrawal *et al.*, 2010; Nicolo *et al.*, 2010; Pandey *et al.*, 2010; Parween *et al.*, 2016). Many POR variants found from patients and normal population have been tested for enzymatic activities (Adachi *et al.*, 2004; Arlt *et al.*, 2004; Fukami et al., 2005, 2006; Homma *et al.*, 2006; Pandey, 2006; Huang *et al.*, 2008; Sim *et al.*, 2009). While mutations in POR can be found in all regions of the proteins, based on analysis of previously identified mutations some general observations can be made. Mutations found in either of the cofactor binding sites (FMN, FAD, and NADPH) generally result in a severe form of the disease with mutations causing loss of FMN or FAD showing most severe effects on activities of all supported redox partners.

Cytochrome P450 3A4 (CYP3A4) is the major hepatic enzyme that metabolizes a large percentage of drugs and endogenous substrates (Klein and Zanger, 2013; Meyer *et al.*, 2013; Zanger and Schwab, 2013). We found that mutations in POR can affect the enzymatic activities of CYP3A4 (Nicolo *et al.*, 2010; Udhane *et al.*, 2017). The POR mutant A287P (common in "Europeans") leads to a 75% reduction of the CYP3A4 enzymatic activity (Flück *et al.*, 2010; Nicolo *et al.*, 2010). The POR mutations that affect binding of cofactor FAD (R457H, Y459H, and V492E) showed no activity in CYP3A4 assays (Flück *et al.*, 2010). The two mutations in POR located in the NADPH binding site, the C569Y and V608F caused 65%–85% loss of the CYP3A4 activity and a c-terminus truncation mutation in POR, R616X, showed no activity (Flück *et al.*, 2010). Effect of POR variants on CYP3A4 activities may also depend on specific substrates; the POR variant Q153R has shown 76%–94% of the WT CYP3A4 activity with substrates midazolam and erythromycin, but when testosterone and quinidine were used as substrates it had 129%–150% of the WT POR activity (Agrawal *et al.*, 2010). The A503V variant of POR caused 20%–40% loss of CYP3A4 activity when midazolam and testosterone were used as substrates but when erythromycin and quinidine were used as substrates, the A503V showed similar to WT activities (Agrawal *et al.*, 2010). A combined analysis of several studies shows that many polymorphisms in POR (P228L, R316W, G413S, A503V, and G504R) retain $>40\%$ activity in assays with most redox partners. In the testing of CYP2C19 and CYP1A2 activities, POR mutations A287P and R457H have been reported to cause total loss of activity (Agrawal *et al.*, 2008). The POR variant Q153R caused an increase in the activity of CYP1A2 by 144% and CYP2C19 activity by 284%, similar to our observation of increased activity of aromatase with POR Q153R (Flück and Pandey, 2017a,b; Udhane *et al.*, 2017). Our recent studies on POR variations have found mutations A115V, T142A, and P284L to cause severe loss of CYP3A4 activities (Udhane *et al.*, 2017).

The CYP2D6 is also a major enzyme involved in drug metabolism and after CYP3A4 it is responsible for the metabolism of a large number of drugs (Zanger and Schwab, 2013). In the assay of CYP2D6 activities with dextromethorphan and bufuralol as substrates, the A287P mutant of POR lost 75% of the activity compared to WT POR. Compared to the WT POR, the POR variant A503V showed activities of 62% with dextromethorphan as substrate and 53% when bufuralol was the substrate in CYP2D6 assays (Sandee *et al.*, 2010). The effects of different CYP isoforms on impact of POR activities has not been studied in detail. One study (Subramanian *et al.*, 2012) tested different alleles of CYP2C9 (*CYP2C9.1*, *CYP2C9.2*, and *CYP2C9.3*) with few POR variants and patterns were similar for all isoforms of CYP2C9 (Subramanian *et al.*, 2012).

The Unknown Factors About POR Mutations

In cases POR mutations leading to the loss of FAD/FMN cofactors, a harmful effect on all redox partner activities are observed. However, in most cases effects of POR on individual redox partner activities could be variable. Biochemical analysis using recombinant proteins is often required to confirm the damaging effects of mutations with each redox partner separately. Several cytochrome P450 proteins for which POR is the redox partner, still have uncharacterized activities and their physiological roles are not defined. These, other partners of POR could also influence the metabolic profiles of patients with PORD. In terms of preventive measures, low retinoic acid in diet and supplementation with steroid metabolites whose production is affected could be utilized as treatment strategies. Preliminary computational docking and functional analysis suggests that the loss of activity caused by some POR variants may be reversed by introduction of external FMN (Nicolo *et al.*, 2010). However, effect of flavin treatment in PORD needs to be tested.

Conclusion and Perspectives

PORD is a complex disorder affecting both the steroid and the drug metabolism of affected individuals with varying effects. Different POR variations can cause a highly variable effect on different metabolic reactions depending on unique nature of the interaction of POR with different redox partners. A careful examination of affected subjects by use of urine/serum steroid analysis is required for initial verification of PORD. In cases of severe loss of drug metabolizing cytochrome P450 enzyme activities, further considerations about clearance of drugs in patients with PORD would require evaluation. Effect of altered clearance of kidney transplant drug tacrolimus has been confirmed in several studies among people with the POR*28 allele (Zhang *et al.*, 2015).

Effects of different POR variations found in nonclinical populations should also be investigated and recent work has shown that some of these variations in POR could lead to severe changes in activities of enzymes dependent on POR (Udhane *et al.*, 2017).

Pediatric Cushing Disease

Ingrid CE Wilkinson, Martin O Savage, and Helen L Storr, Barts and the London School of Medicine and Dentistry, London, United Kingdom

Glossary

ACTH Adrenocorticotrophic hormone.
BSIPSS Bilateral simultaneous petrosal sinus sampling, a method of determining if central Cushing's syndrome.
TSS Transsphenoidal surgery.
Glucocorticoid Steroids produced from the zona fasiculata of the adrenal gland.
HPA axis hypothalamic pituitary adrenal axis.
